Of greater clinical use is the classification of antipsychotics according to affinities for various receptors (Table 67-2). However, the most widely u classification system categorizes antipsychotics as either *typical* or *atypic* called *traditional* or *conventional*) antipsychotics dominated the first 40 antipsychotic therapy. They were categorized according to their affinity fo receptor as either low potency, as exemplified by thioridazine and chlorp high potency, exemplified by haloperidol. These agents ameliorated the symptomsâ€• of schizophrenia, hallucinations, delusions, paranoia, and of thought, but they were of little benefit for the sometimes disabling â€ symptomsâ€• of schizophrenia: avolition, alogia, flattening of affect, and withdrawal. Moreover, they were associated with acute, subacute, and lo disturbances collectively referred to as *extrapyramidal syndromes* (EPS).

The notion of antipsychotic atypicality has evolved over time with the int compounds[78 , 90] and connotes different properties to pharmacologists a From a clinical perspective, an atypical antipsychotic treats both the posi negative symptoms of schizophrenia, is less likely than traditional drugs t at clinically effective doses, and causes little or no elevation of the serun concentration.[49] From a pharmacologic perspective, most atypical antips inhibit the action of serotonin at the 5-HT_{2A} receptor. More than a dozen antipsychotics are now in clinical use or under development. Despite the higher cost, these drugs have largely supplanted traditional antipsychotics their effectiveness in treating the negative symptoms of schizophrenia an somewhat more favorable adverse effect profile.

Mechanisms of Antipsychotic Drug Action

Of the many contemporary theories of schizophrenia, the most enduring h

dopamine hypothesis .[87] First advanced in 1967 and supported by in vivo theory holds that the â€œpositive symptomsâ€• of schizophrenia (hallu delusions, paranoia, and disorganization of thought) occur because of ex dopaminergic signaling in the mesolimbic and mesocortical pathways.[63] T was borne in part from the observation that hallucinations and delusions produced in otherwise normal individuals by drugs that increase dopamin transmission, such

as cocaine and amphetamine, and that these effects could be blunted by antagonists.

Classification	Compound	Usual Daily Adult Dose (mg)	Volume of Distribution (L/kg)	Half-Life (Range, h)	Protei Bindin (%)

TABLE 67-1. Classification of Commonly Used Antipsychotics

There are five subtypes of dopamine receptors (D_1 â€“D_5), but schizoph involves excess signaling at the D_2 subtype.[87] Antagonism of D_2 neurotra sine qua non of antipsychotic activity. Antipsychotics have different poten receptor, reflected by the dissociation constant (K_d), which in turn reflec the drug from the D_2 receptor. For example, the receptor releases clozap quetiapine more rapidly than it does any other drugs.[86,87]

Dopamine receptors are present in many other areas of the central nervo (CNS), including the nigrostriatal pathway (substantia nigra, caudate, and which collectively govern the coordination of voluntary movement), tube pathway, hypothalamus and pituitary, and area postrema of the brainster contains the chemoreceptor trigger zone (CTZ). Antipsychotic-related bloc neurotransmission in these areas is associated with many of the other be adverse effects of these drugs. For example, D_2 antagonism in the CTZ a

and vomiting, whereas blockade of hypothalamic D_2 receptors increases by the pituitary, resulting in breast tenderness and galactorrhea. Blockad nigrostriatal D_2 receptors underlies many of the movement disorders ass antipsychotic therapy.[93, 103]

Antipsychotics interfere with signaling at other receptors, including acety M_2 muscarinic receptors, H_1 histamine receptors, and Î±-adrenergic rece extent to which these other receptors are blocked at doses that effectivel transmission is antipsychotic specific and can be used to predict a drug's profile.[20] For example, drugs that antagonize muscarinic receptors at cli doses (primarily the aliphatic and piperidine phenothiazines, clozapine,

loxapine, and olanzapine) often cause anticholinergic adverse effects duri and can cause anticholinergic delirium following overdose (Table 67-2). blockade of peripheral $Î±_1$ -adrenergic receptors by the aliphatic and pip phenothiazines, clozapine, risperidone, and several other drugs more like postural hypotension during therapy and supine hypotension following ov

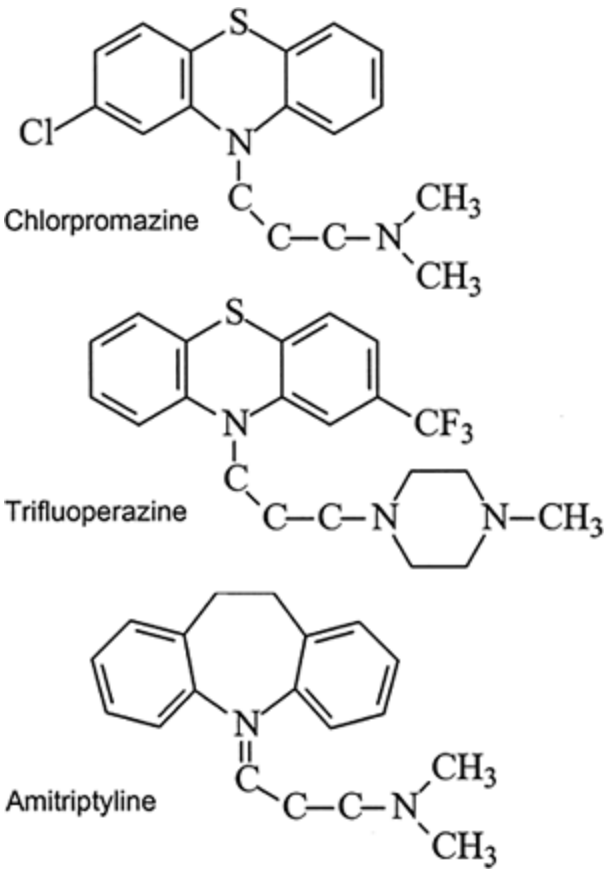

Figure 67-1. Structural similarity between phenothiazines and tricyclic

Several antipsychotics also block voltage-gated fast sodium channels (I_{Na} this effect is of little consequence during therapy, in the setting of overdo slow cardiac conduction (phase 0 depolarization) and impair myocardial This effect, most notable with the phenothiazines, is both rate and voltag and therefore is more pronounced at faster heart rates and less negative potentials.[17] Blockade of the delayed rectifier potassium current (I_{Kr}) ca prolongation of the QTc interval, creating a substrate for development of pointes.[68] QTc prolongation is sometimes evident during maintenance th particularly in patients with previously unrecognized congenital QTc prolo additional risk factors. This effect may partly explain the apparent increas cardiac death among patients treated with antipsychotic drugs.[77]

TABLE 67-2. Toxic Manifestations of Selected Antipsychotics

Several antipsychotics exhibit a relatively high degree of antagonism at t receptor, which conveys two important therapeutic properties: (1) greate treatment of the negative symptoms of schizophrenia and (2) a significar incidence of extrapyramidal side effects. Several antipsychotics are distin

unique effects at other receptors. For example, loxapine and clozapine in reuptake of catecholamines and antagonize Î³-aminobutyric acid $(GABA)_A$ which may explain the apparent increase in seizure activity with these ag detailed description of the pharmacology of the commonly used atypical warranted given their increasing role in therapy.

Clozapine, a dibenzodiazepine compound, binds to dopamine receptors (D serotonin receptors ($5\text{-}HT_{1A/1C}$, $5\text{-}HT_{2A/2C}$, $5\text{-}HT_3$, and $5\text{-}HT_6$) with mo affinity.[9 , 75 , 81] It also antagonizes $Î±_1$ -adrenergic, $Î±_2$ -adrenergic, an receptors. It has the highest binding affinity of any atypical antipsychotic muscarinic receptors.[80] Despite this feature, clozapine paradoxically activ genetic subtype of the muscarinic receptor and frequently produces sialo therapy.[79]

Olanzapine, a thienobenzodiazepine, binds avidly to serotonin ($5\text{-}HT_{2A/2C}$ $5\text{-}HT_6$) and dopamine receptors (D_1 , D_2 , and D_4), although its potency is lower than that of

most traditional antipsychotics.[51 , 81] It is an exceptionally potent H_1 ant more avidly than pyrilamine, which is a widely used antihistamine. It is al affinity for M_1 receptors and is a relatively weak $Î±_1$ antagonist.

Risperidone, a benzisoxazole derivative, has high affinity for several rece serotonin receptors ($5\text{-}HT_{2A/2C}$), D_2 dopamine receptors, and $Î±_1$ and H_1 [79 , 81] It has no appreciable activity at M_1 receptors. Its primary metabol hydroxyrisperidone) is nearly equipotent as the parent compound at D_2 a receptors.[51]

Quetiapine, a dibenzothiazepine, is a weak antagonist at D_2 , M_1 , and 5- but it is a relatively potent antagonist of $Î±_1$ and H_1 receptors.[51 , 81] Of metabolites, at least 2 are pharmacologically active. However, they circula levels and likely contribute little to the drug's clinical effect.

Ziprasidone, a benzothiazole derivative, is a potent antagonist at dopamin several serotonin ($5\text{-}HT_{2A/2C}$, $5\text{-}HT_{1D}$, and $5\text{-}HT_7$) receptors, but it also agonist activity at $5\text{-}HT_{1A}$ receptors.[51 , 52 , 81] Its $Î±_1$ antagonist activity strong, with a binding affinity approximately one tenth that of prazosin.

Aripiprazole, a quinolinone derivative, is a novel compound that binds avi D_2 and D_3 receptors and serotonin 5-HT_{1A}, 5-HT_{2A}, and 5-HT_{2B} receptor evidence suggests that its efficacy in the treatment of schizophrenia and propensity for EPS may relate to partial agonist activity at dopamine D_2 Aripiprazole acts as a partial agonist at serotonin 5-HT_{1A} receptors but is at serotonin 5-HT_{2A} receptors. Its principal active metabolite, dehydroari affinity for dopamine D_2 receptors and thus has some pharmacologic acti that of the parent compound.[66]

Pharmacokinetics and Toxicokinetics

With a few exceptions, the antipsychotics have similar pharmacokinetic regardless of their chemical classification. Most are lipophilic, have a larg distribution, and are generally well absorbed, although anticholinergic effe absorption of some agents. Plasma concentration generally peak within 2 a therapeutic dose, but this can be prolonged following overdose.

Most antipsychotics are substrates for the various isozymes of the hepati P450 (CYP) enzyme system. For example, haloperidol, perphenazine, thi sertindole, and risperidone are extensively metabolized by the CYP2D6 sy functionally absent in approximately 7% of white patients and overexpres of patients, depending on ethnicity.[53] These polymorphisms appear to inf tolerability and efficacy of treatment with these antipsychotics during the [28, 29, 48, 72, 98] but likely do not alter the severity of antipsychotic ov

Drugs that inhibit CYP2D6, such as paroxetine, quinidine, and metoclopra increase the levels of these antipsychotic drugs and increase the risk of In contrast, metabolism of clozapine is primarily mediated by CYP1A2, ar clozapine levels can result following exposure to fluvoxamine, macrolide, antibiotics and after smoking cessation, which normally induces CYP1A2.[3] plays a relatively small role in the elimination of antipsychotics, and dose generally is not necessary for patients with renal disease.

Pathophysiology and Clinical Manifestation

Table 67-3 lists the adverse effects of antipsychotics. Some of these effe

following overdose, but many can occur during the course of therapeutic

Adverse Effects During Therapeutic Use

Extrapyramidal Syndromes

The EPSs (Table 67-4) are a heterogeneous group of disorders that share abnormal muscular activity. Among the typical antipsychotics, the incidenc appears to be highest with the more potent agents such as haloperidol a and lower with the less potent agents chlorpromazine and thioridazine. A antipsychotics are associated with an even lower incidence of EPS. Althou physiologic mechanisms for this observation are not fully understood, se have been put forth. In addition to the aforementioned antagonism of 5-H some atypical agents dissociate more rapidly from the D_2 receptor and in degree of nigrostriatal dopaminergic hypersensitivity during chronic use.[4] However, EPS can occur during treatment with any antipsychotic drug, re typicality or potency.

Acute Dystonia

Acute dystonia is a movement disorder characterized by sustained involu contractions, often involving the muscles of the head and neck, including muscles and the tongue, but occasionally involving the extremities. Thes are sometimes referred to as *limited reactions* , reflecting their transient than their severity. All of the currently available antipsychotics are assoc dystonic reactions.[93] Spasmodic torticollis, facial grimacing,

protrusion of the tongue, and oculogyric crisis are among the more comm manifestations. Laryngeal dystonia is a rare but potentially life-threatenin is easily misdiagnosed because it can present with throat pain, dyspnea, dysphonia rather than the usual features of dystonia.[36]

Disorder	Time of Maximal Risk	Features	Postulated Mechanism	T

TABLE 67-4. The Extrapyramidal Syndromes

Acute dystonia often occurs within a few hours of starting of treatment bu delayed for up to a few days. Left untreated, dystonia resolves slowly ov Risk factors include male gender, young age (children are particularly su previous episode of acute dystonia, and recent cocaine use.[94 , 103] Althou may appear dramatic and sometimes is mistaken for seizure activity, it ra threatening. Of note, drugs other than antipsychotics can sometimes caus dystonia, particularly metoclopramide, the antidepressants, some antima histamine H_2 receptor antagonists, anticonvulsants, and cocaine.[94]

Treatment of Acute Dystonia

Acute dystonia is generally more distressing than serious, but rare cases respiration, necessitating supplemental oxygen and, occasionally, assiste [, 94] The response to parenteral anticholinergic agents often is rapid and every effort should be made to administer benztropine as the first-line age intramuscularly in adults, or 0.05 mg/kg in children). Diphenhydramine of readily available and can be used instead (50 mg IV or intramuscularly in mg/kg in children). Parenteral benzodiazepines such as lorazepam (0.05â IV or intramuscularly) or diazepam (0.1 mg/kg IV) should be used if patie respond to anticholinergics, but they also can be effective as initial therap important to recognize that because the elimination half-life of most ant shorter than that of most antipsychotics, dystonia can recur, and admini additional doses of anticholinergic agents may be necessary over the nex hours.[27] Patients in whom acute dystonia jeopardizes respiration should b at least 12â€“24 hours after initial resolution.

Akathisia

Akathisia (from the Greek, â€œnot to sitâ€•) is characterized by a feelin restlessness, anxiety, or sense of unease, often in conjunction with the of an inability to sit still. Patients with akathisia frequently appear uncom fidgety. They may rock back and forth while they are standing, or they n cross and uncross their legs while they are seated. Akathisia can be diffic and may be misinterpreted as a manifestation of the underlying psychiat especially anxiety.

Akathisia is common and may be an important determinant of adherence acute dystonia, akathisia tends to occur relatively early in the course of coincides with peak antipsychotic concentrations in plasma.[103] The incide highest with typical, high-potency antipsychotics and lowest with atypical Although most cases develop within days to weeks after initiation of treat increase in dose, a delayed-onset or tardive variant is recognized.

The pathophysiology of akathisia is incompletely understood but appears antagonism of postsynaptic D_2 receptors in the mesocortical pathways.[62] Interestingly, a similar phenomenon may occur in patients after commen with antidepressants, particularly the selective serotonin reuptake inhibit

Treatment of Akathisia

Akathisia can be difficult to treat. A reduction in the antipsychotic dose is helpful, as is substitution of another (generally atypical) antipsychotic dr with lipophilic Î²-adrenergic antagonists such as propranolol may reduce of akathisia, but little evidence supports their use.[56 , 73] Benzodiazepines term relief.[57] Anticholinergics such as benztropine or procyclidine may

reduce symptoms of akathisia, although they more likely will be effective induced by antipsychotics with little or no intrinsic anticholinergic activity

Parkinsonism

Antipsychotic drugs can produce a parkinsonian syndrome characterized l akinesia or bradykinesia, and postural instability. It is similar to the idio disease, although the classic â€œpill-rollingâ€• tremor is often less pro syndrome typically develops during the first few months of therapy, part high-potency agents. It is more common among older women. Parkinsonis result from antagonism of postsynaptic D_2 receptors in the striatum.[93]

Treatment of Drug-Induced Parkinsonism

The incidence of drug-induced parkinsonism can be minimized by using th effective dose of antipsychotic. The addition of an anticholinergic attenua

This strategy often is effective in younger patients, although the routine u prophylactic anticholinergics is not recommended. Addition of a dopamine as amantadine is sometimes used, particularly in older patients who may of anticholinergic drugs, but it occasionally aggravates the underlying ps disturbance.[61]

Tardive Dyskinesias

The term *tardive dyskinesia* was coined in 1952 to describe the delayed o persistent orobuccal masticatory movements occurring in 3 women after of antipsychotic therapy.[93] The adjective *tardive* , or late, was used to d movement disorders from those the parkinsonian movements described a incidence of tardive dyskinesia in younger patients is approximately 3â€“5 rises considerably with age. A prospective study of older patients treated potency typical antipsychotics identified a 60% cumulative incidence of t dyskinesia after 3 years of treatment.[46] Potential risk factors for tardive include alcohol use, affective disorder, prior electroconvulsive therapy, d and various genetic factors.[93]

Several distinct tardive syndromes are recognized, including the classic o masticatory stereotypy, chorea, dystonia, myoclonus, blepharospasm, and generally accepted that the atypical antipsychotics are associated with a of tardive dyskinesia and other drug-related movement disorders. Howeve is true of all atypical antipsychotics is unclear. Among the atypical antip clozapine is associated with the lowest incidence of tardive dyskinesia an with the highest incidence (when higher doses are used), although the re observation are uncertain.[73 , 91 , 93]

Treatment of Tardive Dyskinesia

Tardive dyskinesia is highly resistant to the usual pharmacologic treatmen movement disorders. Anticholinergics do not alleviate tardive dyskinesia a it. Calcium channel blockers, Î²-adrenergic antagonists, benzodiazepines, have been of limited success.[34] Clozapine appears to suppress tardive dy temporarily. Although discontinuation of the causative agent may not pro of symptoms, when possible the antipsychotic should be discontinued as s

symptoms begin.

Neuroleptic Malignant Syndrome

Neuroleptic malignant syndrome (NMS) is a potentially life-threatening r emergency. First described in 1960 in patients treated with haloperidol, t has been associated with virtually every antipsychotic.[30] The reported inc ranges from 0.2â€“1.4% of patients receiving antipsychotics,[2,22] but les episodes may go undiagnosed or unreported. As a result, much of what is the epidemiology and treatment of NMS is speculative and based upon ca case series.

The pathophysiology of NMS is incompletely understood but appears to in reductions in central dopaminergic neurotransmission in the hypothalamus core temperature â€œset pointâ€•[39] and leading to altered thermoregula manifestations of autonomic dysfunction. Blockade of striatal D_2 receptors muscle rigidity and tremor.[13,24,95] In some cases, a direct effect on s may play a role in the pathogenesis of hyperthermia.[39] Altered mental sta multifactorial and may reflect hypothalamic and spinal dopamine receptor genetic predisposition, or the direct effects of hyperthermia and other dr also appears to play a role in the pathogenesis of NMS, because antipsyc antagonize $5\text{-}HT_{2A}$ receptors seem to be associated with a lower incidence

Although NMS most often occurs during treatment with a D_2 receptor an withdrawal of dopamine agonists can produce an indistinguishable syndro typically occurs in patients with long-standing Parkinson disease who abru discontinue treatment with dopamine agonists such as levodopa/carbidop or bromocriptine.[13] Hospitalization for aspiration pneumonia, a common older patients with Parkinson disease, is a particularly high-risk setting for particularly dangerous because the cardinal manifestations of NMS are ea misattributed to the combined effects of infection and the underlying mo

The vast majority of NMS cases occur in the context of therapeutic use o rather than following overdose. Postulated risk factors for the developmer include young age, male gender, extracellular fluid volume contraction, us potency antipsychotics, depot preparations, cotreatment with lithium, mul combination, and rapid dose escalation.[2,23,54]

The manifestations of NMS include the tetrad of altered mental status, m (classically â€œlead pipeâ€•), hyperthermia, and autonomic dysfunction. symptoms can appear in any sequence, although a review of 340 NMS cas mental status changes and rigidity usually preceded the development hyp autonomic instability.[96] Signs typically evolve over a period of several da majority occurring within 2 weeks of starting treatment. However, it is im recognize that NMS can occur even after prolonged use of an antipsycho following a dose increase or the addition of another drug.

There is no gold standard for the diagnosis of NMS, and at least 4 differer criteria are proposed.[32 , 3 , 22 , 54] The operating characteristics of these not been formally evaluated. The criteria set forth by the *Diagnostic and Manual of Mental Disorders* , 4th edition (DSM-IV) are perhaps the most their principal limitation is that they make no provision for a causal relat drugs other than antipsychotics.[32] Because NMS is an uncommon and po threatening disorder with highly variable clinical manifestations and no d standard, an algorithmic approach to diagnosis in inadvisable. Rather, cli be aware of its many

possible clinical and laboratory features (Table 67-5) and entertain the NMS in any unwell patient receiving an antipsychotic, particularly when a mentation, unexplained fever, or muscle rigidity is present.

Altered mental status
Delirium, lethargy, confusion, stupor, catatonia, coma
Motor symptoms
â€œLead pipeâ€• rigidity, cogwheeling, dysarthria or mutism, parkinson akinesia, tremor, mutism, dystonic posture, dysphagia, dysphonia, chor
Hyperthermia
Temperature >100.4Â°F (38Â°C)
Autonomic instability
Tachycardia, diaphoresis, sialorrhea, incontinence, respiratory irregulariti dysrhythmias, hypertension or hypotension
Laboratory findings
Increased muscle enzymes (creatine kinase, lactate dehydrogenase, aldo

leukocytosis, renal insufficiency (reflecting volume contraction and pigmentnephropathy), acidemia, myoglobinuria, modest aminotransferase hypoxia, hyponatremia, increased prothrombin time/partial thromboplastir These manifestations can occur in any combination, although hyperthermi degree of increased muscular activity usually are present. Some manifest fleeting. A supportive medication history (see text) is essential to the dia every effort should be made to exclude other potential causes, such as o illnesses and other drugs and toxins.
Adapted from references [2,23,54,95].

Feature	Potential Manifestations

TABLE 67-5. Clinical and Laboratory Features of the Neurolepti Syndrome

Treatment of Neuroleptic Malignant Syndrome: Measures

Treatment recommendations are largely based on general physiologic pri reports, and case series. Therapy should be individualized according to th duration of illness and the modifying influences of comorbidity.[13,97]

The provision of good supportive care is the cornerstone for treatment of essential to recognize the condition as an emergency and to withdraw the agent immediately. When NMS ensues after abrupt discontinuation of a d such as levodopa, the drug should be reinstituted promptly. Most patients should be admitted to an intensive care unit. Supplemental oxygen should administered, and assisted ventilation may be necessary in cases of resp which can result from central hypoventilation, loss of protective airway re rigidity of the chest wall muscles.

The hyperthermia associated with NMS is multifactorial in origin and, whe should be treated aggressively. For those with life-threatening hyperther in an ice-water bath is the most rapidly efficient technique (Chap. 16). I less severe illness, evaporative cooling can be accomplished by removing

clothing, spraying the patient with lukewarm water, and maintaining cons circulation with the use of fans.[100]

Hypotension should be treated initially with large volumes of 0.9% sodiu solution, followed by vasopressors if necessary. Alkalinization of the urine bicarbonate may reduce the incidence of myoglobinuric renal failure in pa creatine kinase concentrations, but maintenance of euvolemia and adequa perfusion are of greater importance. Tachycardia does not require specifi bradycardia may necessitate the use of transcutaneous or transvenous e Venous thromboembolism is a major cause of morbidity and mortality in NMS, and prophylactic doses of low-molecular-weight heparin should be patients who likely will be immobilized for more than 12â€“24 hours.

Pharmacologic Treatment of Neuroleptic Malig Syndrome

Benzodiazepines are the most widely used pharmacologic adjuncts for trea and are considered first line-therapy. Dantrolene and bromocriptine are n and their incremental benefit over good supportive care is debated.[83] Hov drugs are associated with relatively little toxicity, and the absence of de should not preclude their use, particularly in patients with moderate or s

Benzodiazepines are frequently used in the management of NMS because onset of action, which is particularly important when patients are agitated Benzodiazepine actions are nonspecific in nature, but they presumably at sympathetic hyperactivity that characterizes NMS[40] by facilitating GABA- chloride transport and producing neuronal hyperpolarization, in a fashion their beneficial effects in cocaine toxicity. The primary disadvantage of is that they may cloud the assessment of mental status.

Dantrolene reduces skeletal muscle activity by inhibiting ryanodine recep release channels, thereby interfering with calcium release from the sarco reticulum. In theory, this process should reduce body temperature and to consumption. It also should lessen the risk of myoglobinuric renal failure. been suggested to be more useful when muscular rigidity is a prominent NMS.[13] Dantrolene can be given by mouth (50â€“100 mg/d) or by IV infu

mg/kg/d, or up to 10 mg/kg/d in severe cases), although the latter requ reconstitution.[13]

Bromocriptine is a centrally acting dopamine agonist that is given orally o nasogastric tube at doses of 2.5â€“10 mg, 3â€“4 daily. The rationale for i the belief that reversal of antipsychotic-related striatal D_2 antagonism wi manifestations of NMS. Other dopamine agonists anecdotally associated v include levodopa[70, 88] and amantadine.[38, 45] When these drugs are use be tapered slowly after the patient improves to minimize the likelihood o NMS. In severe cases, combined therapy with dantrolene and a dopamine considered given their relative safety.

Electroconvulsive Therapy

Electroconvulsive therapy (ECT) has been reported to dramatically improv manifestations of NMS, presumably by enhancing central dopaminergic tra report, 5 patients received an average of 10 ECT treatments, and resoluti generally seen after the third or fourth session.[69] Whether this result rep effect of ECT or

simply the natural course of NMS with good supportive care alone is not drug therapies for NMS, the efficacy of ECT remains unclear and its indic speculative, but its use seems reasonable in patients with severe, persist treatment-resistant NMS and for those with residual catatonia or psychos resolution of other manifestations.[13, 69]

Adverse Effects on Other Organ Systems

Sedation, dry mouth, and urinary retention occur commonly with antipsy particularly during the initial period of therapy. These symptoms occur m with drugs having potent antihistaminic and antimuscarinic activity. All dr the seizure threshold, but seizure activity rarely complicates therapeutic without additional risk factors. Because hypothalamic dopamine normally prolactin release by the pituitary gland, all antipsychotics with dopamine properties can cause hyperprolactinemia and galactorrhea.

The atypical antipsychotic agents are associated with weight gain, dyslip steatohepatitis, and rare but dramatic instances of glucose intolerance, i cases of diabetic ketoacidosis.[6, 42, 76, 92] Other idiosyncratic reactions use of antipsychotics include photosensitivity, skin pigmentation and cho (which occur with the phenothiazines), myocarditis, and agranulocytosis with several drugs but most notably clozapine, ie, between 0.38% and 2% Most of these conditions result from an immunologically based hypersens and develop during the first month of therapy.

Acute Overdose

Antipsychotic overdose can produce a spectrum of toxic manifestations a organ systems, but most serious toxicity involves the CNS and cardiovas Some of these manifestations are present to a minor degree during thera They tend to be most pronounced during the early period of therapy but continued use.

Impaired consciousness is a common and dose-dependent feature of ant overdose, ranging from somnolence to frank coma. It may be associated airway reflexes, but significant respiratory depression is uncommon. Man antipsychotics, including several of the atypical drugs, are potent musca and can produce dramatic anticholinergic manifestations in overdose.[11, Peripheral manifestations include tachycardia, decreased production of sw flushed skin, urinary retention, diminished bowel sounds, and mydriasis, also occurs. These findings may be present in isolation or coexist with ce manifestations, which can be highly variable and may be mistakenly attrib underlying psychiatric illness. These manifestations include agitation, de psychosis, hallucinations, and coma.

Mild elevations in body temperature are common and reflect impaired he because of impaired sweating and increased heat production in agitated Elevations in body temperature should always prompt a search for other of NMS. Tachycardia is a common finding in patients with antipsychotic o reflects peripheral anticholinergic effects as well as a compensatory respo hypotension. Bradycardia is distinctly uncommon. Although it may be a p event, its presence should prompt a search for alternate causes, including

(particularly Î²-adrenergic antagonists, calcium channel blockers, cardioa and opioids) and myocardial ischemia. Hypotension is a common feature overdose. Peripheral Î±$_1$ -adrenergic blockade reduces vasomotor tone. maintenance of vasomotor tone may be impaired, albeit by an unknown

The electrocardiographic (ECG) manifestations of antipsychotic overdose a those of TCA toxicity (Chaps. 5 and 71) and include widening of the QRS rightward deflection of the terminal 40 msec of the QRS complex (T40mse terminal component of the QRS complex in lead aVR). These changes refl the inward sodium current (I_{Na}). Prolongation of the QTc interval results of the delayed rectifier potassium current (I_{Kr}), creating a substrate for torsade de pointes.[68] This situation is sometimes evident during mainten and may underlie the apparent increase in sudden cardiac death among u antipsychotic drugs.[77] A published meta-analysis of the operating charact ECG in patients with TCA toxicity found the ECG was a relatively poor pre seizures, dysrhythmia, and death.[7] However, the ECG is a dynamic instru particularly in the initial hours following overdose, and few studies have longitudinal changes in the ECG.[55]

Diagnostic Tests

The diagnosis of antipsychotic poisoning is supported by the clinical histo examination, and a limited number of adjunctive tests. Both the clinical a electrocardiographic findings are nonspecific and can occur following over different drug classes, including TCAs, skeletal muscle relaxants, carbam first-generation antihistamines. Moreover, the absence of typical ECG cha exclude a significant antipsychotic ingestion, particularly early following o least 1 additional ECG should be performed in the following 2â€“3 hours.

Historically, positive urine colorimetric testing using ferric chloride or Ph test strips indicated the presence of phenothiazines. Abdominal radiograp densities in the gastrointestinal tract, as some solid dosage forms of phe radiopaque. However, these tests are neither sensitive nor specific, and t routinely recommended.

Plasma concentrations of antipsychotics are not widely available, do not

with clinical signs and symptoms, and do not help guide therapy. Compre drug screens using high-performance liquid chromatography or gas chro mass spectrometry may indicate the presence of antipsychotics, but these available at only a few hospitals and provide only a qualitative result. Blo immunoassays for TCAs may yield a false-positive result in the presence phenothiazines.[5 , 82]

Management

The care of a patient with an antipsychotic overdose should proceed with that other drugs, particularly other psychotropics, may have been coinges confound both the clinical presentation and management. Regularly enco coingestants include antidepressants, sedative-hypnotics, anticholinergic acid, and lithium, as well as ethanol and nonprescription analgesics such acetaminophen and aspirin.

Supportive care is the cornerstone for treatment of patients with antipsy Supplemental oxygen should be administered if hypoxia is present. Patier mental status should receive thiamine, naloxone, and parenteral dextrose Intubation and ventilation are rarely required but may be necessary for p very large overdoses of antipsychotic agents or ingestion of other CNS d symptomatic patients should undergo continuous cardiac monitoring. In a electrocardiogram should be recorded and reliable venous access obtaine Asymptomatic patients with a normal electrocardiogram 6 hours after exp exceedingly low risk of complications and no longer require cardiac moni Symptomatic patients and those with an abnormal ECG should have cont monitoring for a minimum of 24 hours.

Gastrointestinal Decontamination

Gastrointestinal decontamination with activated charcoal (1 g/kg by mouth nasogastric tube) should be considered for patients who present within a large or polydrug overdose. Although this intervention is unproven and ti many antipsychotics exhibit significant antimuscarinic activity and slow g

which increase the likelihood that activated charcoal will be beneficial. O
and whole-bowel irrigation likely will not improve clinical outcomes, and
is absolutely contraindicated because of the high potential for pulmonary

Treatment of Cardiovascular Complications

Vital signs should be monitored closely. Hypotension may result from per
blockade and most likely occurs with older, low-potency antipsychotics su
thioridazine. The hypotension should be treated initially with appropriate
0.9% sodium chloride solution (30â€“40 mL/kg). If vasopressors are req
acting Î± agonists such as norepinephrine or phenylephrine are preferred
dopamine, which is an indirect agonist and likely will be ineffective. Vaso
analogs also can be used. Continuous, intraarterial blood pressure monito
warranted in these cases. Central venous pressure monitoring and pulmo
catheterization rarely influence treatment decisions and should be used or
patient's clinical status is obfuscated by significant coingestion or comorl

(amiodarone, sotalol, and bretylium) can aggravate cardiotoxicity and sho used. When administering sodium bicarbonate to patients with antipsych caution must be taken to avoid hypokalemia, as many of these antipsych cardiac potassium channels thereby prolonging the QT_c . Hypokalemia ca this blockade and potentially produce torsades de pointes.

Sinus tachycardia should not be treated unless it is associated with activ which, although uncommon, may complicate antipsychotic overdose in pa existing coronary disease. Should sinus tachycardia occur, a short-acting antagonist such as esmolol may be preferable. Prolongation of the QTc i no specific treatment other than correction of potential contributing cause hypokalemia and hypomagnesemia. Torsades de pointes should be treated magnesium sulfate, taking care to prevent hypotension, which is dose an dependent. Overdrive pacing with isoproterenol or transcutaneous or tra should be considered if the patient does not respond to magnesium sulfat theory this therapy may worsen the rate-dependent sodium channel bloc

Treatment of Seizures

Seizures associated with antipsychotic overdose are generally short-lived require no pharmacologic treatment. Multiple or refractory seizures shoul search for other causes, including hypoglycemia and ingestion of other p medications. When treatment is necessary, benzodiazepines such as loraz diazepam generally suffice, although phenobarbital may be necessary. A phenytoin is part of the standard algorithm for status epilepticus, it is in xenobiotic-induced seizures; barbiturates are preferred. Refractory seizur respond to propofol infusion or general anesthesia. Seizures complicated hyperthermia are considerably more ominous and warrant aggressive lowe temperature with aggressive rapid cooling measures. Finally, seizures can serum pH and abruptly increase the cardiotoxicity of these drugs; therefo should be recorded following resolution of seizure activity.

Treatment of the Central Antimuscarinic S

Many of the older-generation and newer-generation antipsychotics have

anticholinergic properties. Case reports and observational studies suggest cholinesterase inhibitor physostigmine (Antidotes in Depth: Physostigmin can safely and effectively ameliorate the agitated delirium associated with anticholinergic syndrome by indirectly increasing synaptic acetylcholine l , [101] Although benzodiazepines will control agitation, they will further imp status, obfuscating the assessment of mental status and increasing the ris complications.[21]

Physostigmine should be used with caution. It should not be used in patie dysrhythmias, any degree of heart block, or widening of the QRS complex physostigmine is used, it should be given in 0.5-mg increments every 3â with close observation of the patient. If bradycardia, bronchospasm, or develop, they can be treated with glycopyrrolate 0.2 to 0.4 mg IV. Atropi

be used, although it crosses the bloodâ€“brain barrier and may further w underlying delirium. Physostigmine's effects are transient, typically rangir 30â€“90 minutes, and additional doses are often necessary. Of note, phy not prevent other complications of antipsychotic overdose, particularly th the cardiovascular system.

Other commonly used cholinesterase inhibitors, such as edrophonium, ne pyridostigmine, should not be used to treat anticholinergic delirium becaus cross the bloodâ€“brain barrier. Case reports involving other anticholiner that cholinesterase inhibitors used for treatment of dementia (eg, tacrine galantamine) may be alternatives to physostigmine for patients who can medications orally.[44 , 64 , 71]

Enhanced Elimination

No pharmacologic rationale supports the use of multiple-dose charcoal or urinary pH to increase the clearance of antipsychotics. One volunteer stuc urinary acidification may increase remoxipride elimination,[102] but this pra impractical and possibly dangerous. Because most antipsychotics have lar distribution and extensive protein binding (Table 67-1), neither hemodia hemoperfusion is expected to significantly increase clearance. These mod be considered only if the patient has concomitantly ingested other xenob

to extracorporeal removal, such as lithium.

Summary

Over the past decade, the atypical antipsychotics have largely supplante drugs, which were associated with greater toxicity in overdose and a high extrapyramidal reactions. Consequently, atypical antipsychotics are now i majority of overdoses.

With both typical and atypical antipsychotics, toxicity can occur either du of therapy or following overdose. Of the various toxicities that arise duri use, NMS is the most dangerous. Its manifestations are protean, and it m to recognize. Altered mental status, muscle rigidity, fever, and autonomic its hallmarks, but the diagnosis should be considered in any unwell patien antipsychotics, particularly in the 2 weeks following a change in the anti regimen. Treatment of NMS is largely supportive and often dependent on benzodiazepines. Dantrolene, dopamine agonists such as bromocriptine, electroconvulsive therapy are anecdotally associated with dramatic clinic

The principal manifestations of antipsychotic overdose involve the CNS ar cardiovascular system. Depressed mental status, hypotension, and antich are nonspecific features that support the diagnosis of antipsychotic overd particularly in conjunction with typical ECG findings of sodium channel blo prolongation. Most fatalities following antipsychotic overdose occur in cas coingestion of other CNS depressants or cardiotoxic medications. Supporti mainstay of therapy for patients with antipsychotic overdose, although se nonspecific antidotes, such as activated charcoal, sodium bicarbonate, an physostigmine, may improve outcomes in some patients.

Chapter 68
Lithium

Howard A. Greller

Lithium

MW	=	6.94 daltons

Lithium levels (serum):

Therapeutic level for bipolar depression	=	0.6â€“1.2 mEq/L (mmol/L)

A 55-year-old man was brought to the emergency department (ED) with a 3-day history of progressively worsening confusion and tremor. The patient was an accountant and normally was a highly functioning, intelligent person. Eight days prior to presentation, he saw his primary care physician for complaints of fever, chills, cough, myalgias, arthralgias, and malaise. Symptomatic therapy with an oral decongestant, acetaminophen, and oral hydration was prescribed. His symptoms improved, but he became progressively more confused and tremulous.

Upon questioning the family, the patient was found to have a medical history significant for bipolar disorder, for which he was receiving a stable dose of lithium carbonate for more than 10 years. He had no psychiatric hospitalizations, no history of suicide attempts, and took no other psychiatric medications. No other medications were available in the household.

On physical examination, the patient was a well-appearing, slightly disheveled man in no apparent respiratory distress. His vital signs were: blood pressure, 135/86 mm Hg; pulse, 105 beats/min and regular; respiratory rate, 14 breaths/min; temperature, 99.5Â°F (37.5Â°C); oxygen saturation, 97% on room air; and a rapid bedside glucose concentration, 106 mg/dL.

Examination revealed prominent horizontal nystagmus. Pupils were equal, round, and reactive to light and accommodation. The oral mucosa were dry, but the remainder of the head and neck examination was unremarkable. The chest was clear to auscultation and percussion. Cardiac examination revealed a regular rate and rhythm, without the presence of murmurs, rubs, or gallops. Abdominal examination was unremarkable, and rectal examination revealed good rectal tone, a normal prostate, and no occult blood. The skin was warm, dry, and free of rashes or other findings.

The patient had difficulty complying fully with the neurologic examination because of his altered level of consciousness. He was alert and oriented to person but disoriented to time and place. Throughout the examination, he continuously attempted to get off the bed so that he could â€œattend an important meeting.â€• He was mildly agitated and had a noticeable tremor in his upper extremities. His cranial nerves were normal with the exception of his horizontal nystagmus. His motor strength was normal and symmetric. All deep tendon reflexes were hyperactive and symmetric with clonus in both ankles. The patient was unable to comply with formal cerebellar function testing.

The patient was attached to a cardiac monitor, and 2 L oxygen was administered by nasal cannula. A large-bore intravenous catheter was inserted, and blood samples were obtained for determination of serum electrolytes, complete blood count (CBC), acetaminophen, salicylate, ethanol and lithium concentrations. An infusion of 0.9% sodium chloride solution was started. An electrocardiogram showing sinus tachycardia at a rate of 105, with normal axis, intervals, and T waves and no evidence of acute ST-segment changes. A chest radiograph showed no evidence of active or acute pulmonary disease. The patient was sedated with 1 mg intravenous lorazepam for persistent agitation.

The serum lithium concentration was reported as 2.74 mEq/L, and a repeat specimen was drawn and sent for analysis. The acetaminophen, salicylate and ethanol concentrations were negative. The blood urea nitrogen (BUN)/Cr ratio of 21/1.3 mg/dL was elevated compared to a ratio of 9/0.8 mg/dL determined 3 weeks earlier. All other laboratory values were unremarkable. Infusion of 0.9% sodium chloride solution was increased to 2 times the maintenance rate, and a nephrology consultation was requested.

The repeat lithium concentration was 2.38 mEq/L. Based on the combination of clinical and laboratory findings, hemodialysis was initiated. After 4 hours of hemodialysis the patient's mental status improved by all measures. The immediate postdialysis lithium concentration was 0.74 mEq/L, and the concentration 6 hours postdialysis was 1.41 mEq/L, after which the patient underwent a second

4-hour dialysis. The lithium concentration after the second dialysis was 0.97 mEq/L and did not rebound higher during the remainder of the hospitalization. When the patient was discharged on hospital day 3, he has a normal neurologic examination and had returned to his baseline mental status.

History

Lithium has a long history of use beginning in the mid-19th century, when lithium salts were used to treat gout. The therapy also improved symptoms of mania and depression.[91,161] Lithium was the original â€œactiveâ€• ingredient in the soft drink 7-Up.[3] During the 1930s and 1940s, it was used as a salt substitute (â€œWestsalâ€•) for patients with heart failure but was discontinued after several cases of acute lithium poisoning were described.[40,47,64,42] The beneficial effects of lithium on bipolar disorder were â€œrediscoveredâ€• by Cade in 1949, when he noticed the calming effect of lithium carbonate on guinea pigs.[31,32] The same year, however, the FDA banned the use of lithium in response to reported poisonings.[31,127,142] The FDA lifted the ban in 1970 and approved the use of lithium for treatment of mania.

Lithium is the most efficient long-term therapy for treatment and prevention of bipolar affective disorders,[161] with a demonstrated antisuicidal effect and an ability to improve both the manic and depressive symptoms of the illness.[12,13,60,144,161] Investigations on the use of lithium for compulsive gambling have also demonstrated beneficial results.[71] In most industrialized nations, approximately 1 in 1000 persons is using 1 or more of the various lithium formulations.[6,141]

Pharmacology

The simplicity of the lithium molecule belies the complexity of its mechanism of action. Although lithium has been used therapeutically for almost 50 years, the precise pharmacology of its therapeutic effects has not yet been elucidated.[56] Part of the difficulty in defining the precise mechanism of action of lithium is the difficulty in defining the precise pathophysiology of bipolar disorder. Early efforts focused on dysfunctional neurotransmitter systems, particularly the role of biogenic amines. Lithium

increases basal and stimulation-induced serotonin release and receptor sensitivity to serotonin.[29,162] Lithium modulates the effect of norepinephrine through its interactions with the G-proteinâ€“mediated effects on the Î²-adrenergic receptor, thereby stabilizing fluctuations in the intracellular pool of cyclic adenosine monophosphate (cAMP). It performs this function by inhibiting not only the inhibitory subunit G_i, which raises basal concentrations of cAMP, but also the stimulatory subunit G_s, preventing fluctuations from adrenergic stimulation.[29]

Clinically, the therapeutic effects of lithium (and other mood-stabilizing pharmaceuticals) become evident only after chronic administration, so their mechanism of action likely is not solely the result of acute biochemical interactions. Postulated mechanisms go beyond simple neurotransmitter function or dysfunction and focus on altered cellular signaling, neuronal plasticity, and neurogenesis. Rather than trying to identify any single neurotransmitter system as responsible for the complexity of depressive illness, efforts now are directed at elucidating the functional balance between interacting systems. Along with these advances, a clearer understanding of the action of lithium is developing.[18,29,56,67,90,91,144]

The prevailing theory for the mechanism of action of lithium is the inositol-depletion hypothesis. Inositol is a 6-carbon sugar that forms the backbone of a number of cellular signaling mechanisms. Therapeutic lithium treatment results in decreased myoinositol (the most biologically active stereoisomer of inositol) concentration in the cerebral cortex.[4,67,84] Abnormalities in regional brain myoinositol concentrations are thought to occur in bipolar patients. This theory is partially supported by experimental magnetic resonance spectroscopy data.[146,175] Myoinositol is phosphorylated to form phosphatidyl inositol (PIP), which is further phosphorylated and combined with diacylglycerol (DAG) to form phosphatidyl 4,5-bisphosphate (PIP_2). Upon stimulation of a cell, G-proteinâ€“coupled receptors activate phospholipase C

(PLC), which hydrolyzes PIP_2 to release the secondary messengers DAG and inositol 1,4,5-triphosphate (IP_3).[67,143,146,175] Each of these secondary messengers in turn initiates a cascade of events, including activation of protein kinase C (PKC), which is important for calcium homeostasis and neurotransmitter release,[106,107,118,146] as well as independent mobilization and regulation of intracellular calcium.[14,36,114,129,146] Many extracellular signals, including some serotonin receptor subtypes, activate PLC to exert their actions.[61,105,121]

Serial dephosphorylation of IP_3 leads to regeneration of myoinositol and recycling of the inositol pool. Two enzymes involved in this pathway are inhibited by lithium. The first enzyme, inositol 1,4-bisphosphate 1-phosphatase (IPPase), dephosphorylates the bisphosphate to inositol monophosphate (IMP). The second enzyme, inositol 1-monophosphatase (IMPase), dephosphorylates IMP to myoinositol.

The inhibition of IMPase is interesting and important. First, the mechanism of inhibition is uncommon. Lithium uncompetitively inhibits IMPase by binding to the enzymeâ€“substrate complex and preventing the release of a phosphate. It performs this function by displacing a magnesium ion from the active site after hydrolysis. Essentially, uncompetition means the higher the concentration of the substrate, the more the enzyme is inhibited.[7] This supports a theory about the pathophysiology of bipolar disorder involving an excess of myoinositol and is 1 reason why the mood-stabilizing effects of lithium are thought to be found only in bipolar patients.[67] That is, the uncompetitive nature of the action of lithium serves as a regulator to preferentially block pathologic signaling caused by excessive myoinositol while leaving the normal signaling intact. As described, IMPase is an important step in the cellular recycling of the inositol pool. Lithium inhibits the last step in this cycle.

Myoinositol is also generated de novo from glucose-6-phosphate

by inositol synthase, which forms IMP. The inhibition of IMPase by lithium subsequently leads to myoinositol depletion by preventing the conversion of the newly synthesized IMP to inositol. Interestingly, valproic acid (VPA) also inhibits inositol synthase, illustrating a potential mechanism for the synergy of these complementary mood stabilizers.[119] A third mechanism of intracellular diminution of inositol by lithium (as well as VPA and carbamazepine) is the effect of lithium on reducing activity and transcription of the sodium myoinositol transporter (SMIT), thereby preventing the uptake of exogenous myoinositol by the cell. This mechanism of inhibition can be overcome by increased extracellular concentration of myoinositol.[67,173]

The result of these effects is depletion of the inositol pool available to the cell, causing a series of events at different points in the signal transduction cascade that leads to differential gene transcription and expression. This sequence ultimately is responsible for the

observed clinical effects of lithium on the CNS.[29,143] Experimental data, using dextroamphetamine as a model for clinical mania, have shown that dextroamphetamine increases regional inositol signaling in the human brain, and that pretreatment with lithium attenuates this increase, lending support to the hypothesis.[21]

Another proposed theory for the mechanism of action of lithium is inhibition of the family of glycogen synthase kinase-3 (GSK-3) kinases. GSK-3Î² overactivity is associated with neuronal degeneration and sensitivity to apoptotic stimulation. GSK-3Î² is a key regulator of neuronal cell fate, with a proapoptotic effect in many settings.[42,50,70,78,79 and 80,133] GSK-3Î² is involved in regulating the activity of Î²-catenin, Jun, and cAMP response element-binding protein (CREB), transcription factors important in embryonic patterning, cell proliferation, neuronal modeling and plasticity, neuronal signal transduction, and cytoskeletal remodeling. Lithium inhibits GSK-3Î² indirectly through

phosphorylation (by activation of PKC) and directly through inhibition of enzymatic activity through magnesium mimicry. Inhibition of GSK-3Î² by lithium is thought to be neuroprotective.[29,63,68,126,134,176]

A link between GSK-3Î² activity and bipolar disorder and depression is supported by the finding that serotonergic activity inhibits GSK-3Î² in vivo.[92] Additionally, hypoxia contributes to increased GSK-3Î² activity, which can be counteracted or inhibited through mood-stabilizing drugs. Vascular depression, or depression following stroke, is an organic model of major depression.[111] The finding that this depressive state responds similarly to intervention with mood stabilizers lends additional support to the GSK-3Î² hypothesis.[81] Thus, the depressed serotonergic activity associated with depression, or the hypoxic-induced activation of GSK-3Î², may lead to impaired inhibition of GSK-3Î². Mood stabilizers counteract this dysregulation and may explain their effectiveness in depression. This theory is under active investigation.[29,61,67,68,126,171]

Lithium is implicated in the neuroprotective modulation of the *bcl*-2 gene, which is known for its role in preventing apoptosis and in downregulation of the proapoptotic protein p53. In rats treated with either Li^+ or VPA, concentrations of Bcl-2 protein doubled.[34] These findings, although not necessarily replicated in human beings, are supported by the findings that patients undergoing long-term therapy with either drug had prefrontal cortex volumes significantly greater than in patients not treated with either agent, suggesting a protective effect in human patients.[29,37,45]

In summary, although the precise mechanism of action of lithium is unknown, some common features of investigation have emerged. The potential targets, widely found and disparate in function, all seem to be inhibited by lithium in an uncompetitive fashion, most commonly through displacement of a divalent cation, usually Mg^{2+}. The systems affected by this inhibition vary widely.

Downstream targets seem to modulate secondary cell messengers and intracellular signal transduction, transcription factors and gene expression, and neuronal plasticity and cellular differentiation. Further study is needed to elucidate the complex interaction of these pathways with the action of lithium in order to form an integrated hypothesis.

Pharmacokinetics and Toxicokinetics

The volume of distribution of lithium is between 0.6 and 0.9 L/kg. It displays no discernible protein binding and distributes freely in total body water, except for the cerebrospinal fluid (CSF), from which it is actively extruded.[48,122,148] The extrusion is believed to occur through an active transport process involving sodium/lithium exchange at the arachnoid processes.[49] The immediate-release preparations of lithium are rapidly absorbed from the gastrointestinal (GI) tract. Peak plasma concentrations are achieved within 1â€“2 hours.[76] Sustained-release products demonstrate variable absorption, with a delay to peak of 6-12 hours. In overdose, a longer delay to reach peak concentrations or multiple peaks may occur.[46] Chronic therapy prolongs the elimination of lithium, as does advancing age.[122] Although lithium is rapidly absorbed, tissue distribution is a complex phenomenon, with a significant delay in reaching a steady state. Lithium exhibits preferential uptake into certain tissues (eg, kidney, thyroid, and bone) over others (eg, liver, muscle). Lithium distribution into the brain can take up to 24 hours to reach equilibrium. Lithium is concentrated in red blood cells (RBCs) by both passive diffusion and active transport. RBC concentration may correlate closely with brain concentrations, although further study to confirm this possibility is warranted.[33,128] The pharmacokinetic profile of lithium is described as an open, two-compartment model.[53,77]

Each 300-mg lithium carbonate tablet contains 8.12 mEq lithium.[161] Ingestion of a single 300-mg tablet is expected to

acutely raise the serum lithium concentration by approximately 0.1â€“0.3 mEq/L (assuming a volume of distribution of approximately 0.6â€“0.9 L/kg and a patient weight 50â€–100 kg).

Lithium is eliminated almost entirely (95%) by the kidneys, with a small amount eliminated in the feces.[76] Lithium is also found in sweat, saliva, and breast milk.[43,73,115] In an adult with normal renal function, lithium clearance ranges from 25â€“35 mL/min.[20,158,159] At steady-state equilibrium, as in patients undergoing chronic therapy, total body clearance equals renal clearance.

Lithium is handled by the kidneys much in the same way as sodium. Lithium is freely filtered, and more than 60% is reabsorbed by the proximal tubule. Evidence also indicates a small amount of reabsorption by the loop of Henle and distal tubule.[8,24,25,44,54,89,122,161] Lithium excretion is dependent on factors that affect the glomerular filtration rate (GFR) or decrease sodium concentration. Any condition that makes the kidney sodium-avid (eg, volume depletion or salt restriction) increases lithium reabsorption in the proximal tubule.[8] Risk factors for development of lithium toxicity therefore include advanced age with its associated decrease in GFR, thiazide diuretics, nonsteroidal antiinflammatory drugs, angiotensin-converting enzyme (ACE) inhibitors, decreased sodium intake, and low-output heart failure.[76,89]

The therapeutic index for lithium is narrow. The generally accepted steady-state therapeutic range of serum lithium concentrations is 0.6â€“1.2 mmol/L, although much disagreement exists about whether this serum concentration truly reflects therapeutic efficacy.[58,59,135] Both in therapeutic and overdose situations, clinical signs and symptoms seem to be a more valuable indicator of brain lithium concentrations.[135]

Clinical Manifestations

Similar to other substances having prolonged redistributive phases and tissue burdens, lithium exposure can be divided into 3 main categories of toxicity: acute, acute-on-chronic, and chronic. In acute lithium toxicity, the patient has no body burden of lithium present at the time of ingestion. The toxicity that develops depends on the rate of absorption and distribution. In chronic toxicity, the

patient has a stable body burden of lithium as serum concentration is maintained in the therapeutic range, and then some factor disturbs this balance, either by enhancing absorption, or more commonly, decreasing elimination. For the chronic user of lithium small perturbations in the equilibrium between intake and elimination can lead to toxicity. In acute-on-chronic toxicity, the patient ingests an increased amount of lithium (intentionally or unintentionally) in the setting of a stable body burden. With tissue saturation, any additional lithium leads to signs and symptoms of toxicity.

Acute Toxicity

Lithium is a metal salt. Acute ingestions of lithium-containing preparations produce a clinical picture similar to that of ingestions of other metal salts, with predominant early GI symptoms. Nausea, vomiting, and diarrhea are prevalent. A large volume loss can result from these symptoms. Patients may complain of lightheadedness and dizziness, and they can be orthostatic on evaluation. Neurologic manifestations are a late finding in acute toxicity, as the lithium redistributes slowly into the CNS.

Lithium is associated with a number of electrocardiographic abnormalities, although the evidence for significant effects is tenuous. The most commonly reported manifestation is T-wave flattening or inversion, primarily in the precordial leads.[28,124,160] Lithium is associated with prolongation of the QTc interval.[174] A

study has associated elevated serum lithium concentrations with QTc prolongation >440 msec, although the number of patients studied was small.[72] Associations exist between lithium and sinoatrial nodal dysfunction, with bradycardia. Theoretically, this condition may result from lithium's effect on G-proteinâ€“mediated cAMP generation, and subsequent modification of calcium channel opening and calcium influx in the pacemaker cells.[28,72,124,160] For the most part, lithium has few consequential effects on cardiac function, even in overdose, and malignant dysrhythmias or significant dysfunction is rare.[99,117,122]

Chronic Toxicity

Lithium is primarily a neurotoxin.[2] The earliest case reports of lithium toxicity described predominantly neurologic symptoms.[41,169] Of note, neurotoxicity does not correlate with serum concentrations. The initial clinical condition of the patient and the duration of exposure to an elevated concentration seem to be more closely predictive of outcome than the initial serum lithium concentration.[2,6,16,65,87,116,140,166]

Tremor, a common finding in patients undergoing chronic therapy, can increase with toxicity. Other findings of chronic toxicity include fasciculations, hyperreflexia, choreoathetoid movements, clonus, dysarthria, nystagmus and ataxia.[122,161] Mental status often is altered and can progress from confusion to stupor, coma, and seizures.[30] Electroencephalographic changes are most frequently reported as â€œslowing.â€• The progression of these symptoms follows no order, and any patient undergoing chronic therapy can have 1 or any combination of these features.

The syndrome of irreversible lithium-effectuated neurotoxicity (SILENT) is a descriptive syndrome of the irreversible neurologic and neuropsychiatric sequelae of lithium toxicity.[2] SILENT is defined as neurologic dysfunction caused by lithium in the absence of prior neurologic illness that persists for at least 2 months after

cessation of the drug. Case reports in the literature support these findings and this definition. However, as is true in most case reports, confounders make wide applicability of the findings difficult. Because of the polypharmacy prevalent in psychiatric treatment, long-term neurologic sequelae attributed to lithium are described in patients using lithium in combination with other medications, such as haloperidol, chlorpromazine, carbamazepine, phenytoin, aspirin, valproic acid, amitriptyline, Î²-adrenergic antagonists, calcium channel blockers, ACE inhibitors, diuretics and nonsteroidal antiinflammatory drugs.[2,10,38,52,53,66,104,113,166] However, patients who used lithium without coingestants and had no comorbid illness but sustained lasting dysfunction as a result of lithium toxicity are reported.[6,85,116,123,140,166] Cerebellar findings seem to predominate in SILENT.[2,62,82,85,108] One predictor of persistent neurologic dysfunction seems to be the concomitant finding of hyperpyrexia, an ominous finding in lithium toxicity.[62,108] The mechanism of persistent dysfunction is unclear, but demyelination and cellular loss are proposed.[2,108,116,138]

Acute-on-Chronic Toxicity

Patients undergoing chronic therapy who acutely ingest an additional amount of lithium (either intentionally or unintentionally) are at risk for signs and symptoms of both acute and chronic toxicity. Such patients display prominent GI and neurologic symptoms and can be difficult to diagnose and manage. Serum lithium concentrations in cases of acute or chronic toxicity can be difficult to interpret, and therapy should be guided by the patient's clinical status.

Other Systemic Manifestations of Chronic Lithium Therapy

The most common adverse effect of chronic lithium therapy is the

development of nephrogenic diabetes insipidus. The process thought to be involved is the interference of lithium on magnesium-dependent G proteins that activate vasopressin-sensitive adenylate cyclase, leading to decreased generation of cAMP in the cell membranes of distal tubular cells.[35,109,149,167] Decreased cAMP leads to reduced expression and translocation of the vasopressin-regulated water channel aquaporin-2 (AQP-2), making the distal tubules resistant to the action of vasopressin.[5,39,83,109,110,137,170] Lithium also inhibits the transport of sodium through the amiloride-sensitive Na^+ channel.[157]

Another theory proposed for the mechanism of lithium-induced nephrogenic diabetes insipidus suggests that lithium inhibits GSK-3Î², directly and through a phosphorylation pathway. GSK-3Î² exhibits tonic inhibition of cyclooxygenase-2 (COX-2). When this inhibition is removed by lithium, COX-2 activity leads to increased prostaglandin expression in the renal medulla. Increased prostaglandin expression is thought to play an important role in nephrogenic diabetes insipidus through regulation of glomerular blood flow.[102,130]

Chronic lithium therapy is associated with chronic tubulointerstitial nephropathy, as manifested by the development of renal insufficiency with little or no proteinuria and biopsy findings of tubular cysts. This association was demonstrated in 1 biopsy-based study of 24 chronically treated patients, although the overall prevalence of this condition is low.[109]

Lithium is associated with a number of endocrine disorders. The most prevalent endocrine manifestation of chronic lithium therapy is hypothyroidism. The causative etiology is multifactorial. Lithium is selectively concentrated in the thyroid gland and impairs iodine uptake, synthesis of triiodothyronine (T_3), responsiveness of the gland to thyroid-stimulating hormone (TSH), release of T_3 and

tetraiodothyronine (T_4), and peripheral conversion of T_4 to T_3. Additionally, lithium decreases responsiveness of peripheral tissues to T_3 and leads to the development of antithyroglobulin antibodies.[120,172] Although hypothyroidism is most common, hyperthyroidism and frank thyrotoxicosis also are reported.[15] However, hyperthyroidism, by altering proximal tubule function, leads to decreased lithium excretion.[19] Thus, hyperthyroidism may lead to chronic lithium toxicity through impaired elimination, and the elevated lithium concentrations may mask the manifestations of hyperthyroidism.[120] Further investigation of this condition is warranted.

The combination of hyperparathyroidism and hypercalcemia is frequently reported with chronic lithium therapy, most commonly in women. The mechanism is thought to be modification of calcium feedback on parathyroid hormone release, although stimulation of parathyroid hyperplasia and adenomas is suggested.[1,9,23,88,147,161]

Developmentally, in utero exposure to lithium increases the incidence of congenital heart defects, specifically Ebstein anomaly.[73,126,147] Additionally, many effects similar to those that occur in patients undergoing chronic therapy are found in infants exposed in utero, including thyroid disease and neurotoxicity.[73]

Lithium causes a leukocytosis and an increase in neutrophils. It has been proposed as an adjunct to chemotherapy-induced neutropenia, other marrow suppressive therapies, and acquired immunodeficiency syndrome (AIDS). Although lithium increases the total neutrophil count, no improved clinical outcomes are documented, and its use has been superseded by recombinant colony-stimulating factors.[26,126,132,147,151]

Diagnostic Testing

Because of the prevalence of lithium use, therapeutic drug

monitoring is readily available in most settings, and concentrations should be readily obtainable. A lithium concentration should be requested upon patient presentation and serial measurements requested or considered in most instances, especially in cases of sustained-release ingestions. Emphasis should be placed upon the lithium concentration as a marker of exposure and response to therapy, not necessarily as a determinant of toxicity. The choice of therapy should be guided by the patient's clinical signs and symptoms (and history) rather than an absolute lithium concentration. The sample must be sent in an appropriate lithium-free tube, because certain lithiated-heparin tubes can lead to false-positive results. Serum electrolyte concentrations including renal function should be monitored, because renal function is important in determining the need for more aggressive therapy, including enhanced elimination technique (ie, hemodialysis). If the patient is hypernatremic, nephrogenic diabetes insipidus should be suspected, and determinations of serum and urine osmolarity help confirm the diagnosis. If clinical thyroid disease is suspected, thyroid function tests can be obtained. As with all deliberate ingestions, a serum acetaminophen concentration should be obtained. An electrocardiogram is also indicated for this type of ingestion. The complete blood count may indicate a leukocytosis, which may merely be a stress response or caused by the effects of lithium.

Management

Initial management and stabilization begins with assessment of the basics of resuscitation: airway, breathing, and circulation. Lithium rarely, if ever, affects the airway or breathing of the patient, although coingestants may. Emesis, which occurs at a significant incidence and is associated with acute lithium exposure, may lead to aspiration and respiratory compromise. Once the patient is stable, the nature of the exposure should be determined while physical examination and laboratory assessment commence. The

formulation and nature of the product should be ascertained as immediate-release or sustained-release. Information should be obtained regarding whether or not lithium is part of the patient's medication regimen, which will help determine whether the ingestion is acute, acute-on-chronic, or chronic.

Gastrointestinal Decontamination

For patients who present after an acute (or acute-on-chronic) overdose, a risk-to-benefit analysis of GI decontamination must be undertaken. Two factors should be considered. With an acute overdose and predominance of early GI symptoms, including emesis, self-decontamination may have already started. Second, immediate-release preparations are often rapidly absorbed and may not lend themselves to GI evacuation.

Few GI decontamination options are available to the treating physician. Although syrup of ipecac is no longer generally recommended as a standard decontamination choice, emesis still may be useful in certain instances of sustained-release preparation ingestions when care may be delayed or is distant, as in remote or rural areas. Immediate-release preparations of lithium are rapidly absorbed and produce emesis, whereas sustained-release formulations of lithium (ie, controlled-release tablets) and a slowly dissolving film-coated formulation often are too large to fit through even the largest lavage tube. Thus, orogastric lavage has essentially no role in the acute management of a lithium overdose, unless indicated for a coingestant.

Lithium is a monovalent cation that does not bind readily to activated charcoal.[97] Because no beneficial effect from activated charcoal is expected, the danger of a depressed level of consciousness, potential loss of protective airway reflexes, and prominent emesis contraindicate activated charcoal use, except for treatment of a potential coingestant.

Sodium polystyrene sulfonate (SPS) is a cationic exchange resin often used for treatment of severe hyperkalemia. It binds potassium in exchange for sodium, allowing elimination of excess potassium in the feces. Because of the similarity between potassium and lithium, use of SPS has been proposed for decontamination of patients being treated for lithium toxicity. A number of animal models have been used to examine the effectiveness of this technique.[93,94,95,96,97 and 98,100,101] Use of SPS has many theoretical benefits, including demonstrated effectiveness of lithium binding compared to activated charcoal and the ability of orally administered SPS to reduce serum concentrations of intravenously administered lithium in mice.[95,97,98] Unfortunately, the finding that doses used to increase lithium elimination also lead to significant hypokalemia in human subjects limits the application of this technique.[94,136] In a murine model, potassium supplementation with SPS was found to mitigate process, but only at the expense of elevated lithium concentrations.[100] Two reports in the literature demonstrate increased lithium elimination with SPS, one in a healthy volunteer and another in a patient with an acute overdose. However, the serum potassium concentration was not reported in either case.[57,131] At present, use of SPS in the management of the lithium-poisoned patient cannot be recommended.

Whole-bowel irrigation (WBI) is the only GI decontamination modality that has shown any efficacy in eliminating lithium from human subjects. In one of the few clinical trials of WBI, the lithium serum concentrations of 10 normal volunteers who had ingested sustained-release lithium carbonate were plotted against time over a 72-hour period. In the second phase of the trial, the volunteers received 2 L/hour polyethylene glycol solution 1 hour after the ingestion. This study showed a significant reduction (67%) in the serum concentration, even as early as 1 hour after the ingestion.[150] Thus, use of WBI is recommended for sustained-

release preparations.

Fluid and Electrolytes

The critical initial management of the lithium-poisoned patient should focus on restoration of intravascular volume, both in acute poisonings, with GI losses, and in chronic poisonings, with toxic effects that are often the result of disturbances of renal function and lithium elimination. Many patients with lithium toxicity have volume-responsive decreases in renal function,[122] which can be managed by infusion of 0.9% sodium chloride solution at 1.5â€“2 times the maintenance rate. This therapy increases renal perfusion, increases the GFR, and increases lithium elimination. Urine output must be closely monitored. Electrolyte abnormalities should be corrected. Caution should be used in patients with renal insufficiency or failure or congestive heart failure. Monitoring for the development of hypernatremia in patients suspected of having nephrogenic diabetes insipidus is critical.[161]

Lithium-induced nephrogenic diabetes insipidus can be reversed by discontinuation of the drug and through repletion of electrolytes and free water. However, cases of permanence are reported.[103,109,156] Clinical application of amiloride to mitigate lithium-induced polyuria is reported, although the potential for volume contraction and stimulation of lithium reabsorption limits recommendation of this drug as a routine adjunct to acute care.[17,51,55,86]

Attempts to enhance lithium elimination through forced diuresis with loop diuretics (furosemide), osmotic agents (mannitol), carbonic anhydrase inhibitors (acetazolamide), or phosphodiesterase inhibitors (aminophylline) should be avoided. An initial small increase in elimination may be achieved but typically salt and water depletion develop and are followed by increased lithium retention. Use of sodium bicarbonate for urinary alkalinization does not significantly increase elimination over

volume expansion with sodium chloride and can lead to hypokalemia, alkalemia, and fluid overload; therefore, sodium bicarbonate also should be avoided.

Extracorporeal Drug Removal

Debate surrounds the efficacy and practicality of using enhanced elimination techniques in cases of lithium poisoning. Lithium has physicochemical properties that make it amenable to extracorporeal removal.[69,75,76,89] With these characteristics, lithium seems to be an ideal candidate for hemodialysis. In fact, hemodialysis is often recommended for treatment of acute, acute-on-chronic, and chronic lithium toxicity.[11,74,75 and 76,108,125,155,161,168] However, some characteristics of lithium make extracorporeal elimination difficult. Lithium is predominantly localized intracellularly and diffuses slowly across cell membranes.[122] When traditional intermittent hemodialysis is used for chronic exposures, clearance of the plasma compartment is often followed by a rebound phenomenon of redistribution from tissue stores leading to increased plasma concentrations, in some cases approaching predialysis concentrations.[27] An additional complicating factor is that the brain, the â€œtarget organâ€• of toxicity, is not amenable to rapid artificial elimination processes. Attempts have been made to correlate the serum concentration with the lithium concentration in the CSF and brain. In the few studies where CSF concentrations were obtained, serum and CSF lithium concentrations seemed to correlate, but brain concentrations and toxicity did not.[76,139] Magnetic resonance spectroscopic studies of bipolar patients with steady-state lithium concentrations demonstrated a significant variability between brain and serum concentrations, especially within the therapeutic range.[76,135,139] No consensus recommendation on the appropriate time to initiate therapy is available.[11,76,136] In addition, because of the toxicokinetic profile of lithium, serum concentrations do not correlate well with toxicity.[47,76,152,161]

Hemodialysis or an alternative extracorporeal technique is clearly indicated for 3 groups of patients. The first group consists of patients who are manifesting severe signs and symptoms of neurotoxicity, such as alterations in mental status. The second group consists of patients who have renal failure and show signs or symptoms of lithium toxicity. These patients are unable to eliminate their lithium burden and should be dialyzed. The third group consists of patients who show little or no sign of toxicity but who cannot tolerate sodium repletion therapy; these patients should be considered for early hemodialysis. This group includes patients with congestive heart failure or redistributive diseases such as liver failure, pancreatitis, or sepsis.

If the patient belongs to one of these groups, the next step is to determine the probability that the patient will develop toxicity if elimination is not enhanced. Serum concentrations do not necessarily correlate with toxicity. However, they can be a useful aid in making the decision for hemodialysis. As an adjunct to the clinical presentation, an absolute lithium concentration >4.0 mEq/L (mmol/L) with any type of overdose or a concentration >2.5 mEq/L with chronic toxicity should prompt dialysis. These criteria originate from a case series of 23 patients and review of 100 other patients published in 1978, prior to the introduction of sustained-release products.[65] Although this recommendation has never been prospectively evaluated, it still can serve as a useful guide in the management of the lithium-poisoned patient.[11,20]

The dialysate bath should contain bicarbonate rather than acetate. This composition should help lessen the intracellular sequestration of lithium that occurs because of activation of the sodium/potassium antiporter, with preferential intracellular transport of lithium.[125,155]

Whether hemodialysis diminishes or enhances the risk of permanent neurologic sequelae is a subject of debate.[153,154] Although no controlled studies have analyzed this important

management question, the preponderance of evidence suggests a reduced risk.[2,6,11,76,108,112,122,125,140,161]

Continuous venovenous hemodialysis and continuous venovenous hemodiafiltration are two continuous renal replacement therapies (CRRTs) commonly used for treatment of acute renal failure and volume overload and for elimination of exogenous substances.[20,89,163,164 and 165] Both techniques are effective in patients who are hemodynamically unstable, because blood flow through the filter is pump driven and is not dependent on the patient's arterial blood pressure.[69] Other continuous techniques that use patient blood pressure as the basis for flow through the system also may have application here.[164] Traditional intermittent hemodialysis offers clearance

rates that vary between 50 and 170 mL/min.[20,22,89,122,125,164] Although CRRT techniques offer lower clearance per hour than does intermittent hemodialysis, their overall daily clearances are similar.[20,89] With continued improvements in techniques, use of high volumes, and high dialysate flow rates, clearances are improving, approaching more than half the clearance per hour achieved by intermittent hemodialysis in some studies.[20,69,89,164] Although one case of a rebound phenomenon in a patient treated with continuous arteriovenous hemodiafiltration is reported,[22] no cases with use of venovenous techniques are reported, offering a clear advantage over intermittent hemodialysis. Unfortunately, CRRT requires prolonged anticoagulation with its inherent risks. Nevertheless, these techniques may be beneficial in patients who are hemodynamically unstable, or they can be used in series with traditional dialysis in other patients to prevent redistribution of lithium and rebound of serum concentrations.

Peritoneal dialysis (PD) has been recommended in the past but offers no increased efficacy in clearance of lithium ion over the natural clearance of normal kidneys.[11,69,76,136] Given the infrequent use of this technique and its potential for serious

complications (eg, bowel perforation), PD should not be used in the management of the lithium-poisoned patient.

Summary

Lithium is a simple ion with extremely varied and complex clinical and pathophysiologic effects. It is available in multiple formulations, both immediate-release and sustained-release. Lithium remains an essential part of the pharmacologic arsenal of clinical psychiatry. Because of the complexity of lithium's pharmacokinetic profile, toxicity can develop in a wide range of conditions and can be precipitated by both intentional overdose and therapeutic misadventure. The care of the lithium-poisoned patient should be predicated on rapid identification of the poisoning, followed by management that includes use of volume resuscitation and, when indicated, WBI and hemodialysis or other extracorporal techniques to prevent or treat severe neurologic morbidity and to prevent mortality.

Title: *Goldfrank's Toxicologic Emergencies, 8th Edition*

Chapter 69
Monoamine Oxidase Inhibitors

Lada Kokan

A 50-year-old man with a history of hypertension and depression was found face down on the floor in his home. He was last known to be well 24 hours before arrival of Emergency Medical Services (EMS). A medication list was found and listed clomipramine, tranylcypromine, olanzapine, rosuvastatin, and hydrochlorothiazide. EMS described the patient as nonverbal and diaphoretic but breathing spontaneously. He had mottled skin and involuntary movements of the right arm.

In the emergency department, the patient's vital signs were: blood pressure, 160/130 mm Hg; pulse, 120 beats/min; respiratory rate, 30 breaths/min; rectal temperature, 106.8Â°F (41.6Â°C). On physical examination, the patient was noncommunicative, incontinent of urine, and had shaking movements of his entire body. His pupils were 5 mm and sluggishly reactive bilaterally. Pulmonary, cardiac, and abdominal examinations were unremarkable. His neurologic examination revealed that all four extremities were stiff with neither cogwheel nor lead pipe rigidity

and reflexes that were 2+ in the upper extremities and 1+ in the lower extremities.

Rapid-sequence intubation was immediately performed, for which the patient was given benzodiazepines and neuromuscular blockers. A 500-mL intravenous bolus of 0.9% sodium chloride solution was empirically administered, and the patient was cooled in an ice bath until his temperature was 101Â°F (38.3Â°C).

The initial laboratory results were notable for the following: white blood cell (WBC) count, 14,000/mm^3 ; hemoglobin, 15 g/100 mL; sodium, 163 mEq/L; potassium, 4.6 mEq/L; chloride, 116 mEq/L; HCO^-_3 , 24 mEq/L; blood urea nitrogen (BUN), 69 mg/dL; creatinine, 4.6 mg/dL; glucose, 56 mg/dL. Creatinine kinase concentration was 13,000 U/L, hepatic aminotransferases were normal, and blood ethanol concentration was negative. An arterial blood gas prior to intubation while the patient was being ventilated with a bag-valve-mask on 100% oxygen showed: pH, 7.25; PCO_2 , 45 mm Hg; PO_2 , 127 mm Hg; lactate, 2.9 mmol/L. Initial urinalysis revealed light-red color with 100 red blood cells per high-power field (RBC/HPF) but no WBCs, leukocyte esterase, or nitrates. The cerebrospinal fluid obtained by lumbar puncture was normal. A propofol infusion was started, and cyproheptadine 6 mg was administered via a nasogastric tube.

After resuscitation, additional information regarding the patient's history was obtained from the psychiatrist. The patient had been taking olanzapine 20 mg daily and clomipramine 300 mg daily for an unspecified period. Tranylcypromine had successfully treated his depression in the past but it had been discontinued. However, because he continued to suffer from depression while on the olanzapine and clomipramine regimen, tranylcypromine was restarted 3 weeks prior to presentation. Approximately 1 week prior to presentation, his tranylcypromine dose was increased from 20 to 30 mg daily, and the clomipramine dose was lowered from 300 to 250 mg daily. Shortly after the dose change, he began to

experience palpitations and diaphoresis for which his psychiatrist prescribed terazosin. However, the terazosin was discontinued when the patient developed orthostatic hypotension.

During his hospital stay, the patient remained intubated for 6 days. His creatinine kinase concentrations continued to rise and peaked at 200,000 U/L, whereas his creatinine concentration dropped steadily. Both values normalized by the time of his discharge 8 days later. The patient was taking no antidepressants upon discharge, but his psychiatrist planned to restart tranylcypromine as monotherapy.

History and Epidemiology

The monoamine oxidase inhibitors (MAOIs) were first used in the early 1950s to treat tuberculosis and hypertension. Once their mood-elevating properties were recognized, they were prescribed for the treatment of depression.[3,4] Despite their effectiveness, the use of MAOIs was limited by their potential food and drug interactions and by their toxicity in overdose. As a result, the MAOIs were largely replaced by tricyclic antidepressants during the 1970s. In the 1980s, there was a resurgence of MAOI use for treatment of refractory depression, phobias, and anxiety disorders.[10] Use of MAOIs again declined following the appearance of less toxic antidepressants, such as the selective serotonin reuptake inhibitors (SSRIs). Currently, patients are carefully selected for MAOI therapy based on strict clinical needs and their ability to comply with the rigorous dietary restrictions.[18]

In an attempt to decrease the problems associated with the first generation of MAOIs, drugs selective for the MAOI subtypes were explored. The monoamine oxidase type B (MAO-B) selective drugs, such as selegiline, are used for treatment of Parkinson disease but do not have antidepressant effects. The monoamine oxidase type A (MAO-A) selective drug clorgyline is an effective antidepressant but is associated with the same food and drug interactions as the

first-generation MAOIs. The third-generation MAOIs are both selective and reversible inhibitors of MAO-A (RIMA). The best studied drug of the third-generation MAOIs is moclobemide, which now is being used for an expanded range of indications, including depression, the phobias, anxiety disorders, obsessive-compulsive disorder, and posttraumatic stress disorder.[64]

In 2003, only 2 fatalities from MAOIs were reported to the American Association of Poison Control Centers (Chap. 130). MAOIs were involved in 0.3% of reported exposures to antidepressants and 0.7% of all reported antidepressant-related deaths. For comparison, SSRIs were involved in 55.3% of reported exposures to antidepressants and 38.7% of reported antidepressant-related deaths, whereas cyclic antidepressants were involved in 12.3% of reported exposures to antidepressants and 29.6% of reported antidepressant-related deaths. Thus, the ratio of deaths to exposures (by percent) attributed to each category of antidepressants is almost identical for MAOIs and cyclic antidepressants but approximately 3 times less for SSRIs.

Pharmacology

Monoamines, also known as *biogenic amines* , are a group of neurotransmitters, including norepinephrine, dopamine, and serotonin, that have in common the presence of a single amine group and metabolism by MAO. MAO is a flavin-containing enzyme present on the outer mitochondrial membrane of central nervous system (CNS) neurons, hepatocytes, and platelets. In a 2-step reaction, MAO catalyzes the oxidative deamination of its various substrates. Importantly, the reaction liberates $H_2 O_2$, a reactive oxygen species that is associated with neurodegenerative diseases, including Parkinson disease.

Two isoforms of MAO are differentiated by their anatomical location and substrate specificity (Table 69-1). MAO-A is located

primarily in cells of the gastrointestinal tract, including the liver, and in serotonergic neurons of the locus caeruleus.[52] Gastrointestinal MAO-A reduces the bioavailability of ingested serotonin, tyramine, and other biogenic amines. Circulating monoamines are inactivated in the liver. MAO-B is found primarily in the dopaminergic raphe neurons of the CNS and in platelets.[52] This substrate specificity explains the use of MAO-A inhibitors as antidepressants and MAO-B inhibitors for treatment of Parkinson disease. Certain xenobiotics are substrates for both MAO subtypes, including tyramine, dopamine, octopamine, and tryptamine.[63]

MAO degradation of monoamines helps regulate presynaptic neurotransmitter stores in the nerve terminal. Therefore, inhibition of MAO prevents presynaptic degradation of monoamines, ultimately resulting in increased neuronal release of monoamines (Figure 69-1). Elevated synaptic concentration of serotonin most closely is correlated with the antidepressant effects of MAOIs. As with other antidepressants, the enzymatic inhibitions produced by MAOIs precede their clinical effects by as long as 2 weeks. The reason for this finding is not well characterized but may relate to a time requirement for downregulation of postsynaptic CNS serotonin receptors.[48] The antidepressant activity of MAOIs is correlated with a greater than 85% inhibition of platelet MAO enzymatic activity, and the effect continues to rise linearly above this level of inhibition.[20 , 23]

MAOIs are a chemically heterogeneous group of drugs (Figure 69-2). Iproniazid, the original MAOI, is a derivative of hydrazine, as are the currently available agents phenelzine and isocarboxazid. As with other hydrazine derivatives, seizures are expected after overdose. Tranylcypromine is structurally an amphetamine derivative. As with other amphetamines, release of stored presynaptic neurotransmitter occurs following therapeutic dosing and with overdose, resulting in varying degrees of autonomic hyperactivity.[36]

The first-generation MAOIs, including phenelzine, isocarboxazid, and tranylcypromine, are nonselective inhibitors of both MAO-A and MAO-B. Therefore, patients taking these drugs must be placed on a restrictive diet to prevent adverse events resulting from the ingestion of tyramine. These first-generation MAOIs bind covalently to MAO and irreversibly inhibit the enzyme's function. Thus, patients taking these MAOIs are depleted of the enzyme until new MAO is synthesized, a process that takes up to 2 weeks. Patients taking first-generation MAOIs remain at risk for food and drug interactions during much of this period.

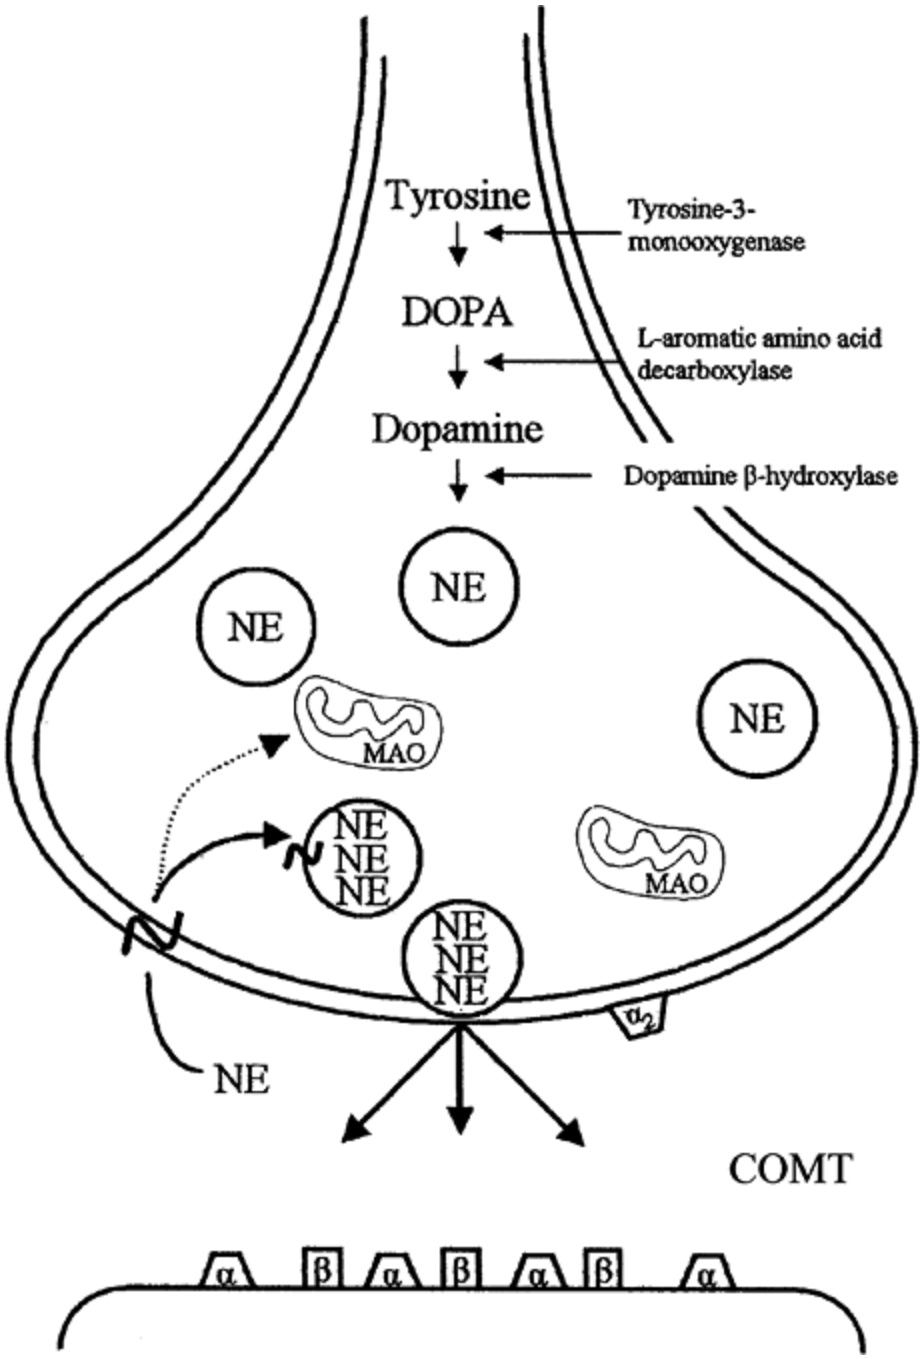

Figure 69-1. Sympathetic nerve terminal. Norepinephrine (NE) is synthesized in the sympathetic nerve cell and stored in vesicles. An action potential causes the vesicles to migrate to and fuse with the presynaptic membrane. NE diffuses across the synaptic cleft and binds with and activates postsynaptic Î±- and Î²-adrenergic receptors. NE then is taken back up into the neuron by the

monoamine reuptake pump and repackaged into vesicles. NE that is taken up by the neuron but escapes repackaging is inactivated by mitochondrial monoamine oxidase (MAO). NE that diffuses away from the synaptic cleft is inactivated by catechol-*O* -methyl transferase (COMT).

Selegiline (deprenyl) is an irreversible inhibitor of MAO-B when used at doses <20 mg/d; above this dose MAOI selectivity is lost. The specificity of MAO-B for dopamine explains the use of selegiline for treatment of Parkinson disease. Approximately 75% of MAO activity in the basal ganglia results from MAO-B.[52 , 66] Selegiline has no antidepressant activity.

Moclobemide, an RIMA, is readily metabolized by MAO, so full MAO function can resume just hours after exposure.[13] Because the enzyme is bound competitively, patients taking moclobemide can still metabolize some ingested monoamines and other drugs.[21]

Another medication with weak MAOI activity is procarbazine, an antitumor agent used for Hodgkin disease. The antibiotic linezolid also has MAOI activity, and patients taking it are placed on a

tyramine-restricted diet.[19 , 7] The plant extract St. John's wort (*Hypericum perforatum*) is licensed in Germany for use as an antidepressant. Although St. John's wort has some weak MAO-inhibiting activity, whether this activity is responsible for its antidepressant effect is debatable. However, it may be the cause of the hypertensive crises, cardiovascular collapse during anesthesia, and serotonin syndrome reported with use of this herbal medication.[32]

MAO-A MAO-B MAO-A and MAO-B

TABLE 69-1. Comparison of Substrate Specificity, Distribution, and Inhibitors of Monamine Oxidase

The hallucinogenic beverage Ayahuasca used by South American natives is an intriguing ethnobotanical solution to the â€œproblemâ€• of gastrointestinal MAO. Dimethyltryptamine, which is derived from several local plant species, is a potent hallucinogen that is not orally bioavailable because of its first-pass metabolism by MAO. *Banisteriopsis caapi* , a plant containing the MAO inhibiting harmine alkaloids, is mixed with dimethyltryptamine-containing plants to improve the bioavailability of this hallucinogenic amine.[41 , 42]

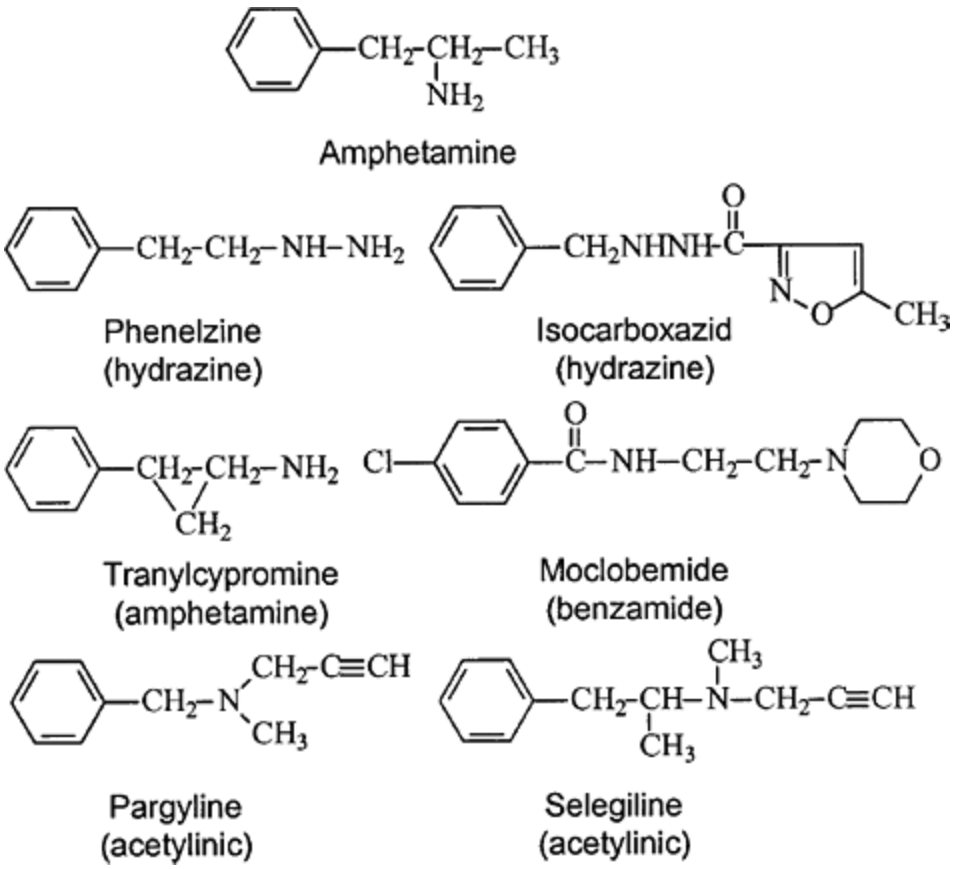

Figure 69-2. Structural similarities between amphetamine and the monoamine oxidase inhibitors.

MAO-B activity in tobacco plants has prompted studies to find a link between the lower platelet MAO-B activity of smokers and the lower rate of Parkinson disease in this group.[9] Selegiline prevents experimentally induced (by MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine/methylphenyltetrahydropyridine [MPTP]) Parkinson syndrome in animal models.[53] This has lead to interest in studying selegiline and other MAO-B inhibitors as neuroprotective agents.

Other enzyme systems inhibited by MAOIs include amine oxidases such as diamine oxidase and semicarbazide-sensitive oxidases, arylamine *N* -acetyltransferase (by tranylcypromine), ceruloplasmin, alcohol dehydrogenase (by tranylcypromine), dopa

decarboxylase, L-glutamic acid decarboxylase, Î³-aminobutyric acid (GABA) decarboxylase and GABA transaminase (by hydrazine MAOIs), alanine aminotransferase (by phenelzine) and other pyridoxine (B_6)-containing enzyme systems.[30] The clinical implications of inhibiting these diverse enzyme systems, other than cytochrome P450, are poorly understood.

Pharmacokinetics and Toxicokinetics

MAOIs are well absorbed orally, and peak plasma concentrations are reached within 2â€“3 hours. MAOIs are hepatically metabolized by both oxidation and acetylation, and the metabolites are excreted in the urine.[3] The rate of phenelzine metabolism is dependent upon the *N* -acetyltransferase phenotype (ie, â€œacetylator statusâ€•) of the patient (ie, fast or slow). However, there is no correlation between

acetylator status and adverse effects of the drug. Moclobemide is metabolized by CYP2C19 to an array of oxidized metabolites that are generally inactive.

The therapeutic and toxic effects of MAOIs lag behind their absorption and excretion characteristics. The irreversible agents have durations of effect that far surpass their pharmacologic half-lives. Thus, when switching from 1 serotonergic agent (ie, MAOI, SSRI, tricyclic antidepressant), a sufficient â€œwashoutâ€• period must be allowed to prevent an adverse drug interaction. This period typically is several weeks, although some psychiatrists advocate cautious rapid conversion.[56]

Monoamine Oxidase Inhibitor Overdose

Significant morbidity and a high mortality are characteristic of patients who overdose with the irreversible, nonselective MAOIs. Mortality is reported from acute ingestions of as little as

170â€“680 mg tranylcypromine (typical daily dose 20â€“30 mg) and 375â€“1500 mg phenelzine (typical daily dose 60â€–90 mg).[58]

A delay in the onset of clinical effects of up to 32 hours following overdose is reported, but effects generally occur by 24 hours.[39] Overdose from irreversible MAOIs is characterized by a spectrum of sympathetic hyperactivity that is followed by cardiovascular collapse in severe cases. In a limited or early phase following overdose, patients typically have irritability, anxiety, flushing, diaphoresis, and tachycardia, and they may complain of a headache. Characteristic clinical findings of severe overdose include hyperthermia, hypertonia, seizures, and marked hypertension. Blood pressure may be normal initially but fluctuates markedly in severe overdose, with severe hypertension followed by hypotension and cardiovascular collapse. Dysrhythmias, marked hyperthermia, obtundation, and disseminated intravascular coagulopathy ensue as multiorgan failure occurs. Other symptoms may include tachypnea, nystagmus, mydriasis, opsoclonus (alternating â€œping-pongâ€• gaze), hallucinations, trismus, neuromuscular irritability, agitation, and delirium.[16, 39]

These effects are attributed to the same elevation of monoaminergic neurotransmitter levels and amphetaminelike activity that confers antidepressant activity to the MAOIs.[36] Thus, presynaptic monoamines are released, stimulating postsynaptic adrenergic and serotonergic receptors and initiating a multiorgan sympathetic response.

Secondary problems resulting from CNS and autonomic hyperactivity may include rhabdomyolysis, renal failure, myocardial infarction, dehydration, intracranial hemorrhage, and ischemia (Chap. 16).

In contrast, moclobemide has a much greater therapeutic index than the irreversible MAOIs. Thus, overdose with moclobemide often results in a relatively benign course if no other xenobiotics are ingested.[31, 43] Ingestion of <8000 mg (or 25 times the

therapeutic dose of moclobemide) typically results in mild or no symptoms (typical daily dose 150â€“600 mg). At lower doses, only fatigue, agitation, tachycardia, and hypertension are noted. No delayed reactions are reported after moclobemide overdose. Despite 1 case in which only 15 tablets reportedly were taken,[22] most deaths from moclobemide overdose also involve coingestion of xenobiotics capable of inducing the serotonin syndrome.[24, 49, 59]

Treatment of patients with MAOI overdose should focus on emergency treatment of the airway, followed by stabilization of blood pressure and assessment for and treatment of hyperthermia, seizures, and muscular rigidity. Patients who overdose with first-generation MAOIs are more likely to benefit from aggressive gastrointestinal decontamination (including orogastric lavage and activated charcoal 1 g/kg) than most other overdose patients because of their high potential for mortality. The lack of early clinical findings of poisoning should not dissuade the use of aggressive gastrointestinal decontamination given the potential for delayed clinical deterioration.

Because fluctuating vital signs are characteristic of MAOI overdose, hemodynamic monitoring should be instituted even for patients who initially are stable. When supporting the patient's vital signs, preference should be given to titratable drugs with a rapid onset and termination of action because of the potential for rapid hemodynamic changes. Sodium nitroprusside and nitroglycerin are best used to treat hypertension because they can be rapidly stopped if hypotension develops. The short-acting Î±-adrenergic antagonist phentolamine given at 2â€“5 mg IV can effectively control hypertension. Use of Î²-adrenergic antagonists is contraindicated for control of hypertension in this setting because of the potential for unopposed Î±-adrenergic mediated vasoconstriction, which could exacerbate hypertension.

Dopamine is not an acceptable agent of choice for hypotension

because its pressor effects are indirect and rely on catecholamine release from sympathetic neurons. Norepinephrine is preferred because it is a direct-acting agent and often is successful when dopamine fails, presumably secondary to catecholamine depletion.

Hyperthermia must be treated aggressively (Chap. 16). Use of ice baths, cold water, and fans are the mainstay of treatment. Benzodiazepines help control muscular rigidity, seizures, and agitation that may be contributing to hyperthermia and tachycardia. Neuromuscular blockade using nondepolarizing xenobiotics is essential for controlling rigidity and hyperthermia if first-line treatment is unsuccessful. Case reports of cyproheptadine added to this standard therapy describe resolution of neuromuscular rigidity and hyperthermia associated with MAOI overdose[4 , 16] (see Serotonin Syndrome).

Seizures should be treated with benzodiazepines (eg, diazepam) in incremental doses. Hypoglycemia should be excluded. Pyridoxine (vitamin B_6) should be empirically administered to patients with refractory seizures, particularly those who ingest a hydrazine-derived MAOI, in an effort to replete GABA stores (Chap. 55 and Antidotes in Depth: Pyridoxine).

All patients with presumed MAOI overdose must be monitored and observed in an intensive care unit for at least 24 hours regardless of the clinical findings because of the potential for delayed toxicity.

Serotonin Syndrome

The serotonin syndrome, more recently suggested to be better termed *serotonin toxicity* ,[15] is a potentially life-threatening complication of antidepressant drug therapy. It often is unrecognized because of its subtle and nonspecific symptomatology. The clinical findings of the serotonin syndrome include autonomic excitation, altered mental status, and increased

neuromuscular tone (Chap. 70). The differential diagnosis typically includes neuroleptic malignant syndrome, malignant hyperthermia, encephalitis, and thyroid storm. However, because no diagnostic test is available, the correct diagnosis of serotonin syndrome must be made on clinical grounds. Several diagnostic schemes exist,[15 , 27 , 47 , 55] but the key diagnostic criteria is the biologic plausibility, that is, the necessity that the patient was exposed to xenobiotic likely to produce serotonin excess in the CNS.

The syndrome is produced most often by concurrent use of 2 or more xenobiotics that increase CNS serotonin activity.[54] All types of MAOIs have been implicated, including the herbal medication St. John's wort.[32] Reports of serotonin syndrome following the combination of a MAOI with any of a number of commonly available prescription (tricyclic antidepressants, SSRIs, meperidine) or nonprescription (dextromethorphan) medications are widespread. The long duration of effect of the irreversible MAOIs explains the prolonged duration of risk for development of the syndrome following discontinuation of the medication. Thus, a washout period of at least 2 weeks is recommended before SSRI therapy is initiated in a patient who has stopped taking a first-generation MAOI.[5]

A washout period is less important with use of moclobemide because the MAOI inhibition with this xenobiotic is reversible within hours.[14] Although moclobemide and the other reversible MAOIs appear to be safer to combine with SSRIs than the older MAOIs,[29] serotonin syndrome following the combination of moclobemide and an SSRI is reported.[31 , 44] However, few fatalities are reported, and the syndromes often are mild.

Treatment of the serotonin syndrome is supportive and focuses on correcting the consequential clinical abnormalities. Hyperthermia is managed with benzodiazepines for sedation and aggressive

cooling measures; nondepolarizing neuromuscular blockade may be required if cooling is insufficient with these methods. Cyproheptadine, a clinically available serotonin receptor antagonist, prevents lethality in animal models of serotonin syndrome[45] and reportedly is beneficial in humans with serotonin syndrome.[26 , 37] It should be strongly considered when the diagnosis of serotonin syndrome is likely. The dose of 4â€“8 mg must be administered orally or by nasogastric tube. Use of dantrolene in patients with serotonin syndrome reportedly is beneficial.[35] Dantrolene is indicated for treatment of malignant hyperthermia, a disease generally considered to be unrelated to serotonin syndrome even though they share certain clinical features. However, because the pathogenesis of the 2 syndromes appear to be related,[61] use of dantrolene for treatment of the serotonin syndrome should be investigated although it cannot be supported at this time.

Hypertensive Crisis Resulting from Food and Drugs

Indirect-acting sympathomimetic agents (eg, tyramine and amphetamine) have a chemical structure and mechanism of action similar to the catecholamines. Like the catecholamines, they are taken up into presynaptic sympathetic nerve terminals and subsequently are moved into storage vesicles. Once in the vesicles, they buffer the pH, causing the stored norepinephrine to be released and transported in a reverse fashion into the synapse (Figure 69-1). In patients taking MAOIs, the decreased norepinephrine degradation increases presynaptic norepinephrine stores. Thus, an indirect-acting sympathetic agent that triggers norepinephrine release may cause a hyperadrenergic syndrome, with supranormal amounts of stored norepinephrine being released into the synapse to stimulate postsynaptic Î±- and Î²-adrenergic receptors. Direct-acting sympathetic agents (eg, epinephrine,

norepinephrine, and isoproterenol) can be used safely in patients taking MAOIs.[7] Rather than causing release of a stored pool of norepinephrine, these agents bind directly with postsynaptic Î±- and Î²-adrenergic receptors. Direct-acting and parenterally administered adrenergic agents are primarily cleared by cell reuptake and catechol-*O* -methyltransferase (COMT), a synaptic enzyme that is not inhibited by MAOIs.

Protein-rich foods are particularly likely to contain decarboxylating bacteria that convert amino acids into pharmacologically active monoamines, such as tyramine.[60] These monoamines normally are degraded by gastrointestinal and hepatic MAO-A before they enter the systemic circulation. However, with inhibition of the hepatic and gastrointestinal MAO, large quantities of monoamines may be absorbed into the systemic circulation. Food interactions occur when pharmacologically active dietary monoamines (eg, tyramine) are ingested by patients taking most MAOIs[40] (Table 69-2). Because this is historically closely associated with ingestion of certain cheeses, it is sometimes called a *cheese reaction.* Similarly, because the etiology of the syndrome is not limited to tyramine but may be caused by other indirectly acting sympathomimetic agents (eg, ephedrine from cold preparations), sometimes it is simply described as a *hypertensive reaction.* Unprovoked hypertensive reactions may occur in patients receiving MAOIs and are not well understood.[38]

Findings typically include hypertension and tachycardia. Headache, altered mental status, intracranial hemorrhage, myocardial ischemia, and seizures may be secondary sequelae of uncontrolled hypertension. Ingestion of as little as 6 mg tyramine may result in a significant vasopressor effect in MAO-inhibited patients.[60] This dose is 1â€“10% of the amount normally needed to achieve a vasopressor effect. Because the development of tyramine reaction requires inhibition of gastrointestinal MAO-A, it can be avoided by MAO-B selective inhibitors such as selegiline and limited by reversible MAOIs such as moclobemide.[5 , 62 , 66] However,

because the presynaptic quantity of norepinephrine is also increased in patients who take MAO-B selective inhibitors, parenteral administration of an indirect-acting catecholamine may produce a dramatic pressor response, even with selegiline.[50] A tyramine reaction associated with St. John's wort is reported.[46]

Because both the absorbed and the liberated monoamines have a short half-life, the clinical effects have a rapid onset and typically abate within several hours. However, as with the serotonin syndrome, the potential for a hypertensive reaction to tyramine or another indirect-acting catecholamine may last up to several weeks following the last dose of MAOI.[5] Interestingly, some psychiatrists advocate the combination of amphetamine-derived stimulant drugs

with MAOIs for treatment of patients with refractory depression or intolerable MAOI related side effects, such as orthostasis.[17]

High tyramine content
- Aged, mature cheeses (65â€“1500 mg/kg)
- Smoked, pickled, aged, putrefying meats or fish (0â€“470 mg/kg)
- Yeast and meat extracts (65â€“2250 mg/kg)
- Red wines (1.5â€“12 mg/kg)
- Broad beans

Moderate tyramine content
- Meat extracts (100â€“300 mg/kg)
- Pasteurized light and pale beers
- Avocados

Low tyramine content
- Distilled alcohol
- Cottage cheese, cream cheese
- Sour cream
- Chocolate, caffeine-containing beverages
- Fruit

Soy sauce
Yogurt

Patients should avoid high tyramine content meals, eat small quantities of meals containing moderate amounts of tyramine, and may eat foods low in tyramine content.

TABLE 69-3. Comparison of MAOI-Related Reactions

Normotensive patients who experience severe hypertension after drug or dietary interactions can be treated with an Î±-adrenergic antagonist such as phentolamine 2â€“5 mg IV. Again, titratable drugs such as nitroprusside and phentolamine are best because they allow controlled lowering of the blood pressure.[12] The dihydropyridine calcium channel blockers (eg, nifedipine) and possibly the oral Î±-adrenergic antagonists (eg, terazosin) can successfully control the hypertensive crisis but should be used carefully.[11 , 28] Particular caution must be exercised in patients with baseline hypertension because overly aggressive blood pressure lowering may reduce cerebral perfusion pressure sufficiently to cause ischemia.

Treatment of individual symptoms in patients with MAOIâ€“food or MAOIâ€“drug interactions is similar to the symptomatic and supportive care described for MAOI overdose. However, patients with MAOIâ€“food or MAOIâ€“drug interactions may not require hospital admission if the interaction is mild, resolution of symptoms is complete, and the patient can be observed for 4â€“8 hours. Patients who develop an altered mental status, seizures, or other end-organ damage must undergo appropriate diagnostic

studies and be managed accordingly.

Table 69-3 compares the characteristics of MAOI overdose with symptoms following interactions of MAOIs with foods and indirect-acting sympathomimetic agents. Interactions with sympathomimetic xenobiotics are predictable and may occur when a patient taking an MAOI also takes one of the several types of xenobiotics mentioned in Table 69-4 .

Other Adverse Drug Events

Several other types of adverse reactions can occur in patients taking MAOIs. Hepatotoxicity from the first generation of hydrazine MAOIs is an infrequent but serious event that led to the discontinuation of iproniazid as an antidepressant.[6] Peripheral neuropathy from vitamin B_6 depletion by the hydrazine-derived MAOIs can occur.[25]

Animal studies and human reports describe a potentiation of the hypoglycemic effects of insulin and sulfonylureas in the presence of MAO inhibition.[8] MAOIs, including selegiline, are insulin secretogogues.[51]

Selegiline

Selegiline overdose is not reported, and the clinical consequences of such an event are unpredictable. Selegiline is metabolized to L-methamphetamine, which may result in hypertension and tachycardia, even at therapeutic doses.[1] Patients taking selegiline may test positive for amphetamines on routine drug-abuse screens. Increased rates of aspartate aminotransferase (AST) and alanine aminotransferase (ALT) elevations are noted with therapeutic use of selegiline. Although rare, an increase in the incidence of cardiac dysrhythmias is reported with selegiline use. Interactions with foods and cold medications are limited, but caution should be exercised.[33] Transdermal administration of

selegiline may actually allow antidepressant effectiveness without the need for dietary restrictions,[2] that is, administration by this route allows delivery to the CNS of a dose sufficient to inhibit MAO-A while avoiding significant inhibition of gastrointestinal MAO. This promising route

of selegiline administration is pending FDA approval before it becomes available. Rasagiline is another irreversible MAO-B selective inhibitor that slows the progression of symptoms in patients with Parkinson disease.[65] However, unlike selegiline it is not metabolized to methamphetamine and may be better tolerated.

Indirect acting
- Amphetamine
- Cocaine
- Hydroxyamphetamine
- Benzphetamine
- Ritodrine
- Methamphetamine
- Methylphenidate
- Phenylpropanolamine
- Fenfluramine
- Pemoline
- Phencyclidine
- Propylhexedrine
- Phentermine
- Tyramine

Direct acting
- Albuterol
- Dobutamine
- Epinephrine
- Ergots
- Norepinephrine
- Isoetharine

- Isoproterenol
- Ethylnorepinephrine
- Isoproterenol
- Metaproterenol
- Methoxamine
- Phenylephrine
- Ritodrine
- Terbutaline

Direct and indirect acting

- Dopamine
- Metaraminol
- Ephedrine
- Mephentermine
- Phenylpropanolamine
- Pseudoephedrine

TABLE 69-4. Sympathomimetic Xenobiotics

Summary

The complex pharmacology of MAOIs makes the first-generation irreversible MAOIs dangerous in overdose and results in a number of interactions that limit their use. As a result, the older MAOIs are largely being replaced by SSRIs and other antidepressants that have less potential for food and drug interactions. In contrast, the newer, reversible MAOIs offer a significant advance in therapy because they are much safer and far less limiting. The serotonin syndrome includes altered mental status and autonomic instability that develop in patients who, among other things, combine MAOIs with other serotonergic xenobiotics. A hypertensive reaction develops from the combination of MAOIs with indirect-acting pressors, classically tyramine from various foods and ephedrine from cold preparations. Newer indications for MAOI administration, such as anxiety and phobias, are broadening the popularity of this

class of xenobiotics.

Chapter 70

Serotonin Reuptake Inhibitors and A Antidepressants

Christine M. Stork

A 36-year-old woman presented to the emergency department 36 hours a intentional ingestion of 1000 mg citalopram. She complained of palpitatio numbness in her arms. Her medical history was significant for bulimia, a abuse, and suicide attempts. In the emergency department, her vital sign pressure, 84/44 mm Hg; pulse, 102â€“160 beats/min; respiratory rate, temperature 99.3Â°F (37Â°C). ECG revealed ventricular bigeminy with a C msec (Figure 70-1A). High-flow oxygen and 2 g intravenous magnesium administered. When she developed ventricular tachycardia, a lidocaine bol were instituted. Torsades de pointes developed (Figure 70-1B). Treatme potassium chloride and potassium phosphate for hypokalemia and a tran pacemaker. Twenty-four hours later, her ECG showed normal sinus rhythm 529 msec (Figure 70-1C). At 48 hours, the QTc narrowed to 442 msec. concentration was 477 ng/mL (therapeutic 40â€“110 ng/mL,) and the didesmethylcitalopram concentration was 123.2 ng/mL (therapeutic 14â€

History and Epidemiology

Most antidepressants inhibit serotonin and/or norepinephrine reuptake as achieve their therapeutic effect. The class of selective serotonin reuptake (SSRIs) includes citalopram, escitalopram (active enantiomer of citalopra fluvoxamine, paroxetine, and sertraline (Figure 70-2). Atypical antidepr past the pharmacologic principles of SSRIs and have other pharmacologic thought to be beneficial for patients with depression.

SSRIs initially were marketed in the United States in the early 1980s and considered a first-line therapy for treatment of depressive disorders.[119] S effective as the tricyclic antidepressants for treatment of major depressio less significant side effects[53] (Chap. 71). As such, they have become the prescribed class of medication for treatment of depression.[138 , 179] SSRIs to treat obsessive-compulsive disorders, panic disorder, alcoholism, obesi medical and psychologic disorders such as migraine headache and chronic syndromes.[52 , 124] The relative safety of the SSRIs when taken in overdo with cyclic antidepressants and monoamine oxidase inhibitors (MAOIs), al desirable.[55]

An increased risk of suicidal behavior is reported with the use of many a compared with nondrug therapy or no therapy.[5 , 109] The reason for this related to delayed onset of drug efficacy coupled with increased energy r initiation. The low fatality rate of SSRI overdose compared with cyclic a and MAOIs was demonstrated in a Swedish study of fatalities from 1994â Citalopram was the cause of only 1.4% of 358 overdose fatalities, even th the most frequently prescribed drug in 2000.[94]

Pharmacology

Table 70-1 lists the pharmacology, therapeutic doses, and metabolism of available SSRIs and other atypical antidepressants. Modulation of seroton norepinephrine neurotransmission has a definitive role in the treatment o depression.[145] The selectivity of SSRIs for serotonin reuptake is structura -trifluoromethyl or *p* -fluoro substitution, which is seen in many of these Serotonin neurons are located almost exclusively in the median raphe nuc

brainstem, where they extend into and are in close proximity to norepine that are located primarily in the locus caeruleus[7] (Figure 70-3). The inte norepinephrine and serotonin likely explains the effectiveness of other at antidepressants that do not directly modulate serotonin neurotransmissio

The exact etiology of depression and the mechanism by which increased and norepinephrine neurotransmission modulates mood remain unclear. S postulated causes of depression include decreased neuronal serotonin st decreased synaptic serotonin, increased serotonin receptor sensitivity, ar overactivity resulting in depressed dopamine neurotransmission.[145 , 164] According to the first theory, desensitization and downregulation of seroto somatodendritic and presynaptic inhibitory autoreceptors occur after exter SSRIs.[27] Ultimately this results in increased activity of raphe neurons, ir synthesis of serotonin, and increased release of serotonin. Unfortunately, in the concentration of serotonin binding sites is reported between depre who respond to SSRIs and those who do not respond.[153] In the second th potentiate the activity of neuronally released serotonin

at 5-HT_{2A} receptors and subsequently decrease the sensitivity of the ser receptor.[27] In depressed patients, these receptors are downregulated aft but no overall difference in receptor activity is observed between depress nondepressed populations. Finally, increased serotonergic activity, particu receptors, is theorized to result in antidepressant activity through reducti dopaminergic release.[187]

Figure 70-1. A. ECG showing bigeminy at point of transition to ventricu B. ECG demonstrating torsades de pointes. C. ECG following resolution of dysrhythmia showing persistent prolongation of the QTc interval.

Unlike tricyclic antidepressants and other atypical antidepressants, SSRIs direct interaction with cholinergic receptors, Î³-aminobutyric acid (GABA) sodium channels, or adrenergic reuptake (Table 70-2).

Pharmacokinetics and Toxicokinetics

The SSRIs display diverse elimination patterns and have numerous active which substantially increase both the duration of therapeutic effectiveness duration during which drug interactions and adverse drug effects can occu drug is discontinued (Table 70-1). Important pharmacokinetic and phar drug interactions are reported with therapeutic dosing (see Serotonin Sy SSRIs and their active metabolites are substrates for, and potent inhibito and other CYP isoenzymes.[73 , 144] For example, fluoxetine, fluvoxamine, venlafaxine, mirtazapine, paroxetine, and sertraline are substrates for C paroxetine, norfluoxetine, and fluoxetine inhibit the same isoenzyme[38] (T Alternatively, mirtazapine induces CPY3A4 isoenzymes, while trazodone r be decreased after this same enzyme is inhibited.[160 , 165] The consequenc interactions are manifest when the metabolism of xenobiotics that rely on isozymes for metabolic transformation is altered (Chap. 9).

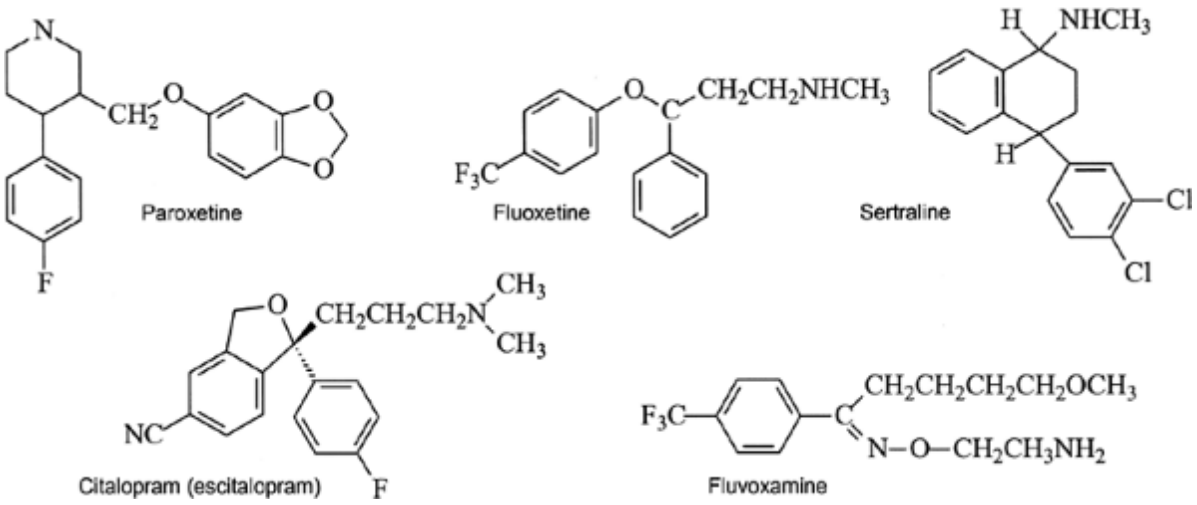

Figure 70-2. Structures of common selective serotonin reuptake inhibito is shown as the s-enantiomer (escitalopram).

Clinical manifestations

Acute Overdose

The majority of effects that occur following overdose are direct extensions pharmacologic activity of SSRIs in therapeutic doses. Excess serotonergic prominent and nonselective. Acute signs and symptoms include nausea, dizziness, blurred vision, and, less commonly, central nervous system (C and sinus tachycardia.[22 , 23] Seizures and QRS complex prolongation are rarely occur with most SSRIs, even after large overdoses[23 , 72 , 91] (Figur

Citalopram

Citalopram and its enantiomer escitalopram cause QTc interval widening a a dose-related manner. These effects are reported at doses as low as 400 citalopram.[33] Larger case series found that these effects typically occur a to doses exceeding 600 mg citalopram or in patients with serum concent than 40 times the expected therapeutic concentrations.[74, 133, 134] In or seizures were an early finding, whereas the development of ECG abnorm delayed for as long as 24 hours following ingestion.[134]

Although the mechanisms are unclear, experimental models suggest that didesmethylcitalopram metabolite of citalopram prolongs the QTc interval , whereas high concentrations of both the parent drug and this metabolite seizures[21, 30] (Chap. 23). The elimination half-life of the R-enantiomer appears to exceed that of the S-enantomer.[184] The implications of this di formation and effects of racemic forms of didesmethylcitalopram are unc

Management

Treatment of patients with acute SSRI overdose is largely supportive. De thiamine should be considered in patients who present with altered menta clinically warranted. Although cardiac manifestations after SSRI overdose a lead ECG should be obtained to identify other cardiotoxic drugs such as t antidepressants to which the patient may have access (Chaps. 5 and 23) citalopram or escitalopram is suspected, 24 hours of cardiac monitoring i to exclude the possibility of QTc prolongation and subsequent risk for ve dysrhythmias. Serum electrolytes and an acetaminophen concentration ma for monitoring and treatment of patients with intentional overdose. After stabilized, oral activated charcoal (1 g/kg) may be useful to adsorb drug the

gastrointestinal tract. Because SSRI overdose is rarely life threatening, g lavage is not generally indicated. Patients with small unintentional overdo other than citalopram and escitalopram are not expected to develop sign and symptoms of poisoning. Fatalities resulting from SSRIs are rare and occur after multiple drug ingestions and manifestations of drug interactio from excess serotonergic effects[66] (see Serotonin Syndrome). Forensic

suggests the minimum lethal concentrations of fluoxetine, paroxetine, an after isolated overdose are 0.63, 0.4, and 1.5 mg/L, respectively. Patien children, with well-defined small unintentional oral ingestions can be man home with close observation.[1][2][3]

Adverse Effects After Therapeutic Doses

Adverse effects commonly attributed to therapeutic doses of SSRIs that a in overdose include gastrointestinal symptoms (anorexia, nausea, vomiti sexual dysfunction in both males and females, headache, insomnia, jitte dizziness, and fatigue.[189] Genetic polymorphism typing holds promise in patients at highest risk for adverse drug events with therapeutic dosing.[1] common adverse effects include sedation, particularly following citalopra paroxetine as a result of their weak anticholinergic activity, and anxiety fluoxetine treatment.[111] The mechanism of serotonin-mediated inhibition function is unclear; however, early human data show that the risk of blee very low.[102 , 105 , 106 , 115 , 135] Other rarely reported adverse effects in onset panic disorder, priapism, photopigmentation, bradycardia, hepatoto urinary incontinence.[25 , 46 , 89 , 90 , 120 , 168] Movement disorders, most akathisia, parkinsonism, myoclonus, and dystonia, also occur after SSRI These extrapyramidal side effects may be related to the complex interpla serotonergic and dopaminergic activity. Predisposing factors for the deve movement disorders include concomitant use of dopamine antagonists suc antipsychotics.[103]

The syndrome of inappropriate antidiuretic hormone (SIADH), in which s hyponatremia may occur rapidly, is associated with SSRI use. In an anim effect appears to be serotonin mediated, with increased concentrations of cortisol, adrenocorticotropin (ACTH), and vasopressin.[57] Rat studies dem stimulation of $5HT_{1C}$ receptors increases antidiuretic hormone secretion.[1] human case control studies have not confirmed defects in osmoregulated vasopressin through normal water loading tests and measurement of vas concentrations after 3â€“11 months of paroxetine use.[113] A review of th identified women older than 70 years who are concomitantly receiving di to be at greatest risk for developing SIADH.[93 , 98] Although reported to o days to 4 months after initiation of therapy, a case-matched control study patients identified that SIADH occurs most frequently within the first 2 w therapy.[121] As a class, hyponatremia is demonstrated to occur when swit SSRI to another.[6] Efforts to predict risk through poor CYP2D6 genotype status or high serum concentrations have not been successful.[170]

Serotonin Syndrome

The most common severe adverse effect associated with SSRIs is the dev serotonin syndrome. This syndrome, also referred to as the *serotonin be hyperactivity syndrome* , was first described in patients treated with MAO given other drugs that enhance serotonergic activity.[35 , 70 , 129 , 166] Hov ingestion of an MAOI is not required for this syndrome to develop, and it is unpredictable (Table 70-4).

Pathophysiology

The pathophysiologic mechanism of the serotonin syndrome is not compl understood but involves excessive selective stimulation of serotonin 5-HT 5-HT_{1A} receptors. Animal models demonstrate that specific stimulation of receptors results in signs and symptoms of serotonin syndrome even whe receptors were inactivated using a specific antagonist.[41] However, a subs study and a human retrospective case series showed that the potency of antagonist therapy was directly related to resolution of symptoms attribut serotonin syndrome.[65] 5-HT_{1D} receptors are not implicated in cases of se syndrome.

Clinical Manifestations

Symptoms of serotonin syndrome include altered mental status, agitation hyperreflexia, diaphoresis, tremor, diarrhea, incoordination, muscle rigidit hyperthermia (Table 70-5). The clinical manifestations of serotonin

syndrome are diverse, and minor manifestations are common after initiatio atypical antidepressant therapy. In fact, a prospective study of depressed given clomipramine demonstrated that 16 of 38 patients experienced syr consistent with the serotonin syndrome.[108] Fourteen of 16 cases demons spontaneous resolution within 1 week without discontinuation of therapy.

Drugs That Inhibit Serotonin Breakdown

- Monoamine oxidase inhibitors (nonselective)

Phenelzine, moclobemide, clorgyline, isocarboxazid[24 ,31 ,35 ,54 ,64 ,69 ,159 ,163 ,166 ,173 ,175]

Harmine and harmaline from Ayahuasca preparations, psychoactive b for religious purposes in the Amazon and Orinoco River basins[31]

Drugs That Enhance Serotonin Release

Amphetamines, especially MDMA (ecstasy)[96 ,163]

Buspirone[10 ,67]

Cocaine[175]

Lithium[99 ,122 ,127]

Mirtazapine[14 ,44]

TABLE 70-4. Potential Causes of Serotonin Syndrome

Life-threatening effects invariably result from hyperthermia caused by ex activity. Sustained severe hyperthermia can lead to death through denatu essential protein and enzymatic function that ultimately results in lactic rhabdomyolysis, myoglobinuria, renal and hepatic dysfunction, dissemina intravascular coagulation, or adult respiratory distress syndrome[116 , 171]

Diagnosis

The serotonin syndrome occurs most frequently following use of combinat serotonergic agents (Table 70-4). Drug interactions resulting in serotoni occur while switching serotonergic pharmacologic agents when an insuffici occurs before initiating the alternative therapy.[150 , 151] Residual pharmac receptor downregulation or upregulation, and the presence of active meta causative in these circumstances. For example, fluoxetine metabolism res active metabolite norfluoxetine, which has comparable pharmacologic effec life substantially longer than that of the parent drug. The metabolite pers result in serotonin syndrome when another serotonergic agent, usually a antidepressant, is given prior to complete clearance of norfluoxetine, whi approximately 2 weeks.[36]

This syndrome is reported in patients following a single dose, high therap or overdoses of certain serotonergic agents in adults and children.[39 , 63 130 , 141 , 148] Although sporadic reports occur, selective MAO subtype B inhibitor drug combinations are rarely reported to result in serotonin synd therapeutic doses.[48 , 118]

- Serotonin syndrome is diagnosed by the presence of at least 4 major major plus 2 minor symptoms following the addition or an increase in serotonergic agent.
- Underlying psychiatric disorder should be excluded.
- Other etiologies must be excluded, including initiation of a neuroleptic dopamine antagonist or withdrawal from a dopamine agonist.

Adapted from Radomski et al.[140]

Major Minor

TABLE 70-5. Diagnostic Criteria for Serotonin Syndrome

Currently no diagnostic test capable of determining whether a patient is serotonin syndrome is available. Although fulminant life-threatening cases recognize, mild cases are more difficult to distinguish from other causes. determine diagnostic criteria, a study that included 38 cases of presumed syndrome was performed. This trial led to suggested diagnostic criteria f syndrome to include three of the following signs and symptomsâ€”altered agitation, myoclonus, hyperreflexia, diaphoresis, tremor, diarrhea, and incoordinationâ€”when other etiologies are excluded.[171] A modification, t Serotonin Toxicity Criteria,[49] which included the variables myoclonus, ag diaphoresis, hyperreflexia, hypertonicity, and fever, was validated in 473

found to correlate best with a clinical toxicologic diagnosis of the seroton syndrome.[171] The most comprehensive review of signs and symptoms in review found altered mental status, other neurologic signs and symptoms and autonomic manifestations most commonly associated with the develo serotonin syndrome. Diagnostic criteria based on these clinical findings ar Table 70-5 .[140]

Management

Treatment of patients with serotonin syndrome begins with supportive ca on decreasing muscle rigidity. Because muscular rigidity is thought to be responsible for hyperthermia and death, rapid external cooling in conjunc aggressive use of benzodiazepines should limit complications and mortalit cases, neuromuscular blockade should be considered to achieve rapid mu The time course of the serotonin syndrome is variable and related to the to decrease drug concentrations of the offending agents. In most patients syndrome resolves within 24 hours after the offending drug is removed. serotonin syndrome can be prolonged when it is caused by drugs with lo protracted duration of effects, or active metabolites.

Animal models indicate that pretreatment with serotonin antagonists can development of the serotonin syndrome.[62 , 84 , 169] Several case reports successful use of 4 mg oral or intravenous cyproheptadine, an antihistam nonspecific antagonist effects at 5-HT_{1A} and 5-HT_{2A} receptors.[71 , 104] Pat responded typically had mild to moderate symptoms of serotonin syndrom not hyperthermic. Cyproheptadine use in this patient group is supported. research is warranted to determine the success of higher doses given to 5-HT_{2A} antagonistic effects in more severely affected patients.[65] Other dr anecdotally reported to be successful for treatment of symptoms caused b serotonin syndrome include methysergide, chlorpromazine, atypical antip propranolol.[64 , 65 , 67 , 75 , 152] Because all of these drugs are of unprove can be dangerous, aggressive cooling and sedation with a benzodiazepine basis of therapy.

Differential Diagnosis of the Serotonin Syndro the Neuroleptic Malignant Syndrome

Many features overlap between the serotonin syndrome and the neurolep syndrome (NMS) (Chap. 67). Some authors call these â€œspectrum disc can be caused by drugs with both antidopaminergic and/or proserotonerg [190] This position is supported by the finding that 5-HT_{2A} agonism results decrease in neuronal dopamine release. Some authors report NMS with u enhancing drugs. However, low concentrations of measured dopamine and concentrations of serotonin metabolites in the NMS patients reported sup hypothesis of central dopaminergic hypoactivity.[8 , 126] It now is clear tha implicated drugs, time course, pathophysiologic mechanism, and manifes distinct[65] (Table 70-6). Altered mental status, autonomic instability, and neuromuscular tone that may result in hyperthermia are common to both The development of NMS involves rapid blockade of dopaminergic neurons whereas the serotonin syndrome appears to result from acute overstimula serotonin receptors (5-HT_{2A}).

In addition to the associated medications, the time courses of the two sy substantially different. Signs and symptoms of the serotonin syndrome d minutes to hours after exposure to the offending agents, whereas NMS t develops days to weeks after daily exposure to the drug in question.[69] In symptoms develop and offending drugs are discontinued, NMS can last for weeks, whereas the serotonin syndrome usually resolves quickly, coincidir offending drug's pharmacokinetic metabolism. A review of the literature i patients presenting with serotonin syndrome were more likely to exhibit hyperactivity, clonus and myoclonus, ocular oscillations, shivering, tremor hyperreflexia, whereas patients presenting with NMS were more likely to bradykinesia and lead pipe rigidity.[65]

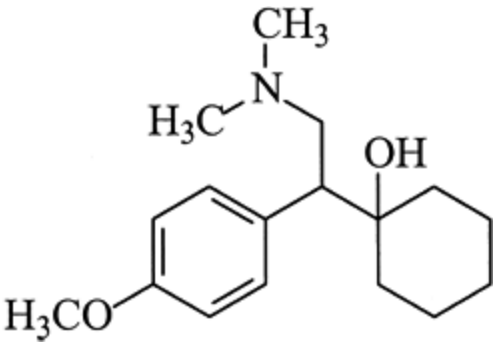
TABLE 70-6. Comparison of Neuroleptic Malignant Syndrome (
Serotonin Syndrome (SS)

Atypical Antidepressants

Atypical antidepressants are defined as not belonging strictly to a set cla antidepressants. They are not SSRIs, cyclic antidepressants, or MAOIs. In atypical antidepressants are the newer antidepressants, most of which ar SSRIs and have additional pharmacologic effects that were selected in an decrease the undesirable side effects of traditional antidepressants.

Serotonin/Norepinephrine Reuptake Inhib

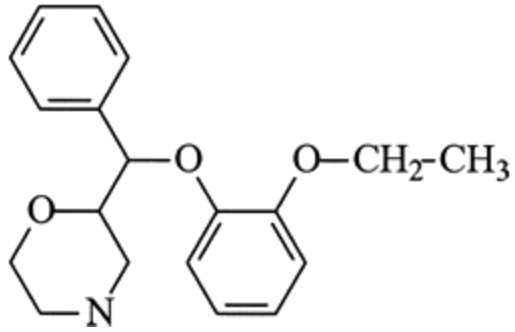


Venlafaxine

In addition to inhibiting serotonin reuptake, venlafaxine inhibits norepine reuptake. Venlafaxine produces rapid downregulation of central Î²-adren which may result in a faster onset of antidepressant effect.[157] Patients wi venlafaxine overdose may present with nausea, vomiting, dizziness, tach depression, hypotension, hyperthermia, elevated hepatic enzyme concent seizures.[86 , 186 , 194] Sodium channel blocking effects are rarely clinically however, QRS prolongation and ventricular tachycardia have resulted in [149 , 194] Although no clinical data regarding efficacy are available, sodiur may be helpful in attenuating these cardiotoxic effects (Antidotes in Dept Bicarbonate).

Overdose information on duloxetine, a similar drug, is limited, but duloxe expected to have similar effects.[177] Milnacipran is an investigational drug expected to have similar effects.[28 , 34]

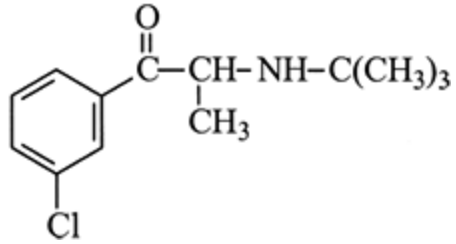
Norepinephrine Reuptake Inhibitors



Reboxetine

Reboxetine is a selective norepinephrine reuptake inhibitor.[182] Lack of e precludes an analysis of overdose data. However, toxicity can be extrapo adverse effects reported in clinical trials and from experience with other possessing similar pharmacologic characteristics. In particular, overdosed should be carefully monitored for tachycardia, hypertension or hypotensic development of seizures. Cases of acute mania and hepatotoxicity are re therapeutic use.[17]

Other Atypical Agents with Reuptake Inhib Part of Their Mechanism



Bupropion

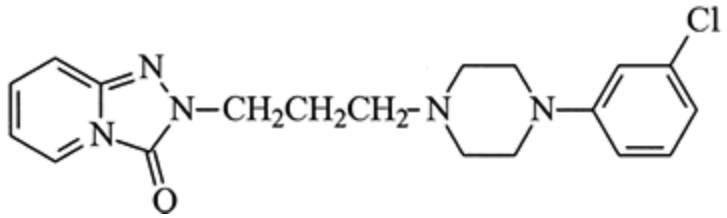
The pharmacologic mechanism of action of bupropion, a unicyclic antidep unclear, but both the parent drug and an active metabolite inhibit the reu dopamine and, to a lesser extent, serotonin and norepinephrine.[145] Exter formulations of bupropion are frequently used as adjuncts in smoking ces therapy.[88] Chronic doses greater than 450â€“500 mg/d place the patient seizures.[42 , 93]

Frequent effects after overdose include tachycardia, hypertension, gastr symptoms, and agitation.[11 , 16] Large acute overdoses may result in seizu without QRS complex prolongation.[29 , 81 , 131 , 161 , 172] In some cases, were delayed for up 10 hours, particularly after ingestion of sustained-re preparations.[80] Symptoms are reported to continue for up to 48 hours.

Several studies suggest that seizures following either bupropion overdose therapeutic doses are caused by its metabolite hydroxybupropion.[56 , 136] hydroxybupropion concentrations are documented after seizures when bu concentrations were no longer detectable. The exact mechanism for seizu hydroxybupropion is unclear at this time.[42 , 56 , 147]

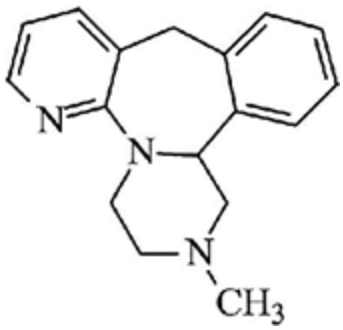
Treatment, when required for seizures, should be supportive and includes of benzodiazepines, followed by barbiturates. If QRS prolongation occurs, should be treated with sodium bicarbonate (Antidotes in Depth: Sodium Early after sustained-release bupropion overdose, activated charcoal shou considered, with use of multiple doses of activated charcoal or whole-bo after large, potentially life-threatening ingestions.

Other serious adverse effects reported after bupropion use include choles hepatocellular hepatic dysfunction, and rhabdomyolysis, with isolated repo pain, dystonia, trigeminal nerve dysfunction, mania, generalized erythro psoriasis, erythema multiforme, dyskinesia, altered vestibular and sensory serum sickness.[2 , 3 , 37 , 40 , 45 , 47 , 59 , 68 , 112 , 176 , 191]



Trazodone

Trazodone is a serotonin agonist that acts through inhibition of serotonin addition, trazodone may have some peripheral Î±-adrenergic antagonist depression and orthostatic hypotension are the most common complicatio overdose of trazodone.[58] Trazodone is rarely reported to cause SIADH. Tl be responsible for seizures, which rarely occur after acute overdose.[9 , 18] reported with therapeutic use of trazodone, may occur occasionally after [58] Management of hypotension includes supportive care and administratior vasopressors, if necessary.



Mirtazapine

The mechanism of mirtazapine action is unique. In addition to serotonin inhibition, mirtazapine increases neuronal norepinephrine and serotonin t adrenergic antagonism.[43] Mirtazapine also blocks some subtypes of 5-HT including 5-HT_2 and 5-HT_3 , which appear to have antidepressive effects.[effects that occur after acute mirtazapine overdoses include altered ment tachycardia.[26 , 181] Large overdoses may cause respiratory depression a of the QTc interval.[26 , 61 , 85 , 143] Because more overdose data are requi precise constellation of symptoms can be attributed to this drug, careful

monitoring is advised. Therapeutic use of mirtazapine causing serotonin hepatitis, hypertension, and reversible agranulocytosis is reported.[1, 83,

Tianeptine

Tianeptine is an investigational drug for treatment of anxiety and depres mechanism of tianeptine is unclear but may include serotonin reuptake e that ultimately reduces expression of serotonin transporter mRNA and se transporter binding sites.[101] No information about this drug in the overdo available. Careful observation is warranted until more information becom

Drug Discontinuation Syndrome

A drug discontinuation syndrome is defined as withdrawal manifestations pharmacologically based and occur after therapeutic use of a drug. Drug syndromes are commonly reported after withdrawal of conventional anti including tricyclic antidepressants and MAOIs[107] (Chaps. 69 and 71). SS reported to cause a discontinuation syndrome that typically begins within drug discontinuation and may last up to 3 weeks.[76] The most frequently symptoms include dizziness, lethargy, paresthesias, nausea, vivid dream and depressed mood.[77, 78, 155, 193] The risk factors associated with de discontinuation syndrome are not fully clarified, although the syndrome is with SSRIs having a shorter elimination half-life (paroxetine > fluvoxamir > fluoxetine). In addition, SSRIs with high-potency serotonin

reuptake inhibition are more frequently implicated (paroxetine > sertralin clomipramine > fluoxetine > venlafaxine > trazodone). Of the SSRIs, par often results in discontinuation syndrome, which is estimated to occur at a cases per million prescriptions. A meta-analysis of published cases from found that 65% of cases were attributed to paroxetine, 17% to sertraline, fluoxetine, and 7% to fluvoxamine.[18] Fluoxetine discontinuation syndrome frequently, at only two cases per million prescriptions.[139] The long elimi of fluoxetine and its active metabolite norfluoxetine probably decrease th discontinuation syndrome by providing a tapered effect after cessation. A compared to the other SSRIs, citalopram appears to have a low incidence

discontinuation symptoms.[114]

Because of difficulty in distinguishing symptoms of discontinuation syndrc underlying disease, many authors have proposed diagnostic criteria for th discontinuation syndrome.[19] All proposed criteria include discontinuation c concordance with CNS effects, gastrointestinal distress, or anxiety.[174]

The biochemical basis of the discontinuation syndrome is hypothesized to serotonin receptor downregulation leading to alterations in serotonergic including interactions with other neurotransmitters (GABA, norepinephrine dopamine).[154] Although postulated, antimuscarinic withdrawal seems an because the antimuscarinic effects of desipramine failed to protect agains withdrawal in a human model.[51]

Treatment of patients exhibiting discontinuation symptoms should include care and reinitiation of the discontinued drug or administration of another reinitiation of the drug is contraindicated. The drug then should be tapere that allows for improved patient tolerance.

Many of the other antidepressants discussed in this chapter also result in discontinuation reactions. Symptoms appear similar to those reported aft discontinuation of SSRIs and are treated in a similar manner.[14 , 92]

Summary

In acute overdose SSRIs or atypical antidepressants usually are not life although a few drugs produce seizures or cardiac toxicity. Treatment is g supportive for all of these drugs. However, significant drug interactions a drug effects are associated with serotonin reuptake inhibitors and may lea life-threatening events. In addition, the management of these patients fr complicated because they likely have concomitant access to more life-th antidepressants such as tricycle antidepressants and MAOIs.

Chapter 71
Cyclic Antidepressants

Erica L. Liebelt

A 2.5-year-old girl was brought to the emergency department (ED) for evaluation of a seizure. The child previously was well and had no other medical problems. The young girl and her sibling ate dinner at a neighbor's house 2 hours prior to this incident. After the girl returned home, the mother noticed that the child looked tired. The girl subsequently had a generalized tonic-clonic seizure that lasted approximately 1 minute. The paramedics described the young girl as postictal, with vital signs of blood pressure, 90/50 mm Hg; pulse 160 beats/ min; respiratory rate 26 breaths/min.

At the request of the paramedics and the ED physician on medical control, the mother called the neighbor to determine whether the girl could have accessed any prescription medications or other pills while she was in the house. The neighbor revealed that her son's amitriptyline bottle had been spilled. According to the neighbor's count, one or two 75-mg amitriptyline tablets were missing.

In the ED 15 minutes later, the girl was still sleepy, but she responded to the physician's questions and cried when the IV line

was placed. Vital signs were: blood pressure, 90/50 mm Hg; pulse, 200 beats/min; respiratory rate, 26 breaths/min; temperature 99.7Â°F (37.6Â°C); and pulse oximeter revealed 97% oxygen saturation on room air. Physical examination demonstrated large (6-mm) pupils that were sluggishly reactive to light, slightly dry mucous membranes, no meningismus, and altered mental status. Initial bedside rapid glucose concentration was 110 mg/dL. Arterial blood gas showed: pH 7.28; PCO_2, 38 mm Hg; PO_2, 94 mm Hg; [HCO_3^-], 13 mEq/L. Blood was obtained for determination of electrolytes, liver enzymes, complete blood count, and amitriptyline concentration. The 12-lead electrocardiogram (ECG) revealed a wide-complex tachycardia with a rate of approximately 200 beats/min and a variable QRS interval with a minimum duration of 220 msec (Figure 71-1A). The girl then had another generalized tonic-clonic seizure, which lasted approximately 60 seconds. Her blood pressure dropped to 60/30 mm Hg. Lorazepam 0.1 mg/kg IV was given, followed by an IV bolus of sodium bicarbonate 1 mEq/kg over 3 minutes and a 1 mg/kg bolus of lidocaine. A 20-mL/kg bolus of 0.9% sodium chloride solution was administered through a second intravenous line, and the blood pressure increased to 88/47 mm Hg. The patient was intubated, orogastric lavage was performed with a 24-French tube, and activated charcoal 1 g/kg was administered via the orogastric tube.

A second ECG obtained 30 minutes after initial interventions showed a heart rate of 150 beats/min and narrowing of the QRS complex to 140 msec with a terminal R wave in lead aVR (R_{aVR}) of 6 mm (Figure 71-1B). A continuous infusion of sodium bicarbonate and 0.9% sodium chloride solution was administered at 60 mL/h by adding 100 mEq hypertonic sodium bicarbonate (1 mEq/mL) to 5% dextrose/0.25% saline to give a cumulative sodium concentration of 138 mEq/L. A venous blood gas showed a pH of 7.43. Prior laboratory studies did not reveal any abnormalities except for a measured [HCO_3^-] of 14 mEq/L. The patient was transferred to the pediatric intensive care unit (PICU) of a tertiary care children's

hospital for further management.

On arrival to the PICU, the patient was sedated. Her blood pressure was 99/53 mm Hg and heart rate was 136 beats/min. A third ECG obtained 10 hours after the initial ECG showed heart rate of 120 beats/min, QRS interval of 80 msec, and R_{aVR} of 4.5 mm (Figure 71-1C). The patient was extubated within 6 hours and remained in the intensive care unit overnight for continuous ECG monitoring. The ECG abnormalities resolved, and the last ECG showed QRS duration of 80 msec and R_{avR} of 1 mm. The patient was awake, alert, and normotensive. The quantitative serum amitriptyline concentration from the sample obtained at the initial hospital was 1003 ng/mL. The patient was discharged home the next day after social service consultation and a total of 24 hours of observation following extubation, termination of sodium bicarbonate infusion, and resolution of ECG abnormalities.

Cyclic antidepressants (CAs) consist of a group of pharmacologically related drugs used for treatment of depression, as well as neuralgic pain, migraines, enuresis, and attention deficit hyperactivity disorder. Most CAs have at least 3 rings inherent in their chemical structure. They include the traditional tricyclic antidepressants (TCAs) imipramine, desipramine, amitriptyline, nortriptyline, doxepin, trimipramine, protriptyline, and clomipramine, as well as cyclic compounds such as maprotiline and amoxapine (Table 71-1). These drugs share unique toxicologic characteristics that have led to an array of basic science and clinical research primarily aimed at innovative and optimal treatment modalities.

History and Epidemiology

Imipramine was the first TCA used for treatment of depression in the late 1950s. However, the synthesis of iminodibenzyl, the â€œtricyclicâ€• core of imipramine, and the description of its chemical characteristics date back to 1889. Structurally related to the phenothiazines, imipramine originally was developed as a

hypnotic agent for the sedation of agitated or psychotic patients and was serendipitously found to alleviate depression. From the 1960s until the late 1980s, the TCAs were the major pharmacologic treatment

for depression in the United States. However, by the early 1960s, cardiovascular and central nervous system (CNS) toxicity were recognized as major complications of TCA overdoses. The newer CAs were developed in the 1980s and 1990s to decrease some of the adverse effects that occurred with older TCAs, improve the therapeutic index, and reduce the incidence of serious toxicity. The newer CAs included the tetracyclic drug maprotiline and the dibenzoxapine drug amoxapine (Table 71-1).

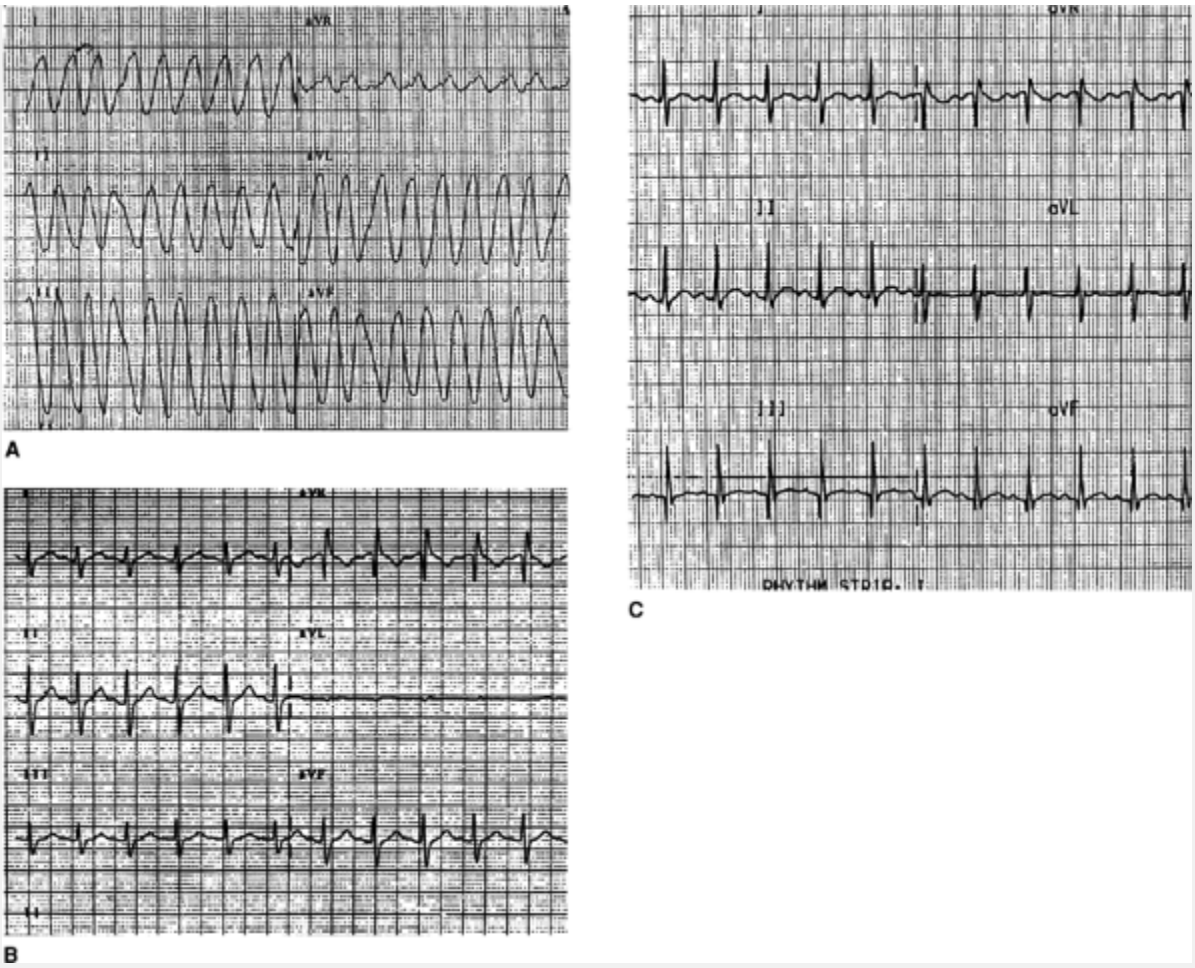

Figure 71-1. Case electrocardiograms. A. Initial ECG shows a wide-complex tachycardia with a variable QRS duration (minimum 220 msec). B. ECG 30 minutes after presentation following sodium bicarbonate shows narrowing of the QRS interval to a duration of 140 msec and an amplitude of R_{aVR} of 6.0 mm. C. ECG 9 hours after presentation shows further narrowing of the QRS interval to 80 msec and decrease in the amplitude of R_{aVR} to 4.5 mm. (Reproduced with permission from Liebelt EL: Targeted management strategies for cardiovascular toxicity from tricyclic antidepressant overdose: The pivotal role for alkalinization and sodium loading. Pediatr Emerg Care 1998;14:293â€“298.[74])

The epidemiology of CA poisoning has evolved significantly in the last 10 years, resulting in great part from the introduction of the newer selective serotonin reuptake inhibitors (SSRIs). The antidepressants are a leading cause of drug-related self-poisonings in the world, primarily because of their ready availability to people with depression who by virtue of the disease are at high risk for overdose. Between 1993 and 1997, 95% of poisoning deaths in England and Wales were associated with TCAs, particularly dothiepin and amitriptyline. TCAs were associated with 5.3 deaths per 100,000 prescriptions.[128] Numerous epidemiologic studies in both the United States and Europe demonstrate that the comparative risk of death is significantly greater with the TCAs as a group compared with the newer antidepressants, including the SSRIs.[60] However, over the last 10 years, more medical indications for TCA use, including chronic pain, obsessive-compulsive disorder, and, particularly in children, enuresis and attention deficit hyperactivity disorder, have emerged, thus increasing their availability even more.

Based on data from the American Association of Poison Control Centers' (AAPCC) Toxic Exposure Surveillance System (TESS), CAs (primarily TCAs) were the leading cause of poisoning fatalities in the United States until 1993, when they were overtaken by the analgesics (Chap. 130). In the last 10 years, the number of deaths caused by CAs reported to poison centers has remained relatively constant, although the total number of CA exposures has decreased slightly. There is a significant underreporting of deaths attributable to antidepressants through the AAPCC TESS data.[54] What cannot be determined from these particular poison center data is whether prehospital deaths have changed and whether the total number of prescriptions for CAs has declined or remained constant, factors that would contribute more meaning to the actual number of deaths.

Children younger than 6 years have consistently accounted for approximately 12â€“13% of all CA exposures during the last 10 years. Antidepressants (specifically TCAs) are the second most

commonly prescribed psychotropic medication in preschool children, with a

>200% increase from 1991â€“1995.[159] Despite the emergence of the SSRIs in the early 1990s, TCAs were still among the top 5 psychotropic drugs most frequently prescribed by pediatric office-based practices in 1995.[59] CA poisoning likely will continue to be among the most lethal unintentional drug ingestions in younger children because only 1 or 2 adult-strength pills can cause serious poisoning in children of this age.

Pharmacology

In general, the TCAs can be classified into tertiary and secondary amines based on the presence of a methyl group on the propylamine side chain (Table 71-1). The tertiary amines amitriptyline and imipramine are metabolized to the secondary amines nortriptyline and desipramine, respectively, which themselves are marketed as antidepressants. In therapeutic doses, the CAs exhibit numerous pharmacologic effects on the autonomic system, CNS, and cardiovascular system. However, the drugs can be distinguished from each other by their relative potencies with which they produce the diverse clinical effects. These pharmacologic differences appear to be pronounced even with therapeutic dosing.

Tertiary Amines	
Amitriptyline Clomipramine Doxepin Imipramine Trimipramine	 Imipramine
Secondary Amines	
Desipramine Nortriptyline Protriptyline	 Nortriptyline
Amoxapine	Maprotiline	
TABLE 71-1. Cyclic Antidepressantsâ€”Classification by Chemical Structure

Therapeutically, CAs inhibit presynaptic reuptake of norepinephrine and/or serotonin, thus functionally increasing the amount of these neurotransmitters at CNS receptors. The tertiary amines, especially clomipramine, are more potent inhibitors of serotonin reuptake, whereas the secondary amines are more potent inhibitors of norepinephrine reuptake. Although these pharmacologic actions formed the basis of the monoamine hypothesis of depression in the 1960s, antidepressant actions of these drugs appear to be much more complex.

Extensive research has led to the â€œreceptor sensitivity hypothesis of antidepressant drug action,â€• which postulates that following chronic CA administration, alterations in the sensitivity of various receptors are responsible for antidepressant effects. Chronic TCA administration alters the number and/or function of central Î²-adrenergic and serotonin receptors.[1,14] In addition, TCAs modulate glucocorticoid receptor gene expression and cause alterations at the genomic level of other receptors.[8,72] All of these actions play a role in the antidepressant effects of TCAs.

Additional pharmacologic mechanisms of CAs are responsible for their side effects and overdose presentations.[27] All of the CAs are competitive antagonists of the muscarinic acetylcholine receptors, although they have different affinities. Acetylcholine blockade is responsible for central and peripheral anticholinergic adverse effects, such as dry mouth, urinary retention, blurred vision, and sedation. The CAs also antagonize peripheral α_1-adrenergic receptors, producing vasodilation and orthostatic hypotension. The membrane-stabilizing effect of CAs is responsible for cardiac conduction abnormalities that occur even at therapeutic doses and, following overdose, is the mechanism of life-threatening cardiac toxicity.[42] Finally, animal research demonstrates interactions of CAs on the Î³-aminobutyric acid (GABA) receptorâ€“chlorideâ€“ionophore complex in the brain. The effects of chronic CA administration on chloride influx, chloride uptake, GABA transport, and specific GABA receptors may offer a novel mechanism of antidepressant drug action and a

mechanism for seizure occurrence after CA overdoses.[80,81,94,138]

Amoxapine is a dibenzoxapine CA derived from the active antipsychotic loxapine. Although it has a 3-ringed structure, this drug has little similarity to the other tricyclics. It is a potent norepinephrine reuptake inhibitor, has no effect on serotonin reuptake, and blocks dopamine receptors. Maprotiline is a tetracyclic antidepressant that predominantly blocks norepinephrine reuptake. Both of these CAs have a slightly different toxic profile than the traditional TCAs.

Pharmacokinetics and Toxicokinetics

CAs are rapidly and almost completely absorbed from the gastrointestinal (GI) tract, with peak concentrations 2â€“8 hours after administration of a therapeutic dose. CAs are weak bases (high pK_a); thus, changes in acidâ€“base status alter the proportion of ionized to nonionized drug. In CA overdose, the decreased GI motility caused by CA anticholinergic effects and the ionization in the acidic gastric media delay CA absorption. Because of extensive first-pass metabolism by the liver, the oral bioavailability of CAs is low and variable, although metabolism may become saturated in overdose, increasing bioavailability. These properties contribute to the recommendations and rationale for delayed GI decontamination and the need for aggressive decontamination.

CAs are highly lipophilic and possess large and variable volumes of distribution (15â€“40 L/kg). They are rapidly distributed to the heart, brain, liver, and kidney, where the tissue-to-plasma ratio generally exceeds 10:1. In the canine myocardium, CA concentrations exceed plasma concentrations by >200-fold.[57] Less than 2% of the ingested dose is present in blood several hours after overdose, and serum TCA concentrations decline biexponentially.[106,123] The CAs are extensively bound to $Î±_1$-acid glycoprotein (AAG) in the plasma, although differential binding among the specific drugs is observed.[2]

Changes in AAG concentration or pH can alter binding and the percentage of free or unbound drug.[107,124] Specifically, a low blood pH (which often occurs in a severely poisoned patient) may increase the amount of free drug, making it more available to exert its effects. Animal studies demonstrate that although administration of AAG increases the concentration of total desipramine and protein-bound desipramine in the serum, the concentration of active free desipramine does not significantly decline.[107] Redistribution of CAs from tissues may account for this small change in the free fraction of the drug. All of these pharmacokinetic properties limit the value of serum antidepressant concentrations in assessing toxicity.

The TCAs undergo demethylation, aromatic hydroxylation, and glucuronide conjugation of the hydroxy metabolites. The tertiary amines imipramine and amitriptyline are demethylated to desipramine and nortriptyline, respectively. The hydroxy metabolites of both tertiary and secondary amines are pharmacologically active and may contribute to toxicity after the first 12â€“24 hours. The glucuronide metabolites are inactive.

Genetically based differences in the activity of the CYP2D6 enzymes account for wide interindividual variability in metabolism and steady-state plasma concentrations. Genetic polymorphisms of the CYP2D6 gene, which is responsible for hydroxylation of imipramine and desipramine, are responsible for the slow metabolism in certain patients.[17,28] These â€œpoor metabolizersâ€• may recover more slowly from an overdose or demonstrate toxicity with therapeutic dosing.[13,136,142] The metabolism of CAs also may be influenced by concomitant ingestion of ethanol and other medications such as barbiturates, which may enhance their metabolism, or by drugs that inhibit the CYP2D6 isoenzyme (eg, SSRIs including fluoxetine, paroxetine, sertraline), which may increase the concentration of the parent CAs.[16,97,132] Patient variables such as age and ethnicity also affect CA metabolism.

Elimination half-lives for therapeutic doses of CAs vary from 7â€“58

hours (54â€“92 hours for protriptyline), with even longer half-lives in the elderly.[114,123] The half-lives may be more prolonged in overdose as a result of saturable metabolism. A small fraction (15â€“30%) of CA elimination occurs through biliary and gastric secretion.[39,82] The metabolites are then reabsorbed in the systemic circulation, resulting in enterohepatic and enterogastric recirculation and reducing their fecal excretion. Finally, <5% of CAs are excreted unchanged by the kidney.[39]

Pathophysiology

The effects on various neurotransmitters and the myocardial cells explain the pathophysiology of CNS and cardiac toxicity. Conduction delays, dysrhythmias, and hypotension characterize the cardiotoxicity caused by CAs. This toxicity results from drug effects on the myocardial action potential, direct effects on vascular tone, and effects mediated by the autonomic nervous system.

The CAs block the rapid inward movement of sodium ions into the fast sodium channel, slowing phase 0 depolarization of the action potential in the distal His-Purkinje system and the ventricular myocardium[42,151,154] (Figure 71-2 and Figure 23-2). Impaired depolarization within the conduction system slows the propagation of ventricular depolarization, which is manifested as prolongation of the QRS interval on the electrocardiogram. The right bundle branch has a relatively longer refractory period, and it is affected disproportionately by intraventricular conduction delay.[100] This slowing of depolarization results in a rightward shift of the terminal QRS axis and the right bundle-branch block pattern that is noted on the ECG of patients who are exposed to CA.[156]

Figure 71-2. Effects of cyclic antidepressants on the fast sodium channel. A. Sodium depolarizes the cell, which both propagates conduction allowing complete cardiac depolarization and opens voltage-dependent Ca^{2+} channels producing contraction. B. Tricyclic antidepressants and other sodium channel blockers alter the conformation of the sodium channel, slowing the rate of rise of the action potential, which produces both negative dromotropic and inotropic effects. C. Raising the Na^{+} gradient across the affected sodium channel speeds the rate of rise of the action potential, counteracting the drug-induced effects. Raising the pH removes the CA from the binding site on the Na^{+} channel. See Figure 71-3 for the effects noted on the ECG.

QTc interval prolongation can occur in the setting of both therapeutic and toxic doses of CAs. This apparent prolongation of repolarization results primarily from slowed depolarization.[118] QTc prolongation can predispose to development of torsades de pointes. Because torsades de pointes is more likely to occur in the setting of bradycardia, it is an unlikely finding in patients with acute CA toxicity.

The associated hypotension is multifactorial. It is caused by direct myocardial depression secondary to sodium channel blockade, which disrupts the subsequent coupling of calcium entry into the cells, thereby impairing myocardial contractility. Downregulation of adrenergic receptors with subsequent blunted physiologic responses to catecholamines is suggested as another mechanism based on evidence of CA-poisoned patients with normal to high serum catecholamine concentrations.[93] Peripheral vasodilation from Î±-adrenergic blockade by CAs also contributes to hypotension, particularly when patients are standing.

The most common dysrhythmia observed following overdose is sinus tachycardia, which primarily results from peripheral muscarinic antagonism. Norepinephrine reuptake inhibition also contributes to

the tachycardia. Wide-complex tachycardia is the characteristic potentially life-threatening dysrhythmia observed in patients with severe CA toxicity. It also probably is multifactorial in etiology. By prolonging antegrade conduction, nonuniform conduction slowing may result, leading to reentrant ventricular dysrhythmias.[151] Ventricular tachycardia may occur in the setting of hypoxia and tissue ischemia, metabolic acidosis, and use of Î²$_1$-adrenergic therapy. However, most examples of wide-complex tachycardia actually are aberrantly conducted sinus tachycardia. In such cases, the preceding P wave may not be apparent because of prolonged AV conduction, widened QRS interval, or both. Electrophysiologic studies in a canine model demonstrate that QRS prolongation is rate dependent, that is, the faster the heart rate, the greater the conduction delay. In these studies, dogs in which heart rate could not accelerate because of a crushed sinus node never developed QRS prolongation. Furthermore, induction of bradycardia through experimental pharmacologic agents prevents or narrows wide-complex tachycardia by allowing time for recovery of sodium channel interaction.[4] Earlier studies demonstrated narrowing of the QRS interval with propanolol administration.[122] This physiologic characteristicâ€”use-dependent kineticsâ€”is characteristic of the sodium channel blockade of type IA antidysrhythmics (Chap. 61).

Attempts to find a causal relationship between TCA administration and myocardial disease through controlled trials have failed.[43,149] However, data suggest that chronic TCA drug treatment causes myocardial injury. Clinical studies using monoclonal antimyosin antibodies, a known marker for myocardial damage, demonstrate increased myocardial uptake of these antibodies in adults undergoing long-term amitriptyline treatment.[84]

Agitation, delirium, and depressed sensorium are primarily caused by the central anticholinergic effects of CAs. The pathophysiology of CA-induced seizures is not fully delineated but may result from a combination of increased concentrations of monoamines (particularly norepinephrine), antidopaminergic properties, anticholinergic

properties, inhibition of neuronal sodium channels, and interactions with GABA receptors. Animal studies demonstrate that the interaction of CAs with the GABA receptorâ€“chlorideâ€“ionophore complex in the brain may be primarily responsible for the convulsant effects of these drugs. Specifically, in drug-naive rats, some CAs inhibited GABA-mediated chloride conductance, which correlated with the frequency of induced seizures.[80] Another study in rats reported that amitriptyline actually augments chloride conductance in CNS tissue.[81] This property suggests yet another complex mechanism for seizures or actually may confer a protective anticonvulsant effect on patients who were chronically taking the drug prior to their overdose. The exact binding site of these drugs is not elucidated, although some evidence suggests at least indirect activity at the picrotoxin binding site on the GABAâ€“chloride complex.[137]

The pulmonary complications of CA overdose include acute lung injury. In one study, amitriptyline exposure caused dose-related vasoconstriction and bronchoconstriction in isolated rat lungs.[141] Many substances implicated in acute lung injury, such as platelet activating factor and protein kinase activation, were important in mediating amitriptyline-induced lung function impairment in this experimental model. Another animal model demonstrated that acute amitriptyline poisoning causes dose-dependent prolonged rises in pulmonary artery pressure, pulmonary edema, and sustained vasoconstriction that could be attenuated by either calcium channel inhibition or a nitric oxide donor.[79]

Clinical Manifestations of Toxicity

The toxic profile is qualitatively the same for all of the first-generation TCAs but is slightly different for some of the other CAs. The progression of clinical toxicity is unpredictable and may be rapid, depending on the patient's age and weight and the quantity of TCA ingested. Patients commonly present to the ED with minimal clinical abnormalities and then develop life-threatening cardiovascular and

CNS toxicity within a couple of hours (Table 71-2).

TABLE 71-2. Clinical Manifestations of Toxicity Resulting from Cyclic Antidepressants

Cardiovascular Toxicity
Conduction Delays
PR interval, QTc interval, and QRS complex prolongation
T40-ms axis rightward rotation (120Â°â€“270Â°)
Atrioventricular block
Dysrhythmias
Sinus tachycardia
Supraventricular tachycardia
Wide-complex tachycardia
Sinus tachycardia with rate-dependent aberrancy
Ventricular tachycardia
Torsades de pointes
Bradycardia
Ventricular fibrillation
Asystole
Hypotension
Central Nervous System Toxicity
Altered mental status
Delirium
Psychosis
Lethargy
Coma
Myoclonus
Seizures
Anticholinergic Toxicity
Altered mental status
Hyperthermia
Urinary retention

Paralytic ileus
Pulmonary Toxicity
Acute lung-injury aspiration

The CAs have a low toxicity threshold, so a small increase over the therapeutic range may result in toxicity. Acute ingestions of 10â€“20 mg/kg of most CAs cause significant cardiovascular and CNS manifestations (therapeutic dose 2â€“4 mg/kg/d). Thus, life-threatening overdose in adults usually is associated with ingestions. 1 g. However, in a 10-kg toddler, as few as two 50-mg imipramine tablets may cause significant toxicity (10 mg/kg), defined as CNS depression, seizures, and/or cardiovascular toxicity. In a series of TCA ingestions in children all patients with single unintentional ingestions >5 mg/kg had toxicity.[89]

Acute Toxicity

Most of the reported toxicity derives from acute ingestions, especially in patients who are chronically taking the medication. Clinical toxicity between these 2 cohorts do not appear to be different, and most studies do not distinguish between them.

Acute Cardiovascular Toxicity

Cardiovascular toxicity is primarily responsible for the morbidity and mortality attributed to CAs. Conduction delays include prolongation of the QRS complex duration and rightward shift of the terminal 40-msec QRS axis (T40-ms). PR, QRS, and QTc interval prolongation can occur in the setting of both therapeutic and toxic doses of TCAs.[83] Second- and third-degree atrioventricular blocks are rare. Sinus tachycardia (rate 120â€“160 beats/min in an adult) is the most common dysrhythmia associated with CA toxicity and usually does not cause hemodynamic compromise. It is present in most patients

with clinically significant TCA poisoning. Ventricular tachycardia is the most common lethal ventricular dysrhythmia but may be difficult to distinguish from sinus tachycardia with aberrant conduction. Ventricular tachycardia occurs most often in patients with prolonged QRS complex duration and/or hypotension.[77,144] Acutely poisoned patients with QRS widening usually have altered mental status. Hypoxia, acidosis, hyperthermia, seizures, and Î²-adrenergic agonists may predispose the patient to ventricular tachycardia.[77,144] However, true fatal dysrhythmias probably are rare, as ventricular tachycardia and fibrillation occur in only approximately 4% of all cases.[45] Both children and adults receiving cardiopulmonary resuscitation have recovered successfully despite periods of asystole exceeding 90 minutes.[102,134,146] Torsade de pointes is not common with acute TCA overdoses but is found more often in patients receiving therapeutic doses of CAs.

Refractory hypotension probably is the most common cause of death from CA overdose.[22,57,140] The etiology of CA-induced hypotension is multifactorial. Hypoxia, acidosis, volume depletion, seizures, or concomitant ingestion of other cardiodepressant or vasodilating drugs can exacerbate hypotension.

Acute Central Nervous System Toxicity

Seizures and altered mental status are the primary manifestations of CNS toxicity. Delirium, disorientation, agitation, and/or psychotic behavior with hallucinations may be present. These alterations in consciousness usually are followed by lethargy that rapidly progresses to obtundation and coma. The duration of coma is variable and does not necessarily correlate or occur concomitantly with electrocardiographic abnormalities.

CA-induced seizures usually are generalized and brief, most often occurring within 1â€“2 hours of ingestion.[30,119] The incidence of seizures is similar to ventricular tachycardia and estimated at 4% in patients presenting with overdose and 13% in fatal cases.[158]

Uncontrolled seizures are uncommon and may result in metabolic acidosis, hyperthermia, rhabdomyolysis, and myoglobinuria with acute renal failure. Abrupt deterioration in hemodynamic status, namely, hypotension and ventricular dysrhythmias, may develop during or within minutes after a seizure.[30,77,144] This rapid cardiovascular deterioration may be the result of seizure-induced acidosis that exacerbates cardiovascular toxicity. The risk of seizures with CA overdoses may be increased in patients undergoing long-term therapy or who have other risk factors such as history of seizures, head trauma, or concomitant drug withdrawal.[133] Myoclonus and extrapyramidal symptoms may occur in CA-poisoned patients.

Other Clinical Effects

Anticholinergic effects can occur early or late in the course of TCA toxicity. Pupils may be dilated and poorly reactive to light. Other anticholinergic effects include dry mouth, dry flushed skin, urinary retention, and ileus.

Reported pulmonary complications include acute lung injury, aspiration pneumonitis, and adult respiratory distress syndrome. Acute lung injury may be the result of coma, hypotension, pulmonary infection, and excessive fluid administration, along with the primary toxic effects of cas.[129,131] Bowel Ischemia, Pseudo-Obstruction, And Pancreatitis Are Associated With Ca Overdose.[91,117,152]

Death directly caused by ca toxicity usually occurs in the first several hours after presentation secondary to refractory hypotension in patients who reach a healthcare facility. Late deaths (>1â€“2 days after presentation) usually are secondary to other factors such as aspiration pneumonitis, adult respiratory distress syndrome from refractory hypotension, and/or infection.[22]

Chronic Toxicity

Chronic ca toxicity usually is manifested by exaggeration of adverse effects, such as sedation and sinus tachycardia, or defined by supratherapeutic drug concentrations in the blood in the absence of an acute overdose.[41] unlike chronic theophylline and aspirin poisoning, this category of toxicity does not appear to cause the same acute life-threatening toxicity. A sparse literature describes the clinical course of this cohort, which may even go unrecognized.

Several reports describe sudden death in children taking therapeutic doses of cas.[113,115,116,148] qtc prolongation with resultant torsade de pointes, advanced atrioventricular conduction delays, blood pressure fluctuations, and ventricular tachycardia are postulated mechanisms, although whether any of these effects contributed to the deaths is unknown. prospective studies using 12-lead ecg, 24-hour ecg recording, and doppler echocardiography in children receiving therapeutic doses of tcas have failed to find any significant cardiac abnormalities compared to children not taking tcas.[10,32] However, authors recommend that tcas not be initiated or continued in any child with a resting qtc interval >450 msec or with bundle-branch block.[32]

Unique Toxicity from â€œAtypicalâ€• Cyclic Antidepressants

Although the incidence of serious cardiovascular toxicity is lower in patients with amoxapine overdoses, the incidence of seizures is significantly greater than for the traditional tcas.[58,69,78] Moreover, Seizures May Be More Frequent Or Status Epilepticus May Develop.[92] similarly, the incidences of seizures, cardiac dysrhythmias, and duration of coma are greater with maprotiline toxicity compared to the tcas.[68]

Diagnostic Testing

Diagnostic testing for CA poisoning primarily relies on indirect bedside tests (ECG) and other nonspecific laboratory analyses. Quantification of CA concentration provides little help in the acute management of patients with CA overdose but provides adjunctive information to support the diagnosis.

Electrocardiography

The ECG can provide important diagnostic information and may predict clinical toxicity after a CA overdose. CA toxicity results in distinctive and diagnostic electrocardiographic changes that may allow early diagnosis and targeted therapy when the clinical history and physical examination are unreliable.

The maximal limb lead QRS complex duration is an easily measured ECG parameter that is a sensitive indicator of toxicity. One investigation reported that 33% of patients with a limb lead QRS interval â‰¥100 msec developed seizures and 14% developed ventricular dysrhythmias.[14] There was a 50% incidence of ventricular dysrhythmias among patients with a QRS duration â‰¥160 msec. No ventricular dysrhythmias occurred in patients with a QRS duration â‰¥ 160 msec. Subsequent studies confirmed that a QRS duration >100 msec is associated with an increased incidence of serious toxicity, including coma, need for intubation, hypotension, seizures, and dysrhythmias, making this ECG parameter a useful indicator of toxicity.[24,75]

A terminal 40-ms axis between 120Â° and 270Â° is associated with TCA toxicity and in 1 study was a more sensitive indicator of drug presence than the QRS complex duration alone.[24,100,156] A terminal QRS vector of 130Â°â€“270Â° discriminated between 11 patients with positive toxicology screens for TCAs and 14 patients with negative toxicology screens.[100] With further analyses, this report concluded that the positive and negative predictive values of this ECG parameter for TCA ingestions were 66% and 100%, respectively, in a population of 299 general overdose patients. A retrospective

study reported that a TCA-poisoned patient was 8.6 times more likely to have a T40-ms axis >120Â° than was a nonâ€“TCA-poisoned patient.[156] Again, this parameter was a more sensitive indicator of TCA altered mental status but not necessarily of seizures and/or dysrhythmias specifically. However, the T40-ms axis is not easily measured in the absence of specialized computer-assisted analysis, which limits its practical utility. An abnormal rightward axis can be estimated by observing a negative deflection (terminal S wave) in leads I and aVL and a positive deflection (terminal R wave) in lead aVR (Figure 71-1B and 71-3).

Easily quantifiable measurements in lead aVR on a routine ECG can predict toxicity (Figure 71-3). When prospectively studied, 79 patients with acute TCA overdoses demonstrated that the amplitude of the terminal R wave and R/S wave ratio in lead aVR (R_{aVR}, R/S_{aVR}) were significantly greater in patients who developed seizures and ventricular dysrhythmias.[75] The sensitivity of R_{aVR} = 3 mm and R/S_{aVR} = 0.7 in predicting seizures and dysrhythmias was comparable to the sensitivity of QRS = 100 msec. In this study, R_{aVR} â‰¥3 mm was the only ECG variable that significantly predicted these complications.

Thus, specific ECG measurements such as QRS interval duration and height of the R wave in lead aVR can be useful parameters in assessing and predicting CA toxicity, although neither is 100% sensitive in predicting cardiac and neurologic complications. However, documenting the absence of these abnormalities on sequential ECGs provides further evidence that cardiac toxicity is not developing. Serial ECGs should be obtained to monitor for worsening of these parameters, which might signal the need for further interventions. Based on published data demonstrating ongoing changes of the QRS and T40-ms axis despite therapeutic interventions, ECG parameters alone are not ideal and should be used in conjunction with the patient's clinical presentation, history, and course during the first several hours for decision making with regard to disposition and interventions.[76]

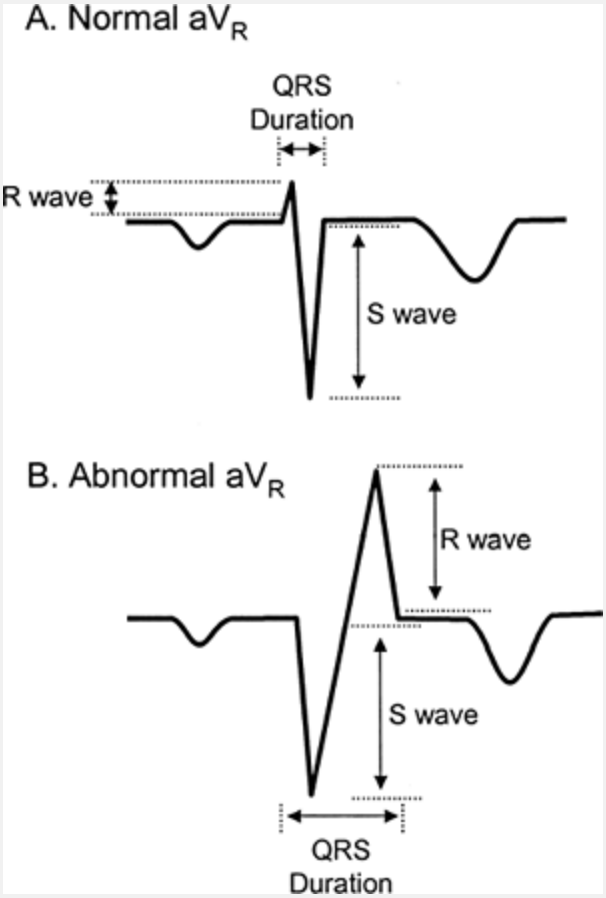

Figure 71-3. Normal QRS complex in lead aVR. B. Abnormal QRS complex in a patient with severe tricyclic antidepressant poisoning. R_{aVR} is measured as the maximal height in millimeters of the terminal upward deflection in the QRS complex. The S wave is measured in millimeters as the depth of the initial downward deflection.

Laboratory Tests

Quantitative determination of CA serum concentration has limited utility in the immediate evaluation and management of patients with

acute overdoses. The pharmacologic properties of CAsâ€”namely, large volumes of distributions, prolonged absorption phase, long distribution half-lives, pH-dependent protein binding, wide intrapatient variability of terminal elimination half-lives, and development of tolerance among people chronically taking these medicationsâ€”limit the value of serum concentrations in predicting acute toxicity. Serum concentrations usually do not correlate with acute clinical toxicity for these reasons. In 1 study, serum drug concentrations failed to accurately predict the risk of seizures or ventricular dysrhythmias.[14]

However, CA concentrations >1000 ng/mL usually are observed in patients with significant clinical toxicity (coma, seizures, and dysrhythmias), although life-threatening toxicity has also been observed in patients with serum concentrations <1000 ng/mL.[11,14,45,71,112,135] This serious toxicity at lower concentrations probably results from a number of factors, including the presence of coingestants, the

circumstances of ingestion (acute or acute on chronic), timing of the concentration in relation to the ingestion, and limitations of measuring the concentration in blood and not the affected tissue. Several studies demonstrate that both single and serial serum concentrations are not predictive of clinical outcome. Quantitative concentrations usually cannot be readily obtained in most hospital laboratories. However, qualitative screens for TCAs using an enzyme-multiplied immunoassay test are available at some hospitals, although false-positive results can occur with many drugs.

Analyzing CA concentrations may be helpful in diagnosing chronic CA toxicity. Therapeutic CA concentrations (including active metabolites) are generally in the range from 50â€“300 ng/mL. Any concentration outside this range, when measured at the appropriate time in association with onset or increase in adverse effects (tachycardia, dizziness, prolonged QTc), is an indication to decrease or stop the medication. Finally, quantitative concentrations may be helpful in

determining the cause of death in suspected overdose patients. Forensic studies have found lethal CA concentrations ranging from 1100â€“21,800 ng/mL. Measurement of liver drug concentrations or parent-to-metabolite drug ratios is preferable in the postmortem setting because CA concentrations may increase up to 5-fold because of postmortem redistribution from tissue to blood[5,6] (Chap. 33).

CAs can be detected qualitatively in the urine by thin-layer chromatography or by high-performance liquid chromatography. Bedside immunoassays are commercially available. False-positive results may occur in the presence of carbamazepine, cyclobenzaprine, diphenhydramine, and cyproheptadine.

Management

Any person with a suspected or known ingestion of a CA requires immediate evaluation and treatment (Table 71-3). The patient should be attached to a cardiac monitor and intravenous access should be secured. Early intubation is advised for patients with CNS depression and/or hemodynamic instability because of the potential for rapid clinical deterioration. A 12-lead ECG should be obtained for all patients. Laboratory tests including concentrations of glucose and electrolytes should be performed for all patients with altered mental status, as well as blood gas analysis to assess the degree of acidemia and to guide alkalinization therapy. Aggressive interventions for maintenance of blood pressure and peripheral perfusion must be performed early to avoid irreversible damage. The options for GI decontamination discussed below then should be considered.

Gastrointestinal Decontamination

Induction of emesis is contraindicated, given the potential for precipitous neurologic and hemodynamic deterioration. Because of the potential lethality of large quantities of CAs, orogastric lavage should be considered in the symptomatic patient with an intentional

overdose. Although the benefits of orogastric lavage for CA toxicity are not substantiated by controlled trials, the potential benefits of removing significant quantities of a highly toxic drug must be weighed against the risks of the procedure[15] (Chap. 8). Because the anticholinergic actions of some CAs may decrease spontaneous gastric emptying, attempts at orogastric lavage up to 12 hours after ingestion may yield unabsorbed drug. Patients with altered mental status or seizures should undergo orogastric lavage after endotracheal intubation only to protect the airway. The benefit of performing orogastric lavage in young children with unintentional ingestions of CAs may not be similar to that in adults with intentional ingestions. These scenarios usually do not result in ingestion of large quantities of pills, and the procedure may be associated with more risks and impracticalities, such as the size of holes in pediatric tubes. Activated charcoal should be administered in nearly all cases. Irrespective of age, an additional dose of activated charcoal several hours later is reasonable after a large ingestion, in a seriously poisoned patient in whom unabsorbed drug may still be present in the GI tract, in case of desorption of CAs from activated charcoal, or if the patient is a slow metabolizer. It is important to monitor for the development of a paralytic ileus to prevent abdominal complications from additional doses of activated charcoal.

TABLE 71-3. Treatment of Cyclic Antidepressant Toxicity

Toxic Effect	Treatment
Conduction Delays	
QRS >100 msec $R_a$vr â‰¥3 mm T40-ms axis >130	• Sodium bicarbonate: 1â€“2 mEq/kg IV boluses at 3- to 5-min intervals to reverse

	the abnormality or to a target serum pH no greater than 7.55 • Controlled ventilation (if clinically indicated for hypoventilation)
Dysrhythmias	
Sinus tachycardia	• No treatment
Wide-complex tachycardia/ventricular tachycardia	• Sodium bicarbonate: 1â€“2 mEq/kg IV boluses to reverse the dysrhythmia or to a target serum pH no greater than 7.55 • Correct hypoxia, acidosis, hypotension • Consider lidocaine: 1 mg/kg slow IV bolus, followed by infusion of 20â€“50 Âµg/kg/min • Consider hypertonic saline (3% NaCl) • Consider magnesium sulfate 25â€“50 mg/kg (maximum 2.0 g) IV over 2 min • Controlled ventilation (if clinically indicated)
Torsades de pointes	• Magnesium sulfate • Overdrive pacing

Hypotension	• Isotonic saline (0.9% NaCl) boluses (up to 30 mL/kg) • Correct hypoxia, acidosis • Sodium bicarbonate: 1â€“2 mEq/kg IV boluses to a target serum pH of no greater than 7.50â€“7.55 • Norepinephrine • Consider extracorporeal mechanical circulation (extracorporeal membrane oxygenation, cardiopulmonary bypass)
Seizures	• Benzodiazepines, propofol • Secure airway with intubation if necessary • Correct hypoxia, acidosis • Barbiturates • Continuous infusion of midazolam or propofol if barbiturates fail • Consider neuromuscular paralysis/general anesthesia if all other measures fail

Wide-Complex Dysrhythmias, Conduction Delays, and/or Hypotension

The mainstay therapy for treating wide-complex dysrhythmias and for reversing conduction delays and hypotension is the combination

of serum alkalinization and sodium loading. Controlled in vitro and in vivo studies in various animal models demonstrate that hypertonic sodium bicarbonate effectively reduces QRS complex prolongation, increases blood pressure, and reverses or suppresses ventricular dysrhythmias caused by CAs.[95,96,104,120,121,122] These studies also showed either equivalent or fewer beneficial effects of hyperventilation, hypertonic sodium chloride, and other nonsodium buffer solutions compared to sodium bicarbonate, suggesting multiple reasons for its effectiveness. A systematic review of all animal and human studies published until 2001 revealed that alkalinization therapy was the most beneficial therapy for consequential dysrhythmias and shock.[12]

Increasing the extracellular concentration of sodium, or sodium loading, may overcome the effective blockade of sodium channels through gradient effects (Figure 71-2). This mechanism explains why in some animal studies sodium bicarbonate was more effective in decreasing cardiotoxicity than were other sodium-free buffer solutions. Hypertonic sodium chloride loading reverses cardiotoxicity in several animal studies,[51,87,104] including doses as high as 15 mEq Na/kg.[86] However, the does of hypertonic saline for TCA poisoning has never been evaluated in humans, and the suggested dose in animals exceeds the amount that most clinicians would consider safe (1â€“2 mEq/kg). Unfortunately, no controlled human studies investigate which of the proposed mechanisms is most important, although the mechanism most likely is a combination. Furthermore, no controlled human studies demonstrate that sodium bicarbonate is effective; however, numerous reports and extensive clinical experience support its efficacy in treating serious CA cardiotoxicity.[12,18,19,52,53]

The optimal dosing and mode of administration of hypertonic sodium bicarbonate and the indications for initiating and terminating this treatment are unsupported by controlled clinical studies. Instead, the information is extrapolated from animal studies, clinical experience, and an understanding of the pathophysiologic mechanisms of CA

toxicity. A bolus, or rapid infusion over several minutes, of hypertonic sodium bicarbonate (1â€“2 mEq/kg) should be administered initially.[19,86,104] Higher doses have successfully treated patients, but experience is limited. Continuous ECG monitoring should be in place to follow the progression of ECG abnormalities. Additional boluses every 3â€“5 minutes can be administered until the QRS interval narrows and the hypotension improves. Blood pH should be monitored after several bicarbonate boluses, aiming for a target pH of no greater than 7.50â€“7.55. Because CA may redistribute from the tissues into the blood over several hours, it may be reasonable to begin a continuous sodium bicarbonate infusion to maintain the pH in this range. Differences in outcomes between repetitive boluses alone and boluses with further bicarbonate infusions are not well studied. Although diluting sodium bicarbonate in 5% dextrose in water and infusing it slowly renders it less able to raise the sodium gradient at the cell, the beneficial effects of pH elevation still may be warranted. No evidence supports prophylactic alkalinization in the absence of severe cardiovascular toxicity.

Use of hypertonic saline solutions (3% NaCl) or combined sodium bicarbonate and 0.9% sodium chloride solutions for rapid infusion theoretically should be efficacious, although these modalities are not adequately studied in humans. A case report describes the successful use of 7.5% NaCl to treat hypotension and QRS widening with ventricular ectopy in a patient with a nortriptyline overdose who was unresponsive to boluses of sodium bicarbonate and 0.9% sodium chloride solution.[90] The role of hypertonic saline remains undefined. However, it could be considered in situations of refractory hypotension, wide-complex tachycardia, and/or dysrhythmias. Potential risks of this treatment include fluid overload, sodium overload, and hyperchloremic metabolic acidosis.

Hyperventilation is a more rapid and easily titratable method of serum alkalinization but is not as effective as a single modality in reversing cardiotoxicity.[63,86] Simultaneous hyperventilation and sodium bicarbonate administration may result in profound alkalemia

and should be performed only with extreme caution and careful monitoring of pH.[157] Hyperventilation without bicarbonate administration may be indicated in patients with acute lung injury or congestive heart failure in whom administration of large quantities of sodium are contraindicated.

Alkalinization and sodium loading with hypertonic sodium bicarbonate and/or hypertonic saline along with controlled ventilation (if clinically indicated) should be administered to all overdose patients presenting with major cardiovascular toxicity. Indications include any conduction delays (QRS > 100 msec, R_{aVR} â‰¥3 mm, and/or an unexplained or new right bundle-branch block), wide-complex tachycardia, and hypotension. It is imperative to initiate treatment until CA toxicity can be excluded because of the risk for rapid and precipitous deterioration. Although commonly assumed, it is unclear whether the failure of the QRS complex to narrow with sodium bicarbonate treatment excludes CA toxicity.

Alkalinization may be continued for at least 12â€“24 hours after the ECG has normalized because of the drug's redistribution from the tissue. However, the time observed for resolution or normalization of conduction abnormalities is extremely variable, ranging from several hours to several days despite continuous bicarbonate infusion.[76] In some patients, clinical improvement occurred both before and during ECG changes. We recommend stopping alkalinization when the patient improves clinically and shows improvement, not necessarily normalization, of abnormal ECG findings.

Antidysrhythmic Therapy

Lidocaine is the antidysrhythmic most commonly advocated for treatment of CA-induced dysrhythmias, although no controlled human studies demonstrate its efficacy.[18,19,105] Because lidocaine has sodium channel-blocking properties, some investigators argue against its use in CA poisoning.[1] These theoretical concerns are not well supported in the literature or in theory. The use of class IA

(quinidine, procainamide, disopyramide, and moricizine) and class IC (flecainide, propafenone) antidysrhythmics is absolutely contraindicated because they have similar pharmacologic actions to CAs and thus may worsen the sodium channel inhibition caused by CAs and exacerbate cardiotoxicity. Class III antidysrhythmics (amiodarone, bretylium, and sotalol) prolong the QTc interval and, although unstudied, may be contraindicated as well.

Because magnesium sulfate has antidysrhythmic properties, it may be beneficial in the treatment of ventricular dysrhythmias. Animal studies of the effects of magnesium on CA-induced dysrhythmias yield conflicting results.[64,65] However, successful use of magnesium sulfate in the treatment of refractory ventricular fibrillation after TCA overdose is reported.[67] The routine use of magnesium requires further evaluation and currently is not recommended.

Based on electrophysiologic studies in animal models, the wide-complex tachycardia/ventricular tachycardia caused by CAs is rate dependent.[3,121] Slowing the heart rate in the presence of CAs may allow more time during diastole for drug unbinding from sodium channels and might result in an improvement in ventricular conduction, which then could abolish the reentry mechanism for

dysrhythmias. This mechanism was the rationale for the past use of physostigmine and propranolol. Thus, it is hypothesized that decreasing the sinus rate may itself be effective in abolishing ventricular dysrhythmias by eliminating rate-dependent conduction slowing. Propranolol terminated ventricular tachycardia in an animal model but unfortunately also caused significant hypotension.[122] In 1 case series, patients developed severe hypotension or had a cardiac arrest shortly after receiving a Î²-adrenergic antagonist.[37] Other animal studies suggest that preventing or abolishing tachycardia by sinus node destruction or by using bradycardic agents that impede sinus node automaticity without affecting myocardial repolarization or contractility may successfully prevent CA-induced ventricular dysrhythmias.[3,4] The combined negative inotropic effects of Î²-

adrenergic antagonists and CAs along with the significant cardiac and CNS effects reported with physostigmine use do not support their routine use in the management of CA-induced tachydysrhythmias.

Use of phenytoin as an antidysrhythmic agent in CA toxicity has been extensively studied. Several animal and human studies indicate phenytoin is successful in preventing or reversing some conduction abnormalities.[27,47,85] However, these studies were not well controlled for other confounding factors, such as blood pH and sodium bicarbonate administration, they had very small numbers, and, in some, the cardiotoxicity was not severe. Phenytoin may have a prodysrhythmogenic effect in the presence of CAs, thus inducing or worsening ventricular dysrhythmias.[23] Based on available evidence, phenytoin is not recommended for wide-complex tachydysrhythmias associated with CAs.

Hypotension

Hypotension is the most common cause of death secondary to CA toxicity.[130] Standard initial treatment for hypotension should include volume expansion with isotonic saline and alkalinization/sodium loading with hypertonic sodium bicarbonate (if conduction abnormalities also are present). Hypotension unresponsive to these therapeutic interventions necessitates the use of inotropic and/or vasopressor drug support and possibly extracorporeal cardiovascular support.

The choice of specific direct-acting or indirect-acting drug(s) for treatment of CA-associated hypotension is controversial. Available data are limited and contradictory. Norepinephrine, epinephrine, dopamine, and dobutamine are proposed to be effective drugs for hypotension, but no controlled human studies are available. Furthermore, the pharmacologic properties of CAs complicate the choice of a specific agent. Specifically, CA blockade of neurotransmitter reuptake theoretically could result in depletion of intracellular catecholamines. This blockade of norepinephrine and

dopamine reuptake then could blunt the effect of dopamine, which is dependent on the release of endogenous norepinephrine for its inotropic activity.[20] This Î±-adrenergic blockade and downregulation of receptors induced by CAs suggest that a direct-acting vasopressor such as norepinephrine is more efficacious than an indirect-acting catecholamine such as dopamine. Norepinephrine at high doses may be dysrhythmogenic and might exacerbate cardiovascular toxicity. Pure Î²-adrenergic agonists, such as isoproterenol and dobutamine, and even combination Î±- and Î²-adrenergic agonists, such as dopamine, theoretically could worsen the hypotension.

Animal data comparing various drugs are conflicting, and their direct applicability to clinical human poisoning is limited.[33,56,150] Both norepinephrine and epinephrine increased the survival rate in TCA-poisoned rats.[66] In addition, epinephrine was superior to norepinephrine when used both with and without sodium bicarbonate, and the most effective treatment regimen in their study was epinephrine plus sodium bicarbonate; neither drug precipitated dysrhythmias. The authors propose that epinephrine is more efficacious because it augments myocardial perfusion more than norepinephrine and improves the recovery of CA sodium channel blockade by hyperpolarization of the membrane potential through its stimulation of increased potassium intracellular transport.

Limited clinical data suggest that norepinephrine is more efficacious than dopamine.[145] In a retrospective study of 26 adult hypotensive patients, response rates to norepinephrine (5â€“53 Âµg/min) were significantly better than response rates to dopamine (5â€“10 Âµg/kg/min).[147] Patients who did not respond to dopamine at vasopressor doses (10â€“50 Âµg/kg/min) responded to norepinephrine (5â€“74 Âµg/min). However, the retrospective nature of this study, the subsequent lack of standard management therapies (which are indications for instituting vasoactive agents), and the heterogeneity of the population limit its generalizability. In another case report of CA toxicity, glucagon is reported to cause sustained increases in blood pressure.[126]

Based on the available data, pharmacologic effects, theoretical concerns, and experience, norepinephrine (0.1â€“0.2 Âµg/kg/min) is recommended for hypotension that is unresponsive to volume expansion and hypertonic sodium bicarbonate therapy. Central venous pressure and/or pulmonary artery catheterization may be necessary to guide the choice of additional vasopressor or inotropic agents, especially in the presence of other cardiodepressant drugs.

If pharmacologic measures fail to correct hypotension, extracorporeal life support measures should be considered. Extracorporeal membrane oxygenation, extracorporeal circulation, and cardiopulmonary bypass are successful adjuncts for refractory hypotension and life support when maximum therapeutic interventions fail.[46,70,155] These modalities can provide critical perfusion to the heart and brain and maintain metabolic function while giving the body time to metabolize and eliminate toxic concentrations of the drug by maintaining hepatorenal blood flow. Extracorporeal measures then may allow the impaired myocardium to recover.

Central Nervous System Toxicity

Endotracheal intubation should be performed in any comatose patient or in a patient with a significantly depressed mental status with acute CA toxicity. Use of flumazenil in the patient with known or suspected CA ingestion is contraindicated. Several case reports of patients with CA overdoses describe seizures following administration of flumazenil.[48,73,88] Physostigmine was used in the past to reverse the CNS toxicity of CAs[21,98] (Antidotes in Depth: Physostigmine). However, physostigmine is not recommended because it may increase the risk of cardiac toxicity, cause bradycardia and asystole, and precipitate seizures in CA-poisoned patients.[109]

Seizures caused by CAs usually are brief and may stop before treatment can be initiated. Recurrent seizures, prolonged seizures

(>2 minutes), and status epilepticus require prompt treatment to prevent worsening acidosis, hypoxia, and development of hyperthermia and rhabdomyolysis. Benzodiazepines are effective as first-line therapy for seizures.[9] If this therapy fails, barbiturates or propofol should be administered. Propofol also acts at the GABAâ€“chlorideâ€“ionophore complex. Propofol controlled refractory

seizures resulting from amoxapine toxicity.[92] Failure to respond to barbiturates should lead to consideration of neuromuscular paralysis and general anesthesia with continuous EEG monitoring. Phenytoin is not recommended for seizures because data do not demonstrate clear beneficial effects and administration could cause cardiovascular toxicity.[9,23]

Enhanced Elimination

No specific treatment modalities have demonstrated clinical significant efficacy in enhancing the elimination of CAs. Some investigators propose multiple doses of activated charcoal to enhance CA elimination because of their small enterohepatic and enterogastric circulation.[82] Human volunteer studies and case series of patients with CA overdoses suggest that the half-life of CAs may be decreased by multiple-dose activated charcoal (MDAC).[26,61,101,143] MDAC reduced the apparent half-life of amitriptyline to 4â€“40 hours in overdose patients, compared to previously published values of 30 to >60 hours.[143] Changes in the severity or duration of clinical toxicity, however, were not reported. Other investigators showed in human volunteers that MDAC reduced the half-life of therapeutic doses of amitriptyline approximately 20% compared with no activated charcoal administration.[61] However, the methodologic flaws and equivocal findings of these studies and the lack of any positive outcome data for this intervention from additional studies do not provide overwhelming evidence supporting its use in this setting.[25,44] The pharmacokinetic properties of CAs (large volumes of distribution, high plasma-protein binding) weighed against the small increases in

clearance and the potential complications of MDAC, such as impaction, intestinal infarction, and perforation, do not warrant its routine use.[25] However, MDAC conceivably might shorten the duration of clinical toxicity in patients who are â€œslow metabolizers.â€• One additional dose of activated charcoal may be given to patients with evidence of significant CNS and cardiovascular toxicity if bowel sounds are present.

Measures to enhance urinary CA excretion have a minimal effect on total clearance.[61] Hemodialysis is ineffective in enhancing the elimination of CAs because of their large volumes of distribution, high lipid solubility, and extensive protein binding.[50] Hemoperfusion overcomes some of the limitations of hemodialysis but should not be that effective because of the large volumes of distributions of CAs.[106] Several uncontrolled case reports anecdotally described improvement in cardiotoxicity during hemoperfusion, although the finding may have been coincidental.[36] Currently, little substantial evidence supports the use of hemoperfusion in the management of CA overdose.

Investigational Therapies

The development and investigation of an affinity-purified ovine polyclonal Fab fragment to TCAs spanned more than 10 years.[29,55,62,110] Initial clinical trials showed favorable results with TCA-specific Fab fragment treatment in improving both cardiovascular and CNS toxicity.[49] The emergence of the SSRIs with the resultant significant decrease in TCA prescriptions and the significant cost of producing the TCA-specific Fab have limited the interest in clinical trials and production of this new therapy.

Experimental studies demonstrate that induction of ventricular tachydysrhythmias during TCA toxicity is dependent upon heart rate.[3] The bradycardic agent UL-FS 49 effectively impedes the marked sinus tachycardia and frequency-dependent ventricular conduction delay associated with amitriptyline toxicity in a canine

model.[4] Pretreatment with this drug effectively prevented the onset of sustained ventricular tachydysrhythmias. In addition, unlike other Î²-adrenergic antagonists that have negative inotropic affects, UL-FS 40 did not appear to adversely influence hemodynamics, thereby potentially decreasing the risk of significant hypotension associated with its use. This investigational drug warrants further clinical studies in patients presenting with marked sinus tachycardia and conduction delays to determine its effectiveness in preventing wide-complex dysrhythmias and/or ventricular tachydysrhythmias.

Hospital Admission Criteria

All patients who present with known or suspected CA ingestion should undergo continuous cardiac monitoring and serial electrocardiography for a minimum of 6 hours. Fears of delayed complications and inability to predict toxicity led clinicians in the past to adopt all-inclusive admission guidelines for suspected CA ingestion. The once-standard practice of admitting all patients with CA ingestion for medical monitoring because of the risk of late complications or sudden death is not supported by the current literature. Most patients develop major clinical toxicity within several hours of presentation.[26] Several retrospective studies support a disposition algorithm that takes into account presenting clinical signs and symptoms.[7,26,39,144] If the patient is asymptomatic at presentation, undergoes GI decontamination, has normal ECGs, or has sinus tachycardia (with normal QRS complex) that resolves, and the patient remains asymptomatic in the healthcare facility for a minimum of 6 hours without any treatment interventions, the patient may be medically cleared for psychiatric evaluation (if appropriate) or discharged home as appropriate.

A prospective study of 67 patients used the Antidepressant Overdose Risk Assessment (ADORA) criteria to identify patients who were at high risk for developing serious toxicity and thus proposed the following criteria for hospitalization.[34] In this study, the presence of

QRS interval >100 msec, cardiac dysrhythmias, altered mental status, seizures, respiratory depression, or hypotension on presentation to the ED (or within 6 hours of ingestion if the time was known) was 100% sensitive in identifying patients with significant toxicity and subsequent complications. Furthermore, none of the low-risk patients (defined as absence of all these criteria) developed any further toxicity or complications, supporting the decision for medical clearance and/or discharge.

Criteria specifically for ICU admission (other than patients requiring ventilatory and/or blood pressure support) versus an inpatient bed with continuous cardiac monitoring are less clear and probably more institution dependent.[139]

The disposition of patients with persistent isolated sinus tachycardia or prolonged QTc with no concomitant altered mental status or blood pressure changes is not clearly defined. Previous studies demonstrate that these 2 parameters alone are not predictive of subsequent clinical toxicity or complications.[34,35,45] In addition, the sinus tachycardia may persist for up to 1 week following ingestion.[99,127] However, another study of pure TCA overdose patients reported that a heart rate >120 beats/min and QTc interval >480 msec were associated with an increased likelihood of major toxicity.[24] These patients might be good candidates for observation units with continuous ECG monitoring and serial ECGs for 24 hours.

Inpatient Cardiac Monitoring

The duration of cardiac monitoring in any patient initially exhibiting signs of major clinical toxicity depends on many factors.

Certainly the duration of CA cardiotoxicity and neurotoxicity may be prolonged, as might be expected from the long serum half-life of CAs, in patients who are slow hydroxylators, or in the presence of a coingestant that alters the metabolism of CAs or causes cardiac or neurologic toxicity. Recommendations in the older literature for

48â€“72 hours of ICU monitoring even in mild CA ingestions stem from isolated case reports of late-onset dysrhythmias, CNS effects, and sudden deaths.[38,40,108,125] However, review of these cases shows inadequate gastric decontamination, inadequate therapeutic interventions, and significant ongoing complications of overdose. Several retrospective studies demonstrate that late, unexpected complications in CA overdoses (eg, seizures, dysrhythmias, and death) do not occur in patients who had few or no major signs of toxicity at presentation or a normal level of consciousness and normal ECG for 24 hours.[22,31,45,111,139] All fatalities resulting directly from CA toxicity occur in the first 12â€“24 hours.

Using normalization of ECG abnormalities as an end point for therapy and discharge is problematic. Some studies document the variable resolution and normalization of QRS prolongation and T40-ms axis rotation.[103,131] Based on the available literature, it is reasonable to recommend that after the mental status and blood pressure normalize, patients should be monitored for another 24 hours off all therapy, including alkalinization, antidysrhythmics, and inotropics/vasopressors. If the patient shows improvement of ECG abnormalities with these criteria, the patient can be discharged to a monitored bed on the ward with a low risk of further complications.

Summary

CA poisoning continues to be a cause of serious morbidity and mortality worldwide. The distinctive characteristics of these drugs can cause significant CNS and cardiovascular toxicity, the latter being responsible for mortality as a result of overdose of these drugs. Cardiovascular toxicity ranges from mild conduction abnormalities and sinus tachycardia to wide-complex tachycardia, hypotension, and asystole. CNS toxicity includes delirium, lethargy, seizures, and coma. The ECG is a simple, readily available diagnostic test that can predict the development of significant toxicity, particularly seizures and/or dysrhythmias. Management strategies

are based primarily on the pathophysiology of these drugs, namely, sodium channel blockade in the myocardium. Alkalinization and sodium loading with hypertonic sodium bicarbonate and isotonic saline are the principal modes of specific therapy for cardiovascular toxicity. Guidelines for observing or admitting patients to the hospital may be based on initial clinical presentation and/or development of clinical symptomatology and ECG changes.

Chapter 72
Sedative-Hypnotics

David C. Lee

A 73-year-old man was brought to the emergency department by ambulance after his family found him unconscious in his bedroom. On presentation, he was lethargic and intermittently followed commands. He had a medical history significant for hypertension and coronary artery disease. According to the family, he recently was prescribed a new medication as a sleeping aid. Initial vital signs were: blood pressure, 138/90 mm Hg; heart rate, 65 beats/min; respiratory rate, 12 breaths/min; oral temperature, 98.3Â°F (36.8Â°C); room air pulse oximetry, 94%. His pupils were 3 mm, and there were no signs of trauma. He had an appropriate gag reflex, and his physical examination was otherwise unremarkable. His bedside glucose concentration and electrocardiogram were normal. He was treated with 2 mg intravenous naloxone and 100 mg intravenous thiamine without response. He was placed on supplemental oxygen (FiO_2 28%), which raised his oxygen saturation to 96%. However, he had periods of bradypnea during which his saturation fell to 90%. His family produced a recently prescribed bottle of zolpidem. After firmly establishing with the family that he

did not have a history of seizures, use of cyclic antidepressants, or dependence on benzodiazepines, the decision was made to reverse his sedation with flumazenil (1 mg intravenously), upon which he awoke. He admitted to â€œhaving a few drinksâ€• and had taken his new medication to help him sleep. His blood alcohol concentration was 180 mg/dL, and results of routine laboratory screening was unremarkable. He was admitted to the hospital for medical observation and psychiatric evaluation. He required no further medical intervention other than supplemental oxygen, and he was discharged 24 hours later.

Sedative-hypnotics are drugs that are prescribed to induce a calming effect, limit excitability (sedative), or induce drowsiness and sleep (hypnotic). *Anxiolytics* or *tranquilizers* are other medical terms that are often used to describe drugs that are sedative-hypnotics. The term *tranquilizer* has fallen out of favor because of the lack of precision. The term *anxiolytic* is the preferred term because this medication diminishes feelings of anxiety. Other drugs that are not classically considered sedative-hypnotics, such as serotonin reuptake inhibitors, are used successfully to treat anxiety conditions. Because many different types of drugs and dietary supplements are used for their sedative or hypnotic effect, this group of xenobiotics actually encompasses a wide range of various compounds. This chapter focuses primarily on pharmaceutical drugs used solely for their sedative-hypnotics effects, specifically drugs that primarily interact with the Î³-aminobutyric acid (GABA) receptor (Table 72-1).

History and Epidemiology

Throughout history, sedative-hypnotic use and abuse have been commonplace. Mythology of ancient cultures is replete with stories of poisons or compounds that cause sleep or a state of unconsciousness (Chap. 1). Overdoses were reported soon after the commercial introduction of bromide preparations, the first commonly available class of sedative-hypnotic agent, in 1853. Other commercial

xenobiotics that subsequently were developed include chloral hydrate, paraldehyde, sulfonyl, and urethane.

The barbiturates were introduced in 1903 and quickly supplanted the older xenobiotics. This class of drugs dominated the sedative-hypnotic market for the first half of the 20th century. Unfortunately, because barbiturates have a relatively low therapeutic-to-toxic ratio and substantial potential for abuse, they quickly became a major health problem. By the 1950s and 1960s, barbiturates were frequently implicated in overdoses and were responsible for the majority of drug-related suicides. As fatalities from barbiturates increased, attention shifted to preventing their abuse and finding less toxic alternatives.[22, 141] These â€œsaferâ€• drugs included methyprylon, glutethimide, ethchlorvynol, and methaqualone. Unfortunately, many of these drugs also had significant undesirable effects. With the introduction of benzodiazepines in the early 1960s, barbiturates and the alternative drugs were quickly supplanted.

Intentional and unintentional overdoses with sedative-hypnotic agents are common. According to the American Association of Poison Control Centers, the sedative-hypnotic class of agents is consistently one of the top 5 classes of drugs associated with, although not usually causative of, overdose fatalities (Chap. 130). With the ubiquitous worldwide use of sedative-hypnotics, they probably also are associated with substantially more deaths than are officially reported.

Chlordiazepoxide, the first commercially available benzodiazepine, initially was synthesized by Hoffman-LaRoche in 1955 and marketed in 1960. Now more than 50 benzodiazepines are marketed, and more are being developed. In the 1980s, benzodiazepines captured >80% of the sedative market and >50% of the hypnotic market.[70, 159] Compared with an overdose of barbiturates, an overdose of a benzodiazepine alone accounts for relatively few deaths.[49] Most deaths associated with benzodiazepines result from mixed overdoses of benzodiazepines and other respiratory depressants, especially

alcohol.[61]

Because of the popularity of benzodiazepines and the perception of widespread abuse, changes in local regulations and restrictions in

prescribing practices for benzodiazepines led to a resurgence in the use of older sedative-hypnotic agents in specific areas. In New York State, where restrictions were implemented in 1989 for prescribing benzodiazepines by the use of designated prescriptions issued by the state to physicians, a 60% decrease in benzodiazepine prescriptions was noted, as well as a 125% increase in meprobamate, 136% increase in chloral hydrate, and 30% increase in butabarbital prescriptions in the following year[67 , 189] and a proportional increase in overdoses of some of these drugs. Although benzodiazepines represent most of the market for prescribed sedatives, the recently introduced hypnotic agents zolpidem, zaleplon and eszopiclone have replaced benzodiazepines as the most prescribed pharmaceutical sleeping aids.

[b] This table is an approximation of equipotent doses of drugs affecting the benzodiazepine receptor and several barbiturates. All of the full agonist benzodiazepines have similar amnestic, anxiolytic, sedative, and hypnotic effects. These effects are a reflection of dose and plasma concentration. There can be significant variation of these effects according to age and gender.

Trade Name	Equipotent Dosing Oral Dose (mg)[b]	Plasma $t_{1/2}$	Protein Binding (%)	Vd (L/kg)	Active Metabolite Important

TABLE 72-1. Pharmaceutical Sedative-Hypnotics

Pharmacology

All of the sedative-hypnotics produce central nervous system (CNS) depression. Most clinically effective sedative-hypnotics produce their physiologic effects by enhancing the function of GABA-mediated chloride channels. The presence of sedative-hypnotics alters the receptor and affects the function of the chloride channel. These alterations include increasing the frequency of opening or the duration of opening.[4] The varying effects of the sedative-hypnotics can be explained further by their action on the various GABA receptor subtypes. Different sedative-hypnotics have variable affinities for certain GABA receptors with specific subunits (Chap. 14).

$GABA_A$ receptors are the primary mediators of inhibitory neurotransmission in the brain. The $GABA_A$ receptor is a pentameric structure composed of various polypeptide subunits associated with a chloride channel on the postsynaptic membrane. These subunits are classified into 3 families (Î±, Î², Î³). Variations in the 5 subunits of the GABA receptor confer the potency of its sedative, anxiolytic, hypnotic, amnestic, and muscle-relaxing properties. The most common $GABA_A$ receptor in the brain is composed of $Î±_1$ $Î²_2$ $Î³_2$ subunits. Almost all sedative-hypnotics bind to $GABA_A$ receptors containing the $Î±_1$ subunit. One possible exception is etomidate, which produces sedation at the $Î²_2$ unit and anesthesia at the $Î²_3$ subunit.[30 , 122 , 142 , 172] Low doses of benzodiazepines are effective only at $GABA_A$ receptors with the $Î³_2$ subunit. Even within the classes of sedative-hypnotics, there are varying affinities for different subunits.[40 , 106]

Many sedative-hypnotics have activity at multiple different receptor sites. Not only do sedative-hypnotics increase the effects of GABA-mediated inhibitory neurotransmission, many sedative-hypnotics, such as trichloroethanol, decrease the effects of glutamate-mediated excitatory neurotransmission.[35 , 132 , 149] Barbiturates, benzodiazepines, etomidate, and propofol interact with *N* -methyl-D-aspartate (NMDA) and AMPA/kainate receptor function. Barbiturates and propofol markedly attenuate the excitatory effects of glutamate.[24 , 48 , 130 , 190] Benzodiazepines inhibit adenosine metabolism and reuptake, thereby potentiating both A_1 -adenosine (negative dromotropy) and A_2 -adenosine (coronary vasodilatation) receptor-mediated effects.[118 , 157] Benzodiazepines interact with serotonergic pathways. Diazepam modulates morphine analgesia via serotonergic pathways, and the anxiolytic effects of clonazepam can be partially explained by upregulation of serotonergic receptors, specifically 5-HT_1 and 5-HT_2 .[8 , 119 , 180]

Pharmacokinetics/Toxicokinetics

Most sedative-hypnotics are rapidly absorbed in the gastrointestinal (GI) tract, with the rate-limiting step consisting of dissolution and dispersion of the drug. Barbiturates and benzodiazepines are primarily absorbed in the small intestine. Clinical effects are determined by the relative ability of these drugs to penetrate the bloodâ€“brain barrier. Drugs that are highly lipophilic penetrate most rapidly. The ultrashort-acting barbiturates are clinically active in the most vascular parts of the brain (gray matter first), with sleep occurring within 30 seconds of administration.

After initial distribution, many of the sedative-hypnotics undergo a redistribution phase as they are dispersed to other body tissues, specifically fat. Drugs that are redistributed, such as the lipophilic (ultrashort-acting) barbiturates and some of the benzodiazepines (diazepam, midazolam), may have a brief clinical effect as the early peak concentrations in the brain rapidly decline. The clinical activity of many of these drugs is determined by their rapid distribution and redistribution (alpha phase) and not by their elimination (beta phase) (Chap. 9).

Many of the sedative-hypnotics are metabolized to pharmacologically active intermediates. This is particularly true for chloral hydrate and some of the benzodiazepines. Benzodiazepines can be demethylated, hydroxylated, or conjugated with glucuronide in the liver. Glucuronidation proceeds rapidly with the production of inactive metabolites. Benzodiazepines, such as diazepam, undergo demethylation that yields active intermediates with a more prolonged therapeutic half-life than the parent compound. Because of the individual pharmacokinetics of sedative-hypnotics and the production of active metabolites, there often is no correlation between the therapeutic half-life and the biologic half-life.

The majority of sedative-hypnotics, such as the highly lipid-soluble barbiturates and the benzodiazepines, are highly protein bound. These drugs are poorly filtered by the kidney, and elimination occurs principally by hepatic metabolism. Chloral hydrate and meprobamate

are notable exceptions. Drugs with a low lipid-to-water partition coefficient, such as meprobamate and the longer-acting barbiturates, are poorly protein bound and more subject to renal excretion. Renal elimination can be increased by manipulation of urinary pH (Chap. 10). Phenobarbital is a classic example of a drug whose elimination can be manipulated with this technique. Most other drugs are not amenable to pH manipulation.

Toxicodynamics

Overdoses of combinations of sedative-hypnotics can be more toxic than overdoses of a single xenobiotic because multiple xenobiotics can produce synergistic clinical effects mediated by interactions on the GABA receptor (Chap. 14). For example, both barbiturates and benzodiazepines act on the GABA site, but barbiturates prolong the opening of the chloride ionophore, whereas benzodiazepines increase the frequency of ionophore opening.[159] Various sedative-hypnotics may increase the affinity of another xenobiotic at their respective binding sites. For example, pentobarbital increases the affinity of Î³-hydroxybutyrate (GHB) for its non-GABA binding site.[161] Propofol potentiates pentobarbital's effect on chloride influx at the GABA receptor.[168] Propofol also increases the affinity and decreases the rate of dissociation of benzodiazepines from their site on the GABA receptor.[21 , 144] These actions increase the clinical effect of each xenobiotic and may lead to deeper CNS and respiratory depression.

Another mechanism of synergistic toxicity is the alteration of metabolism. The combination of ethanol and chloral hydrate, historically known as a â€œMickey Finn,â€• has additive CNS depressant effects. Chloral hydrate competes for alcohol dehydrogenase, thereby prolonging the half-life of ethanol. The metabolism of ethanol generates the reduced form of nicotinamide adenine dinucleotide NADH, which is needed as a cofactor for the metabolism of choral hydrate to trichloroethanol, an active metabolite. Finally, ethanol inhibits the conjugation of

trichloroethanol, which in turn inhibits the oxidation of ethanol (Figure 72-1).[154 , 155]

Because of the great variety of drugs, multiple drugâ€“drug interactions can occur that may prolong the half-life of many sedative-hypnotics and significantly increase their potency. For example, the half-life of midazolam, which undergoes hepatic metabolism via cytochrome CYP3A4, can increase dramatically in the presence of certain drugs that compete for metabolism.[124] Specifically, the half-life of midazolam rises 400-fold when coadministered with itraconazole.[7]

Tolerance

Ingestions of relatively large doses may not have the predicted effects in patients who chronically use sedative-hypnotics. These patients often develop *tolerance* , defined as the progressive diminution of effect of a particular drug with repeated administrations that results in a need for greater doses to achieve the same effect. Tolerance can be secondary to pharmacodynamic or pharmacokinetic

factors. However, in the majority of cases, tolerance to sedative-hypnotics is caused by pharmacodynamic changes[160] (Chap. 15).

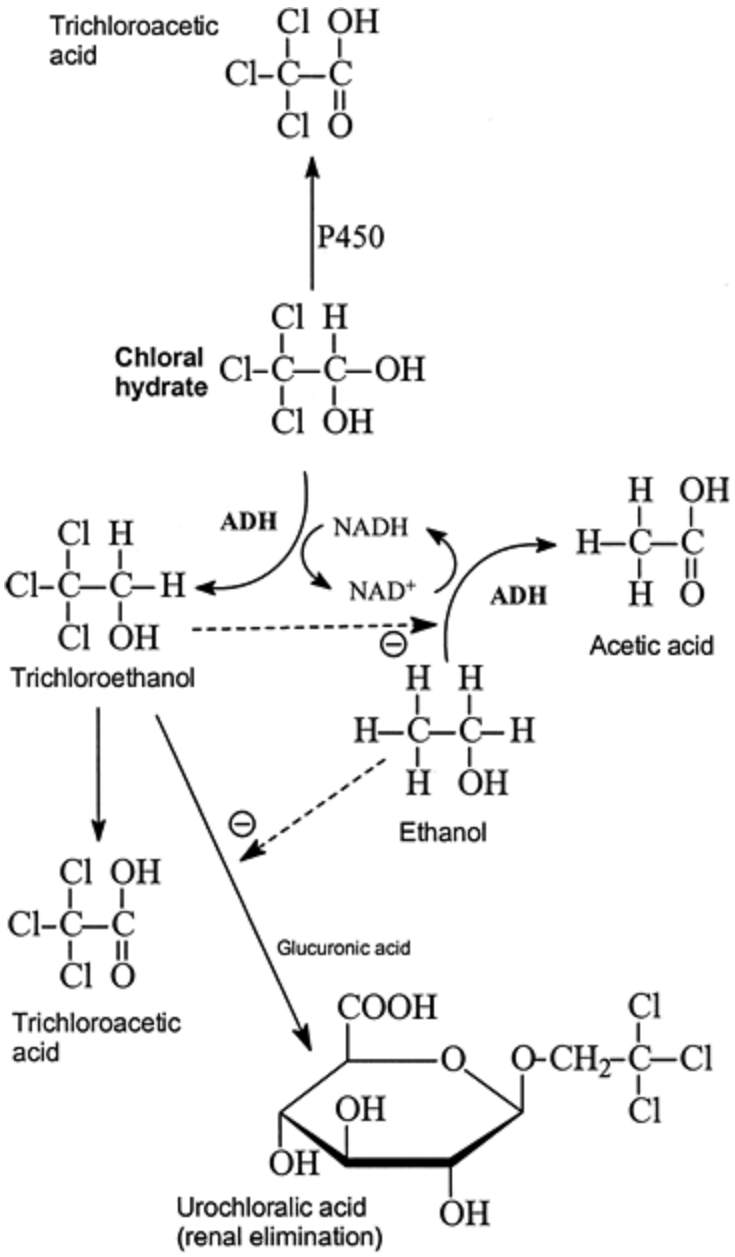

Figure 72-1. Metabolism of chloral hydrate and ethanol, demonstrating the interactions between chloral hydrate and ethanol metabolism. Note the inhibitory effects *(dotted lines)* of ethanol on trichloroethanol metabolism and the converse. *(Adapted from Sellers EM, Lang M, Koch-Weser J, et al: Interaction of chloral hydrate and ethanol in man. I. Metabolism. Clin Pharmacol Ther 1972;13:40.)*

Pharmacodynamic tolerance occurs when adaptive neural and

receptor changes (â€œplasticityâ€•) occur after repeated exposures. These changes include a decrease in the number of receptors (â€œdownregulationâ€•), reduction of firing of receptors (â€œreceptor desensitizationâ€•), structural changes in receptors (â€œreceptor shiftâ€•), and reduction of coupling of sedative-hypnotics and their respective $GABA_A$ -related receptor site. In this setting, a drug has a decreased effect even though drug concentrations do not change significantly. For example, benzodiazepine-dependent patients have decreased $GABA_A$ receptor density and sensitivity.[52, 136] Chronic benzodiazepine administration in rats causes uncoupling of the benzodiazepine receptor and the chloride channel in the GABA receptorâ€“chloride channel complex.[3, 137] Pharmacodynamic tolerance secondary to receptor changes can occur quickly, even during short-term use.[69] With certain xenobiotics, tolerance develops within minutes.[31, 71] In one study using IV infusions of thiopental at variable rates and a specific EEG pattern, rapidly increasing thiopental concentrations were needed to produce a constant state of anesthesia.[17]

The â€œMellanby effectâ€• describes the development of acute tolerance such that, at a given serum concentration, a greater clinical effect occurs when serum concentrations are rising than when they are declining. This effect, initially described for alcohol, may also apply to all sedative-hypnotics drugs.[31, 72, 90, 104] Acute tolerance may not follow a linear pattern, and increasing tolerance may occur at certain thresholds. In a study in which rats were infused with propofol at variable rates and monitored by EEG, acute tolerance occurred only at certain times.[72] Thus, pharmacodynamic tolerance can occur rapidly and have a nonlinear relationship to dose.

Pharmacokinetic tolerance occurs when metabolic changes cause decreasing concentrations of a chronically administered drug. For example, repeated use of phenobarbital induces hepatic microsomal enzyme expression, thereby decreasing its own half-life. Increasing doses of phenobarbital may be required to achieve the same steady-

state concentration.

Cross-tolerance readily exists among the sedative-hypnotics. For example, chronic use of benzodiazepines not only decreases the activity of the benzodiazepine site on the GABA receptor but also decreases the binding affinity of the barbiturate sites.[4, 68] Diazepam-tolerant mice are tolerant to the sedative-hypnotic properties of isoflurane.[50]

After therapy is terminated, tolerance can be lost as the desensitized target receptors return to their original level of function. The rate at which this process occurs is governed by the biologic half-life of the particular sedative-hypnotic and any biologically active intermediates produced. Tolerance persists for a period of time after the active xenobiotics are eliminated.[147]

Dependence and Withdrawal

Physical drug dependence refers to a condition of physiologic withdrawal induced by sudden termination of a drug. All sedative-hypnotics produce dependence and withdrawal. Approximately one third of chronic benzodiazepine users experience withdrawal when benzodiazepine use is suddenly decreased or discontinued.[85] Factors that contribute to the severity of withdrawal include shorter half-life of the agent, higher daily dosage, and underlying medical and psychological illness (Chap. 15).

Other areas of concern are unrecognized development of dependence and iatrogenic precipitation of withdrawal. Potent, fast-acting, short-lived sedatives are commonly used in the critical care setting. However, these same characteristics increase the potential for dependence. Rapid weaning from these medications or use of flumazenil may precipitate withdrawal. Delayed presentation of withdrawal after extubation and cessation of sedation occurs often with rapid weaning.[19, 164] Approximately one third of intensive care unit patients who were mechanically ventilated for >1 week suffered

from acute withdrawal when opioids or sedative-hypnotic agents were discontinued.[25]

Clinical Manifestations

Patients with significant sedative-hypnotic overdoses manifest slurred speech, ataxia, and incoordination, a syndrome similar to ethanol intoxication. Patients with moderate to severe toxicity are stuporous or comatose. In the most severe cases, all neurologic responses may be lost. In most instances, respiratory depression parallels CNS

depression. Hypoventilation produces respiratory acidosis and contributes to cardiovascular depression.

Hypothermia
Barbiturates, bromides, ethchlorvynol
Unique odors
Chloral hydrate, ethchlorvynol
Cardiac dysrhythmias
Meprobamate
  Bradycardia
GHB
  Tachydysrhythmias

Anticholinergic signs
Glutethimide

Clinical Signs Sedative-Hypnotics

TABLE 72-2. Clinical Findings of Sedative-Hypnotic Overdose

Although the physical examination rarely identifies particular sedative-hypnotics, it can give clues to the class of sedative-hypnotics (Table 72-2). Hypothermia has been described with most of the sedative-hypnotics but may be more pronounced with barbiturates.[74 , 148 , 183] Barbiturates may cause fixed drug eruptions that often are bullous and appear over pressure-point areas. However, this phenomenon is not specific to barbiturates and has been documented with other xenobiotics, including carbon monoxide, methadone, imipramine, glutethimide, and benzodiazepines. Methaqualone can cause muscular rigidity and clonus.[1] Glutethimide can present with anticholinergic signs and symptoms.[59] Chloral hydrate may present with vomiting, gastritis, and cardiac dysrhythmias.[58 , 93 , 123 , 171]

Large intravenous doses of sedative-hypnotics are associated with toxicities that are independent of the characteristics of the sedative-hypnotic but rather are associated with their diluents. Propylene glycol inducing hypotension, hyperosmolar states, and metabolic acidosis occur in patients with prolonged use of lorazepam and etomidate.[87 , 96 , 105 , 143 , 170] In one study, two thirds of critical care patients given high doses of lorazepam (0.16 mg/kg/h) for more than 48 hours had significant accumulations of propylene glycol as manifested by hyperosmolar anion gap metabolic acidosis.[6] Fatal reactions are associated with the carrier base of intravenous propofol.[139]

Diagnostic Testing

In the undifferentiated comatose patient without a clear history and when overdose is a primary concern, laboratory testing, including electrolytes, liver enzymes, thyroid function tests, blood urea nitrogen (BUN), creatinine, glucose, venous or arterial blood gas analysis, and cerebrospinal fluid analysis, may be useful to exclude metabolic abnormalities. Diagnostic imaging studies, such as head CT scans, may be warranted on a case-by-case basis.

Routine laboratory screening for â€œdrugs of abuseâ€• generally are not helpful in the management of undifferentiated comatose adult patients, although they may be useful for epidemiologic purposes in a particular community. These tests vary in type, sensitivity, and specificity. The majority of sedative-hypnotics, including the most common class, benzodiazepines, typically are not included or detected on drug-abuse screens (Chap. 7).

The typical benzodiazepine screen identifies metabolites of 1,4-benzodiazepines, such as oxazepam or desmethyldiazepam. Many benzodiazepines that are metabolized to alternative compounds remain undetected. Benzodiazepines that are 7-amino analogs, such as clonazepam and flunitrazepam, may not be detected because they do not have a metabolite with a 1,4-benzodiazepine structure. Alprazolam and triazolam are not detected because they undergo minimal metabolism.[44]

Specific laboratory concentrations (eg, alcohol or phenobarbital) may be helpful to confirm or disprove overdoses of a xenobiotic. However, specific concentrations of sedative-hypnotics other than phenobarbital are not routinely performed in most hospitals. Abdominal radiographs may detect GI chloral hydrate because of its radiopacity (Chap. 6).

Although immediate identification of a particular sedative-hypnotics agent may be helpful in predicting the length of toxicity, it rarely affects the acute management of the patient. Phenobarbital may be the exception, for which urinary alkalinization may alter management.

Management

Historically, analeptics and other nonspecific arousal agents (Antiquated Antidotes in Depth) were used, but their use is to be condemned. Deaths secondary to sedative-hypnotic overdose result from cardiorespiratory collapse. Therefore, careful attention should focus on monitoring and maintaining adequate airway, oxygenation, and hemodynamic support. Supplemental oxygen, respiratory support, and prevention of aspiration are the cornerstones of treatment. Hemodynamic instability, although often a secondary or a delayed manifestation of sedative-hypnotic poisoning typically following respiratory collapse, should be approached with volume expansion. Vasopressors should be used only when patients do not respond to intravenous fluids or when evidence of volume overload is present. Patients with chloral hydrate overdoses classically present with both respiratory depression and cardiac toxicity, including lethal ventricular dysrhythmias, resulting from its active halogenated metabolite trichloroethanol. In the setting of cardiac dysrhythmias, judicious use of Î²-adrenergic antagonists is proposed.[16 , 58 , 181]

Decontamination

All clinically stable patients with significant ingestions should receive activated charcoal. Multiple-dose activated charcoal (MDAC) increases phenobarbital elimination by 50â€“80%.[10 , 11 , 15 , 181] However, in the only controlled study, no difference could be demonstrated in outcome measures (time to extubation and length of hospitalization) in intubated, phenobarbital-poisoned patients who were randomized to single-dose activated charcoal versus MDAC.[135] Although inconclusive, after ensuring an adequately protected airway, activated charcoal has potential benefits that outweigh any risk (Antidotes in Depth: Activated Charcoal).

Although the efficacy of delayed orogastric lavage is controversial, orogastric lavage should be considered in patients who overdose with xenobiotics that may slow GI motility or may develop concretions, specifically phenobarbital and meprobamate.[78 , 152]

No antidotes counteract all sedative-hypnotic overdoses. Flumazenil, a competitive benzodiazepine antagonist, rapidly reverses the sedative effects of benzodiazepines. However, use of flumazenil has a poor risk-to-benefit ratio in patients who present with a depressed mental status and have an undifferentiated overdose (Antidotes in Depth: see Flumazenil).

Patients with sedative-hypnotic overdose require invasive therapy for few situations other than respiratory support. Hemodialysis should be considered in patients with chloral hydrate overdose who develop life-threatening cardiac manifestations and patients who ingest extremely large quantities of phenobarbital and meprobamate and require prolonged intubation times.

Because the lethality of sedative-hypnotics is associated with their ability to cause respiratory depression, asymptomatic patients can be downgraded to a lower level of care after a period of observation. Patients who have been monitored for a period of time (8â€“12 hours) without signs or respiratory depression can be transferred to a general medical floor. Patients with symptomatic overdoses of long-acting drugs, such as meprobamate and clonazepam, or drugs that can have significant enterohepatic circulation, such as glutethimide, will require 24 hours of observation (Chap. 11).

Specific drugs

Barbiturates

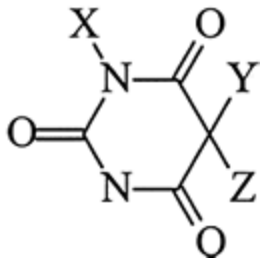

Figure. No Caption Available.

Barbital became the first commercially available barbiturate in 1903. Although many other barbiturates subsequently were developed, their popularity has greatly waned since the introduction of benzodiazepines. Barbiturates are derivatives of barbituric acid (2,4,6-trioxo-hexa-hydropyrimidine), which itself has no CNS depressant properties. Various side chains at the X, Y, and Z sites (see barbiturate chemical structure) influence lipophilicity, potency, and rate of elimination. Barbiturates with long side chains tend to have increased properties in all three areas. However, the observed clinical effects also depend on absorption, redistribution, and the presence or absence of active metabolites. For this reason, the duration of action of barbiturates (like those of benzodiazepines) do not correlate well with their biologic half-lives.

After ingestion, barbiturates are preferentially absorbed in the small intestine and are eliminated by hepatic and renal mechanisms. Longer-acting barbiturates tend to be more lipid soluble and more protein bound, have a high pK_a , a more rapid onset and shorter duration of action, and are metabolized almost completely in the liver. Renal excretion of unchanged drug is significant for phenobarbital. Elimination of phenobarbital, a long-acting barbiturate with a relatively low pK_a (7.24), can be influenced by manipulation of urinary pH. Alkalinization of the urine with sodium bicarbonate to maintain a urinary pH of 7.5â€“8.0 can increase the amount of phenobarbital excreted by 5- to 10-fold. This procedure is not effective for the short-acting barbiturates because they have higher pK_a values, are more protein bound, and are primarily

metabolized by the liver with very little excretion by the kidneys (Chap. 10).

Barbiturates (especially the shorter-acting barbiturates) can accelerate their own hepatic metabolism by enzyme autoinduction. Barbiturate use results in a marked increase in the enzyme content of the hepatic smooth endoplasmic reticulum and an increased rate of metabolism of a number of xenobiotics. Phenobarbital is a nonselective inducer of hepatic cytochromes, with the greatest effect on CYP2B1, CYP2B2, and CYP2B10.[80] Not surprisingly, a variety of drug interactions are reported following the use of barbiturates. Clinically significant interactions as a result of enzyme induction lead to increased metabolism of Î²-adrenergic antagonists, corticosteroids, doxycycline, estrogens, phenothiazines, quinidine, and theophylline.

Similar to other sedative-hypnotics, patients with significant barbiturate overdoses present with CNS and respiratory depression. Hypothermia and cutaneous bullae are often present.[12 , 43] These two signs are also described for other patients with sedative-hypnotic overdoses, but they may be more pronounced with barbiturates.[74 , 148] Early deaths caused by barbiturate ingestions result from respiratory arrest and cardiovascular collapse, whereas delayed deaths result from acute renal failure, pneumonia, acute lung injury, cerebral edema, and multiorgan system failure.[2 , 60]

Benzodiazepines

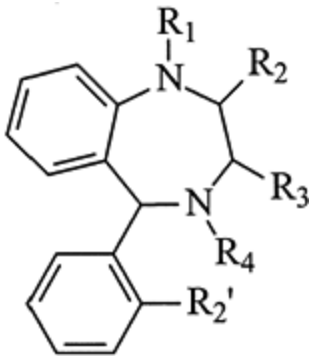

Figure. No Caption Available.

The commercial use of benzodiazepines began with the introduction of chlordiazepoxide for anxiety in 1961 and shortly thereafter of diazepam for seizures in 1963.[50] Benzodiazepines are used principally as sedatives. Temazepam and triazolam are exceptions; they are used as hypnotics to produce sleep. Clonazepam is the only benzodiazepine approved for use as a chronic anticonvulsant agent. Benzodiazepines rarely causes paradoxical psychological effects, including nightmares, delirium, psychosis, and transient global amnesia.[2,13,14,46,115] The incidence and intensity of CNS adverse events increases with age.[112]

The benzodiazepines are organic bases with a benzene structure and a 7-member diazepine moiety. Similar to barbiturates, various side chains at R1, R2, R2â€², R3, R4, R5, and R7 influence potency, duration of action, metabolites, and rate of elimination. Benzodiazepines tend to be highly protein bound and lipophilic. They passively diffuse into the CNS, their main site of action. Because of their lipophilic nature, benzodiazepines are extensively metabolized via oxidation and conjugation in the liver prior to their renal elimination.

Benzodiazepines have a unique distribution and subtypes of receptor sites. Benzodiazepines associated with GABA receptors tend to bind at specific areas in the CNS. Two structurally different â€œcentralâ€• benzodiazepine receptors are found in the brain: type I ($Ï‰_1$) and type II ($Ï‰_2$). Type I receptors tends to be located throughout the brain and contain the $GABA_A$ Î± subunit.[40] They are hypothesized to affect anxiety, sleep, and amnesia. Type II receptors are concentrated predominantly in the hippocampus, striatum, and the spinal cord. They are hypothesized to affect muscle relaxation and dependence.

Benzodiazepines are also active at certain types of benzodiazepine receptors that are not associated with the GABA receptor.

These receptors differ structurally, pharmacologically, and physiologically from GABA-associated benzodiazepine receptors. The function and structure of these receptors are not well defined, so attempts to classify them are not satisfactory. These receptors are located predominantly on the outer membrane of the mitochondria, but they also are present in erythrocytes that lack mitochondria.[125, 126, 131] Although presently termed *peripheral*, they also are located in the brain. Peripheral benzodiazepine receptors are found throughout the body, with the greatest concentrations in steroid-producing cells in the adrenal gland, anterior pituitary gland, and reproductive organs. The exact endogenous ligands that bind to these receptors are not clearly elucidated. Several types of endogenous benzodiazepinelike substances, endozepines, anthralin, porphyrins, and diazepam-binding inhibitor are proposed to bind to these receptors.[54]

The exact role of these receptors is unclear, but benzodiazepines are postulated to influence basic cellular functions such as mitochondrial respiratory control, cell growth, and cell differentiation. Peripheral benzodiazepine receptors appear to affect several biologic systems designed to cope with stress, such as the hypothalamic-pituitary system, sympathetic nervous system, renin-angiotensin system, and neuroendocrine-immune system.[54, 188] They may have a â€œneurosteroidâ€• effect by modulating steroidogenesis.[39, 101, 121]

Peripheral benzodiazepine receptors may be significant in modulating pathologic conditions such as hepatic encephalopathy, anxiety disorders, and abnormal immune function. Peripheral benzodiazepine receptors are markedly decreased after neurotoxic insults caused by the excitatory amino acid domoic acid and the neurotoxins soman and 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP).[82, 83, 88] These peripheral receptors are increased in encephalopathies caused by hepatic failure and thiamine deficiency.[23, 91, 94, 95] Cardiac benzodiazepine receptor sites are linked to calcium channels

(specifically to dihydropyridine sites) in animal tissues.[92, 107, 108, 109, 110, 111] This mechanism may theoretically support the use of benzodiazepines for treatment of the cardiac toxicity of xenobiotics such as chloroquine, cocaine, and other sympathomimetics.[9, 75, 99, 116]

Another unique property of the benzodiazepines is their relative safety even after substantial ingestion, which probably results from their GABA receptor properties.[40, 127] Unlike many other sedative-hypnotics, benzodiazepines do not open GABA channels independently at high concentrations. Benzodiazepines are not known to cause any specific systemic injury, and their long-term use is not associated with specific organ toxicity. Deaths resulting from benzodiazepine ingestions alone are extremely rare. Most often deaths are secondary to a combination of alcohol or other sedative-hypnotics.[61, 156] Supportive care is the mainstay of treatment.

Tolerance to the sedative effects of the benzodiazepines occurs more rapidly than does tolerance to the antianxiety effects.[100, 146] Abrupt discontinuation following long-term use of benzodiazepines may precipitate benzodiazepine withdrawal, which is characterized by autonomic instability, changes in perception, paresthesias, headaches, tremors, and seizures. Withdrawal from benzodiazepines is common, manifested by almost one third of long-term users.[85] Alprazolam and lorazepam are associated with more severe withdrawal symptoms and more frequent recurrent symptoms compared with chlordiazepoxide and diazepam,[85, 86] drugs that may protect the user because of the effects of their active metabolites. Withdrawal can occur when a chronic user of a particular benzodiazepine is switched to another benzodiazepine that has different receptor activity.[102]

Chloral Hydrate

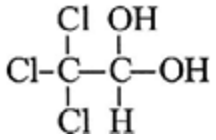

Figure. No Caption Available.

Chloral hydrate belongs to one of the oldest classes of pharmaceutical hypnotics, the chloral derivatives. Chloral hydrate was introduced in 1832. It still is used most commonly in children, although its use has substantially decreased.

Chloral hydrate is well absorbed but is irritating to the GI tract. It has a wide tissue distribution, rapid onset of action, and rapid hepatic metabolism by alcohol dehydrogenase. Trichloroethanol, the first active metabolite, is lipid soluble and is responsible for chloral hydrate's hypnotic effects. Chloral hydrate is metabolized by hepatic alcohol dehydrogenase (Figure 72-1). Trichloroethanol has a plasma half-life of 4â€“12 hours and is metabolized to inactive trichloroacetic acid by alcohol and aldehyde dehydrogenases. It is also conjugated with glucuronide and excreted by the kidney as urochloralic acid. Less than 10% is excreted unchanged.

Metabolic rates in children vary widely because of variable development and function of hepatic enzymes.[41] The elimination half-life of chloral hydrate and trichloroethanol is markedly increased in children younger than 2 years. The half-life of trichloroethanol ranges between 27.8 Â± 21.3 hours in newborns and between 9.7 Â± 1.7 hours in toddlers. Several comprehensive studies of clinical and pharmacologic characteristics of chloral hydrate use in neonates and infants suggest that even single-dose administration results in prolonged chloral hydrate, trichloroethanol, and trichloroacetic acid half-lives.[103 , 140] This latter metabolite still could be detected 6 days after administration in infants. These factors may be of concern in neonates and in infants exposed to repetitive doses.

Acute chloral hydrate poisoning is atypical of the other sedative-

hypnotics. Cardiac dysrhythmias appear to be the main cause of death.[58] Chloral hydrate and its metabolites reduce myocardial contractility, shorten the refractory period, and increase myocardial sensitivity to catecholamines.[18,26,166,181] Persistent cardiac dysrhythmias (ventricular fibrillation, ventricular tachycardia, torsades de pointes) are common terminal events.[58] Standard antidysrhythmics often are ineffective. A Î²-adrenergic antagonist currently is considered the drug of choice for treatment of most dysrhythmias secondary to chloral hydrate toxicity.[16,18,186] Chloral hydrate can also cause GI toxicity. Overdoses can produce vomiting, hemorrhagic gastritis, and rarely gastric and intestinal necrosis, leading to perforation and esophagitis with stricture formation.[93,123,171] Chloral hydrate is radiopaque and occasionally is detected on radiographs. Few hospital-based laboratories have the ability to rapidly detect chloral hydrate or its metabolites.

Ethchlorvynol

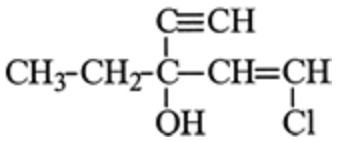

Figure. No Caption Available.

Ethchlorvynol was introduced in 1955 as a substitute for barbiturates. It is no longer legally available in the United States. It is rapidly absorbed and primarily metabolized by the liver, with a half-life of approximately 25 hours after a single use. However, it is readily

stored in adipose tissue because of its high lipophilicity, and its half-life can exceed 100 hours following overdoses. Whether its major metabolite ethynyl 3,4-diol is active is unclear. Because of the

drug's formulation, stomach contents often reveal a pink-tinged (500-mg capsules) or green-tinged (750-mg capsules) content. Extraction of the compound and intravenous injection is an alternative route of abuse. Acute lung injury often occurred rapidly afterward.[34] Symptoms and signs of ethchlorvynol overdoses can resemble barbiturate overdoses, including prolonged coma, hypothermia, and bullous lesions. Prolonged coma and a pungent plastic or vinyl odor on the breath are characteristics of ethchlorvynol poisoning.[163]

Glutethimide

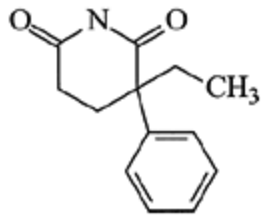

Figure. No Caption Available.

Glutethimide was introduced in 1954 as a substitute for barbiturates. It is no longer legally available in the United States. It is poorly water soluble and is slowly and erratically absorbed from the GI tract. Absorption may be significantly enhanced by coingestion of ethanol. It concentrates in fat-containing tissues because of its lipophilic nature. It is metabolized in the liver. More than 14 metabolites are identified, some of which are biologically active and may contribute to its toxicity.[36] High lipid solubility and delayed absorption may explain the cyclic variation in CNS depression that occurs in patients with acute overdoses. The enterohepatic circulation of metabolites may explain the fluctuating clinical course that occurs in severely intoxicated patients. Active metabolites include 2-phenylglutarimide and Î³-butyrolactone (a precursor of GHB). Unlike many of the other sedative-hypnotic agents, glutethimide can cause anticholinergic symptoms.[59] It reportedly

produces thick and tenacious bronchial secretions with impairment of ventilation.[28] Psychosis, seizures, cerebellar ataxia, and peripheral neuropathy are associated with prolonged use of glutethimide.[28]

Methaqualone

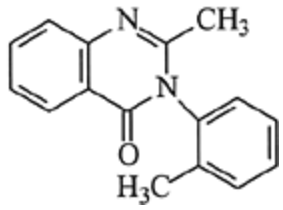

Figure. No Caption Available.

Methaqualone was introduced in 1956 as another substitute for barbiturates. It has anticonvulsant, anesthetic, antihistaminic, and antispasmodic characteristics. Its effects as a mood â€œelevatorâ€• led to extensive abuse and its subsequent withdrawal from the US market. The drug is rapidly and completely absorbed from the GI tract within 2â€“3 hours. It is highly protein bound (70â€“90%) and almost exclusively metabolized in the liver to 4-hydroxymethaqualone and numerous other hydroxy metabolites.[20, 73] Unlike many of the other sedative-hypnotics, hyperreflexia, clonus, and significant muscular hyperactivity can occur. Paresthesias and polyneuropathies can be residual effects after overdoses.[1]

Methyprylon

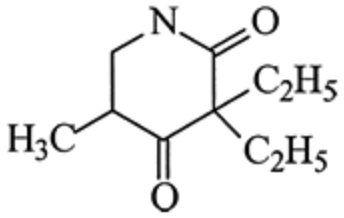

Figure. No Caption Available.

Methyprylon was introduced in the 1950s and is used only as a hypnotic. It is no longer legally available in the United States. It is rapidly absorbed in the GI tract and is metabolized almost entirely in the liver by oxidation and dehydrogenation. Because methyprylon is water soluble, hemodialysis was used in severe cases but was rarely indicated.[32 , 134]

Meprobamate/Carisoprodol

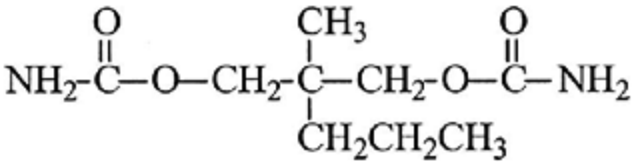

Figure. No Caption Available.

Meprobamate was introduced in 1950 and was used for its muscle-relaxant characteristics. Carisoprodol, which was introduced in 1955, is metabolized to meprobamate. These propanediol carbamates have pharmacologic effects on the $GABA_A$ receptor similar to those of the barbiturates. Like barbiturates, meprobamate can directly open the GABA-mediated chloride channel and may inhibit *N* -methyl-D-aspartate (NMDA) receptor currents.[145] They both are rapidly absorbed from the GI tract. The drug is metabolized in the liver to inactive hydroxylated and glucuronidated metabolites that are excreted almost exclusively by the kidney. Of all the nonbarbiturate tranquilizers, meprobamate most likely will produce euphoria.[76 , 77] Large masses or bezoars of pills have been noted in the stomach at autopsy.[152] Thus, orogastric lavage with a large-bore tube and MDAC may be indicated for significant meprobamate ingestion. Whole-bowel irrigation may be helpful if multiple pills or small concretions are noted. Because patients can experience recurrent toxic manifestations as a result of concretion formation and delayed absorption, careful monitoring of the clinical course is essential even

after the patient shows initial improvement.

Bromides

Bromides were previously used as â€œnerve tonics,â€• headache remedies, and anticonvulsants. Although pharmaceutical bromides have largely disappeared from the US pharmaceutical market, bromide toxicity still occurs because of the availability of bromide salts of common drugs, such as dextromethorphan.[120] Cases occur in immigrants and travelers from other countries where bromides are still therapeutically used.[51] The drug is irritating to the GI tract and is difficult to ingest. A sufficient amount is retained to achieve a toxic concentration without vomiting. Bromide has a long plasma half-life (12 days), and toxicity typically occurs over time as concentrations accumulate in tissue. Bromide and chloride ions have a similar distribution pattern in the extracellular fluid. It is postulated

that because the bromide ion moves across membranes slightly more rapidly than the chloride ion, it is more quickly reabsorbed in the tubules from the glomerular filtrate than the chloride ion. Although osmolar equilibrium persists, CNS function is progressively impaired by a poorly understood mechanism, with resulting inappropriateness of behavior, headache, apathy, irritability, confusion, muscle weakness, anorexia, weight loss, thickened speech, psychotic behavior, tremulousness, ataxia, and eventually coma.[27 , 187] Delusions and hallucinations can occur. Bromide can lead to hypertension, increased intracranial pressure, and papilledema. Chronic use of bromides can lead to dermatologic changes, with the hallmark characteristic of a facial acneiform rash.[65 , 167] Toxicity with bromides during pregnancy may lead to accumulation of bromide in the fetus.[133] A spurious hyperchloridemia may result from bromide's interference with the chloride assay on older analyzers[184] (Chap. 17).

Zolpidem/Zaleplon

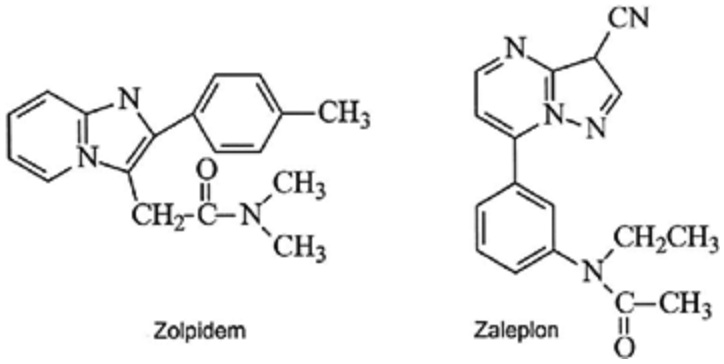

Figure. No Caption Available.

Zolpidem is an imidazopyridine hypnotic. Zaleplon is a pyrazolopyrimidine hypnotic. These xenobiotics have supplanted benzodiazepines as the most commonly prescribed hypnotics.[47] Although zolpidem and zaleplon are structurally unrelated to the benzodiazepines, they bind preferentially to the type I ($Ï‰_1$) benzodiazepine receptor subtype in the brain, specifically the $GABA_A$ $Î±_1$ subunit.[40] Zolpidem and zaleplon have a lower affinity for type II ($Ï‰_2$)receptors than benzodiazepine hypnotics, so they have potent hypnotic effects and less addiction potential.[40,64] Unlike benzodiazepines that prolong the first 2 stages of sleep and shorten stages 3 and 4 of rapid eye movement (REM) sleep, zolpidem and zaleplon have little effect on the stages of sleep. Because of their selectivity, they appear to have minimal effect at other sites on the GABA receptor that mediate anxiolytic, anticonvulsant, or muscle-relaxant effects.[89,173] Both drugs are hepatically metabolized. In isolated overdoses, drowsiness and CNS depression are common, but coma and respiratory depression are exceptionally rare. Even at 40 times the therapeutic dose, no biologic or electrocardiographic abnormalities have been reported.[53] Flumazenil can reverse the effects of both agents.[97,179] Withdrawal is documented with abrupt discontinuation but typically is mild.[62,177] Deaths have resulted when zolpidem was taken in large amounts with other CNS

depressants.[53]

Propofol

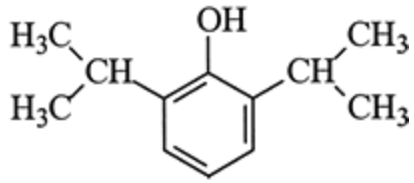

Figure. No Caption Available.

Propofol is a rapid-acting intravenous sedative-hypnotic that is a postsynaptic $GABA_A$ agonist. It induces presynaptic release of GABA.[117] Propofol also interacts with dopamine release at various sites. It promotes nigral dopamine release possibly via $GABA_B$ receptors[128 , 153] and has partial agonist properties at dopamine (D_2) and NMDA receptors.[151] It is used for either induction or maintenance of general anesthesia. Propofol is highly lipid soluble, so it crosses the bloodâ€“brain barrier rapidly. Onset of anesthesia usually occurs in less than 1 minute, with duration of action after short term dosing of 3â€“8 min because of its rapid redistribution from the CNS.

Propofol use is associated with various adverse outcomes. Acutely, propofol causes dose-related respiratory depression. Transient apnea may occur. The drug may decrease systemic arterial pressure and cause myocardial depression. Although propofol does not typically cause dysrhythmias or myocardial ischemia, atropine-sensitive bradydysrhythmias have been noted, specifically sinus bradycardia and Mobitz type I atrioventricular block.[165 , 176 , 185] Prolonged infusions for more than 48 hours at rates of 5 mg/kg/h are associated with acidosis, cardiac, and skeletal muscle injury.[79] Propofol is suggested to induce disruption of mitochondrial free fatty acid metabolism, causing a syndrome similar to other mitochondrial myopathies.[29 , 158] Case reports associate propofol with lactic

acidosis and fatal myocardial failure in children and young adults.[129] Cases of metabolic acidosis may be associated with an inborn disorder of acylcarnitine metabolism.[182] However, a direct cause-and-effect relationship remains unproven.

The unique nature of the carrier base, a milky soybean emulsion formulation, is associated with multiple adverse events. It is a fertile medium for many organisms, such as enterococcal, pseudomonal, staphylococcal, streptococcal, and candidal strains. In 1990, the Centers for Disease Control and Prevention (CDC) reported an outbreak of *Staphylococcus aureus* associated with contaminated propofol. This carrier base also impairs macrophage function and causes[29] hypertriglyceridemia,[45 , 84 , 98] abnormalities in blood coagulability, platelet function,[5 , 38 , 66] and histamine-mediated anaphylactoid reactions.[42 , 81]

Etomidate

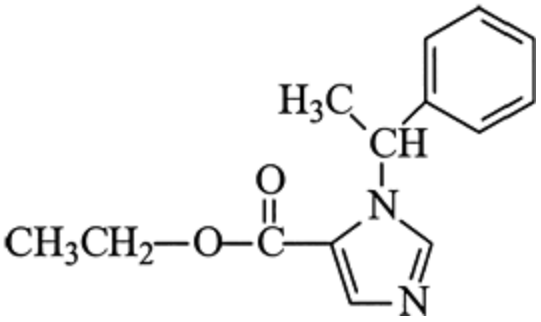

Figure. No Caption Available.

Etomidate is a nonbarbiturate, hypnotic agent primarily used as an anesthesia induction agent. It is active at the $GABA_A$ receptor, specifically the $Î²_2$ and $Î²_3$ subunits.[122 , 142] Only the intravenous formulation is available in the United States. The onset of action is less than 1 minute and its duration is less than 5 minutes.

Etomidate is commercially available as a 2 mg/mL solution in a 35% propylene glycol solution (Amidate).[169] The propylene glycol is

implicated in the development of a hyperosmolar metabolic acidosis.[105, 169, 170] Etomidate has minimal effect on cardiac function, but rare cases of hypotension are reported.[55, 56, 57, 63, 162] It has proconvulsant and anticonvulsant properties.[33, 138] Involuntary muscle movements are common during induction. They may be caused by etomidate interaction with glycine receptors at the spinal cord level.[37, 113, 114]

Etomidate depresses adrenal production of cortisol and aldosterone even after a single dose.[150, 174, 175] This effect is suggested to increase mortality with long-term etomidate use.[178]

Summary

Sedative-hypnotics in combination with alcohol and other respiratory depressants are among the most common drugs implicated in deaths resulting from poisoning. Patients with sedative-hypnotic overdoses often present with the primary manifestation of CNS depression; however, death typically results from respiratory depression. Careful monitoring and supportive care are the cornerstones of treatment. Specific antidotes such as flumazenil and treatments such as hemodialysis are rarely indicated.

Antidotes in Depth

Flumazenil

Mary Ann Howland

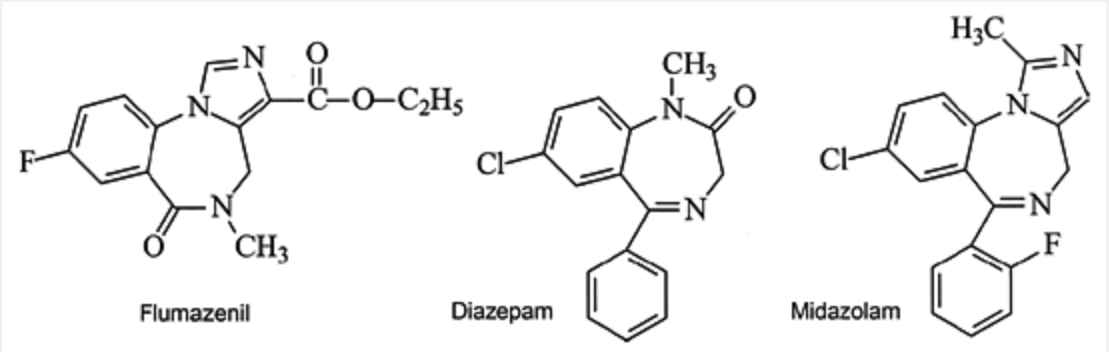

Figure. No Caption Available.

Flumazenil is a competitive benzodiazepine receptor antagonist. It has no role in cases of unknown overdose because seizures and dysrhythmias may occur when the effects of a benzodiazepine are

reversed in a mixed overdose. Flumazenil also has the potential to induce benzodiazepine withdrawal symptoms, including seizures in patients who are benzodiazepine dependent. Flumazenil does not reliably reverse the respiratory depression induced by intravenous benzodiazepines but does reverse central nervous system (CNS) depression.[50] Flumazenil is ideal for the few patients who are naive to benzodiazepines and who overdose solely on a benzodiazepine. Because the duration of effect of flumazenil is shorter than that of most benzodiazepines, repeat doses may be necessary and vigilance is warranted. Flumazenil has no role in the management of ethanol intoxication but may be considered for patients with hepatic encephalopathy. However, further study is needed before its routine use can be recommended.[3] Case reports raise the possibility of a role for flumazenil in patients with paradoxical reactions to therapeutic doses of midazolam. Flumazenil is not expected to be effective in overdoses such as baclofen in which a benzodiazepine receptor is not involved.[13] Flumazenil is effective for overdoses of zolpidem and zaleplon, nonbenzodiazepines that interact with Ï‰1 receptors, a subclass of central benzodiazepine receptors.[36,46,47]

History

Haefely and Hunkeler's initial work on chlordiazepoxide synthesis[62] led to an attempt to develop benzodiazepine derivatives that would act as antagonists.[27] This endeavor initially was unsuccessful, so they investigated the promising Î³-aminobutyric acid (GABA) hypothesis of benzodiazepine mechanism of action. In 1977, the then-new technique of radioligand binding identified specific high-affinity benzodiazepine binding sites. Other investigators simultaneously isolated a product produced by a *Streptomyces* species that had the basic 1,4-benzodiazepine structure. Synthetic compounds subsequently were derived from this molecule to act as potential tranquilizers. Hunkeler attempted to produce benzodiazepines with potent anxiolytic and

anticonvulsant activity and diminished sedative and muscle-relaxing properties. Testing revealed these derivatives had high in vitro binding affinities but lacked in vivo activity. An inability to enter the CNS was considered an explanation for the discordance. During an experiment that attempted to demonstrate CNS penetration of these derivatives, diazepam given to incapacitate the animals had a surprisingly weak effect. This lack of potency led to the discovery of a benzodiazepine antagonist. Further modifications led to the synthesis of flumazenil (Ro 15-1788).[18,48]

Pharmacology

Flumazenil is a water-soluble benzodiazepine analog with a molecular weight of 303 daltons. It is a competitive antagonist at the benzodiazepine receptor, with very weak agonist properties in animal models and in humans.[45] The benzodiazepine receptor modulates the effect of GABA on the $GABA_A$ receptor by increasing the frequency of Cl^- channel opening, leading to hyperpolarization. Agonists such as diazepam stimulate the benzodiazepine receptor to produce anxiolytic, anticonvulsant, sedative, amnestic, and muscle-relaxant effects at low doses and hypnosis at high doses.[28] Inverse agonists bind the benzodiazepine receptor and result in the opposite effects of anxiety, agitation, and seizures. Antagonists, such as flumazenil, competitively occupy the benzodiazepine receptor without causing any functional change and without allowing an agonist or inverse agonist access to the receptor. The zero set point of intrinsic activity may be influenced by the activity of the GABA system or by chronic treatment with benzodiazepines.[20] Positron emission tomography investigations reveal that 1.5 mg flumazenil leads to an initial receptor occupancy of 55%, whereas 15 mg causes almost total blockade of benzodiazepine receptor sites.[53]

The structures of flumazenil, diazepam, and midazolam are shown in the figure. Table A21-1 summarizes the physiochemical and

pharmacokinetic properties of flumazenil.[32]

TABLE A21-1. Physicochemical and Pharmacologic Properties of Flumazenil

pK_A	Weak base
Partition coefficient at pH 7.4	14 (octanol/aqueous PO_4 buffer)
Volume of distribution	1.06 L/kg
Distribution half-life ($t_{1/2}\hat{I}\pm$)	â‰¤5 minutes
Metabolism	Hepatic: three inactive metabolites
	High clearance
Elimination	First order
Protein binding	54â€“64%
Elimination half-life ($t_{1/2}\hat{I}^2$)	53 minutes

Onset of action	1â€“2 minutes
Duration of action	Dependent on dose and elimination ofbenzodiazepine, time interval, dose offlumazenil, and hepatic function

Volunteer Studies

Volunteer studies demonstrate the ability of flumazenil to reverse the effect of benzodiazepines.[16] Reversal is dose dependent and begins within minutes. Peak effects occur within 6â€“10 minutes.[50] Most individuals achieve complete reversal of benzodiazepine effect with a total IV dose of 1 mg.[4,12] A 3-mg IV dose produces similar effects that last approximately twice as long as the 1-mg dose.

Conscious Sedation

A number of studies evaluated patients undergoing conscious sedation for endoscopy or cardioversion who received diazepam or midazolam.[5,11,12,34,35] When a benzodiazepine is given for conscious sedation during a procedure, flumazenil appears safe and effective for reversal of sedation and partial reversal of amnesia and cognitive impairment.[22] Most patients respond to total doses of 0.6â€“1 mg. Administering flumazenil slowly at a rate of 0.1 mg/min minimizes the disconcerting symptoms associated with rapid arousal, such as confusion, agitation, and emotional lability. Resedation occurs within 20â€–120 minutes, depending on the dose and pharmacokinetics of the benzodiazepine and the dose of flumazenil. For this reason, patients must be carefully monitored and subsequent doses of

flumazenil given as needed. Because the amnestic effect of benzodiazepines and the cognitive and psychomotor effects are not fully reversed, posttreatment instructions should be reinforced in writing and given to a responsible caretaker accompanying the patient.[16,22] Because of the risk of resedation, many practitioners elect not to use flumazenil routinely.

Two cases of patients undergoing endoscopy who developed seizures following benzodiazepine reversal are reported.[57] One patient had a history of seizures, and the other had no obvious etiology. Both patients recovered uneventfully.

Use for Paradoxical Reaction to Midazolam

Paradoxical reactions to benzodiazepines are uncommon.[24,41] The mechanism is unclear and has been attributed to a disinhibition reaction.[19] Management strategies include administering higher doses of the benzodiazepines, adding other drugs such as opioids or droperidol, stopping the procedure, and using flumazenil.[31,49,58,59] Three patients undergoing endoscopy were premedicated with meperidine, droperidol, and midazolam in doses up to 10 mg.[17] Each patient exhibited paradoxical agitation and restlessness. Following flumazenil 0.5 mg IV, the patients became calm and sedated, allowing successful completion of endoscopy. A satisfactory explanation has not been established.

Effects on Benzodiazepine-Induced Respiratory Depression

Flumazenil has not consistently reversed benzodiazepine-induced respiratory depression and is not approved for this use.[50,55] If respiratory depression is mediated through the benzodiazepine receptor, then flumazenil should be effective as a reversal agent,

but this effect does not occur consistently.[14,25,39,43,55] The effect of IV midazolam on respiratory depression was examined using oxygen saturation measurements and plethysmography to determine minute ventilation volumes in patients undergoing endoscopy.[14] Flumazenil awakened patients rapidly but failed to affect minute ventilation and had little effect on oxygen saturation. When a benzodiazepine was used concomitantly with an opioid, the effects on ventilation were even more confusing.[63,65] Rebound respiratory depression and prolonged hypoxic episodes were documented. Flumazenil may even have a slight respiratory depressant effect when combined with an opioid.[63] Clinical assessment of respiratory rate is inadequate for detecting hypoxia. Benzodiazepine-induced apnea should be managed with standard procedures such as supplemental oxygen, airway stabilization, bag-valve-mask ventilation, and endotracheal intubation, if indicated.

Use in the Overdose Setting

Use of flumazenil in the overdose setting is controversial. The first argument against flumazenil use is the rare morbidity and mortality associated with benzodiazepine use. An analysis of 702 patients who had taken benzodiazepines alone or in combination with ethanol or other drugs and were admitted to a medical intensive care unit (ICU) over a 14-year period revealed a 0.7% fatality rate (5 deaths) and 9.8% complication rate (69 patients).[30] In comparison, the fatality rate for patients with nonbenzodiazepine-related overdoses was 1.6% (55/3430 patients). In the pure benzodiazepine group, 2 patients died and 18 (12.5%) of 144 patients had complications, mostly aspiration pneumonitis and decubitus ulcers. Proponents of flumazenil therapy suggest that some of the 29 diagnostic procedures used in the patients were unnecessary, and some of the complications could have been prevented. Opponents of flumazenil therapy suggest that many of the cases of aspiration pneumonitis occurred

prior to hospital admission and that the patients also suffered from trauma and infectious disease, making most diagnostic procedures necessary.

In an effort to develop indications for safe and effective use of flumazenil, overdosed comatose patients were retrospectively assigned to either a low-risk or nonâ€“low-risk group.[26] Low-risk patients had CNS depression with normal vital signs, no other neurologic findings, no evidence of ingestion of a tricyclic antidepressant by history or electrocardiogram (ECG), no seizure history, and absence of an available history of chronic benzodiazepine ingestion. All other patients fell into the nonâ€“low-risk category. Of 35 consecutive comatose patients, 4 patients were assigned to the low-risk group. Flumazenil caused complete awakening in 3 patients and partial awakening in the fourth patient in the low-risk group, with no adverse effects. In the nonâ€“low-risk group of 31 patients, flumazenil caused complete awakening in 4 patients and partial awakening in 5 patients. Seizures occurred in 5 patients, of whom 1 had a history of seizures, 5 were long-term benzodiazepine

users, 4 had abnormal vital signs, and 3 had evidence of hyperreflexia or myoclonus. Therefore, although flumazenil use probably was safe and effective in the low-risk group, few patients met the criteria for inclusion in that risk group. The risk of seizures is substantial in the nonâ€“low-risk group.

TABLE A21-2. Indications for Flumazenil Use in the Overdose Setting

Pure benzodiazepine overdose in a nontolerant individual who has

- CNS depression
- Normal vital signs, including SaO_2
- Normal ECG
- Otherwise normal neurologic examination

In conclusion, the risks of flumazenil usually outweigh the benefits in overdose patients.[54] When nonâ€“benzodiazepine-dependent patients ingest benzodiazepines alone in overdose, as rarely occurs in adults but might be expected in children, the risks associated with flumazenil use may be limited.[68] Table A21-2 summarizes the indications for flumazenil use in the overdose setting.

Adverse Effects and Safety Issues

Flumazenil has been studied in more than 3500 patients worldwide, including healthy volunteers and overdosed or consciously sedated patients. The safety of flumazenil in healthy volunteers is well established, with no discernible objective or subjective effects. However, precipitation of seizures in benzodiazepine-dependent patients, unmasking of dysrhythmias in patients who coingest benzodiazepine with a prodysrhythmic drug, and resedation within 20â€“120 minutes in patients receiving benzodiazepine for conscious sedation are recognized adverse effects associated with flumazenil administration.

The ability of flumazenil to precipitate acute benzodiazepine withdrawal seizures in a more controlled environment than the overdose setting was demonstrated by reversal of long-term benzodiazepine sedation in the ICU. A study of 1700 patients revealed that 14 patients developed adverse drug reactions, probably half related to abrupt arousal.[5] Two patients with a history of epilepsy developed tonic-clonic seizures, and 1 patient developed myoclonic seizures.[5] Dose-dependent induction of withdrawal reactions is suggested. Small doses of flumazenil (<1 mg) may allow sufficient occupation of the benzodiazepine receptor sites by benzodiazepines so that abrupt withdrawal seizures are uncommon.

In a study of 12 patients receiving midazolam sedation for 4 Â± 3 days, 0.5 mg flumazenil was administered as a rapid bolus. Norepinephrine and epinephrine plasma concentrations rose within 10 minutes, returned to baseline within 30 minutes, and correlated with increased heart rate, blood pressure, and myocardial oxygen consumption.[33]

Flumazenil causes a significant overshoot in cerebral blood flow and may cause a large increase in intracranial pressure in patients who received midazolam for severe head injury.[70]

Thirty published case studies involving 758 patients with drug overdoses were reviewed.[21] In total, 387 patients participated in double-blind study protocols and 371 patients in open-label studies.[21] Fifty percent of cases were mixed overdoses. The doses of flumazenil ranged from 0.2â€“5 mg. Five cases of seizures were temporally related to flumazenil administration, all after large bolus doses. In 3 of the 5 patients, high concentrations of tricyclic antidepressants were present in the blood. The seizures resolved without treatment or following administration of a small dose of a benzodiazepine. Dysrhythmias developed in 2 patients given small doses of flumazenil, both presumably associated with the presence of a tricyclic antidepressant. Of 497 patients enrolled in two

clinical US studies sponsored by the manufacturer,[21] 6 patients developed seizures (5 had coingested tricyclic antidepressants) and 1 patient who had taken a tricyclic antidepressant and carbamazepine had a junctional tachycardia, which normalized after several minutes. Thus, in reviewing 1255 patients, 11 patients had seizures and 3 developed dysrhythmias, for an incidence of approximately 0.9%. The consensus report was that (a) flumazenil is not a substitute for primary emergency care; (b) hypoxia and hypotension should be corrected before flumazenil is used; (c) small titrated doses of flumazenil should be used; (d) flumazenil not be used in patients with a history of seizures, evidence of seizures or jerking movements, or evidence of a cyclic antidepressant overdose; and (e) flumazenil should not be used by inexperienced clinicians.

An analysis of all seizures associated with flumazenil gathered from previously published cases or reports to the manufacturer was published.[57] Forty-three patients had seizures and 6 patients died, but the author believed that none of the deaths were attributable to flumazenil.[57] Four patients developed status epilepticus; 2 were presumed to be caused by concomitant tricyclic antidepressant exposure, and the other 2 patients had received benzodiazepines to treat status epilepticus prior to flumazenil therapy. In 6 of 43 seizure episodes, the relationship to flumazenil use was believed to be inadequately defined. The remaining 37 patients were stratified into 5 categories. In category 1, 7 patients were given flumazenil after they had received a benzodiazepine for treatment of a seizure disorder. Six of these 7 patients received >1 mg flumazenil. In category 2, 20 patients received flumazenil for reversal of a benzodiazepine in a mixed-drug overdose. Many of these patients had coingested tricyclic antidepressants. Thirteen of these patients received >1 mg flumazenil. Two of the patients in this group developed status epilepticus and died, possibly secondary to a severe tricyclic antidepressant overdose. Category 3 included 5 patients who received benzodiazepines for

suppression of nonâ€“drug-induced seizures. Two of these 5 patients received >1 mg flumazenil. Category 4 included 3 patients with acute benzodiazepine overdoses in the presence of chronic benzodiazepine dependence. Category 5 included 2 patients who received a benzodiazepine for conscious sedation. Therefore, flumazenil use may place the patient at risk for seizures by unmasking a toxic effect in mixed overdose, by removing the protective anticonvulsant effect in a patient with nonâ€“drug-induced seizures, or by precipitating acute benzodiazepine withdrawal.

The risks of flumazenil appear to greatly outweigh the potential benefits of reversal when benzodiazepines are used chronically or acutely to treat a seizure disorder. Flumazenil is best avoided in the overdose setting when evidence indicates ingestion of a drug capable of causing seizures or dysrhythmias. For example, any indication that theophylline, carbamazepine, chloral hydrate, chloroquine, and/or chlorinated hydrocarbons was ingested is a contraindication to flumazenil use.[66] Flumazenil should not be used when involvement of a cyclic antidepressant is strongly suggested based on history, clinical findings, or ECG findings (prolonged QRS complex).[29,38,44,66] In the event of flumazenil-induced seizures, a therapeutic dose of a benzodiazepine such as diazepam should be effective. Flumazenil is a competitive antagonist; higher doses of benzodiazepines will reverse higher doses of flumazenil. Table A21-3 summarizes the contraindications to flumazenil use.

TABLE A21-3. Contraindications to Flumazenil Use

- Prior seizure history or current treatment of seizures
- History of ingestion of a xenobiotic capable of provoking seizures or cardiac dysrhythmias
- Long-term use of benzodiazepines
- ECG evidence of cyclic antidepressants (terminal rightward 40 msec axis, QRS or QTc prolongation)
- Abnormal vital signs; hypoxia

Dosing

Slow IV titration (0.1 mg/min) to a total dose â‰¤1 mg seems most reasonable. Extravasation should be avoided because of the risk of local irritation. Resedation may occur at 20â€“120 minutes, and readministration of flumazenil may be necessary. Although not approved by the FDA, continuous IV infusion of flumazenil 0.1â€“1.0 mg/h in 0.9% sodium chloride solution or 5% dextrose in water has been used following the loading dose.[36,67,69]

Availability

Flumazenil is available as Romazicon in a concentration of 0.1 mg/mL with parabens in 5-mL and 10-mL vials.

Role in Nonbenzodiazepine Toxicity

Hepatic Encephalopathy

Hepatic encephalopathy is considered a reversible metabolic

encephalopathy characterized by a spectrum of CNS effects. Symptoms may progress from confusion and somnolence to coma. The current hypothesis implicates an increase in GABAergic tone in the development of encephalopathy.[6,56]

Animal studies of hepatic encephalopathy secondary to galactosamine or thioacetamide (hepatotoxins) demonstrate an increase in GABA effect, which is antagonized by flumazenil, bicuculline (a GABA-receptor antagonist), and isopropylbiclophosphate chloride (a calcium channel blocker).[6] Cerebrospinal fluid (CSF) from these animals contained a benzodiazepine receptor ligand with agonist activity. Rat studies involving hepatic encephalopathy resulting from acute liver ischemia showed only a slight response to flumazenil but significant improvement after administration of a partial inverse agonist.[10,64]

Human studies have detected benzodiazepine-binding activity in the CSF, but not in serum, of patients with hepatic encephalopathy. One group identified 4â€“19 peaks representing benzodiazepine-binding ligands from the frontal cortex of 11 patients who died of hepatic encephalopathy.[9] Two of the peaks were identified as diazepam and *N*-desmethyldiazepam. Brain concentrations of these substances were 2â€“10 times higher than normal in 6 of the patients and were normal in 5 patients. Patients with idiopathic recurring stupor who have measurable â€œendozepinesâ€• (endogenous benzodiazepine ligands) in serum and CSF are reported.[51,61]

Flumazenil improves the clinical and electrophysiologic responses of patients with hepatic encephalopathy and idiopathic recurring stupor.[7,17,51,61] Some patients with encephalopathy have improved from stage IV to stage II encephalopathy after IV flumazenil. Maximal improvement after flumazenil lasts approximately 1â€“2 hours and gradually dissipates within 6 hours. The response rate in a meta-analysis averaged

approximately 30%.[23] The proposed explanations for the unresponsiveness include cerebral edema, hypoxia, other systemic diseases or complications, and irreversible CNS damage.

Animal and human data convincingly support the concept that increased GABAergic tone is responsible for hepatic encephalopathy. Evidence for endogenous benzodiazepine ligands that enhance GABA action also are demonstrated but controversial.[1,2] The source of these benzodiazepine receptor agonists is unclear, but diet and/or production by gut bacteria is postulated.[6] Most authorities believe endogenous de novo synthesis is unlikely and propose prior benzodiazepine exposure and persistence as an explanation. Neurosteroids and hemoglobin metabolites are also implicated in the pathophysiology of hepatic encephalopathy.[2,52]

Flumazenil can lead to improvement of the clinical condition of a subgroup of patients with hepatic encephalopathy and may prove useful as an addition to conventional therapy.[8] Additional research is necessary to identify prospective responders, dosing considerations, and adverse effects.

Ethanol Intoxication

Animal studies indicate that many of the actions of ethanol are mediated through GABA neurotransmission.[60] Acute ethanol administration appears to enhance GABA transmission and inhibit *N*-methyl-D-aspartate (NMDA) excitation. Chronic ethanol administration leads to downregulation of the GABA system. Ethanol enhances $GABA_A$-induced chloride influx in a dose-dependent fashion without a direct effect on chloride. Flumazenil does not influence this action of GABA. Chronic ethanol use selectively increases the sensitivity to inverse benzodiazepine agonists, invoking a change in coupling or conformation of the receptor. These changes may explain the development of tolerance and the kindling and production of seizures that occur on

withdrawal.

Two double-blind studies in patients with benzodiazepine or ethanol overdose evaluated the response to flumazenil. In one study of 13 patients with suspected ethanol intoxication, 6 had no response to placebo when it was given first, whereas all 13 patients responded to 5 mg flumazenil.[42] Improved consciousness occurred after 15 minutes, and respiratory rates increased from 14 to 16 breaths/min. Heart rate and blood pressure were not affected. The 5-mg dose of flumazenil was selected because no improvement in mental status or vital signs was observed when 1 mg flumazenil was administered to 4 patients.

Another comparable study demonstrated similar results.[37] Flumazenil (1 mg) administered to 9 ethanol-intoxicated patients produced the same effects as placebo. Subsequent administration of 2â€“5 mg flumazenil in the open part of the study produced a clear improvement in the modified Glasgow coma scale in 5 of 11 patients. However, a closer inspection of phase 1 of the study reveals that an arousal reaction occurred in 7 of 9 patients after the flumazenil dose and in 5 of 9 patients following placebo administration. It is conceivable that the improvement in phase 2 was a continuation of the arousal reaction.

One case report indicates that ethanol-induced respiratory depression was reversed by flumazenil,[40] but whether the actual data support the authors' conclusions is unclear.

A randomized, double-blind, crossover study of 8 male volunteers given IV ethanol to achieve a constant serum ethanol concentration

of 160 mg/dL was conducted.[15] Once stabilized, the volunteers were given either placebo or 5 mg flumazenil. Subjective and objective psychomotor tests were conducted, with no differences noted between volunteers given flumazenil and volunteers given placebo. The probability of ethanol reversal at the suggested doses

appears unlikely.

Based on this information, flumazenil likely does not have a significant effect on ethanol intoxication. Low doses of flumazenil (<1 mg) have no effect. The 5-mg doses reportedly produce favorable changes in sensorium, but these findings may be the result of confounding factors. Because we would never administer 5 mg flumazenil in the overdose setting due to the increased risk of adverse effects at this dose, flumazenil cannot be recommended for reversal of ethanol intoxication.

Chapter 73
Amphetamines

William K. Chiang

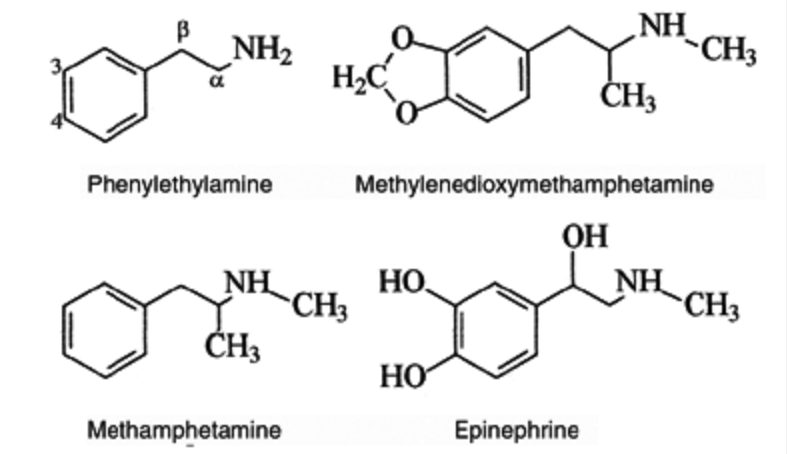

Figure. No Caption Available.

A 25-year-old woman was brought to the emergency department (ED) by ambulance from a dance club. The paramedics reported that

the patient had become agitated in the club and had a generalized seizure. They also reported that the patient had used â€œecstasyâ€• during the night. The woman was delirious, agitated, hallucinating, and paranoid. At times she was exceedingly hyperactive, jumping repeatedly on and off the stretcher. Frequently, she appeared to be involved with her hallucinations.

The physical examination revealed a blood pressure of 170/100 mm Hg; pulse of 120 beats/min and regular; respiratory rate of 18 breaths/min; rectal temperature of 102.7Â°F (39.3Â°C); and a pulse oximetry reading of 97% on room air. The patient appeared to be of normal habitus, acyanotic, and anicteric, but diaphoretic. Her head was normocephalic. Her pupils were dilated to 6 mm bilaterally, and they reacted slowly to light. The conjunctivae, extraocular movements, and the fundi were normal. Her neck was supple, exhibiting no thyromegaly. Examination of her heart was unremarkable, except for tachycardia. Her lungs were clear. The abdomen was soft, nontender, and without hepatomegaly; bowel sounds were normal. The extremities were normal, without any evidence of track marks, bruises, swelling, or rash. The patient moved all her extremities spontaneously and had normal symmetric deep-tendon reflexes with plantar flexion.

A rapid bedside glucose was 95 mg/dL. She was treated with a total of 20 mg of diazepam IV (given in 10-mg increments) for sedation and attached to a continuous cardiac monitor. She was given 1.5 L of 0.9% sodium chloride solution over 60 minutes. External cooling with ice packs around the axillae and groin was initiated. She became calm and less paranoid. Her rectal temperature decreased to 100Â°F (37.7Â°C) within 15 minutes.

Her complete blood count was remarkable for an elevated white blood cell count of 15,000 cells/mm^3. The serum electrolytes were

remarkable for: sodium, 109 mEq/L; potassium, 3.6 mEq/L; chloride, 81 mEq/L; bicarbonate, 20 mEq/L; blood urea nitrogen (BUN), 10

mg/dL; creatinine, 1.1 mg/dL; and glucose, 105 mg/dL. The liver enzymes were normal. The urinalysis was negative for blood and protein, and the urine osmolality was 497 mOsm/kg. The chest radiograph was normal. The electrocardiogram (ECG) revealed a sinus tachycardia. A noncontrast head computed tomography (CT) scan was normal.

Further therapy consisted of the administration of 3% sodium chloride solution at 50 mL/h for 6 hours with frequent serum sodium concentration monitoring. The repeat serum sodium concentration after 6 hours was 123 mEq/L. The patient's mental status improved and she had no further seizures. At this time, the patient was placed on free water restriction and her sodium slowly improved to 130 mEq/L by 24 hours. By that time, the patient's mental status had completely normalized. Her liver enzymes, renal function, and urinalysis remained normal. The patient was discharged from the hospital after 4 days without any sequelae.

Amphetamine is the trivial name and acronym for racemic Î²-phenylisopropylamine or Î±-methylphenylethylamine and belongs in the family of phenylethylamines. Numerous substitutions of the phenylethylamine structure are possible, resulting in different amphetaminelike compounds. Commonly, these compounds are referred to as amphetamines or amphetamine analogs, although phenylethylamines is more precise. For the purposes of this chapter, the term *amphetamines* refers to amphetamine analogs, and *amphetamine* specifically refers to Î²-phenylisopropylamine.

Since the initial marketing of amphetamines, continued abuse and misuse have been substantial.[17,101,184] Amphetamines have been advocated by the medical communities for the treatment of depression, obesity, enuresis, postencephalitic parkinsonism, coma, ADHD, and even alcoholism.[101,138] By 1970, the legal annual production of amphetamines was more than 10 billion tablets, with the majority diverted for illicit usage.[101]

Currently, there are very few medical indications for amphetamines,

including narcolepsy, attention deficit hyperactivity disorder, and short-term weight reduction.[122] The prescriptive amphetamines include methylphenidate, pemoline, phentermine, phendimetrazine, amphetamine, dextroamphetamine, and methamphetamine. Because of structural differences, some amphetamines are marketed as nonamphetamine products in their package inserts. Despite the controlled status of amphetamines, there has been a resurgence of amphetamine abuse, particularly with methamphetamine and methylenedioxymethamphetamine (MDMA).[47,99,208,210,265,272]

History and Epidemiology

Edeleano first synthesized amphetamine (racemic Î²-phenylisopropylamine) in 1887. However, it was not rediscovered until the 1920s, when there was significant concern about the supply of ephedrine for asthma therapy. In the search for the synthesis for ephedrine, Alles from UCLA rediscovered dextroamphetamine and Ogata from Japan discovered methamphetamine (*d*-phenylisopropylmethylamine hydrochloride).[101] Amphetamine was marketed as Benzedrine inhaler, a nasal decongestant, by Smith, Kline, and French in 1932.[17] Amphetamine tablets were available in 1935 for the treatment of narcolepsy, and were advocated as anorexiants in 1938. The stimulant and euphoric effects of amphetamines were widely recognized, resulting in diverse forms of abuse and misuse. Amphetamine abuse was reported as early as 1936.[138] Benzedrine inhalers, each containing 250 mg of amphetamine, were widely abused, leading to a ban by the FDA in 1959. Propylhexedrine (Benzedrex) inhalers, a less-potent amphetaminelike substance marketed in 1949, supplanted Benzedrine inhalers.[7] Propylhexedrine was also significantly misused.[6]

Both amphetamine and methamphetamine were supplied as stimulants for soldiers and prisoners of war in World War II.[17,185] Widespread methamphetamine abuse in Japan persisted for more

than a decade after the war. From 1950 to the 1970s, there were sporadic periods of widespread amphetamine use and abuse in the United States. In the 1960s, various amphetamine derivatives such as methylenedioxyamphetamine (MDA) and *para*-methoxyamphetamine (PMA) were popularized as hallucinogens. Until 1971, only a small proportion of the amphetamines produced by pharmaceutical companies was used for legitimate medical problems.[101,187] The Controlled Substance Act of 1970 placed amphetamines in Schedule II to regulate the diversion of pharmaceutical amphetamines for nonmedicinal uses.[52] Amphetamine abuse subsequently declined in the 1970s.[38,148,187]

In the 1980s, the so-called designer amphetamines (Table 73-1), mostly methylenedioxy derivatives of amphetamine and methamphetamine, came into vogue, as a mechanism of circumventing existing regulations. The most well known substances were MDMA and 3,4-methylenedioxyethamphetamine (MDEA), but more than 200 different derivatives are known.[62,248] Before 1986, the Controlled Substances Act classified drugs as illegal only after they were synthesized and formally recognized by their structure, effects, or illegal usage. During this period, any analogs (such as these â€œdesigner drugsâ€•) not yet formally classified could be sold legally. In 1986, the standard became prospective for any agent that was used as a stimulant, hallucinogen, or depressant, and for any agent designed as such.[26] In effect, this amendment eliminated the legal loophole that allowed the designer drug industry to flourish. Although the meaning of the term â€œdesigner drugsâ€• has changed and is no longer legally relevant, many of these analogs are still widely illicitly available.[117,130,177]

From the late 1980s to the 1990s, a dramatic resurgence of methamphetamine abuse spread throughout much of the United States. A high purity preparation of methamphetamine hydrochloride was marketed in a large crystalline form termed â€œiceâ€• by abusers.[9,42,65,184] In fact, methamphetamine surpassed cocaine and became the primary substance of abuse among those seeking care in

the drug treatment programs of San Diego and San Francisco counties in the 1990s.[99,114] From 1991 to 1994, the number of methamphetamine-related deaths in the United States reported by medical examiners tripled from 151 to 433, with a disproportional distribution from the Los Angeles, San Diego, San Francisco, and Phoenix metropolitan areas. The number of methamphetamine-related emergency department visits also increased from 4900 in 1991 to 17,400 in 1994.[99] The number of methamphetamine-related emergency department visits has remained stable since the mid-1990s despite significant local geographical changes.[71] Recently, methamphetamine use has become particularly prevalent among men having sex with men in New York City.[106] Although the initial source of methamphetamine was from Pacific Rim countries such as Korea and Taiwan, currently the majority is produced in the United States.[43,78,265] Methamphetamine is the most common illicit drug produced by clandestine laboratories in the United States at this time. Because of the ease and low cost of methamphetamine synthesis, the end user cost of methamphetamine is less than one-third

that of cocaine.[78] Methamphetamine production in United States was primarily located in California and Oregon in the late 1990s, but it has spread through every state, although it remains particularly prevalent in the midwest and western United States.[265] The number of clandestine methamphetamine laboratory seizures nationally increased from 327 in 1995 to 15,994 in 2004.[125] Both the cost and the prolonged duration of effect may contribute to the increased popularity of methamphetamine.[99,150,265]

Xenobiotic	Clinical Manifestations	Structure
4-Bromo-2,5-dimethoxy-amphetamine (DOB)	Marked psychoactive effect potency >mescaline Sold as impregnated paper, like LSD Delayed onset of action, peak 3–4 h Fantasy, mood altering for 10 h, resolution 12–24 h Agitation, sympathetic excess	4-Bromo-2,5-methoxyphenyl-ethylamine (2CB, MFT)	Relaxation Sensory distortion Agitation Hallucination Potency >mescaline	Methcathinone (cat, Jeff, Khat, ephedrone)	Comparable to hallucinogenic and sympathetic effects of methamphetamine	4-Methyl-2,5-dimethoxyamphetamine (DOM/STP) (serenity, tranquility, peace)	Narrow therapeutic index Euphoria, perceptual distortion Hallucinations, sympathetic stimulation	3,4-Methylenedioxyamphetamine (MDA, love drug)	Empathy, euphoria Agitation, delirium, hallucinations, death associated with sympathetic excess	3,4-Methylenedioxyethamphetamine (MDEA, Eve)	Comparable to MDMA Sympathetic excess	3,4-Methylenedioxymethamphetamine (MDMA, Adam, ecstasy, XTC)	Psychotherapy "facilitator" Euphoria, empathy Nausea, anorexia Anxiety, insomnia Sympathetic excess	para-Methoxyamphetamine (PMA)	Potent hallucinogen Marked stimulant effect	2,4,5-Trimethoxyamphetamine	Similar to mescaline	
TABLE 73-1. Designer Amphetamines

Beginning in the mid-1990s, MDMA became and remains the amphetamine most widely used by college students and teenagers. MDMA is used by this population in large gatherings, known as â€œraveâ€• or â€œtechnoâ€• parties in England, Australia, and the United States.[215,216,272] MDMA use is prevalent in parties and clubs worldwide. Other MDMA-like analogs are often used or sold as MDMA in these gatherings.[10,272] Despite the popularity of MDMA, recent data in the United States demonstrates a decline in its past year use from 3.2 million in 2002 to 2.1 million in 2003.[259]

Reports of methcathinone (a Khat-derived substance) use in the midwestern United States,[94,282] and a resurgence of 4-bromo-2,5-methoxyphenylethylamine (2CB) in dance clubs occurred in the 1990s.[75,88] Fortunately, the fear for the widespread use of these agents never materialized. Although the trend of a particular amphetamine analog waxes and wanes, use and abuse of amphetamines in general is likely to continue to be consequential.

Pharmacology

The pharmacologic effects of amphetamines are complex but the primary mechanism of action is the release of catecholamines, particularly dopamine and norepinephrine, from the presynaptic terminals. Although there are conflicting mechanistic models of amphetamine induction of catecholamine release, the variable results may be directly correlated with the different concentrations of amphetamines used in experimental models. The best models to study the mechanism of action of amphetamines are based on dopaminergic neurons; similar mechanisms are invoked for norepinephrine and serotonin. Two storage pools exist for dopamine in the presynaptic terminals: the vesicular pool and the cytoplasmic pool. The vesicular storage of dopamine and other biogenic amines is maintained by the acidic environment inside the vesicles and the persistence of a stabilizing electrical gradient with respect to the cytoplasm. This environment is maintained by an adenosine

triphosphate (ATP)-dependent active proton transport system.[243] At low doses, amphetamines release dopamine from the cytoplasmic pool by exchange diffusion at the dopamine uptake transporter site in the membrane. At moderate doses, amphetamines diffuse through the presynaptic terminal membrane and interact with the neurotransmitter transporter on the vesicular membrane to cause exchange release of dopamine into the cytoplasm. Dopamine is subsequently released into the synapse by reverse transport at the dopamine uptake site.[243,261] At high doses, an additional mechanism is invoked as amphetamine diffuses through the cellular and vesicular membranes, alkalinizing the vesicles, permitting dopamine release from the vesicles and delivery into the synapse by reverse transport.[261,262] Binding selectivity to the neurotransmitter transporters largely determine the range of pharmacologic effects for the particular amphetamine. The MDMA affinity for serotonin transporters is 10 times greater than that for dopamine and norepinephrine transporters, hence producing primarily serotonergic effects.[97]

Amphetamines may also block the reuptake of catecholamines by competitive inhibition.[102,122] However, the effects of this mechanism are considered to be minor. At higher doses, amphetamines can cause the release of serotonin (5-hydroxytryptamine [5-HT]) and affect central serotonin receptors. Certain amphetamines, such as MDMA and 4-bromo-2,5-dimethoxyamphetamine (DOB), have more significant serotonergic effects.[85,122] Amphetamines are structurally similar to nonhydrazine amine-derivative monoamine oxidase inhibitors such as phenelzine and tranylcypromine, and most also have weak monoamine oxidase-inhibiting activities, the clinical significance of which is unclear.[212]

The most identifiable effects of amphetamines are those caused by catecholamine release and the resultant stimulation of peripheral Î±- and Î²-adrenergic receptors. In the central nervous system, increased norepinephrine at the locus caeruleus mediates the anorectic and alerting effects, and also some locomotor

stimulation.[101] The increase in central dopamine (particularly at the neostriatum) mediates stereotypical behavior and some of the other locomotor activities.[51,92,102,140] The activity of dopamine in the neostriatum appears to be linked to glutamate release and inhibition of GABAergic efferent neurons.[92,139,140] Stimulation of the glutamatergic system contributes significantly to the stereotypical behavior, locomotor activities, and neurotoxicity of amphetamines.[18,24,139,140,256,257] The effects of serotonin and dopamine on the mesolimbic system alter perception and cause psychotic behavior.[92,121] Because amphetamines directly interact with neurotransmitter transporters, minor modifications of the molecule may significantly alter its pharmacologic profile.[128] The Î±-methyl group in the amphetamine structure introduces chirality to the molecule. Except for MDMA and certain MDMA analogs, the *d*-enantiomers are much more potent (typically 4â€“10 times) than the *l* forms of amphetamines. Substitution at different positions of the phenylethylamine molecule alters general clinical effects of amphetamines, as demonstrated by animal discrimination studies and human observations. Compounds with methyl substitution at the Î± carbon, such as amphetamine and methamphetamine, possess strong stimulant, cardiovascular, and anorectic properties.[91,196] Large group substitution at the Î± carbon reduces the stimulant and cardiovascular effects, but retains the anorectic properties (such as in phentermine).[12] Substitution at the *para* position of the phenyl ring enhances the hallucinogenic or serotonergic effects of amphetamines (such as in *para*-chloroamphetamine and MDMA).[12,82,181] Although some of these generalizations enable scientists to understand the effects of amphetamines, there are many exceptions, and such generalizations may not apply when large doses of a particular molecule are ingested.[72] In terms of the spectrum of activities, methamphetamine has the most potent cardiovascular effects, and DOB has the most potent hallucinogenic or serotonergic effects.[91,196]

Pharmacokinetics and Toxicokinetics

In general, amphetamines are relatively lipophilic and hence they can readily cross the bloodâ€“brain barrier. They have large volumes of distribution, varying from 3â€“5 L/kg for amphetamine and 3â€“4 L/kg for methamphetamine and phentermine, to 11â€–33 L/kg for methylphenidate. Pemoline is the exception as it has a small volume of distribution (0.2â€–0.6 L/kg).[11] Amphetamines differ from catecholamines in that they lack the catechol structure (hydroxyl groups at the 3 and 4 positions of the phenyl ring) and are resistant

to metabolism by catechol-*O*-methyltransferase (COMT).[122] The addition of an Î±-methyl group in amphetamines confers resistance to metabolism by monoamine oxidase. These characteristics permit better oral bioavailability and longer duration of effects.[196]

Amphetamines are eliminated via multiple pathways, including diverse routes of hepatic transformations, and by renal elimination. For MDMA and its analogs, *N*-dealkylation, hydroxylation, and demethylation are the dominant hepatic pathways.[43,44,172] Depending on the particular substance, active metabolites of secondary amphetamines and ephedrine derivatives may be formed.[11,43] *N*-demethylation of methamphetamine and MDMA result in the formation of amphetamine and MDA, respectively.[43] Dealkylation and demethylation are mainly performed by cytochrome P450 (CYP) isozymes, including CYP1A2, CYP2D6, and CYP3A4, but they are also performed by flavin monooxygenase (FMO).[172] Polymorphism of CYP2D6 in humans was discovered as a result of decreased *p*-hydroxylation of amphetamine in certain individuals. Since its discovery, CYP2D6 polymorphism has been implicated in drug toxicity, substance use and abuse, and lack of drug efficacy in selected individuals.[246] Increased amphetamine toxicity is a potential concern in patients with decreased CYP2D6 activity. Although animals with CYP2D6 deficiency are more susceptible to MDMA toxicity,[49] limited studies in humans do not demonstrate an association of

mortality and CYP2D6 deficiency.[86,199] In general, because multiple enzymes and pathways (including renal) are involved in amphetamine eliminations, it is less likely that CYP2D6 polymorphism or drug interactions with CYP3A4 alone will significantly increase toxicity. However, it is unclear if toxicity is enhanced when multiple mechanisms for altering drug metabolism and renal dysfunction are present simultaneously.

Renal elimination is substantial for amphetamine (30%), methamphetamine (40â€“50%), MDMA (65%), and phentermine (80%). Amphetamines are relatively strong bases with a typical pK_a range from 9â€“10, and renal elimination varies depending on the urine pH.[11] The half-life of amphetamines varies significantly: amphetamine, 8â€–30 hours; methamphetamine, 12â€–34 hours; MDMA, 5â€–10 hours; methylphenidate, 2.5â€–4 hours; and phentermine, 19â€–24 hours.[11,43] Repetitive administration, which occurs typically during binge use, may lead to drug accumulation and prolongation of the apparent half-life and duration of effect.[132]

Clinical Manifestations

The clinical effects of amphetamines are largely related to the stimulation of central and peripheral adrenergic receptors. These clinical manifestations and complications are similar to those from cocaine use and may be indistinguishable except for the duration of effect of amphetamines, which tends to be longer (up to 24 hours).[65]

Compared to cocaine, amphetamines are less likely to cause seizures, dysrhythmias, and myocardial ischemia. This may be related to the sodium channel-blocking effects and to the thrombogenic effect of cocaine.[93] Psychosis appears to be more likely with amphetamines than cocaine, which may be related to the more prominent dopaminergic effects of amphetamines.[8,92] Tachycardia and hypertension are the most common manifestations of cardiovascular toxicity. Most patients present to the emergency department, however, because of the CNS manifestations.[65,129,276]

These patients are anxious, volatile, aggressive, and may have life-threatening agitation. Visual and tactile hallucinations, as well as psychoses, are common.[21,66,67,112,164,226,239] Other sympathetic findings include mydriasis, diaphoresis, and hyperthermia (Table 73-2).[66,70]

Death from amphetamine toxicity most commonly results from hyperthermia, dysrhythmias, and intracerebral hemorrhage.[39,61,79,135,142,163,206,227] Direct CNS effects may result in seizures. Tachycardia, hypertension, and vasospasm may lead to cerebral infarction,[95,153,231] intraparenchymal and subarachnoid hemorrhage,[57,110,126,141,258,281] myocardial ischemia or infarction,[81,207,269] aortic dissection,[57,69] acute lung injury,[29,193,194] obstetrical complications, fetal death,[162] and ischemic colitis.[16,119,133] Dysrhythmias vary from premature ventricular complexes to ventricular tachycardia and ventricular fibrillation.[135,165] Agitation, increased muscular activity, and hyperthermia can result in metabolic acidosis, rhabdomyolysis,[54] acute tubular necrosis (acute renal failure), and

coagulopathy.[70,87,134,143] Unless these systemic signs and symptoms are rapidly reversed, multiorgan failure and death ensue.

TABLE 73-2. Amphetamine Toxicity

Acute Toxicity
Cardiovascular system
Hypertension
Tachycardia
Dysrhythmias
Myocardial ischemia
Aortic dissection
Vasospasm

- Central nervous system
  - Hyperthermia
  - Agitation
  - Seizures
  - Intracerebral hemorrhage
  - Headache
  - Euphoria
  - Anorexia
  - Bruxism
  - Choreoathetoid movements
  - Hyperreflexia
  - Paranoid psychosis
- Other sympathetic symptoms
  - Diaphoresis
  - Tachypnea
  - Mydriasis
  - Tremor
  - Nausea
- Other organ systems
  - Rhabdomyolysis
  - Muscle rigidity
  - Acute lung injury
  - Ischemic colitis

Chronic toxicity

- Vasculitis
- Cardiomyopathy
- Pulmonary hypertension
- Aortic and mitral regurgitation
- Permanent damage to dopaminergic and serotonergic neurons

Laboratory abnormalities

- Leukocytosis
- Hyperglycemia
- Hyponatremia

Elevated CPK
Elevated liver enzymes
Myoglobinuria

Amphetamine users seeking intense â€œhighsâ€• may go on â€œspeed runsâ€• for days to weeks. Because of the development of acute tolerance, they use increasing amounts of amphetamines during these periods, usually without much sustenance or sleep, attempting to achieve their desired euphoria.[17,52,155,252,263] Acute psychosis resembling paranoid schizophrenia may occur during these binges and has contributed to both amphetamine-related suicides and homicides.[73,151] Return to a normal sensorium occurs within a few days after discontinuation of the drug. Once an amphetamine user experiences psychosis, it is likely to be recurrent, even after prolonged abstinence, which may be related to a kindling phenomenon.[17,204,263] Amphetamine-induced psychosis has contributed to the understanding of dopamine's function in schizophrenia. Typically after such binges, patients may sleep for prolonged periods, feeling hungry and depressed when awake. During this period of depression or withdrawal, the patient continues craving amphetamines.[112,152,158]

There are some direct neurologic effects of amphetamines. Compulsive repetitive behavior patterns are reported in humans and animals. Individuals may constantly pick at their skin, grind their teeth (bruxism), or perform repetitive tasks, such as constantly cleaning their house or car.[17] MDMA users often carry pacifiers to relieve bruxism. Choreoathetoid movements, although uncommon, are reported with acute and chronic amphetamine usage.[149,167,171,219,238,251] The etiology of the choreoathetoid movements may be related to increased dopaminergic activity at the striatal area.

Necrotizing vasculitis is associated with amphetamine abuse.[19,46] Angiography typically demonstrates beading and narrowing of the

small and medium-size arteries (see Fig. 6-25).[233,258] Progressive necrotizing arteritis[57] can involve multiple organ systems, including the central nervous, cardiovascular, gastrointestinal, and renal systems. Complications include cerebral infarction and hemorrhage, coronary artery disease, pancreatitis, and renal failure.[46,109,166,233,258,258,281] The etiology of the arteritis remains unclear. Although various contaminants associated with parenteral drug use were postulated as potential etiologies, oral and IV amphetamine use in animal models are also associated with vasculitis, suggesting that this is a direct amphetamine effect.[234,235,266] Cardiomyopathy is also reported with acute and chronic amphetamine abuse.[19,123,200,254] Excessive catecholamine exposure in patients with pheochromocytomas and chronic cocaine use may be responsible for their associated cardiomyopathies; amphetamine-induced cardiomyopathy may be produced by similar mechanisms.[101,137,275]

Primary pulmonary hypertension, a rare and potentially fatal disease, is reported with chronic methamphetamine and propylhexedrine use.[6,68,156,241] However, substantial epidemiologic risk for primary pulmonary hypertension is demonstrated only with fenfluramine and aminorex (2-amino-5-phenyl-2-oxazoline).[23,103,249] Pulmonary hypertension was associated with the use of aminorex as an anorectic agent in Europe from 1965 to 1968.[104] In 1996, a case-controlled study substantiated the increased risk of pulmonary hypertension with the use of amphetamine appetite-suppressant drugs, particularly with fenfluramine.[1] The risk of pulmonary hypertension was increased 23-fold when the cumulative use of anorectic agents totaled more than 3 months.[1] Pulmonary hypertension may develop following exposure to anorectic agents that may be as brief as 3 weeks.[103] The exact cause of the pulmonary hypertension is unclear. Increased serotonin or direct effects of 5-HT_{2B} receptors in the pulmonary vasculature is postulated to result in pulmonary vasoconstriction and endothelial proliferation.[120,193,229] Interestingly, although fenfluramine is a

weak agonist for 5-HT_{2B} receptors, its metabolite norfenfluramine is a potent agonist for 5-HT_{2B} receptors and may be responsible for causing pulmonary hypertension.[124] Pulmonary hypertension that develops following the use of anorectic drugs may be partially reversible after withdrawal of the agent; however, the median survival of patients studied during the European aminorex epidemic was 3.5 years from the time of diagnosis.[103] With current advances in therapy, improved survival is expected.[232]

Valvular heart disease is also associated with the use of the appetite-suppressants fenfluramine, dexfenfluramine, and phentermine, particularly if the duration of therapy is greater than 4 months.[50,83,131,145,273] The initial reports, in 1997, implicated significant aortic and mitral regurgitation with the use of these drugs and the prevalence was as high as 32%.[37] These reports resulted in the withdrawal of fenfluramine and dexfenfluramine. Subsequent studies demonstrated mostly mild aortic regurgitation and possible mitral regurgitation; the overall prevalence varies from study to study, ranging from 0.14% to 22.7%.[83,131,145,271] The highest risks appear to be in patients taking combination therapy with fenfluramine and phentermine, and those who used the drug for prolonged periods (>4 months).[131] The dramatic differences in the overall prevalence rate in these studies may be related to differences in patient population, duration of therapy, and the timing of echocardiography (ie, during therapy or after the cessation of therapy). The most recent meta-analysis demonstrated a 12% prevalence rate of valvular regurgitation (mostly aortic) with more than 90-day use of the appetite-suppressants, compared to 5.9% in the unexposed group. There was no difference when the appetite-suppressants' use was less than 90 days.[236] Echocardiographic findings of the valvular dysfunctions typically improve following cessation of these drugs.[118] The exact etiology of the valvular disease is postulated to be related to increased serotonin or direct effects on 5-HT_{2B} receptors. Similar valvular disorders are recognized in patients exposed to persistently increased serotonin

levels with conditions such as malignant carcinoid syndrome; its unclear why carcinoid syndrome predominately affects right-sided valves versus primarily left-sided valves for these drugs.[228]

Although the chronic administration of MDMA and its analogs are better publicized, chronic administration of various amphetamines, including amphetamine and methamphetamine, to animals, alters dopamine and serotonin transporters functions, depletes dopamine and serotonin in the neuronal synapses, and produces irreversible destruction of those neurons.[15,85,222,223,225,242,278] The etiology of neuronal toxicity may be related to the generation of free oxygen radicals, resulting in the generation of toxic dopamine and serotonin metabolites and neuronal destruction.[85,157,244,278,279] Based on animal models, dose, frequency and duration of exposure, and ambient temperature can affect neurologic injuries. Intact dopamine or serotonin transporters are necessary to produce neurologic injury. Drugs that inhibit transporter functions may prevent neurologic injuries in animals.[97] Significant differences are also noted across species; mice are typically resistant to MDMA-induced neurologic injury.[175] Although not as well-studied as MDMA, recent studies of former methamphetamine users demonstrated impaired memory and psychomotor functions, as well as corresponding dopamine transporter dysfunction and abnormal glucose metabolism on PET scans.[245,267,268] However, we still do not understand the difference in species susceptibility to neurologic injuries, the duration of effects in primates and humans, and functional

consequences of neurotoxicity in humans. The potential for permanent neurologic effects associated with chronic amphetamine use in humans requires further study. Despite the first report of neurologic injuries from methamphetamine in animals in 1976, many questions remain unanswered.

Finally, multiple medical complications can result from parenteral drug use and from the associated contaminants. Contamination with infectious agents may result in HIV infection, hepatitis, and malaria.

Bacterial and foreign-body contamination may result in endocarditis, tetanus, wound botulism, osteomyelitis, and pulmonary and soft-tissue abscesses.[41]

Diagnostic Testing

Diagnosis by history is rarely reliable as patients often do know the exact drug they have used.[148] Also, there is no readily available drug-specific serum analysis. Qualitative urine immunoassay testing for amphetamines is available, but it is not valuable in the acute overdose setting. Typically, the turnaround time for the test result is at least several hours, which is far too long to be clinically useful. Both false-positive and false-negative results are common. Many cold preparations contain structurally similar substances (such as pseudoephedrine) that may cross-react with the immunoassay.[48,55,80,213] Likewise, selegiline, a selective monoamine oxidase type B (MAO-B) inhibitor used for the treatment of parkinsonism, is metabolized to amphetamine and methamphetamine. Patients taking selegiline will react positively with most amphetamine-testing techniques.[138] Even a true-positive result only means the patient has used an amphetamine analog within the last several days. In addition, most immunoassays do not react with all amphetamines, resulting in false-negative results. For example, MDMA frequently goes unrecognized on standard urinary drug testing.[16,48] Although newer, rapid, serum qualitative drug screens are available, false-positive and false-negative results remain common and may be misleading. The gold standard for drug testing, gas chromatographyâ€“mass spectrometry analysis, can misidentify isomeric substances such as *l*-methamphetamine, which is present in nasal inhalers, with *d*-methamphetamine, if performed by inexperienced personnel.[253] In summary, the suspicion of amphetamine toxicity cannot be confirmed rapidly with a high level of reliability by the laboratory.

The physical and psychological assessment is nonspecific, and

polydrug abuse is quite common. As such, the prevalence of amphetamine abuse in the local geographic region should heighten the suspicion of amphetamine toxicity in patients with an appropriate presentation. Management decisions must be determined by the clinical manifestations and impressions.

Blood specimens should be sent for glucose, BUN, and electrolyte assays. Hyponatremia should be considered for any patient with an altered sensorium and suspected MDMA usage (Chap. 17). An ECG should be obtained to exclude ischemia, hyperkalemia, and drug toxicity (cyclic antidepressant), and continuous cardiac monitoring should be initiated. A complete blood count, urinalysis, coagulation profile, chest radiograph, CT of the head, and lumbar puncture may be necessary, depending on the clinical presentation.

Management

Table 73-3 summarizes the therapeutic approach to a patient with amphetamine toxicity. The initial medical assessment of the agitated patient must include the vital signs and a rapid complete physical examination. An often-neglected vital sign is the rectal temperature.

TABLE 73-3. Management of Patients with Amphetamine Toxicity

Agitation
Benzodiazepines (usually adequate for the cardiovascular manifestations)
Diazepam 10 mg (or equivalent) IV, repeat rapidly until the patient is calm (cumulative dose may be >100 mg of diazepam)
Seizures
Benzodiazepines
Barbiturates
Propofol
Hyperthermia
External cooling
Control agitation rapidly
Gastric decontamination and elimination
Activated charcoal for oral ingestions
Hypertension
Control agitation first
Î±-Adrenergic receptor antagonist (phentolamine)
Vasodilator (nitroprusside, nitroglycerin)
Delirium or hallucinations with abnormal vital signs
If agitated: benzodiazepines
Delirium or hallucinations with normal vital signs
Consider haloperidol or droperidol (consider risk/benefit)

Hyperthermia, a frequent and rapidly fatal manifestation in patients with drug-induced delirium, requires immediate interventions to achieve cooling.[87,134,143] Some patients will require physical restraint to gain clinical control and prevent personal harm to themselves or others. Because agitation and resistance against physical restraint may lead to rhabdomyolysis and continued heat generation, intravenous chemical sedation should be instituted immediately. Blood specimens should be sent for glucose, BUN, and electrolyte assays. Hyponatremia should be considered for patients

with altered sensorium and suspected MDMA usage (Chap. 17). Intravenous (IV) glucose ($D_{50}W$, 0.5â€“1 g/kg) and thiamine 100 mg should be given as indicated.

Because the clinician cannot accurately distinguish the diverse etiologies of drug-induced delirium, the choice of chemical sedation should be safe and effective regardless of the etiology. The most appropriate choice of sedation is a benzodiazepine because these drugs have a high therapeutic index and good anticonvulsant activity. They are effective for the treatment of delirium induced by acute overdose of cocaine, amphetamines, and other drugs, and the delirium associated with ethanol and sedative-hypnotic withdrawal.[63,66,93,205] The dose of benzodiazepine should be titrated rapidly intravenously until the patient is calm. In our clinical experience, cumulative benzodiazepine dosages required in the initial 30 minutes to achieve adequate sedation frequently exceeds 100 mg of diazepam or its equivalent. Antipsychotics, particularly potent dopamine antagonists such as haloperidol and droperidol, are frequently recommended by others for amphetamine-induced delirium. Antipsychotics may actually antagonize some of the effects of amphetamines via dopamine blockade.[63,64,76] In animal models, haloperidol may be

superior to diazepam in preventing mortality from amphetamine toxicity.[34,59,63,64] In clinical experience, however, the benzodiazepines appear to be as efficacious as the antipsychotics in the management of amphetamine toxicity.[66] Antipsychotics may lower the seizure threshold, alter temperature regulation, may cause acute dystonia and cardiac dysrhythmias, and do not interact with the benzodiazepineâ€“Î³-aminobutyric acid (GABA)â€“chloride channel receptor complex. All of these effects may worsen the clinical outcomes related to occult or concomitant cocaine toxicity and ethanol withdrawal.[93,98,205]

Rhabdomyolysis from amphetamine toxicity usually results from agitation and hyperthermia.[82,143] Sedation prevents further muscle

contraction and heat production. External cooling should be instituted for significant hyperthermia. Adequate IV hydration and cardiovascular support should maintain urine output of 1â€“2 mL/kg/h. Although urinary acidification can significantly increase the elimination and decrease the half-lives of amphetamine and methamphetamine,[11,13,14,58] this pH manipulation does not decrease toxicity, and, in fact, may increase the risk of renal compromise and acute tubular necrosis from rhabdomyolysis by precipitating ferrihemate in the renal tubules.[54] Patients with acute renal failure, acidemia, and hyperkalemia will likely require urgent hemodialysis.

Amphetamine body packers should be treated similarly to those who transport cocaine (Chap. 74). Any sympathomimetic symptom suggesting leakage of the packets requires surgical intervention.[270] Fluids, benzodiazepines, intubation, and external cooling may be necessary to stabilize these patients.

Individual Xenobiotics

Methamphetamine

Methamphetamine abuse in the United States is not new. From the 1950s to the 1970s, there were multiple epidemics of methamphetamine abuse.[17] Methamphetamine was and sometimes still is referred to as â€œcrack,â€• â€œspeed,â€• â€œyaba,â€• and â€œgo.â€• The pharmacologic profile of methamphetamine is quite similar to amphetamine, although the effects on the central nervous system are more substantial.[42] â€œIce,â€• the common name for methamphetamine in the 1990s because of the crystal forms, does not differ pharmacologically from other forms of methamphetamine. Methamphetamine is readily absorbed by the oral, parenteral, and inhalational routes. Because of a prolonged half-life of 19â€“34 hours, the duration of its acute effects can be greater than 24 hours.[42,65,66]

Since the 1990s, the activity and purity of methamphetamine available on the street is substantially higher than previous epidemics because of the method of synthesis.[160] Methamphetamine is now typically greater than 80â€“90% pure and almost exclusively in the dextroisomer form, which is most active on the CNS.

Methamphetamine is easily synthesized with the proper chemicals and minimal equipment.[84] The primary ingredient of methamphetamine synthesis is ephedrine, which can be hydrogenated into methamphetamine. The ephedrine method, using pharmaceutical grade L-ephedrine, produces a product with few contaminants that is stereochemically pure.[65,214] The production of the large crystal is possible by creating a supersaturated solution of methamphetamine hydrochloride.[65] Nonprescription sales of ephedrine are now restricted and monitored in many states.[265] Phenyl-2-propanone (P2P), as an alternative ingredient, can be methylated into ephedrine and then into methamphetamine.[28] Because of the strict control of ephedrine and P2P, illicit chemists use phenylacetic acid to synthesize P2P.[28,56] Lead acetate, which is used as a substrate for the reaction, resulted in an epidemic of lead poisoning associated with methamphetamine abuse in Oregon.[3,40] Lead levels reported in drug users were as high as 513 Âµg/dL, and some samples of illicitly manufactured methamphetamine had lead contents as high as 60% by weight.[40] Mercury contamination was also documented, although clinical mercury toxicity has not been reported.[26] The number of potential chemicals involved in the methamphetamine manufacturing process is significant, and without any legal monitoring, contamination of the product and the environment is inevitable.[4,28,127,154] In fact, 20â€“30% of the illicit methamphetamine manufacturing sites discovered were discovered because of laboratory explosion.[78,125] In California's San Bernardino County alone in 1995, 360 methamphetamine laboratories were identified and closed by drug enforcement agents.[78] These makeshift methamphetamine laboratories pose a significant health risk to law enforcement officers and the general public, causing respiratory and

eye irritation, headaches, and burns.[35] Currently, sale of other potential amphetamine synthesis ingredients, such as hydrochloric acid, hydrogen chloride gas, anhydrous ammonia, red phosphorus, and iodine, are also monitored and restricted in the United States.[28,36,265]

3,4-Methylenedioxymethamphetamine

MDMA was first synthesized in 1912, and was rediscovered in 1965 by Shulgin.[26] It is currently one of the most widely abused amphetamines by college students and teenagers.[47,208,272,276] It is commonly known as â€œecstasy,â€• â€œE,â€• â€œAdam,â€• â€œXTC,â€• â€œM&M,â€• and â€œMDM.â€• Other structural relatives of MDMA, MDEA (â€œEveâ€•) and MDA (â€œlove drugâ€•), are also used or distributed as MDMA in areas of MDMA use. These xenobiotics have similar clinical effects and acute and chronic toxicity. Recently, other MDMA-related substances are also found in â€œraveâ€• scenes, 2CB, 2,4-dimethoxy-4-(*n*)-propylthiophenylethylamine (2C-T7), and *N*-methyl-1-(3,4-methylenedioxyphenyl)-2-butanamine (MBDB).[33,75,88,146] The term, â€œecstasyâ€• may be used for all of these substances. Typically, MDMA is available in colorful and branded tablets that vary from 50 mg to 200 mg. MDMA and similar analogs are so-call entactogens (meaning touching within), capable of producing euphoria, inner peace, and a desire to socialize.[177,255] In addition, some psychologists used MDMA to enhance psychotherapy until the Controlled Substances Act of 1986.[195] People who use MDMA report that it enhances pleasure, heightens sexuality, and expands consciousness without the loss of control.[26,100,177] Negative effects reported with acute use included ataxia, restlessness, confusion, poor concentration, and memory problem.[255] MDMA has about one-tenth the CNS stimulant effect of amphetamine. Unlike amphetamine and methamphetamine, MDMA is a potent stimulus for the release of serotonin.[30,60,102] The concentration of MDMA required to stimulate the release of serotonin is 10 times less than that required for the

release of dopamine or norepinephrine. In animal models, the stereotypic and the discriminatory effects of MDMA and its congeners can be distinguished from those of other amphetamines.[31,195]

The sympathetic effects of MDMA are mild in low doses. However, when a large amount of MDMA is taken, the clinical presentation is similar to that of other amphetamines and deaths can result from abuse.[70,116,117,191,276] Those patients at greatest risk develop dysrhythmias, hyperthermia, rhabdomyolysis, and disseminated

intravascular coagulation.[70,117,250] Significant hyponatremia has been well reported with MDMA use.[2,113,173,197] MDMA and its metabolites increase the release of vasopressin (antidiuretic hormone) and may be related their serotonergic effects.[77,115] Furthermore, large free-water intake combined with sodium loss from physical exertion (in dance clubs) may be crucial to the development of hyponatremia.

A major concern with MDMA usage is its long-term effects on the brain. In numerous animal models, acute administration of MDMA leads to the decrease in serotonin reuptake transporter (SERT) function and numbers. Recovery in SERT function may take several weeks. Repetitive administration of MDMA ultimately leads to permanent damage to serotonergic neurons, typically causing injury to the axons and the terminals while sparing the cell bodies.[174,178,180,201,220,222] Some regeneration of synaptic terminals can occur even with neuronal damage, but functional recovery is not complete. Intact SERT function is necessary for MDMA-induced neurotoxicity. Xenobiotics that inhibit the uptake of serotonin prevent MDMA-induced neurotoxicity in animals. Animal data suggest that MDMA induces hydroxyl free-radical generation and decreases antioxidants in serotonergic neurons.[224,247] MDMA does not directly cause neurotoxicity, but its metabolites 3-Î±-methyldopamine and *N*-methyl-Î±-methyldopamine do produce neurotoxicity in animals.[186] When sufficient antioxidants are depleted, neuronal damage may occur.

The evidence for these potential neurotoxic effects in humans is less clear. Indirect evidence of serotonergic effects in humans includes lower concentrations of 5-hydroxyindoleacetic acid (5-HIAA) in the cerebral spinal fluid (CSF) of MDMA users than in controls.[221] Case reports and studies of MDMA users demonstrate alteration in mood, sleep, anxiety, cognition, memory, and impulse controlâ€”all functions that are believed to be affected by serotonin.[5,176,179,181,185] Either single-photon emission tomography (SPECT) or positron emission tomography (PET) demonstrates decreased SERT function in MDMA users, even after prolonged abstinence.[27,202,218] Memory deficits appeared to persist even in abstinent MDMA users.[96,190] A major deficit in human studies is finding comparable control groups; it is possible that people with psychiatric problems are more likely to be MDMA users.[182] MDMA users are also associated with other drug use. Currently, there are no human histopathologic (postmortem) data for MDMA users.[147] Further studies are required to address the long-term neuropsychiatric effects of MDMA.

Propylhexedrine

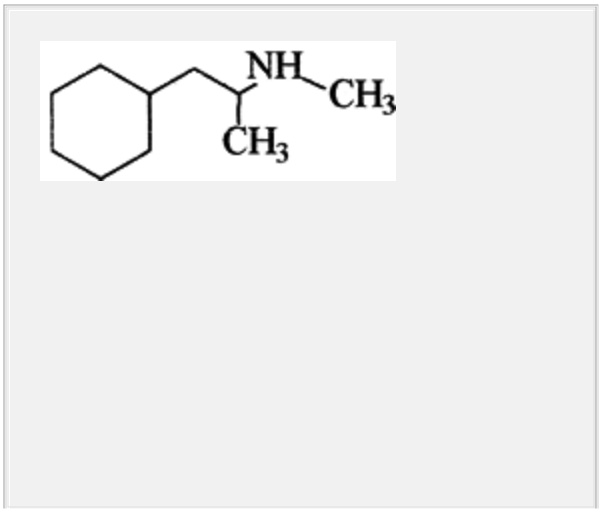

Figure. No Caption Available.

Smith, Kline, and French introduced propylhexedrine in 1949 as the primary active ingredient in Benzedrex nasal inhaler, to replace amphetamine in nasal inhalers because of the widespread abuse.[7,82] Propylhexedrine is an alicyclic aliphatic sympathomimetic amine that is structurally similar to amphetamine, with a local vasoconstrictive effect and approximately 10% of the CNS stimulatory effect of amphetamine.[7] Propylhexedrine abuse became prevalent after the removal of amphetamine from nasal inhalers. The abusers disassembled the inhaler and ingested the cotton pledget vehicle of propylhexedrine itself, diluted it in beverages, or reconstituted the drug for intravenous injection. Numerous effects were reported with propylhexedrine abuse, including sudden death, myocardial infarction, cardiomyopathy, pulmonary hypertension, and acute psychosis.[6,7,53,68,82,161,169,170,274] Although propylhexedrine in nasal inhalers has largely been replaced by safer sympathomimetic agents (Chap. 50), the drug is still readily available and is abused as an inexpensive, legal â€œhigh.â€•

Khat, Cathinone, and Methcathinone

Khat (also known as quat and gat), the fresh leaves and stems from the *Catha edulis* shrub, is a commonly used drug in eastern and central Africa, and in parts of the Arabian peninsula. Attention to khat was highlighted in the early 1990s by the media coverage of war in Somalia and Ethiopia. Khat is sold in small bundles of leaves in the local markets of these countries. The leaves and the tender stems are chewed or occasionally concocted into tea. Khat chewing has a significant role at social gatherings in these countries.[168] There is a trend of increasing khat consumption and binges among adolescents in these countries.[203] When the dried leaves and stems were studied, the primary active ingredient was thought to be

cathine (norpseudoephedrine), present as 0.1â€“0.2% of the dried material. Cathine has about one-tenth the stimulant effects of D-amphetamine. Numerous other amphetaminelike compounds are also isolated, but occur in minute quantities.[136] When the fresh leaves are analyzed, however, cathinone (benzylketoamphetamine), a more potent psychoactive compound, was demonstrated to be the primary active agent.[89,105,136] As the leaves age, cathinone is degraded into cathine, which also explains why dried khat is neither popular nor widely distributed. Imported fresh khat must be consumed within a week, before it loses much of its potency. The primary effects of khat are increased alertness, insomnia, euphoria, anxiety, and hyperactivity. Increased khat consumption is linked to psychosis. Significant adrenergic complications are much less frequent than those associated with amphetamine abuse.

Methcathinone, the methyl derivative of cathinone, chemically synthesized from ephedrine, has been abused in Russsia and other former members of the Soviet Union for many years. The potency of methcathinone is comparable to that of methamphetamine.[90,280] Methcathinoneâ€”also termed ephedrone, or sold under the street names of â€œcatâ€• or â€œJeffâ€•â€”currently remains widely abused in Russia. Methcathinone abuse was first reported in Michigan in the early 1990s and is now reported in other states as well.[74]

Ephedrine or Ma-Huang Herbal Products

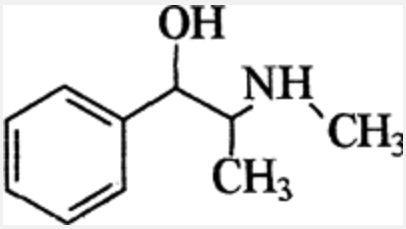

Figure. No Caption Available.

Ephedrine is commonly found in nonprescription cold preparations. Ephedrine is also the active substance in the Chinese plant ma-huang, which has been used for centuries for the treatment of asthma. Although ephedrine is much less potent than amphetamine, when combined with other catecholamine-stimulating xenobiotics or when taken in large quantities, significant toxicity may occur.[25,32,209,240] In the United States, numerous ephedrine products, such as â€œgo,â€• â€œultimate xphoria,â€• â€œup your gas,â€• and â€œherbal ecstasy,â€• are marketed primarily to teenagers. Some of these products

contain more than 500 mg of ephedrine, which may be combined with pseudoephedrine, phenylpropanolamine, and caffeine; other products contain the plant extract ma-huang.[159,209,211] Many of these products are marketed as legal stimulants or safe herbal stimulants for a natural â€œhigh.â€• Similarly, ma-huang is also widely marketed as a â€œsafeâ€• herbal weight-reducing product. Sales appeared to increase when it was recognized that phenylpropanolamine was associated with brain hemorrhage in women.[144] Unfortunately, these products are linked to numerous

deaths and adverse reactions.[107,108,192,211,264,277,282] Because these products are sold as food supplements, they are not regulated by the FDA unless a product can be demonstrated to be unsafe (Chap. 43). In 2004, the FDA finally banned the use of ephedra products. In April 2005, a federal judge in Utah reversed the ban of ephedra sales in Utah, illustrating the difficulty of the FDA in the regulation of herbal products.[111] Herbal products with *Citrus aurantium* (bitter orange), contain a number of adrenergic amines, including synephrine, have now supplanted ephedra products. *Citrus aurantium* has similar pharmacologic effects and toxicity as ephedra.[20,198]

Summary

Amphetamine usage is increasing dramatically throughout the United States. Similarly, ED visits and morbidity and mortality related to amphetamines parallel amphetamine usage. Many of these complications are similar to those of cocaine, such as agitation, hyperthermia, rhabdomyolysis, myocardial ischemia, and cerebral infarction. Physicians, more than ever, must understand the pathophysiology of amphetamines and be ready to diagnosis and treat its toxicity. The chronic effects of amphetamines as demonstrated in animal models pose serious concerns for humans, particularly as amphetamine usage becomes more prevalent; further studies are required to achieve prevention and management.

Chapter 74
Cocaine

Robert S. Hoffman

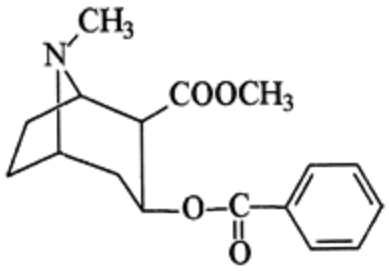

Figure. No Caption Available.

A 54-year-old man called 911 because of chest discomfort that had begun about 4 hours earlier. The patient had a history of cigarette smoking, daily cocaine use, and a questionable history of hypertension. He stated that shortly following the use of 1 g of cocaine, he developed midsternal chest pressure that radiated to the back, was worse with exertion, and was associated with nausea and three episodes of vomiting. When emergency medical services (EMS) technicians arrived they gave him oxygen, 162 mg of aspirin, and sublingual nitroglycerin spray. The pain resolved by

the time he arrived to the hospital.

On arrival at the hospital the patient was alert and in no distress and his vital signs were as follows: blood pressure, 145/95 mm Hg; pulse, 114 beats/min; respirations, 20 breaths/min; temperature, 96.8Â°F (37Â°C). His oxygen saturation while breathing room air was 97% by pulse oximetry, and a rapid reagent glucose test was normal. Physical examination was remarkable for normal pupils, the absence of diaphoresis, normal chest auscultation, and normal heart sounds. The patient was neurologically and cognitively intact.

The patient was attached to a continuous cardiac monitor, given high flow oxygen, an ECG was obtained (Fig. 74-1), and a chest radiograph was ordered. An intravenous line was inserted and blood samples were obtained and sent for electrolytes, glucose, cardiac enzymes, and a complete blood count analysis. Additionally, about 1 hour after arrival, 10 mg of diazepam was given IV for continued tachycardia. Following that, his repeat vital signs were: blood pressure, 141/93 mm Hg; pulse, 115 beats/min. Another 5 mg of diazepam was administered IV but resulted in no change in the patient's vital signs. The chest radiograph was unremarkable.

Approximately 2 hours after admission to the emergency department, the troponin I was reported as positive at 1.5 ng/mL and the patient was given 325 mg of aspirin and an intravenous loading dose of heparin, followed by a continuous heparin infusion. Two doses of metoprolol (2.5 mg each) were administered IV 10 minutes apart, for persistent tachycardia. Within 10 minutes of the second dose the patient complained of severe crushing substernal chest pain, and became diaphoretic and nauseated. Shortly thereafter his systolic blood pressure dropped to 50 mm Hg. The patient was intubated and resuscitative attempts included administration of atropine, epinephrine, vasopressin, and glucagon. A bedside ultrasonogram showed global akinesis of the

heart and the patient died about 3 hours after presentation.

After review of the case an adverse drug event report was filed with the hospital's drug safety committee citing a probable interaction between cocaine and metoprolol.

History and Epidemiology

Cocaine is a natural alkaloid contained in the leaves of *Erythroxylum coca* , a shrub that grows abundantly in Columbia, Peru, Bolivia, the West Indies, and Indonesia. As early as the 6th century the inhabitants of Peru chewed or sucked on the leaves for social and religious reasons. In the 1100s, the Incas used cocaine-filled saliva as local anesthesia for ritual trephinations of the skull.[69]

In 1859, Albert Niemann isolated cocaine as the active ingredient of the plant. By 1879 Vassili von Anrep demonstrated that cocaine could numb the tongue.[114] However, Europeans knew little

about cocaine until 1884, when the Austrian ophthalmologist Karl Koller introduced cocaine as an effective local anesthetic for eye surgery and Koller's colleague, Sigmund Freud, wrote extensively on the psychoactive properties of cocaine.[57] Following these revelations, Merck, Europe's main cocaine producer increased production from less than 0.75 pounds in 1883 to more than 150,000 pounds in 1886.[109]

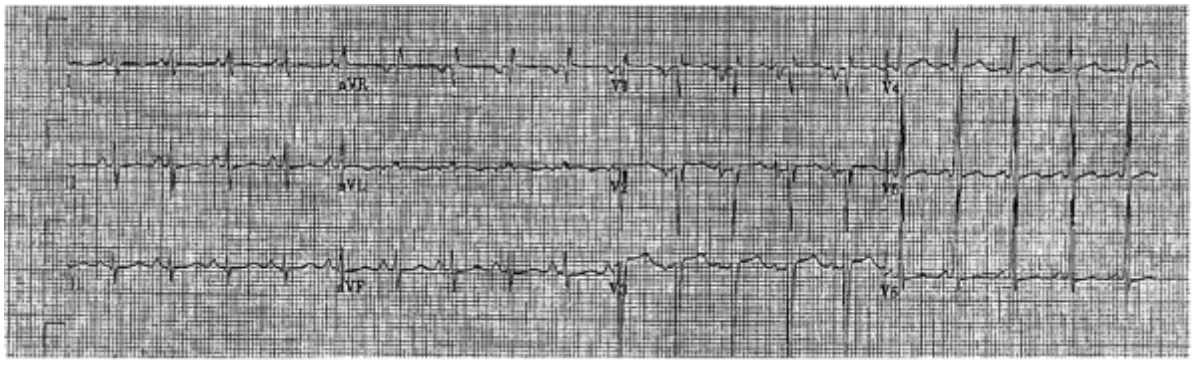

Figure 74-1. The ECG from the 54-year old man with cocaine-associated chest pain described in the case. The ECG shows 1â€“2 mm elevations of the ST segments in the anterior leads (V_2 , V_3).

Nearly simultaneously, reports of complications resulting from the therapeutic use of cocaine began to appear. In 1886, a 25-year-old man had a â€œpulselessâ€• syncopal event after cocaine was applied to his eye to remove a foreign body.[220] By 1887 more than 30 cases of severe toxicity were reported,[189] and by 1895 at least 8 fatalities resulting from a variety of doses and routes of administration were summarized in one article.[59] Recreational cocaine use was legal in the United States until 1914, when it was restricted to medical professionals. It was not until 1982, however, that the first cocaine-associated myocardial infarction was reported in the United States.[28]

Today, cocaine remains an approved pharmaceutical, primarily used either for topical anesthesia of cutaneous lacerations or as both a vasoconstrictor and topical anesthetic for otolaryngology procedures. Multiple factors, including severe complications despite the use of approved doses, complicated regulatory standards for storage, record keeping requirements, and comparable available alternatives have fostered a decline in the medicinal use of cocaine.[19 , 65 , 135] Unfortunately, the recreational use of cocaine remains a significant problem. Although drug use statistics are always questionable, recent estimates suggest that almost 34 million Americans have used cocaine at least once, with just over 2 million being current regular users.[41]

Pharmacology

The alkaloidal form of cocaine (benzoylmethylecgonine) is extracted from the leaf by mechanical degradation in presence of a hydrocarbon. The resultant product is converted into a hydrochloride salt and extracted into an aqueous phase, which is

subsequently evaporated to yield a white powder (cocaine hydrochloride). Cocaine hydrochloride can be insufflated or applied to other mucous membranes, dissolved in water and injected, or ingested, but it rapidly degrades during pyrolysis. Smokeable cocaine (crack) is formed by dissolving cocaine hydrochloride in water and adding a strong base. A hydrocarbon solvent is added, the cocaine base is extracted into the organic phase, and then evaporated. The term free-base refers to the use of cocaine base in solution. Typically a tobacco or marijuana cigarette is dipped into the free-base solution and allowed to dry prior to smoking.

Cocaine is rapidly absorbed following all routes of exposure; however, when applied to a mucous membrane or ingested its vasoconstrictive properties slow the rate of absorption and delay the peak effect. Whereas bioavailability exceeds 90% with intravenous and smoked cocaine, it is only approximately 80% following nasal application.[105] Data for ingested cocaine and application to other mucus membranes such as the urethra, vagina, or rectum are inadequately documented. Table 74-1 lists the typical onsets and durations of action for various uses of cocaine.

Following absorption cocaine is approximately 90% bound to plasma proteins. Although binding to both albumin and Î±$_1$ -acid glycoprotein are reported, it appears that albumin binding is less important.[174] Based on human volunteer studies, the volume of distribution is reported to be about 2.7 L/kg.[105] It is unclear if the volume of distribution changes with overdose.

Peak levels were determined in nonnaive human volunteers by administering intravenous, nasal, or smoked doses that were selected to produce approximately the same subjective peak effects.[105] The resultant peak levels were as follows: after intravenous injection of 20.5 mg, 180 Â± 56 ng/mL; after nasal administration of 95 mg, 220 Â± 39 ng/mL; and after smoking of 40 mg, 203 Â± 88 ng/mL. In this same study, the terminal

elimination half-life of cocaine was on the order of 1 hour.

TABLE 74-1. Pharmacology of Cocaine

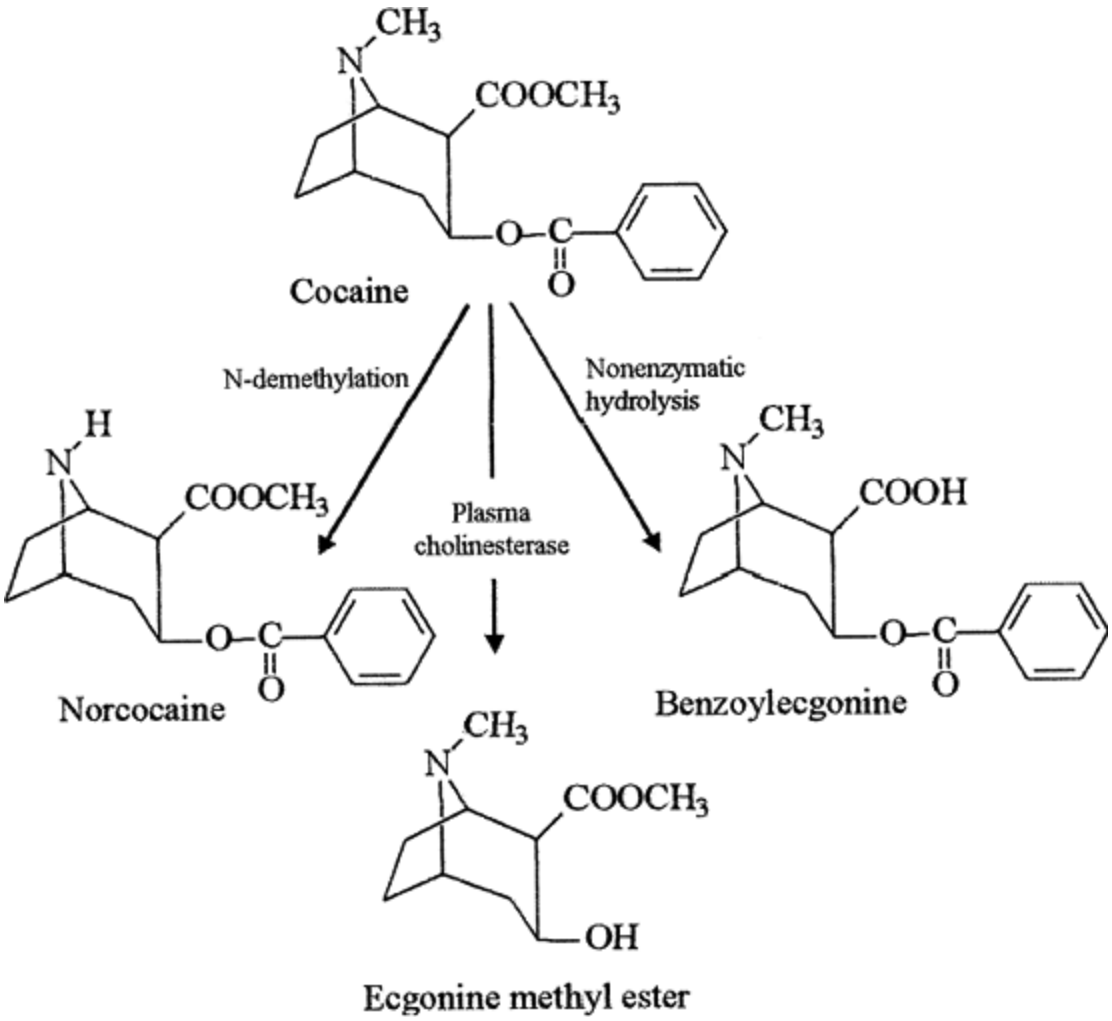

Figure 74-2. Metabolism of cocaine. The three principle metabolic pathways of cocaine are depicted.

The metabolism of cocaine is very complex and dependent on both genetic and acquired factors. Three major pathways of cocaine metabolism are well described (Fig. 74-2). Cocaine undergoes *N* -demethylation in the liver to form norcocaine, a minor metabolite that rarely accounts for more than 5% of drug.[101 , 129 , 212 , 213] However, norcocaine readily crosses the bloodâ€“brain barrier and produces clinical effects in animals that are quite similar to cocaine.[13 , 34 , 108 , 150 , 151 , 157 , 198 , 201 , 235] Nearly half of a

dose of cocaine is both nonenzymatically[213] and enzymatically hydrolyzed[39] to form benzoylecgonine (BE). In vitro, BE has little or no effect on cardiac sodium or potassium channels,[34 , 49] and when injected into animals, it is virtually inactive.[150 , 151 , 157 , 198 , 208] When either injected directly into the cerebral ventricles[151 , 201] or applied to the surface of cerebral arteries,[138] BE is a potent vasoconstrictor. These effects should not be discounted even though BE crosses the bloodâ€“brain barrier poorly in relationship to cocaine,[151] as some BE is probably formed from cocaine that has already entered the CNS. Other studies demonstrate that intravenous BE can produce cerebral vasoconstriction[32] and seizures.[117 , 150] Finally, plasma cholinesterase (PChE) and other esterases metabolize cocaine to ecgonine methyl ester (EME). In normal individuals, between 32 and 49% of a given dose of cocaine is metabolized to EME.[4 , 101] Like BE, EME crosses the bloodâ€“brain barrier poorly[151] and its biologic effects remain a source of debate. Although many authors accept that EME has little or no pharmacologic activity,[34 , 49 , 150 , 151 , 198] diverse animal models demonstrate contradictory results, concluding that EME is a vasodilator,[138 , 172 , 199] sedative, an anticonvulsant,[201] and protective metabolite against lethal doses of cocaine.[84]

The role of genetic or acquired alterations in PChE activity has been of interest for many years. Early in vitro studies showed that cocaine was poorly metabolized in isolated serum samples from patients with succinylcholine sensitivity (low PChE activity). Although these findings led many authors to speculate that patients with low PChE activity would be exquisitely sensitive to cocaine, evidence to support this contention lagged behind by more than 10 years. In several studies and case series, patients with low PChE activity demonstrate increased sensitivity to cocaine,[43 , 82 , 166] findings which are corroborated in multiple animal models.[20 , 21 , 83 , 136 , 147 , 214 , 239]

Multiple other metabolites of cocaine are well characterized.[30]

Some deserve mention because of their clinical or diagnostic importance. In 1990, a unique metabolite was identified in patients who smoke cocaine, which has subsequently come to be known either as anhydroecgonine methyl ester (AEME) or methylecgonide.[103] The presence of this compound and its metabolite, ecgonidine, can be used to help determine the route of administration in cocaine users. Additionally, AEME has demonstrable agonism at the muscarinic (M_2) receptors, which may have important clinical implications.

Ethanol has a unique pharmacologic interaction with cocaine. A transesterification reaction between the two drugs produces a unique agent, benzoylethylecgonine, which is also called ethyl cocaine or cocaethylene.[14] In human volunteers, given cocaine and ethanol, cocaethylene accounted for approximately 17% of the metabolites, producing a decrease in the amount of BE and an increase in the amount of EME formed.[73] Cocaethylene has a relatively long duration of action and like cocaine, it is neurotoxic, cardiotoxic, and dysrhythmogenic.

Pathophysiology

General Effects

Cocaine blocks the reuptake of biogenic amines. Specifically, these effects are described on serotonin and the catecholamines dopamine, norepinephrine and epinephrine. Several innovative animal investigations have helped to elucidate the particular roles of each neurotransmitter. Mice lacking the dopamine transporter are relatively insensitive to the locomotor effects of cocaine.[61] Tachycardia emanates from adrenally derived epinephrine, whereas hypertension results from neuronally derived norepinephrine.[218 , 219] Serotonin is an important modulator of dopamine and has a role in cocaine addiction and reward and seizures.[71 , 127 , 146 , 163]

Whereas much emphasis has been placed on the reuptake blockade of these biogenic amines, it is clear that this effect is insufficient to account for the clinical manifestations of cocaine toxicity. First, other xenobiotics that block the reuptake of biogenic amines, such as cyclic antidepressants, produce quite distinct clinical manifestations (Chap. 71).[219] Also, xenobiotics that block the effects of dopamine, epinephrine, and norepinephrine not only fail to protect against toxicity, they actually exacerbate it.[24 , 67 , 122 , 194] Although this may, in part, result from an unopposed Î±-adrenergic effect, hypertension and vasospasm fail to explain the increase in psychomotor agitation, hyperthermia, and seizures that result.[24 , 67] These effects most likely result from an interaction between cocaine and excitatory amino acids. Cocaine increases excitatory amino acid concentrations in the brain.[207] Excitatory amino acid antagonists prevent both seizures and death in experimental animals.[15 , 185] Finally, because experimental evidence in animals[24 , 67 , 202] and clinical experience in humans demonstrate that sedation treats both the central effects of cocaine and the peripheral effects of biogenic amines, a newer model was proposed (Fig. 74-3). This model emphasizes the necessity of diffuse central nervous system agitation as a prerequisite for cocaine toxicity, explains experimental and clinical observations, and provides insight into a pharmacologic approach to acute toxicity.

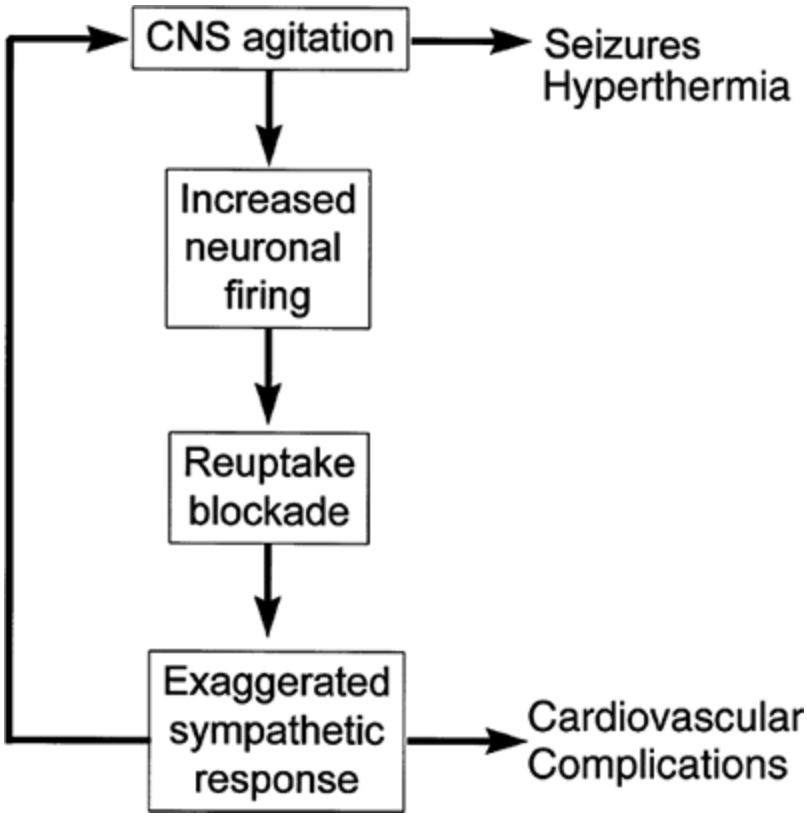

Figure 74-3. Cocaine-induced CNS effects modulate peripheral events.

Specific Organ System Effects

Atherogenesis, Coagulation, and Ischemic Cardiac Events

Cocaine use is associated with cardiac ischemia and infarction in young people, and may account for as much as 25% of myocardial infarctions in patients younger than 45 years old.[181] One simple mechanisms is that hypertension and tachycardia increase myocardial oxygen demand. Although this may be sufficient in some individuals, it is clear that cocaine also produces profound vasoconstriction. Although evidence suggests that cocaine-induced

vasoconstriction is mediated through neuronal norepineprhine,[123, 137] benzoylecgonine has a direct effect on vessels that appears to be calcium mediated.[137] The simultaneous use of nicotine (common in substance users) has additive, if not synergistic, effects with cocaine.[156] Additional contributory factors include effects on atherogenesis and coagulation.

Rabbits fed a normal diet do not develop atherosclerotic vascular disease. However, when that diet includes cocaine and cholesterol, rabbits develop classic atherosclerotic lesions.[115, 125, 126] Experiments with human endothelial cells demonstrate that cocaine directly increases the permeability to lipids by altering tight junctions.[116] This probably promotes the formation of subendothelial atherosclerotic plaques.

Enhanced coagulation and impaired thrombolysis compound the effects of accelerated atherogenesis and vasospasm. In both in vitro and in vivo experiments, cocaine activates human platelets and causes Î±-granule release, resulting in platelet aggregation.[76, 121] Thus even in the absence of endothelial injury, cocaine can initiate a thrombotic cascade while simultaneously enhancing the activity of plasminogen activator inhibitor type 1 (PAI-1), thereby impairing clot lysis.[155]

It is reasonable, although unstudied, to assume that any or all of these effects described in the cardiovascular system can produce ischemia or infarction in other tissues as well (see Clinical Manifestations below).

Dysrhythmias

Like other local anesthetics (Chap. 64) cocaine blocks neuronal sodium channels, thereby preventing saltatory conduction. Because of homology between neuronal and cardiac sodium channels, cocaine also inhibits the rapid inward Na^+ current responsible for phase 0 depolarization of the cardiac action potential (Chaps. 5 , 23 , and 71). Experimental evidence

suggests that cocaine enters the sodium channel and binds on the inner membrane.[34, 114, 180] Like many sodium channel-blockers, binding is both pH and use dependent (ie, binding increases as pH falls or heart rate increases; Chap. 61).[35, 229] Furthermore, although norcocaine has a greater affinity for inactivated sodium channels, it has a much more rapid offset of action than cocaine.[34] Consequently, cocaine can be characterized as a Vaughn-Williams type I antidysrhythmic agent (Chap. 61). Cocaine-induced QRS prolongation, as might be expected, is exacerbated by Vaughn-Williams type IA antidysrhythmic agents,[236] and ameliorated by lidocaine or hypertonic sodium bicarbonate.[8, 66, 173] Another effect of sodium channel blockade, the Brugada pattern, is also associated with cocaine use.[134, 168] In addition to its sodium channel-blocking properties, cocaine also blocks cardiac potassium channels (Chaps. 5 and 23). This results in QTc prolongation[177, 217, 229] and even can produce torsade de pointes.[200]

Pulmonary

Despite what is now well accepted as an association between cocaine use and asthma,[187] this relationship was not recognized until smoked cocaine became prevalent.[47] Furthermore, experiments in human volunteers demonstrate that only smoked cocaine (not intravenous cocaine) produces bronchospasm.[216] Although it is possible that bronchospasm results from direct administration of cocaine to the airways, inhaled contaminants of cocaine, or thermal insult, AEME (the unique pyrolytic metabolite of cocaine that acts as a muscarinic agonist) produces bronchospasm in experimental animals.[26]

Clinical Manifestations

Many clinical manifestations of toxicity develop immediately following cocaine use. These are typically associated with the sympathetic overactivity and their duration of effect is predictable

based on the pharmacokinetics of cocaine use. Other manifestations, such as those associated with tissue ischemia, may present in a delayed fashion, with a clinical latency of hours to even days after last cocaine use. The reasons for this delay are not entirely apparent but may relate to anesthesia and an altered sensorium associated with acute cocaine use, changes in receptor regulation,[159] or affects on platelets, coagulation, and thrombolysis, which incite a slow cascade leading to thrombosis.

Vital sign abnormalities that develop during cocaine toxicity are characteristic of the sympathomimetic toxidrome. Thus, varying degrees of hypertension, tachycardia, tachypnea, and hyperthermia occur. Although any of these vital signs can be life-threatening, experimental and clinical evidence suggests that hyperthermia is the most critical.[24,67,143] Initially, with typically used doses, and at any time with a massive dose, apnea, hypotension, and bradycardia can result, all from direct suppression (anesthesia) of brainstem centers.[113,148] These effects are fleeting and rarely noted when patients present to healthcare as either the sympathetic overdrive rapidly ensues, or sudden death results. Additional sympathomimetic findings include mydriasis, diaphoresis, and neuropsychiatric manifestations.

Cocaine produces end-organ toxicity in virtually every organ system in the body. These events result from vasospasm, hemorrhage secondary to increased vascular sheer force (dP/dT), or enhanced coagulation. Each organ system is discussed separately in the following sections.

Central Nervous System

Seizures, coma, headache, focal neurologic signs or symptoms, or behavioral abnormalities that persist longer than the predicted duration of effect of cocaine should alert the clinician to a potential catastrophic adverse CNS event. Hemorrhage can occur

at any anatomic site in the CNS. Subarachnoid, intraventricular, and intraparenchymal bleeding are all well described in association with cocaine use.[37, 130, 142, 182, 203] Although the early discussions suggested that patients with these events were predisposed because of the presence of arteriovenous malformations or congenital aneurysms,[238] subsequent larger studies failed to support this analysis, suggesting that effects can occur independently of preexisting disease.[2, 161] Presumably CNS bleeding is simply a manifestation of abnormal sheer force. Spontaneous extraaxial bleeding is also associated with cocaine use.[193]

Both vasospastic (bland) infarction and transient ischemic attack (TIA) are also reported in association with cocaine use.[37, 38, 130] In one epidemiologic study, women younger than age 45 years who had strokes were 7 times more likely to report cocaine use than controls.[178] Patients can present with any of the classic physical findings associated with thrombotic or embolic stroke. Although these initial clinical symptoms may resemble hemorrhagic infarction, the pathophysiology is distinct. Vasospasm can also produce consequential injury to the spinal cord, resulting in paralysis from an anterior spinal artery syndrome.[37, 154]

Seizures are commonly provoked by cocaine.[87, 158] Although an underlying seizure focus is not a prerequisite, it is clear that cocaine use can serve as a trigger in patients with epilepsy.[118]

Headache is also well described in cocaine users. While the exact mechanism is unclear, hypertension, vasospasm, or dysregulated neurotransmitters might all be contributory. In addition to typical tension headache, classic migraine and cluster headaches are also reported.[176, 195]

Eyes, Nose, and Throat

Sympathetic excess produces mydriasis through stimulation of the

dilator fibers of the iris. Although often quite large, these pupils characteristically retain their ability to respond to light. Like other mydriatics, cocaine can produce acute angle closure glaucoma.[72] Vasospasm of the retinal vessels can produce both unilateral and bilateral loss of vision.[85, 132] Additionally, although cocaine produces excellent corneal anesthesia, it is highly toxic to the corneal epithelium. Following both intentional and unintentional application of cocaine to the eye, the superficial corneal layer is shed, resulting in pain and decreased acuity.[183] This technique was formerly used as a therapeutic modality for the removal of retained foreign bodies. The loss of eyebrow and eyelash hair from thermal injury associated with smoking crack cocaine is called madarosis.[215]

Chronic cocaine use can produce perforation of the nasal septum. This finding most likely results from repeated ischemic injury with resultant tissue loss. Although this ischemia is usually asymptomatic and necrotic tissue is sloughed, at least 1 case of wound botulism (Chap. 46) presumably resulted from the accumulation of necrotic tissue in the nose, which served as a culture medium for *Clostridia botulinum* .[120]

Angioedema and oropharyngeal burns are associated with smoking crack cocaine.[22, 111, 149] Even esophageal burns are associated with cocaine use.[27] These effects are mostly likely the result of either inhaling or swallowing superheated fumes or hot liquid (from the smoking apparatus) rather than direct toxicity from cocaine.

Pulmonary

Pneumothorax, pneumomediastinum, and pneumopericardium are reported following both intranasal cocaine use and smoking crack.[139, 196, 221, 225] These findings do not represent direct drug toxicity per se; rather, they are epiphenomenon related to the mechanism of drug use. Following insufflation or inhalation,

the user performs a classic Valsalva maneuver in an attempt not to release the drug. Bearing down against a closed epiglottis increases intrathoracic pressure and an alveolar bleb ruptures against the pleural, mediastinal or pericardial surfaces.

Cocaine use exacerbates reversible airway disease and it is common for patients to present with shortness of breath and wheezing.[47 , 169 , 187 , 188] Like so many manifestations of cocaine toxicity, it is unclear whether this is a direct effect of cocaine or related to inhalation of some contaminant of the drug. However, as discussed above, the muscarinic (M2) agonistic effects of the pyrolysis metabolite AEME might be contributory. Another cause for cough and shortness of breath has been termed crack lung, which refers to hemorrhagic alveolitis resulting from cocaine use.[55 , 112] Although hemorrhagic alveolitis may be related to pulmonary hypertension, the presence of fever, elevated IgE, and a clinical response to corticosteroids suggests a possible immune-mediated illness.

Vasospasm and subsequent thrombosis of the pulmonary artery or its branches can produce pulmonary infarction.[40] Patients present with shortness of breath and pleuritic chest pain characteristic of a pulmonary embolus. Clinical signs and symptoms of ventilationâ€“perfusion (V/Q) mismatch (Chap. 22), as well as abnormalities on arterial blood gas analysis, are noted.

Cardiovascular

Chest pain or discomfort is a common emergency department complaint in cocaine users.[17] Although myocardial infarction is a common concern, only approximately 5% of patients with complaints referable to the heart will manifest biochemical evidence of myocardial injury.[92 , 230] Many will have an ischemic cardiac event, but for the remainder the differential diagnosis is broad.[124] Entities to consider include the pulmonary and esophageal etiologies described above, referred abdominal

symptoms (see Abdominal below), chest wall injury,[64] aortic dissection,[100, 131, 171, 184] coronary artery dissection,[11, 211] and dysrhythmia. No single sign or symptom or combination of signs and symptoms reliably identifies cardiovascular injury from among the discussed differential diagnosis.[92]

Chronic cocaine use is associated with a dilated cardiomyopathy,[78, 124, 167, 233] the etiology of which is presumed to be the result of repeated subclinical ischemic events. Patients may present with signs and symptoms of congestive heart failure or pulmonary edema. The pathologic finding of contraction band necrosis also suggests that there may be some direct catecholamine toxicity as this finding only commonly occurs with cocaine and amphetamine use, pheochromocytoma, and in patients receiving high-dose vasopressor agents.[52, 228]

Abdominal

Abdominal pain, or other gastrointestinal complaints also suggest a broad differential diagnosis. Cocaine users have a disproportionate incidence of perforated ulcers.[128, 175, 205] The etiology has not been elucidated, but may be related to local ischemia of the gastrointestinal tract or increased acid production associated with sympathetic activity. Vasospasm produces ischemic colitis that can present with abdominal pain or bloody stools.[133, 160] More severe or

persistent vasospasm, with or without thrombosis, can lead to intestinal infarction[58, 79, 97, 170] with attendant hypotension and metabolic acidosis. Signs and symptoms of bowel obstruction such as vomiting or distension might suggest body packing (gastrointestinal drug smuggling). Although less common, splenic[42, 162] and renal infarctions[44, 152, 192] may also occur. Spontaneous hemoperitoneum was also reported, although occult trauma could not be definitively excluded.[9]

Animals frequently develop hepatotoxicity following cocaine administration. In human cocaine users, minor abnormalities of liver enzymes are common and rarely associated with symptoms.[119] When more severe liver injury occurs, it is usually associated with multisystem organ dysfunction from hyperthermia or another injury.[5] Isolated hepatic injury from cocaine is distinctly uncommon and may result from differences in metabolic pathways, as animals are known to make a hepatotoxic metabolite of cocaine that has not been described in humans.[227]

Musculoskeletal

Rhabdomyolysis is common in all conditions that produce an agitated delirium with or without associated hyperthermia, and cocaine is no exception.[31 , 99 , 190] Unlike most other toxicologic disorders, however, psychomotor agitation is not a prerequisite for cocaine-associated rhabdomyolysis.[241] Muscle injury may result from vasospasm or some yet-to-be-described direct muscle toxin. Patients with cocaine toxicity can present with a spectrum of illness that ranges from asymptomatic enzyme and electrolyte abnormalities characteristic of rhabdomyolysis, to localized or diffuse muscle pain, to frank compartment syndrome and renal failure.[45 , 53]

Traumatic injury is also fairly common in the setting of cocaine use. Clinicians should be aware of the possibilities of occult fractures or other injuries that may be masked by the anesthetic properties of cocaine.[144 , 145]

Neuropsychiatric

The neuropsychiatric effects of cocaine are most likely dose dependent. Low-dose administration produces alertness, exhilaration, hypersexual behavior, and other â€œdesiredâ€• effects. These effects rarely bring users to healthcare facilities. As

the cocaine dose increases, agitation, aggressive behavior, confusion, disorientation, and hallucinations can develop.

Other possible manifestations include a variety of movement disorders that most likely result from depletion or dysregulation of dopamine. Patients may develop acute dystonias[23, 50, 226] or choreoathetoid movements that are also termed crack-dancing. Following binge use of cocaine, a â€œwashed-outâ€• syndrome occurs that is best described by dopamine depletion.[210, 222] Patients complain of anhedonia, want to sleep, and have trouble initiating and sustaining movement. However, they are arousable with minimal stimulation and usually remain cognitively intact.

Laboratory Assay Specimen BE Cocaine Cut-Off Value

TABLE 74-2. Laboratory Assays for Cocaine and Benzoylecgonine (BE)

Obstetrical

The majority of obstetrical findings associated with cocaine use involve developmental issues in the fetus and newborn that probably result from a combination of chronic vascular insufficiency from cocaine-induced spasm of the uterine artery or distal vessels and other risk factors, such as poor maternal nutrition, cigarette smoking, and a lack of prenatal care. These events are extensively reviewed elsewhere.[25 , 48 , 179] Acute cocaine use during pregnancy is associated with abruptio placentae, causing patients to present with abdominal pain and vaginal bleeding.[1 , 54] The remaining maternal and fetal complications comprise every possible complication described in nonpregnant patients.

Diagnostic Testing

Cocaine and benzoylecgonine, its principle metabolite, can be detected in blood, urine, saliva, hair, and meconium. Routine

drug-of-abuse testing relies on urine testing using a variety of immunologic techniques (Chap. 7). Although cocaine is rapidly eliminated within just a few hours of use, benzoylecgonine is easily detected in the urine for 2â€“3 days following last use.[4] When more sophisticated testing methodology is applied to chronic users, cocaine metabolites can be identified for several weeks following last use.[232] Table 74-2 lists a variety of methods used to identify cocaine and BE, as well as their cut-off values.

Urine testing, even using rapid point-of-care assays, offers little to clinicians managing patients with presumed cocaine toxicity because it cannot distinguish recent from remote cocaine use. In addition, whereas a negative test usually excludes cocaine use, false-negative testing can result either when there is a large quantity of urine in the bladder and the cocaine use was very recent or when the urine was intentionally diluted by increased fluid intake.[29] Regardless of the cause, although there is cocaine in the urine, its urine concentration is below the cut-off value for the test, and therefore interpreted as negative. Under these circumstances, repeat testing is almost always positive. While false-positive tests do occur, they are more common with hair testing than urine or blood because of the increased risk of external contamination.[29 , 186] Because of the very low rate of false-positive results, confirmation of a positive urine is unnecessary for medical indications (Chap. 7).

The greatest usefulness for cocaine testing is in cases of unintentional poisoning or suspected child abuse and neglect. Here

confirmation of a clinical suspicion is essential to support a legal argument. In addition, there may be some usefulness for urine testing of body packers, especially when the concealed substance is unknown.[223] While many body packers will have negative urine throughout their hospitalization, a positive urine test is suggestive of the concealed drug, and possibly more importantly, a conversion from a negative study on admission to a positive study

not only confirms the substance ingested, but also suggests packet leakage, which could be a harbinger of life-threatening toxicity. Another indication for urine testing for cocaine occurs in young patients with chest pain syndromes where the history of drug use is not forthcoming.[88]

Routine diagnostic tests such as a bedside rapid reagent glucose, electrolytes, renal function tests, and markers of muscle and cardiac muscle injury are more likely to be useful than urine drug testing. An ECG may show signs of ischemia or infarction, or dysrhythmias that require specific therapy. However, in the setting of cocaine-associated chest pain, the ECG has neither the sensitivity nor the specificity necessary to permit exclusion or confirmation of cardiac injury.[95] Cardiac markers are therefore always required adjuncts when considering myocardial ischemia or infarction. Because cocaine use is associated with diffuse muscle injury, assays for troponin are preferred over myoglobin or myocardial band enzymes of creatine phosphokinase (CPK-MB).[94] Additionally, a chest radiograph may be useful to exclude certain etiologies in patients with chest discomfort, or to identify free air under the diaphragm when gastrointestinal perforation is suspected. Supplemental diagnostic studies, such as CT scans of the head, chest, or abdomen and functional cardiac imaging, should be guided by the clinical condition of the patient.

Management

General Supportive Care

As in the case of all poisoned patients, the initial emphasis must be on stabilization and control of the patient's airway, breathing, and circulation. If tracheal intubation is required, it is important to recognize that cocaine toxicity may be a relative contraindication to the use of succinylcholine. Specifically, in the setting of rhabdomyolysis, hyperkalemia may be exacerbated by

succinylcholine administration, and life-threatening dysrhythmias may result (Chap. 66). Additionally, it is essential to recognize that PChE metabolizes both cocaine and succinylcholine.[104] Thus their simultaneous use could either prolong cocaine toxicity or paralysis, or both. Human data are insufficient to predict which interaction is more likely to occur. If hypotension is present, the initial approach should be an intravenous bolus of 0.9% sodium chloride solution as many patients are volume depleted as a result of poor oral intake and excessive fluid losses from uncontrolled agitation, diaphoresis, and hyperthermia.

In the setting of cocaine toxicity it is important to recognize that both animal[24 , 67] and human[143] experience suggests that hyperthermia is a critical vital sign abnormality, such that a determination of the core temperature is an essential element of the initial evaluation, even when patients are severely agitated. When hyperthermia is present, immediate rapid cooling with ice water immersion, or the combined use of mist and fan, is required to achieve a rapid return to normal core body temperature (Chap. 16). It may be necessary to sedate or paralyze and intubate the patient in order to facilitate the rapid cooling process. Pharmacotherapy including antipyretics (acetaminophen or salicylates), drugs that prevent shivering (chlorpromazine or meperidine), and dantrolene[56] are not indicated as they are inefficient or ineffective and have the potential for adverse drug interactions.

Sedation remains the mainstay of therapy in patients with cocaine-associated agitation. It is important to remember that cocaine use is associated with hypoglycemia and that many of the peripheral findings of hypoglycemia are the result of a catecholamine discharge.[16 , 153] Consequently, a rapid reagent glucose test should be obtained, or hypertonic dextrose should be empirically administered if indicated, prior to or while simultaneously achieving sedation. Both animal models[24 , 67] and extensive clinical experience in humans support the central role of

benzodiazepines. Although the choice among individual benzodiazepines is not well studied, an understanding of the pharmacology of these drugs allows for rational decision making. The goal is to use parenteral therapy with a drug that has a rapid onset and a rapid peak of action, making titration easy. Using this rationale, midazolam and diazepam are preferable to lorazepam, because lorazepam's significant delay to peak effect often results in oversedation when it is dosed rapidly, or in prolonged agitation when the appropriate dosing interval is used. Drugs should be administered in initial doses that are consistent with routine practices and increased incrementally based on an appropriate understanding of their pharmacology. For example, if using diazepam, the starting dose might be 5â€“10 mg, which can be repeated every 3â€“5 minutes and increased if necessary. Large doses of benzodiazepines may be necessary (on the order of 1 mg/kg of diazepam). This may result from cocaine-induced alterations in benzodiazepine receptor function.[62 , 63 , 107]

On the rare occasion when benzodiazepines fail to achieve an adequate level of sedation, either a rapidly acting barbiturate or propofol should be administered. Controlled animal experience clearly contraindicates the use of phenothiazines and butyrophenones.[24 , 67 , 237] In animal models, these drugs enhance toxicity (seizures) or lethality, or both. Additional concerns regarding these drugs include their ability to interfere with heat dissipation, exacerbate tachycardia, prolong the QTc interval, and induce torsades de pointes, or precipitate dystonic reactions.

Once sedation is accomplished, often no further therapy is required. Specifically, hypertension and tachycardia usually respond to sedation and volume resuscitation. In the uncommon event that hypertension and or tachycardia persist, the use of a Î²-adrenergic antagonist or a mixed Î±- and Î²-adrenergic antagonist is absolutely contraindicated. Again, in both animal models and human reports, these drugs increase lethality and fail

to treat the underlying problem.[12 , 24 , 67 , 122 , 194] The resultant unopposed Î±-adrenergic effect may produce severe and life-threatening hypertension or vasospasm. A direct-acting vasodilator like nitroglycerin or nitroprusside or an Î±-adrenergic antagonist (such as phentolamine) may be considered. Other nonspecific therapies for rhabdomyolysis should be considered.

Decontamination

The majority of patients who present to the hospital following cocaine use will require no gastrointestinal decontamination as the most popular methods of cocaine use are smoking and intravenous and intranasal administration. If the nares contain residual white powder presumed to be cocaine, gentle irrigation with 0.9% sodium chloride solution will help remove adherent material. Less commonly, patients may ingest cocaine in an attempt to conceal evidence during an arrest (body stuffing) or transport large quantities

of drug across international borders (body packing). These patients may require intensive decontamination, possibly including surgery.

Specific Management

End-organ manifestations of vasospasm that do not resolve with sedation, cooling, and volume resuscitation should be treated with a vasodilator (such as phentolamine). When possible it is preferable to deliver direct intraarterial administration into the affected vascular bed. Because this approach is not always feasible, systemic therapy is indicated. Phentolamine can be dosed intravenously in increments of 1â€“2.5 mg, repeated as necessary until symptoms resolve or systemic hypotension develops.

Acute Coronary Syndrome

A significant amount of animal, in vitro, and in vivo human experimentation has been directed at defining the appropriate approach to a patient with presumed cardiac ischemia or infarction. In some instances an approach that is similar to the treatment of atherosclerotic heart disease (ASHD) is indicated, although there are certain notable exceptions. An overall approach to care is available in the American Heart Association guidelines and a number of reviews.[3 , 96 , 124]

High-flow oxygen therapy is clearly indicated as it may help overcome some of the supplyâ€“demand mismatch that occurs with coronary insufficiency. Likewise, based on experience with ASHD and given that cocaine induces platelet aggregation, it is reasonable to administer aspirin. In addition, there is probably a role for administration of morphine as it has been directly demonstrated to relieve cocaine-induced vasoconstriction[191] and offers the same theoretical benefits of preload reduction and reduction of catecholamine release in response to pain that provides its advantage in patients with ASHD.

At this point, the treatment of patients with cocaine-induced chest pain begins to deviate from the standard accepted approach to patients with ASHD. Nitroglycerin is clearly beneficial in that it reduces cocaine-induced coronary constriction of both normal and diseased vessels and relieves chest pain and associated symptoms in patients with cocaine-associated chest pain.[18 , 91] However, in several clinical trials, benzodiazepines are at least as effective or superior to nitroglycerin.[7 , 98] Although the reasons for this are unclear, possible etiologies include blunting of central catecholamines or direct effects on cardiac benzodiazepine receptors. Either or both drugs can be used in standard dosing.

Over the last decade, the benefits of Î²-adrenergic antagonism are continually demonstrated in patients with ASHD. In contrast, Î²-adrenergic antagonism increases lethality in cocaine-toxic

animals[24,67] and in humans, exacerbates cocaine-induced coronary vasoconstriction,[122] and produces severe paradoxical hypertension.[194] Similarly, with regard to coronary constriction, labetalol is no better than placebo.[12] Thus in the setting of cocaine use, Î²-adrenergic antagonism is absolutely contraindicated. If, after the measures mentioned above have been initiated, hypertension or vasospasm is still present and treatment is indicated, phentolamine is preferred based on its demonstrable experimental and clinical results.[90,123] If tachycardia does not respond to accepted therapies above, then a small dose of a diltiazem can be administered and titrated to effect.[10] Prior to administering any drug with strong negative inotropy, it is essential to confirm that the tachycardia is not compensatory for a low cardiac output that results from global myocardial dysfunction. Noninvasive methods of assessment of cardiac function have been used successfully in patients with cocaine-related acute coronary syndromes.[6]

There are no data on the use of either unfractionated or low-molecular-weight heparins, glycoprotein IIb/IIIa inhibitors, or clopidogrel. The decision whether or not to use any of these agents should be based on a risk-to-benefit analysis with a consideration of whether the patient might have underlying atherosclerotic heart disease. When acute thrombosis is likely, thrombolytic therapy should be considered. Mechanistically, cocaine inhibits endogenous thrombolysis through augmentation of the inhibitor of tissue plasminogen activator. Additionally, there is sufficient clinical evidence to support the safety of thrombolytic therapy in patients with cocaine-associated myocardial infarction.[81,89] Even though the number of patients treated with thrombolytic therapy is insufficient to demonstrate efficacy in terms of mortality, evidence of revascularization is encouraging. Similar to patients with ASHD, it is preferable to provide a mechanical approach to revascularization, especially given that spasm may be a fairly common etiology of cocaine-induced

infarction.[204] When cardiac catheterization facilities are unavailable, thrombolysis is an acceptable alternative, given contraindications such as persistent hypertension, dissection, trauma, and altered mental status have been addressed.

Dysrhythmias

Most patients present with sinus tachycardia that resolves following sedation, cooling, rehydration, and time to metabolize the drug. Similarly, other dysrhythmias should also be treated with benzodiazepines, cooling, and rehydration as they will often spontaneously revert because of the short duration of effect of cocaine. However, cocaine use is associated with atrial, supraventricular, and ventricular dysrhythmias, some of which may require additional pharmacotherapy.[102 , 124] Even torsades de pointes is reported.[200] Most notably, wide complex tachycardias result from sodium channel blockade. When approaching patients with cocaine-associated dysrhythmias, there are several important points to consider. The first is that Î²-adrenergic antagonism is absolutely contraindicated. Furthermore, classic types IA and IC antidysrhythmics are also contraindicated because of their ability to exacerbate cocaine-induced sodium and potassium channel blockade.[124 , 236] Additionally, although popular in many advanced cardiac life support dysrhythmia algorithms, the effects of amiodarone are largely unknown in the setting of cocaine toxicity. Because of the lack of data demonstrating a benefit for amiodarone, and because of concerns about its Î²-adrenergic antagonist effects, the use of this drug cannot be recommended. At this time finally, although adenosine and synchronized cardioversion may transiently help convert narrow complex tachycardias, if a substantial amount of cocaine is not metabolized, the patient will likely revert back to his or her original rhythm as these therapeutic interventions have short durations of effect. Thus for rapid atrial fibrillation and narrow complex reentrant tachycardias, a calcium channel blocker such as

diltiazem is preferred. For wide-complex dysrhythmias a trial of hypertonic sodium bicarbonate has demonstrable usefulness analogous to treating patients with tricyclic antidepressant overdose (see Antidotes in Depth: Sodium Bicarbonate).[110 , 173 , 229 , 236] When the use of hypertonic sodium bicarbonate fails to treat the dysrhythmia, lidocaine can be used. Although lidocaine blocks sodium channels, its fast-on, fast-off properties allow it to antagonize the effects of cocaine. The benefits and safety of lidocaine were demonstrated in multiple animal models[77 , 236] and in humans with cocaine-associated myocardial infarction.[206]

Disposition

Patients who present to healthcare facilities with classic sympathomimetic signs and symptoms that resolve spontaneously or with minimal sedation and no signs of end-organ damage can be safely discharged after short periods of observation. Once hyperthermia, rhabdomyolysis, or other signs of end-organ damage are evident, hospital admission is usually required.

For patients with chest pain, a specific management algorithm has been derived based on substantial clinical experience. Those patients with clearly diagnostic or evolving ECGs suggestive of ischemia or infarction, positive cardiac markers, dysrhythmias other than sinus tachycardia, congestive heart failure, or persistent pain require admission. Patients who become pain free and whose ECGs are stable are candidates for discharge if a single cardiac marker obtained at least 8 hours after the onset of chest pain is negative.[231] For all patients it is essential to provide a referral for detoxification, as repeated cocaine use is the greatest risk factor for future cardiovascular complications.[93 , 231]

Special Situations: Body Packers and

Body Stuffers

Cocaine body stuffers ingest drug in an attempt to avoid detection or prosecution. The drug is normally unwrapped or wrapped for transport, and therefore often readily available for gastrointestinal absorption. Although detection may be possible using diagnostic imaging studies,[33, 80] the sensitivity and specificity are presumed to be poor.[46, 81] If symptoms of cocaine toxicity develop, they are usually manifest within a few hours of ingestion,[209] although the onset of toxicity may be more delayed with crack-vial ingestion.[80] Although it is generally accepted that life-threatening toxicity is uncommon as a result of delayed and incomplete absorption of a relatively small dose, serious toxicity and death are reported.[51, 75, 106, 141, 168]

Decontamination with multiple-dose oral activated charcoal therapy should be sufficient in most cases as cocaine is very well adsorbed to activated charcoal.[140] Whole-bowel irrigation (WBI) with polyethylene glycol electrolyte lavage solution (PEG-ELS) can also be considered. Clinical toxicity should be managed as described above.

In contrast, body packers ingest large amounts (often 0.5â€“1 kg) of well-wrapped drug in an attempt to smuggle cocaine across international borders. Although rigorous data are not available, the majority of these packets do not open. However, when they rupture, the amount of drug per packet exceeds the lethal dose of cocaine, and numerous fatalities are reported.[60] The assessment and management of body packers has been extensively reviewed.[223] The presence of mechanical bowel obstruction or *any* sign of packet rupture is considered an absolute indication for surgery. In asymptomatic patients, WBI with PEG-ELS is initiated and dosed in a standard fashion (see Antidotes in Depth: Whole-Bowel Irrigation and Other Intestinal Evacuants). Single- or multiple-dose activated charcoal therapy may also be considered. Although it may be beneficial to have activated charcoal in the gut

should a packet rupture, activated charcoal can be detrimental if it spills into the peritoneal cavity during surgery. These relative risks and benefits should be assessed in each patient.

Although plain abdominal radiography may underestimate the number of packets present, it is usually positive initially, and can be used sequentially to assess the efficacy of WBI. Often patients will require antiemetics and or promotility agents to facilitate WBI.[224]

When plain abdominal radiography is negative, a confirmatory study, such as oral contrast abdominal radiography or an oral contrast-enhanced CT scan, should be ordered.[86] Because these diagnostic imaging studies are not infallible,[70] it is generally prudent to feed and observe the patient for 24 hours after the chosen study is negative. Figure 74-4 presents an algorithm to help clarify these issues.

Summary

Cocaine is a unique drug that combines local anesthetic, vasoconstrictive, and neuropsychiatric properties. Although its legitimate pharmaceutical use has diminished because of its high abuse potential, it remains a prevalent recreational drug of abuse. Cocaine produces the prototypical agitated delirium that

characterizes the sympathomimetic toxic syndrome. Most patients can be treated with sedation and cooling, but others require more intensive individualized care. The most essential and difficult aspect of care is providing access to programs that support cocaine detoxification.

Chapter 75
Ethanol

Luke Yip

A 44-year-old man was found comatose in a homeless shelter. The paramedics were told that the patient had a long history of alcoholism and that he was drinking heavily until 1â€“2 days prior to coming to the shelter. Since then the patient had repeated bouts of vomiting and no significant oral intake. The initial assessment by the paramedics was notable for: blood pressure, 100/72 mm Hg; pulse, 120 beats/min; respiratory rate, 32 breaths/min. The patient was placed on high-flow oxygen, an intravenous (IV) line was inserted with 0.9% NaCl solution infused at 150 mL/h, and blood samples were obtained for analysis. The patient was given 2 mg of naloxone, 25 g of dextrose, and 100 mg of thiamine IV without clinical response, and was transported to the emergency department (ED).

On arrival at the ED, the patient's vital signs were unchanged from the prehospital values; his rectal temperature was 100.4Â°F (38Â°C) and pulse oximetry was 100% on high-flow oxygen. His head was atraumatic, sclera were anicteric, and his pupils were 3 mm in size, equal, round, and reactive to light, with a normal funduscopic

examination. His mucous membranes were dry, and his gag reflex was present. There was no characteristic odor to the patient's breath. There was no meningismus. Chest and abdominal examinations were normal except for a liver edge, which was palpable 3 finger breadths below the costal margin. Rectal tone was normal, stool was dark and negative for occult blood, and there was no bowel or bladder incontinence. The patient was comatose, and the remainder of the neurologic examination was nonfocal.

A rapid bedside glucose test was 120 mg/dL. His ECG revealed a sinus tachycardia with normal intervals and without ectopy. A portable chest radiograph showed haziness over both lung bases. A complete blood cell count (CBC) revealed a leukocytosis, 16,000/mm^3, without a left shift; hematocrit, 52%; platelets, 150,000/mm^3. Blood chemistries were remarkable for sodium, 148 mEq/L; potassium, 2.9 mEq/L; chloride, 108 mEq/L; bicarbonate, 9 mEq/L; glucose, 130 mg/dL; BUN, 50 mg/dL; creatinine, 1.6 mg/dL; aspartate aminotransferase (AST), 168 U/L; alanine aminotransferase (ALT), 80 U/L; and an elevated Î³-glutamyl transpeptidase (GGTP) and alkaline phosphatase. The serum lactate was 2.2 mEq/L (0.6â€“1.7 mEq/L). The prothrombin and partial thromboplastin times, serum lipase, and serum ammonia were normal. Blood ethanol concentration was undetectable. Urinalysis was remarkable for a specific gravity of 1.030, 1â€“2 (+) ketones, and no crystals. His arterial blood gas was remarkable for: pH, 7.08; PCO_2, 12 mm Hg; and PO_2, 110 mm Hg.

The intravenous fluid was changed to dextrose 5% in 0.9% sodium chloride solution (D_5NS) with supplemental potassium, thiamine, folate, and multivitamins. Intravenous ceftriaxone 2 g and gentamicin 490 mg were administered for a presumed aspiration pneumonitis. The patient was given an intravenous loading dose of ethanol followed by an ethanol infusion, while investigations focused on the patient's altered mental status and anion gap metabolic acidosis. A CT scan of the patient's head was remarkable for cerebral atrophy. Analysis of the cerebrospinal fluid from a lumbar puncture

was unremarkable, and specimens were sent for cultures. Investigation into the causes of an anion gap metabolic acidosis was unrewarding (Chaps. 17 and 103). The patient was admitted to the intensive care unit where hemodialysis was performed because of persistent acidâ€“base derangement in spite of supportive care. The patient made a gradual recovery. The patient's blood was later confirmed to be negative for a toxic alcohol as well as formate and glycolate, suggesting the probable diagnosis of alcoholic ketoacidosis.

History and Epidemiology

Ethanol, or ethyl alcohol, is commonly referred to as alcohol. This term is somewhat misleading because there are numerous other alcohols to which a patient may be exposed (Chap. 103). However, ethanol is probably the most commonly used and abused drug in the world. Its use is pervasive among adolescents and adults of all socioeconomic groups, and represents a tremendous financial and social cost.

The ethanol content of alcoholic beverages is expressed by volume percent or by proof. Proof is a measure of the absolute ethanol content of distilled liquor, and is calculated by determining its specific gravity at an index temperature. In the United Kingdom, the Customs and Excise Act of 1952, declared proof spirits (100 proof) as those in which the weight of the spirits is 12/13 the weight of an equal volume of distilled water at 11Â°C (51Â°F). Thus, proof spirits are 48.24% ethanol by weight, or 57.06% by volume. Other spirits are designated over- or underproof, with the percentage of variance noted. In the United States, a proof spirit (100 proof) is one containing 50% ethanol by volume. The derivation of proof comes from the days when sailors in the British Navy suspected that the officers were diluting their rum (grog) ration and demanded â€œproofâ€• that this was not the case. They achieved this by pouring a sample of grog on black granular gunpowder. If the

gunpowder ignited by match or spark, the rum was up to standard, 100% proof that the liquor was 50% ethanol. This became shortened to 100

proof (Table 75-1). In addition to beverages, ethanol is present in hundreds of medicinal preparations, used as a diluent or solvent in concentrations ranging from 0.3% to 75%.[26,39,48,144,148,186] Mouthwashes may have up to 75% ethanol (150 proof), and colognes typically contain 40â€“60% ethanol (80â€“120 proof).[15,87,148,157] These products occasionally cause intoxication, especially when unintentionally ingested by children.[28,44,76,187]

Ethanol MW: 46 daltons
Specific gravity: 0.7939 (~0.8) g/mL
Volume of distribution (Vd): 0.6 L/kg

$$\text{Serum ethanol concentration (mg/dL)} = \frac{\text{dose (mg)}}{\text{Vd (L/kg)} \times \text{body weight (kg)} \times 10}$$

$$\text{mmol} = \frac{\text{mg}}{\text{MW}} = \frac{\text{mg}}{46}$$

$$\text{mmol/L} = \frac{\text{mg/dL}}{4.6}$$

For a 70-kg individual:

Dose of ethanol	Blood ethanol concentration
10 mL/kg of 10% (20 proof)	167 mg/dL (36.30 mmol/L)
3 mL/kg of 10% (20 proof)	50 mg/dL (10.87 mmol/L)
1.5 mL/kg of 10% (20 proof)	25 mg/dL (5.43 mmol/L)
150 mL (5 "shots") of 40% (80 proof)	143 mg/dL (31.09 mmol/L)
30 mL (1 "shot") of 40% (80 proof)	27 mg/dL (5.87 mmol/L)

Blood concentration consistent with legal intoxication = 10.87–17.39 mmol/L (50–80 mg/dL or 0.05–0.08 g/dL [%])

Average reduction in blood ethanol level (elimination phase):
Nontolerant adult: 3.26–4.35 mmol/L/h (15–20 mg/dL/h, 100–125 mg/kg/h)
Tolerant adult: 6.52–8.70 mmol/L/h (30–40 mg/dL/h, 175 mg/kg/h)

TABLE 75-1. Basic Information and Calculations

Veisalgia, â€œalcohol hangover,â€• comes from the Norwegian *kveis*, â€œuneasiness following debaucheryâ€• and the Greek *algia*, â€œpain.â€• The â€œhangoverâ€• syndrome is attributed to congeners, substances that appear in alcoholic beverages in addition to ethanol and water.[24,29,30] Congeners contribute to the special characteristics of taste, flavor, aroma, and color of a beverage. The combinations and exact amounts of congeners vary with the type of beverage, ranging from 33 mg/L in vodka, to averages of 500 mg/L in some whiskies, and as much as 29,000 mg/L in specially aged whiskies or brandies.[24,29,30] The conventional listing of congeners includes fusel oil (a mixture containing amyl, butyl, propyl, and methyl alcohol), aldehydes, furfural, esters, low-molecular-weight organic acids, phenols, and other carbonyl compounds, tannins, solids, and a relatively large number of additional organic and inorganic compounds, usually in trace amounts.[24,30]

Consumption of illicitly produced ethanol (â€œmoonshineâ€•) has resulted in methanol, lead, or arsenic poisoning.[41,62,84,103,109,128,145] Incidental lead contamination is also reported in draught beers or wine contained in lead-capped bottles.[161,162] Of historic interest is the addition of cobalt salts to beer to stabilize the â€œheadâ€• (foam) leading to outbreaks of congestive cardiomyopathy among heavy beer drinkers in Canada and Belgium in the 1960s (Chap. 89). The clinicopathologic pattern of this disease is distinct from the classical alcoholic cardiomyopathy.[120,122]

Alcoholism is the leading cause of morbidity and mortality in the United States. The prevalence of alcohol dependence in the United States has been relatively stable, at around 6% for men and 2% for women.[23] The overall estimated annual cost of health expenses related to ethanol is $185 billion.[135] More than 70% of the estimated

costs are attributed to lost productivity, most of which result from alcohol-related illness or premature death. Most of the remaining estimated costs are expenditures for healthcare services to treat alcohol-induced disorders (14.3%), property and administrative costs of ethanol-related motor vehicle crashes (8.5%), and criminal justice system costs of ethanol-related crime (3.4%). More than 200,000 Americans die annually of alcoholism, far more than those who die of all illicit drugs of abuse combined. Ethanol is the leading cause of mortality in people 15â€“45 years of age. In 2003 there were 15,281 ethanol-related traffic fatalities in the United States, which accounted for 40% of total traffic fatalities.[133] Among 16â€–20-year-old male drivers, an increase of 20 mg/dL in blood ethanol concentration is estimated to more than double the relative risk of a fatal single-vehicle crash injury, compared with sober drivers of the same age and gender.[198] When the blood ethanol concentration is between 80 and 100 mg/dL (17.39 and 21.74 mmol/L), between 100 and 150 mg/dL (21.74 and 32.61 mmol/L), and greater than 150 mg/dL (32.61 mmol/L), the relative risk is 52, 241, and 15,560, respectively.

The Global Burden of Disease Study identified three effects of alcohol: harmful effects in relation to injuries; harmful effects in relation to disease; and the protective effect in relation to ischemic heart disease.[135] Overall, alcohol accounted for 3.5% of mortality and disability, 1.5% of all deaths, 2.1% of all life years lost, and 6% of all the years lived with disability.[135] In the United States, according to National Highway Traffic Safety Administration (NHTSA) information, as of August 2005, all 50 states plus the District of Columbia and Puerto Rico had laws establishing a blood alcohol concentration of â‰¥80 mg/dL (17.39 mmol/L) as

illegal per se.[134] The term *illegal per se* refers to state laws that make it a criminal offense to operate a motor vehicle at or above a specified ethanol (or drug) concentration measured in the blood, breath, or urine. In nontolerant individuals, blood ethanol

concentration as low as 20 mg/dL (4.35 mmol/L) impairs driving-related skills.[135,199] Gross motor control and orientation may be significantly affected at concentrations of 50 mg/dL (10.87 mmol/L).[126] Clinical ethanol intoxication is usually apparent at blood ethanol concentration of 50 mg/dL (10.87 mmol/L). However, ethanol-tolerant patients may not exhibit impairment even at concentrations greater than 300 mg/dL (65.22 mmol/L).[1] There appears to be a doseâ€“response relationship between alcohol consumption and risk of death in men 16â€“34 years of age and in women 16â€–54 years of age. The consumption at which the risk is lowest increases with age, reaching 64â€–80 g/wk in men older than age 65 years and 24â€–30 g/wk in women older than age 65 years. The consumption at which the risk is increased by 5% above this minimum is 40â€–50 g/wk in men ages 16â€–24 years and 64â€–80 g/wk in women ages 16â€–24 years, increasing to 272â€–340 g/wk and 160â€–200 g/wk in men and women older than age 65 years, respectively.[192] Meta-analysis of aggregate data from epidemiologic doseâ€“response ethanol and mortality cohort studies suggests that the level of alcohol consumption at which all-cause risk is lowest is approximately 5 g/d, and that alcohol exerts a protective effect (J-shaped doseâ€“response curve) up to a daily intake of approximately 45 g.[8] Responsible drinking limits of ethanol for men are 8â€–10 g/d up to age 34 years; 16â€–20 g/d between 34 and 44 years of age; 24â€–30 g/d between 44 and 54 years of age; 32â€–40 g/d between 54 and 84 years of age; and 40â€–50 g/d for men older than age 85 years. Women are advised to limit their drinking to 8â€–10 g/d up to age 44 years; to 16â€–20 g/d between 44 and 74 years of age; and to 24â€–30 g/d for women older than age 75 years.[192] However, no safe level of prenatal ethanol exposure has been established. The combination of a national tolerance of drinking and heavy advertising of ethanol makes it especially appealing to young people. In a society that is increasingly concerned with drug abuse, the excessive use of alcohol constitutes a serious and pervasive problem, as well as a major health issue.

Pharmacology

Ethanol is a colorless, odorless, volatile, liquid hydrocarbon. It is fully miscible in water and is lipid soluble. It readily diffuses across lipid membranes, accounting for its ubiquitous multiorgan effects.

Despite ethanol's long history of use and study, no specific receptor for ethanol has been identified and the mechanism of action leading to intoxication remains the subject of debate.[147] Ethanol affects a large number of membrane proteins that participate in signaling pathways, including neurotransmitter receptors, enzymes, and ion channels,[132,183] and there is extensive evidence that ethanol interacts with a variety of neurotransmitters.[45,179,180] The major actions of ethanol involve enhancing the inhibitory effects of Î³-aminobutyric acid (GABA) at $GABA_A$ receptors and blockade of the *N*-methyl-D-aspartate (NMDA) subtype of glutamate, an excitatory amino acid (EAA) receptor.[33,92,93,183] Animal studies indicate that the acute effects of ethanol result from competitive inhibition of glycine's binding to the NMDA receptor, resulting in disruption of excitatory glutamatergic neurotransmission. Persistent glycine antagonism and attenuation of glutamatergic neurotransmission by chronic ethanol exposure results in tolerance to ethanol by enhancing EAA neurotransmission and NMDA receptor upregulation.[77,131,175,179,180] The latter appears to involve selective increases in NMDA R2B subunit levels and other molecular changes in specific brain loci.[3] The abrupt withdrawal of ethanol thus produces a hyperexcitable state that leads to the ethanol withdrawal syndrome and excitotoxic neuronal death.[16,33,180] Chronic ethanol administration also results in tolerance, dependence, and an ethanol withdrawal syndrome, mediated, in part, by desensitization and or downregulation of $GABA_A$ receptors. GABA-mediated inhibition, which normally acts to limit excitation, is eliminated in the absence of ethanol during ethanol withdrawal syndrome, and further intensifies this excitation. Augmentation of excitatory neurotransmission may lead to enhanced oxidative stress, which, in concert with reduced

inhibitory neurotransmission, may contribute to ethanol withdrawal-associated neurotoxicity in humans.[16,33,77,179,180] In addition, NMDA receptors function to inhibit the release of dopamine in the nucleus accumbens and mesolimbic structures, which modulates the reinforcing action of addictive agents like ethanol.[18,19,165] By inhibiting NMDA receptor activity, ethanol could increase dopamine release from the nucleus accumbens and ventral tegmental area, and could thus create dependence (Chap. 14).

Pharmacokinetics and Toxicokinetics

Ethanol is rapidly absorbed from the gastrointestinal (GI) tract, with approximately 20% absorbed from the stomach and the remainder from the small intestine.[137] Factors that enhance absorption include rapid gastric emptying, ethanol intake without food, the absence of congeners, dilution of ethanol (maximum absorption occurs at a concentration of 20%), and carbonation. Under optimal conditions for absorption, 80â€“90% of an ingested dose is fully absorbed within 60 minutes. Factors that delay or decrease ethanol absorption include high concentrations of ethanol (by causing pylorospasm), presence of food, coexistence of GI disease, coingestion of drugs (eg, aspirin and *N*-butylscopolamine),[85,142] time taken to ingest the drink, and individual variation. Any of these factors and individual variation may delay absorption for 2â€“6 hours.

Alcohol dehydrogenase (ADH), the principal enzyme responsible for ethanol oxidation, is an intracellular enzyme that is also present in the stomach and the liver.[106] It is an inducible enzyme, and there is a functional polymorphism of the ADH gene.[43] Class IV ADH (Ï*f*-ADH) is the major ADH expressed in human gastric mucosa and oxidizes a small proportion of the ingested ethanol, thus reducing the amount available for absorption. This effect is more pronounced in men than in women, and in nonalcoholics than in alcoholics.[10,53] Ï*f*-ADH is usually present in non-Asians, whereas in a majority of Pacific Rim Asians, the enzyme activity is either low or undetectable.[10,11,37] The

predominant hepatic ADH is class I ADH and it contains the isozymes ADH1, ADH2, and ADH3. The atypical ADH, ADH2*2, is responsible for an unusually rapid conversion of ethanol to acetaldehyde and is present in 90% of Pacific Rim Asians.

As a result of decreased first-pass metabolism caused by inhibition of the activity of alcohol dehydrogenase in the gastric mucosa,[35] histamine-2 (H_2) receptor antagonists, cimetidine and ranitidine, slightly increase the bioavailability of imbibed ethanol.[6,20,22,47] In alcoholics and those persons with higher ethanol concentrations, cimetidine may also delay ethanol clearance by inhibiting the microsomal ethanol oxidizing system (MEOS) (cytochrome

P450 [CYP] 2E1).[70] However, the increase in blood ethanol concentration from such an interaction is of questionable clinical significance.[5,6,20,21]

In the liver, ADH metabolizes ethanol to acetaldehyde, which is converted to acetate by mitochondrial nicotinamide-adenosine dinucleotide (NAD)-dependent aldehyde dehydrogenase (ALDH). Twelve ALDH genes (ALDH1 to ALDH10, succinic dehydrogenase, and methylmalonate semialdehyde dehydrogenase) are identified in humans. There is a functional polymorphism of the mitochondrial ALDH2 gene, and expression of an inactive form of the ALDH2 results in impaired acetaldehyde metabolizing capacity. The variant allele ALDH2*2 encodes a protein subunit that confers low activity to the enzyme, resulting in marked differences in the steady-state kinetic constants, which appears to be most prevalent in Pacific Rim Asians.[2,27,64,170,171] Homozygous ALDH2*2 individuals are strikingly sensitive to a small dose of ethanol (0.2 g/kg), as evidenced by the intense flushing, pronounced cardiovascular hemodynamic effects, and subjective perception of general discomfort.[43,64,146,176,181] This effect may also be associated with the ADH2*2 and ADH3*1 alleles, and is similar to that induced by disulfiram (Chap. 77). The alcohol-induced flushing response may involve prostaglandin and histamine release. Both prostaglandin antagonists (aspirin)[178] and

antihistamines (H_1 and H_2)[123,166,173] may attenuate this response.

For a typical 70-kg person, a â€œstandard drinkâ€• (15 g of ethanol), defined as 1 oz (30 mL) of 100 proof liquor, about a 4-oz (120-mL) glass of wine (12% ethanol), or about a 10-oz bottle (300-mL) of beer (5% ethanol), could raise blood ethanol concentration by 43 mg/dL (9.35 mmol/L). However, this is the theoretical maximum ethanol concentration, based on instantaneous and complete ethanol absorption and no distribution or metabolism following a â€œstandard drinkâ€• by a typical 70-kg person.

Following complete distribution, ethanol is present in body tissues in a concentration proportional to that of the tissue water content. The concentration in the blood is maintained by back diffusion, which occurs whenever the concentration in the blood falls below that of the tissues. Ethanol freely passes through the placenta, exposing the fetus to ethanol concentrations comparable to that achieved in the mother.

Ethanol is primarily (>90%) eliminated by the liver via enzymatic oxidation, with 5â€“10% excreted unchanged by the kidneys, lungs, and sweat. Ethanol is metabolized via at least three different pathways: the aforementioned alcohol dehydrogenase (ADH) pathway, located in the cytosol of the hepatocytes; the MEOS (CYP2E1), located on the endoplasmic reticulum; and the peroxidaseâ€“catalase system, associated with the hepatic peroxisomes (Fig. 75-1.).[137]

The ADH system is both the main pathway for ethanol metabolism in the body and is the rate-limiting step. ADH is a zinc metalloenzyme that uses oxidized nicotinamide adenine dinucleotide (NAD^+) as a hydrogen ion acceptor to oxidize ethanol to acetaldehyde. In this process, a hydrogen ion is transferred from ethanol to NAD^+, converting it to its reduced form, NADH. Subsequently, a hydrogen ion is transferred from acetaldehyde to NAD^+. Under normal conditions acetate is converted to acetylcoenzyme A (acetyl-CoA), which enters the Krebs cycle and is metabolized to carbon dioxide

and water. The entry of acetyl-CoA into the Krebs cycle is dependent on thiamine (Antidotes in Depth: Thiamine Hydrochloride).

The MEOS (CYP2E1) is responsible for very little ethanol metabolism in the uninitiated drinker, but becomes more important as the ethanol concentration rises or as ethanol use becomes chronic (Fig. 75-1.). CYP2E1 uses oxidized nicotinamide adenine dinucleotide phosphate ($NADP^+$) as an electron acceptor to oxidize ethanol to acetaldehyde.[95] In this process, electrons are transferred from ethanol to $NADP^+$, converting it to its reduced form, NADPH. Subsequently, acetaldehyde is further oxidized to acetate, as a hydrogen ion is transferred from acetaldehyde to $NADP^+$. Ethanol's ability to induce the MEOS forms the basis for the well-established interactions between ethanol and a host of other xenobiotics metabolized by this system.[36,52]

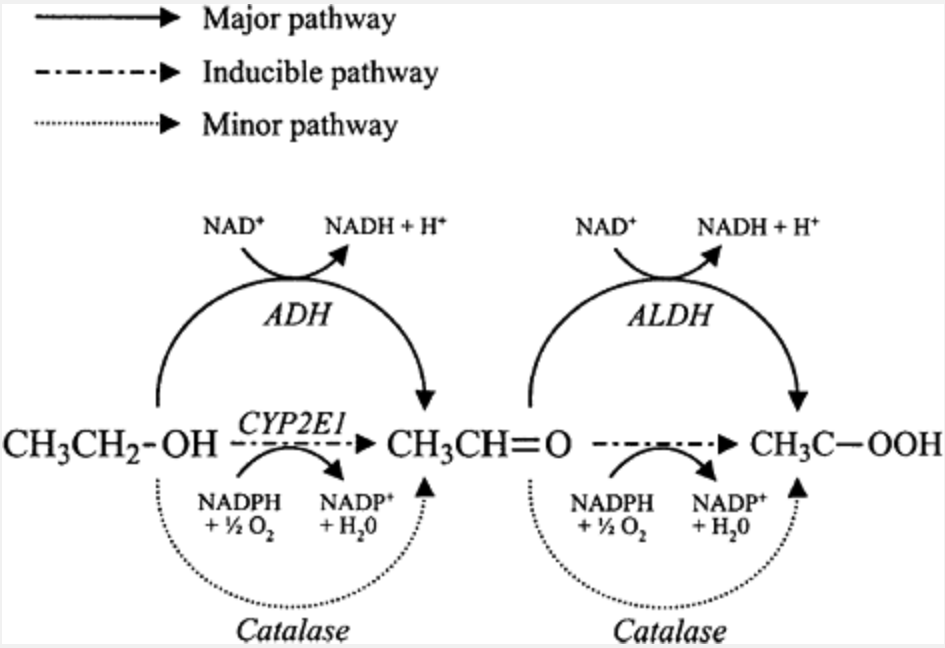

Figure 75-1. Ethanol oxidation. The major, minor, and inducible pathways used for ethanol metabolism.

ADH is saturated at relatively low blood ethanol concentrations. As the system is saturated, ethanol elimination changes from first-order to zero-order kinetics (Chap. 9). In adults, the average rate of ethanol metabolism is 100â€“125 mg/kg/h in occasional drinkers and up to 175 mg/kg/h in habitual drinkers.[17,63] As a result, the average-sized adult metabolizes 7â€“10 g/h and the blood ethanol concentration falls 15â€–20 mg/dL/h (3.26â€–4.35 mmol/L/h). Tolerant drinkers, by recruiting CYP2E1, may increase their clearance of ethanol to 30 mg/dL/h (6.52 mmol/L/h).[17,63] Studies of ethanol-intoxicated patients indicate that although the average ethanol clearance rate is about 20 mg/dL/h (4.35 mmol/L/h), there is considerable individual variation (standard deviation of about 6 mg/dL/h [1.30 mmol/L/h]).[17,63]

Xenobiotic Interactions

Ethanol interacts with a variety of xenobiotics (Table 75-2.).[186] The most frequent interactions occur as a result of an ethanol-induced increase in hepatic xenobiotic-metabolizing enzyme activity. In contrast, acute ethanol use may inhibit metabolism of other xenobiotics, which may be a result of decreased hepatic enzyme activity or blood flow. The interaction between ethanol and disulfiram (Antabuse) is well described, and it can be life-threatening (Chap. 77).

Acute intoxication with ethanol can transiently prolong the elimination of certain xenobiotics, such as phenytoin, because of competition for shared metabolic pathways; an increase in the MEOS (CYP2E1) with chronic ethanol ingestion leads to accelerated metabolism and shortens the half-lives of drugs such as phenytoin, methadone, isoniazid, and warfarin.[83]

Ethanol has additive sedative effects when ingested with antihistamines, cyclic antidepressants, phenothiazines, opioids, and other sedative-hypnotics such as benzodiazepines, barbiturates,

glutethimide, and chloral hydrate (â€œMickey Finnâ€•). Ethanol also potentiates the pharmacologic effects of vasodilators and oral hypoglycemic agents, and may enhance the antiplatelet action of aspirin.

TABLE 75-2. Ethanol Xenobiotic Interactions

Xenobiotics	Adverse Effects
Antihistamines (H_1)	Enhanced CNS depression
Carbamates	Disulfiramlike effect
Cephalosporins[a]	Disulfiramlike effect
Chloral hydrate	Enhanced CNS depression
Chloramphenicol	Disulfiramlike effect
Chlorpropamide	Disulfiramlike effect
Cocaine	Formation of cocaethylene
Coprinus mushrooms	Disulfiramlike effect
Disulfiram (Antabuse)	Nausea, vomiting, abdominal pain, flushing, diaphoresis, chest pain, headache, vertigo, palpitations

Griseofulvin	Disulfiramlike effect
Heroin	Enhanced CNS depression
Isoniazid	Increased incidence of hepatitis; increased metabolism[b]
Methadone	Increased methadone metabolism[b]
Metronidazole	Disulfiramlike effect
Nitrofurantoin	Disulfiramlike effect
Phenytoin	Increased phenytoin metabolism
Ranitidine, cimetidine	Increased ethanol concentration
Sedativeâ€“hypnotics	Enhanced CNS depression
Thiram derivatives	Disulfiramlike effect
Warfarin	Increased warfarin metabolism[b]

[a]Those containing a *N*-methylthiotetrazole side chain.
[b]Effect possibly associated with chronic alcohol consumption.

Concomitant use of cocaine and ethanol leads to the formation of an active metabolite, cocaethylene, through transesterification of

cocaine by the liver.[152] Cocaethylene has a longer half-life than cocaine itself (2 hours vs. 48 minutes), which might explain some of the delayed cardiovascular effects attributed to cocaine use.[7,193] Both ethanol and cocaethylene inhibit the metabolism of cocaine, thereby prolonging the elimination of cocaine and enhancing its effect (Chap. 74).[143]

Case reports and retrospective case series suggest that chronic ethanol consumption may predispose a person to acetaminophen (APAP) hepatotoxicity (Chap. 34)[42,113,119,158,202] even when APAP has been taken according to the manufacturer's recommended dosage of not more than 4 g daily.[201] Because ethanol induces cytochrome P450, the enzyme involved in the metabolism of acetaminophen to its hepatotoxic intermediate, *N*-acetyl-*p*-benzoquinoneimine (NAPQI), a theoretical basis for this association exists. However, in a double-blind placebo-controlled study, where confirmed alcoholics were given acetaminophen 4 g daily or placebo for 3 consecutive days, there were no differences between the two groups with regard to liver enzymes or to coagulation profiles.[94] Recent fasting, common in alcoholics, was also associated with a predisposition to acetaminophen hepatotoxicity, likely as a consequence of depletion of glutathione (Chap. 34).[191] However, in a retrospective study, heavy drinkers did not develop more severe hepatoxicity following APAP overdose when compared to nondrinkers.[114]

Pathophysiology

Ethanol affects practically every organ system in the body (Table 75-3); the relationships between ethanol use, nutrition, and liver disease are reviewed elsewhere.[105] In addition to the harmful effects of ethanol itself (eg, impairment of protein synthesis), its metabolite, acetaldehyde, is inherently toxic to biologic systems.[100,107,182,200] Acetaldehyde directly impairs cardiac contractile function, disrupts cardiac excitationâ€“contractile coupling, inhibits myocardial protein

synthesis, interferes with phosphorylation, causes structural and functional alterations in mitochondria and hepatocytes, and inactivates coenzyme A. Acetaldehyde can also react with intracellular proteins to generate adducts. Acetaldehyde adducts are believed to play an important role in the early phase of alcoholic liver disease, and in advanced liver disease they contribute to the development of hepatic fibrosis.

Ethanol metabolism through the hepatic CYP2E1 pathway generates highly reactive oxygen radicals, including the hydroxyethyl radical (HER) molecule. Elevated oxygen radical levels generate a state of oxidative stress, which leads to cell damage. Oxygen radicals can also initiate lipid peroxidation, resulting in reactive molecules such as malondialdehyde (MDA) and 4-hydroxy-2-nonenal (HNE). These reactive molecules react with proteins or acetaldehyde to form adducts, which contribute to the development of alcoholic liver injury.

Oxidation of ethanol generates an excess of reducing potential in the cytosol in the form of NADH, with the ratio of NADH to NAD^+ being dramatically increased. This ratio, also known as the redox potential, determines the ability of the cell to carry on various oxidative processes. The unfavorable change in redox potential as a consequence of ethanol metabolism contributes to the development of metabolic disorders (eg, impaired gluconeogenesis, alterations in fatty acid metabolism, fatty liver, hyperlipidemia, hypoglycemia, lactic acidemia, hyperuricemia [gouty attacks]), increased collagen and scar tissue formation associated with alcoholism, and a clinical syndrome of alcoholic ketoacidosis.

Recent studies in alcoholic liver disease have focused on Kupffer cell activation by endotoxin that is released by intestinal bacteria. When Kupffer cells are activated, they produce regulatory nuclear factor-kappa B (NF-Î´B) and generate significant amounts of superoxide radicals (O_2^-) and cytokines (tumor necrosis factor and interleukin-8), which are an essential factor in the injury to hepatocytes

associated with alcoholic liver disease.[118,190]

Clinical Features

Ethanol is a selective CNS depressant at low doses and a general depressant at high doses. Initially, it depresses those areas of the brain involved with highly integrated functions. Cortical release leads to animated behavior and the loss of restraint. This paradoxical CNS stimulation is caused by disinhibition. In cases of mild intoxication, the signs of ethanol inebriation are quite variable. The patient may be energized and loquacious, expansive, emotionally labile, and increasingly gregarious, or may appear to have lost self-control, exhibit antisocial behavior, and be ill-tempered. As the degree of intoxication increases, there is successive inhibition and impairment of neuronal activity. The patient may become irritable, abusive, aggressive, violent, dysarthric, confused, disoriented, or lethargic. With severe intoxication, there is loss of airway protective reflexes, coma, and increasing risk of death from respiratory depression. An ethanol-naive adult with a blood ethanol concentration >250 mg/dL (54.35 mmol/L) is usually comatose.[1]

The acute effects of ethanol ingestion also depend on the habituation of the drinker. This is mainly a result of the development of

tolerance, which has both a metabolic (pharmacokinetic) and a functional (pharmacodynamic) component.[169] Metabolic tolerance to ethanol is based on enhanced elimination by the ADH enzyme and CYP2E1 system. Functional tolerance (resistance to the effects of ethanol at the cellular level) is a more important determinant of habituation and may be mediated through alterations in serotonergic and adrenergic neurons.[88,89,168] Acute alcohol tolerance may be demonstrated by the Mellanby effect, which involves the comparison of physiologic responses or behavioral effects at the same blood ethanol concentration on the ascending and descending limbs of the blood ethanol curve. Impairment is greater at a given blood ethanol

concentration when the blood ethanol concentration is increasing, than for the same blood ethanol concentration when the blood ethanol concentration is falling.[136,185] Although individuals who are acutely intoxicated move through a progressive sequence of events, the association of a particular aspect of intoxication with a specific blood ethanol concentration is not usually possible without knowing the pattern of ethanol use of the patient. Acute ethanol intoxication occurs in habitual drinkers when they raise their ethanol concentration an equivalent amount above baseline, and specific clinical manifestations of inebriation typically occur in habitual drinkers at a significantly higher blood ethanol concentration than in nontolerant individuals. Regardless, the absolute change above baseline may be important.

A patient may present with obvious signs and symptoms consistent with ethanol intoxication that include flushed facies, diaphoresis, tachycardia, hypotension, hypothermia, hypoventilation, mydriasis, nystagmus, vomiting, dysarthria, muscular incoordination, ataxia, altered consciousness, and coma. However, an ethanol-intoxicated patient may present to the ED with a broad range of diagnostic possibilities and should prompt the physician to carefully evaluate the patient for a variety of covert clinical and metabolic disorders. A

meticulous and systematic approach to the evaluation and management of an inebriated patient will help the clinician avoid potential pitfalls in such a situation.[56] The presence or absence of an odor of ethanol on the breath is an unreliable means of ascertaining whether a person is intoxicated or whether ethanol was recently consumed.[130] Diplopia, visual disturbances, and nystagmus may be evident, which may be caused by the toxic effects of ethanol or may represent Wernicke encephalopathy. Hypothermia may be exacerbated by environmental exposure, from malnutrition and loss of carbohydrate or energy substrate, and from ethanol-induced vasodilation. Ethanol intoxication can impair cardiac output in patients with preexisting cardiac disease.[66] Dysrhythmias, such as atrial fibrillation and nonsustained ventricular tachycardia, as well as atrioventricular block, are documented in binge drinkers.[40,67,68] The association between ethanol use and cardiac dysrhythmias, particularly supraventricular tachydysrhythmias in apparently healthy people, is called â€œholiday heart syndrome.â€•[90,96,121] The syndrome was first described in people with heavy ethanol consumption, who typically presented on weekends or after holidays, and it may also occur in patients who binge, but who usually drink little ethanol. The most common dysrhythmia is atrial fibrillation, which usually reverts to normal sinus rhythm within 24 hours. Although the syndrome may recur, the clinical course is benign in patients without anatomic cardiac pathology, and specific antidysrhythmic therapy is usually not warranted.[54,68]

Acute heavy ethanol drinking may precipitate silent myocardial ischemia in patients with stable angina pectoris.[155] Variant angina is reported to occur in patients following ethanol ingestion at a time when the blood ethanol concentration has decreased almost to zero.[49,82,116,124,141,156,172] Acute altered mental status in an alcoholic patient can be the result of a variety of causes, including acute ethanol or toxic ethanol intoxication; hypoglycemia; therapeutic or illicit drug overdose; Wernicke-Korsakoff syndrome;

head trauma; a postictal condition; infection; an intracranial hematoma (acute or chronic); hepatic encephalopathy; an electrolyte or acidâ€“base disorder; or ethanol withdrawal. Ethanol-induced seizures are reported in adults, but are more frequent in children. Sometimes they are associated with hypoglycemia.[28,76] Patients presenting with acute ethanol intoxication commonly have decreased serum ionized magnesium concentrations, although their total serum magnesium concentration is within the normal range.[197] Total body magnesium may be depleted because of poor dietary intake, decreased GI absorption secondary to ethanol, and renal wasting as a consequence of the ethanol-related diuresis.[50,81,154,160,167]

Diagnostic Tests

There are numerous qualitative and quantitative assays for ethanol in biologic fluids and exhaled breath. Immunoassay or gas chromatography is commonly used for determination of ethanol in liquid specimens in most hospitals. Hospital laboratory analysis of blood samples for ethanol content is usually based on serum (liquid portion of whole blood after the cellular components and clotting factors are removed), rarely on plasma (acellular liquid portion of whole blood), and forensic ethanol concentration is defined in whole blood. Serum contains slightly more water than does plasma and whole blood, and will have a slightly higher ethanol concentration. The median ratio of serum to whole blood ethanol concentration is 1.15 (range: 0.88â€“1.59:1)[151] and the mean ratio of plasma to whole blood ethanol concentration is 1.10 (range: 1.03â€“1.24:1).[80] As a result, a serum ethanol concentration of 88â€“159 mg/dL (19.13â€“34.57 mmol/L) is equivalent to a whole-blood ethanol concentration of 100 mg/dL (21.74â€“39.75 mmol/L).

The excretion of ethanol by the lungs is first order and obeys the Henry law: The ratio between the concentration of ethanol in the alveolar air and the blood is constant. Although the alveolar air-to-blood constant is quite low and very little ethanol is excreted by this

route, the fixed relationship forms the basis for the sampling of a person's breath to estimate their blood ethanol concentration. The mean breath-to-blood ratio is 1:2300 during the postabsorptive phase of ethanol kinetics and a ratio of 1:2100 is used in forensic casework.[137] There are individual and interindividual variations in the normal blood-to-breath ethanol ratio, and log-transformation of the values is used to calculate means and confidence intervals.[69,79,97] Breath ethanol analyzers make use of electrochemical sensors for ethanol oxidation or infrared spectral analysis for ethanol determination.[137] They are widely available and are routinely used by law enforcement agencies as ethanol-screening devices. In the ED, they have been shown to accurately predict serum ethanol levels.[188] However, the unconscious or uncooperative patient may be unable to comply with the proper use of the breath alcohol analyzer. Breath-ethanol devices adapted with mouth cups and nasal tubes, to sample the breath of unconscious patients, produce results that correlate fairly well with serum ethanol concentrations.[46,61] Breath-ethanol concentration may not always reflect the concentration of ethanol in blood. Potential sources of interference include recent use of ethanol-containing products, belching or vomiting of gastric ethanol contents, inadequate exhalation, obstructive pulmonary disease, mouth ethanol retained in the bridges or periodontal spaces, and poor technique.[4,101,177] Multidose inhalers (eg, Tornalate [bitolterol mesylate with 38% ethanol], Bronkometer [isoetharine mesylate with 30% ethanol], Primatene Mist [adrenaline with 34% ethanol], and salbutamol) and mouthwashes (eg, Listerine [26.9% alcohol], Scope [18.9% alcohol], and Lavoris [6.0% alcohol]) may contain significant concentrations of ethanol and can cause elevations of breath ethanol above the legal criteria for intoxication.[12,65,110,125] However, these effects are transient and may be prevented by a 10â€“15-minute interval between the use of multidose inhaler or mouthwash and breath-ethanol testing.[65,110,125]

Ethanol-saliva testing is a promising alternative to breath ethanol analysis in the rapid assessment of blood ethanol levels in patients,

regardless of their mental status.[31,163] Fatty acid ethyl esters (FAEEs) may be a highly sensitive test for recent ethanol use.[14,38,164] Because FAEEs remain in the system for at least 24 hours, they may have a role as a marker of recent ethanol use, even after ethanol is completely metabolized. However, their availability is limited and their place in patient management is undefined.

Blood tests that should be considered for patients with ethanol intoxication or alcoholic ketoacidosis include CBC, electrolytes, BUN, creatinine, ketones, acetone, lipase, liver enzymes, a prothrombin time, ammonia, calcium, and magnesium. Patients with an anion gap metabolic acidosis should have urine ketones and serum lactate concentration analysis (Chaps. 17 and 103). High serum acetone concentrations may be indicative of isopropanol intoxication, whereas elevated serum or urinary ketones concentrations may be indicative of alcoholic ketoacidosis, starvation ketosis, or diabetic ketoacidosis. Because the laboratory nitroprusside reaction detects only ketones (acetoacetate and acetone) and not Î²-hydroxybutyrate, the assay for urinary ketones in patients with alcoholic ketoacidosis may be only mildly positive.

A blood ethanol concentration analysis should be included in the initial laboratory studies.[75] If the blood ethanol concentration is inconsistent with the patient's clinical condition, prompt reevaluation of the patient is indicated to elucidate the etiology of the altered mental status, including toxicâ€“metabolic, trauma-related, neurologic, and infectious etiologies. Comatose patients with concentrations below 300 mg/dL (65.22 mmol/L), and those with values in excess of 300 mg/dL (65.22 mmol/L) who fail to improve clinically during a limited period of close observation, should have a head CT scan, followed by a lumbar puncture if warranted. Because chronically ethanol-tolerant patients are prone to trauma and coagulopathies, both of which can cause intracerebral bleeding, the threshold for head CT scanning should be low.

Management of the Intoxicated Patient

Ethanol is rapidly absorbed from the gastrointestinal tract. In situations where recent ingestion (within 1 hour of presentation), delayed absorption, and concomitant ingestions are under consideration, gastrointestinal decontamination may be considered. Occasionally, the extremely intoxicated or comatose patient may have severe respiratory depression, necessitating endotracheal intubation and ventilatory support.

Any patient presenting to the ED with an acute altered mental status mandates immediate investigation and treatment of reversible etiologies such as hypoxia, hypoglycemia, and opioid intoxication. In addition, Wernicke encephalopathy should be considered. Supplemental oxygen should be administered if the patient is hypoxic; intravenous dextrose (0.5â€“1.0 g/kg), thiamine 100 mg, and naloxone should be administered as clinically indicated. Abnormal vital signs should be addressed and stabilized. Patients who are combative and violent should be both physically and then chemically restrained with a benzodiazepine. Caution should be taken because of additive effects of ethanol and benzodiazepine on respiratory depression. Attempts by those who are clinically intoxicated to sign out against medical advice, or attempt to leave, should also be prevented (Chap. 135). The patient's fluid and electrolyte status should be assessed and abnormalities corrected. Multivitamins with folate, thiamine, and magnesium may be added to the maintenance IV solution.

A variety of techniques and xenobiotics have been advocated, either to reverse the intoxicating effects of ethanol or to enhance its elimination. Neither coffee nor caffeine itself counteracts the impaired psychomotor functions that occur with acute intoxication (Antiquated Antidotes in Depth).[138] Earlier anecdotal reports suggested a role for naloxone in reversing ethanol intoxication, but these reports could not be reliably reproduced.[139] The specific

benzodiazepine antagonist flumazenil has no predictable effect on ethanol intoxication.[51] It is unlikely that a specific ethanol antagonist will be discovered because ethanol's mechanisms of action are complex and are not apparently mediated by a single receptor. Rapid intravenous saline (1 L) loading does not accelerate ethanol clearance in intoxicated patients.[104] Hemodialysis is an effective means of enhancing the systemic elimination of ethanol because of the small volume of distribution and low molecular weight of ethanol. In severe ethanol poisoning that results in respiratory failure or coma, hemodialysis may be an adjunct treatment to supportive care. However, this is rarely indicated or necessary.

Indications for Hospitalization

A patient with uncomplicated ethanol intoxication can be safely discharged from the ED after a careful observation and social service or psychiatric counseling. An individual should not be discharged while still clinically intoxicated. However, consideration may be given to a situation where the intoxicated patient is discharged to a protected environment under the supervision of a responsible, not intoxicated, adult. In this case, the clinical assessment of the patient is more important than the blood ethanol level. Indications for hospital admission include persistently abnormal vital signs; persistently abnormal mental status, with or without an obvious cause; a mixed overdose with other concerning xenobiotics; concomitant serious trauma; consequential ethanol withdrawal, and an associated serious disease process, such as pancreatitis or gastrointestinal hemorrhage.

Chronic alcoholism leads to an organic brain syndrome that is irreversible. The patients' socioeconomic condition and their ability to comply with a treatment plan are critical in making a disposition. Alcoholics requesting ethanol detoxification can be admitted for rehabilitation. Inpatient detoxification programs differ substantially from outpatient programs, but their most consequential advantages

may be that they enforce abstinence, provide more support and structure, and separate the patient from the social surroundings associated with drinking.[135] For patients who are not admitted, a referral should be offered to Alcoholics Anonymous or another suitable ethanol rehabilitation program.

Ethanol-Induced Hypoglycemia

Mechanism of Ethanol-Associated Hypoglycemia

Hypoglycemia associated with ethanol consumption is believed to occur when ethanol metabolism provides a high cellular reduction-to-oxidation (redox) ratio. This redox state favors the conversion of pyruvate to lactate, diverting pyruvate from gluconeogenesis (Fig. 75-2.).[74] Hypoglycemia typically occurs when there is a reduced caloric intake and only after the hepatic glycogen stores are depleted, as in an overnight fast. The mechanism by which hypoglycemia is associated with ethanol consumption in the well nourished individual is less well defined.

Population at Risk

Although the conditions that cause hypoglycemia in adults may also be present in infants and children, children with their smaller livers have less glycogen stores than adults and are more likely to develop hypoglycemia. Hypoglycemia associated with ethanol consumption usually occurs in malnourished chronic alcoholics and children (Chap. 48). It may also occur in binge drinkers who do not eat. A 22% incidence of hypoglycemia was reported in one retrospective study of children with documented ethanol ingestion.[102] In another retrospective study of pediatric and adolescent patients, there was a 3.4% incidence of hypoglycemia (serum glucose concentration <67 mg/dL [3.72 mmol/L]).[44] Ethanol-intoxicated children younger than 5

years of age have an increased risk of developing hypoglycemia, and it is the most common reported clinical abnormality related to ethanol ingestion in this age group.[98,99]

Clinical Features

Patients with ethanol-associated hypoglycemia usually present with an altered consciousness 2â€“10 hours following ethanol ingestion. Other physical findings include hypothermia and tachypnea. Laboratory findings, in addition to hypoglycemia, usually include a positive blood ethanol concentration, ketonuria without glucosuria, and mild acidosis. Management of ethanol-induced hypoglycemia is similar to other causes of hypoglycemia (Chap. 48).

Alcoholic Ketoacidosis

The development of alcoholic ketoacidosis (AKA) requires a combination of physical and physiologic events to occur, and each of these conditions may be independent of the others. The normal response to starvation and depletion of hepatic glycogen stores is for amino acids to be converted to pyruvate. Pyruvate serves as a substrate for gluconeogenesis by being converted to acetyl-CoA, which enters the Krebs cycle, or undergoes conversion to fatty acids. As described earlier, ethanol metabolism generates NADH, resulting in an excess of reducing potential. This high redox state favors the conversion of pyruvate to lactate, diverting pyruvate from being a substrate for gluconeogenesis. To compensate for the lack of normal metabolic substrates, the body mobilizes fat from adipose tissue and increases fatty acid metabolism as an alternative source of

energy. This response is mediated by a decrease in insulin and an increased secretion of glucagon, catecholamines, growth hormone, and cortisol. Fatty acid metabolism results in the formation of acetyl-CoA, and it combines with the excess acetate that is generated from ethanol metabolism to form acetoacetate (Fig. 75-3).[74] Most of the

acetoacetate is reduced to Î²-hydroxybutyrate as a consequence of the excess reducing potential or low redox state of the cell. Volume depletion interferes with the renal elimination of acetoacetate and Î²-hydroxybutyrate and contributes to the acidosis. Lactic acidosis caused by hypoperfusion or infection may coexist with the underlying ketoacidosis.

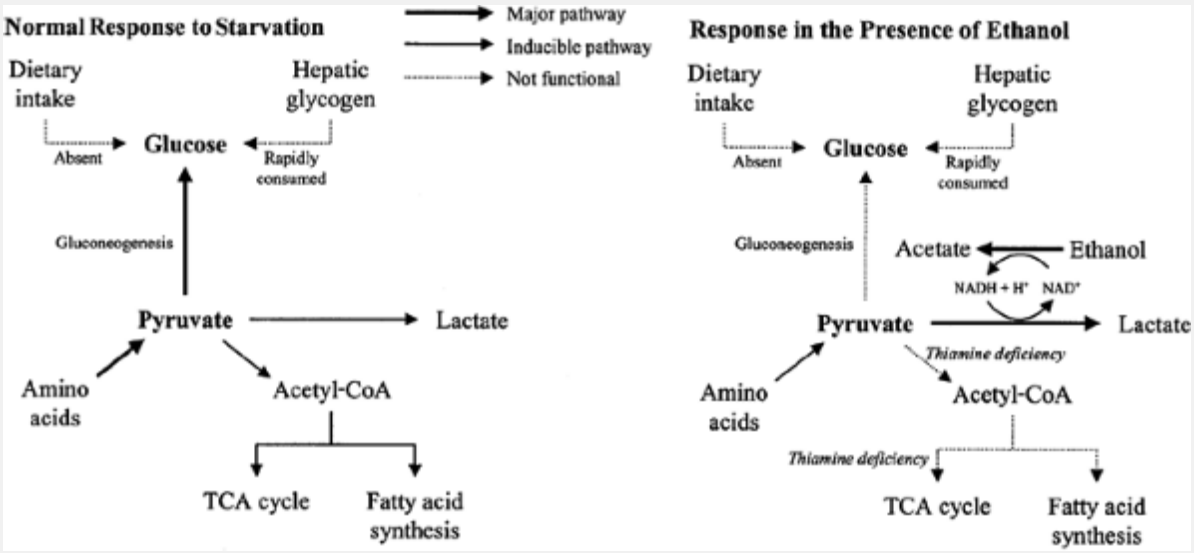

Figure 75-2. Central role of pyruvate in ethanol-induced hypoglycemia. TCA cycle = tricarboxylic acid cycle. *(Modified, with permission, from Hoffman RS, Goldfrank LR: Ethanol-associated metabolic disorders in Endocrine Metabolic Disorders. Emerg Med Clin North Am 1989;7:945.)*

Clinical Features

Patients with AKA are typically chronic ethanol users, presenting after a few days of â€œbingeâ€• drinking, who become acutely starved because of cessation in oral intake as a consequence of binging itself, or because of nausea, vomiting, abdominal pain from

gastritis, hepatitis, pancreatitis, or a concurrent acute illness.[56,57,59] The patient may appear acutely ill with dehydration, tachypnea, tachycardia, and hypotension. Underlying medical conditions such as sepsis, meningitis, pyelonephritis, or pneumonia may be present, and alcohol withdrawal may develop, all of which should be considered and systematically excluded. The diagnosis of AKA is a diagnosis of exclusion.

The blood ethanol concentration is usually low or undetectable because ethanol intake ceased substantially earlier in the clinical course. The hallmarks of AKA include an elevated anion gap metabolic acidosis with a serum lactate concentration insufficient to account for the gap. However, some patients will have a normal arterial pH or be alkalemic because of an associated primary metabolic alkalosis caused by vomiting and a compensatory respiratory alkalosis (Chap. 17).[55] When patients with AKA were compared

with patients with diabetic ketoacidosis (DKA), those with AKA tended to have a higher blood pH, lower serum potassium and chloride concentrations, and a higher serum bicarbonate concentration.[58] The anion gaps in patients with AKA and DKA are very similar, with Î²-hydroxybutyrate being the primary anion contributor and lactate having a less-consequential role.[58]

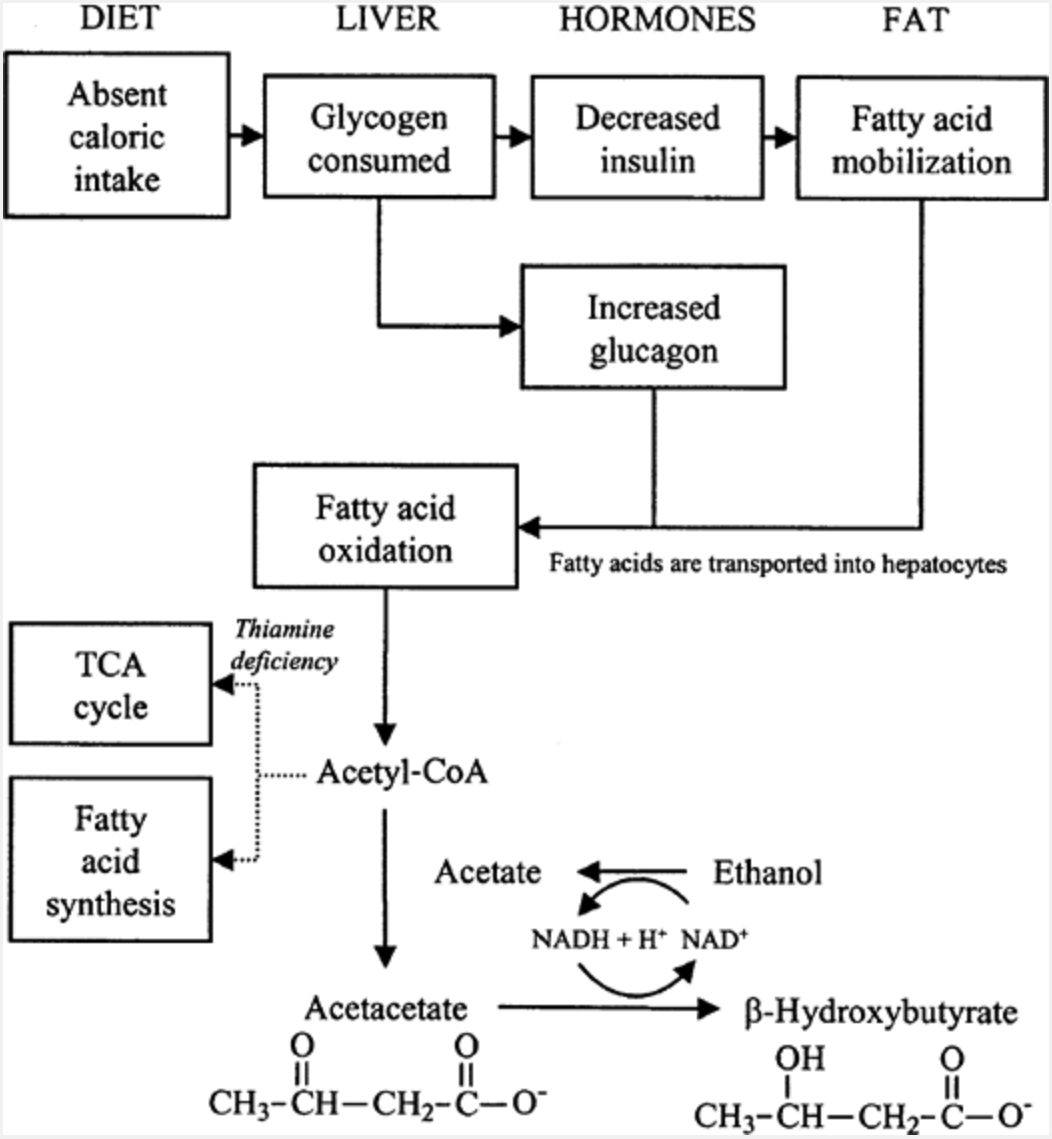

Figure 75-3. Mechanism of alcoholic ketoacidosis. TCA cycle = tricarboxylic acid cycle. *(Modified, with permission, from Hoffman RS, Goldfrank LR: Ethanol-associated metabolic disorders in Endocrine Metabolic Disorders. Emerg Med Clin North Am 1989;7:952.)*

The nitroprusside test used to detect the presence of ketones in

serum and urine may be negative or mildly positive in patients with AKA because the nitroprusside reaction only detects molecules containing ketone moieties. This includes acetone and acetoacetate but not Î²-hydroxybutyrate. Reliance on the nitroprusside test alone may underestimate the severity of ketoacidosis. Specific assays for Î²-hydroxybutyrate may be performed, but are not readily available in most hospital laboratories. The blood glucose may be low or mildly elevated. It is postulated that ethanol-induced hypoglycemia occurs first, causing increased levels of cortisol, growth hormone, glucagon, and epinephrine; this may correct the hypoglycemia and mobilize fatty acids, which are converted to ketones.[32] Therefore, alcoholic hypoglycemia and alcoholic ketoacidosis may be sequential events of the same process, depending on the point in this process at which the patient is evaluated.

Management

Treatment should begin with adequate crystalloid fluid replacement, dextrose, and thiamine. Supplemental multivitamins, potassium, and magnesium should be instituted on an individual basis. The administration of dextrose will stimulate the release of insulin, decrease the release of glucagon, and reduce the oxidation of fatty acids. Exogenous glucose also facilitates the synthesis of adenosine triphosphate (ATP), which reverses the pyruvate-to-lactate and NAD^+-to-NADH ratios. The provision of thiamine facilitates pyruvate entry into the Krebs cycle, thus increasing ATP production. Volume replacement restores glomerular flow and improves excretion of organic acids. Administration of either insulin or sodium bicarbonate in the management of AKA is usually unnecessary.[59]

During the recovery phase of AKA, Î²-hydroxybutyrate is converted to acetoacetate. As this process occurs, the nitroprusside test may become more positive because of higher levels of acetoacetate, resulting in a transient hyperketonemia that actually represents improvement of the metabolic status.

Mortality is rare from either ethanol-induced ketoacidosis or hypoglycemia. However, these patients may succumb to other precipitating or coexisting medical or surgical disorders[56] such as occult trauma, pancreatitis, gastrointestinal hemorrhage or hepatorenal dysfunction, and infections.

TABLE 75-4. The Brief Michigan Alcoholism Screening Test

Question	Circle Correct Answer		Points
1. Do you feel you are a normal drinker?	Yes	No	N2
2. Do friends or relatives think you are a normal drinker?	Yes	No	N2
3. Have you ever attended a meeting of Alcoholics Anonymous?	Yes	No	Y5
4. Have you ever lost friends or girlfriends/boyfriends because of drinking?	Yes	No	Y2
5. Have you ever gotten into trouble at work because of drinking?	Yes	No	Y2
6. Have you ever neglected your obligations, your family, or your work for 2 or more days in a row because	Yes	No	Y2

you were drinking?			
7. Have you ever had delirium tremens (DTs) or severe shaking, or heard voices, or seen things that weren't there after heavy drinking?	Yes	No	Y2
8. Have you ever gone to anyone for help about your drinking?	Yes	No	Y5
9. Have you ever been in a hospital because of drinking?	Yes	No	Y5
10. Have you ever been arrested for drunk driving after drinking?	Yes	No	Y2
Score 6 = Probable diagnosis of alcoholism.

Alcoholism

Alcoholism is traditionally defined as a chronic, progressive disease characterized by tolerance and physical dependence to ethanol and pathologic organ changes. Alcoholism is a multifactorial, genetically influenced disorder,[27,71,135,146,153,159,174] and should be suspected in any patient who presents to the ED with unexplained trauma, seizures, or inappropriate behavior. Physical findings associated with

long-term alcoholism include flushed facies, parotid enlargement, gynecomastia, cardiomyopathy, hepatomegaly, stigmata of cirrhosis, testicular atrophy, palmar erythema, Dupuytren contractures, peripheral neuropathy, nutritional deficiencies, and recurrent infections.

Concern for early detection and intervention led to attempts to create reliable diagnostic screening systems. The brief Michigan Alcoholism Screening Test (MAST) (Table 75-4)[149] and the CAGE (cut down, annoyance, guilt, eye-opener) questions (Table 75-5)[117,189] represent two such tools. As can be seen from these screening tools, the presence of physical tolerance and/or dependence is not essential for a diagnosis of alcoholism. Emphasis instead is placed on the social and behavioral concomitants of heavy drinking.[129] In the ED setting, questions concerning the patient's ability to function physically and psychologically are just as appropriate as quantifying the amount of ethanol consumed per day.

Alcoholism is commonly associated with affective disorders, especially depression.[127,150] There is a higher rate of alcoholism amongst patients with bipolar disorder than in the general population, and there may be a genetic relationship between alcoholism and depression.[86,140,194,195] Ethanol affects mood, judgment, and self-control, creates a clinical condition conducive to violence directed at

self and others, and is an important risk factor for suicide. Although many people drink in an attempt to ameliorate their depression, all available evidence suggests that alcoholism adversely affects mood and cognitive ability. Research indicates an increased incidence of alcoholism in families, and twin studies suggest that a tendency to drink is partly under genetic control.[9,86,91,108] Chromosomal linkage analysis has implicated chromosomes 9, 15, and 16 in the genetic predisposition to alcoholism.[13,34,112] Genetic epidemiologic studies strongly suggest that expression of polymorphism in ADH and ALDH genes may be markers for risk of alcoholism.[25,27,43,174,176] The

ADH2*2 and ADH3*1 alleles that encode for high ADH activity (eg, rapid conversion of ethanol to acetaldehyde), and the variant ALDH2*2 allele that encodes for inactive gene product (eg, slow conversion of acetaldehyde to acetate), are associated with a reduced risk of alcoholism. The combined ADH2*2/*2-ALDH2*2/*2 (homozygous) genotype appears to offer virtual absolute protection against alcoholism. The incidence of both ADH2*1/*1 and ALDH2*1/*1 was significantly higher in patients with ethanol dependence and in patients with alcoholic liver disease.

TABLE 75-5. The CAGE Questions

1. Have you ever felt you should cut down on your drinking?
2. Have people annoyed you by criticizing your drinking?
3. Have you ever felt bad or guilty about your drinking?
4. Have you ever had a drink first thing in the morning to steady your nerves or to get rid of a hangover (eye-opener)?

Two or more affirmatives = probable diagnosis of alcoholism.

Reprinted, with permission, from West LJ Maxwell DS, Noble EP, Soloman DH: Alcoholism. Ann Intern Med 1984;100:412â€“420.

Although it is a serious disease with important health and economic consequences, alcoholism remains underdiagnosed and remains a treatment challenge.[115,196] In general, healthcare providers tend to have an overly pessimistic view of the benefits of treating alcoholism. Particularly problematic is the apparent inability of most healthcare workers to effectively deal with the problem when it

affects their colleagues. Successful efforts to combat alcoholism will require increased public education and greater acceptance of alcoholism as a medical illness amenable to treatment.

Various strategies are employed to treat alcoholism, including psychosocial and pharmacologic interventions. A review of the evidence regarding the pharmacologic treatment of ethanol dependence focusing on 5 categories of drugsâ€”the opioid antagonists naltrexone and nalmefene; acamprosate; disulfiram; various serotonergic agents; and lithiumâ€”found as follows:[60] Naltrexone reduces the risk of relapse to heavy drinking and the frequency of drinking compared with placebo, but does not substantially enhance abstinence. Acamprosate reduces drinking frequency, although its effects on enhancing abstinence or reducing time to first drink are less clear. Controlled studies of disulfiram reveal a mixed outcome pattern; some evidence suggests that drinking frequency is reduced, but minimal evidence exists to support improved continuous abstinence rates. There is limited data on serotonergic agents and the data is not encouraging. However, most studies are confounded by high rates of comorbid mood disorders. Lithium lacks efficacy in the treatment of primary ethanol dependence. Topiramate is a drug used to treat partial and generalized tonicâ€“clonic seizures. Clinical evidence suggests topiramate may aid chronic drinkers to wean themselves off alcohol and may ameliorate alcohol withdrawal symptoms.[78] The nonpharmacologic treatment for alcoholism may also be successful. Data derived from several studies and membership surveys indicate that recovery rates of 40â€“80% can be achieved in treatment programs based on the 12-step approach of Alcoholics Anonymous.[72,73,184] This approach appears to be more effective with patients who have social network support.[111]

Summary

Ethanol is widely used in our society, and ethanol use problems

impose a staggering personal, social, and economic burden. Most people are responsible drinkers of ethanol. However, some people drink alcohol in ways that are detrimental to themselves or others. Domestic violence, child abuse, fires, falls, rape, and other crimes, such as robbery and assault, and medical conditions, such as cancer, liver disease, and heart disease, are all associated with ethanol misuse. An interesting area for future study in ethanol research is the finding that genetics may be an important determinant in vulnerability to alcohol dependence. This finding suggests a biologic basis of alcoholism.

Acute ethanol intoxication and chronic alcoholism are among the most common and complex toxicologic and societal problems. These patients may present with a diversity of clinical problems that challenge clinicians to be meticulous and systematic in their evaluation and management of these patients.

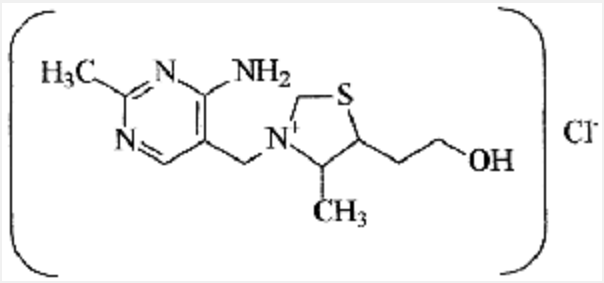
Thiamine Hydrochloride

Robert S. Hoffman

Biochemistry



Vitamin B_1 (Thiamine Hydrochloride)

Thiamine (vitamin B_1) is a water-soluble vitamin that is essential in the creation and utilization of cellular energy. As a coenzyme in

the pyruvate dehydrogenase complex, thiamine diphosphate, the active form of thiamine, accelerates the conversion of pyruvate to acetylcoenzyme A (acetyl-CoA). This reaction occurs at thiamine's C2 atom, which is located between the nitrogen and sulfur atoms on the thiazolium ring.[21] In the protein-rich environment of the enzyme complex, this C2 atom is deprotonated to form a carbanion that rapidly attaches to the carbonyl group of pyruvate, thereby stabilizing it for decarboxylation.[28] In a series of subsequent reactions, the hydroxyethyl group that remains bound to thiamine diphosphate is transferred to lipoamide, where an acetyl group is later broken off and attached to coenzyme A (CoA). This overall process links anaerobic glycolysis to the Krebs cycle, where subsequent aerobic metabolism produces the equivalent of 36 moles of adenosine triphosphate (ATP) from each mole of glucose (Fig. A22-1). When pyruvate cannot be converted to acetyl-CoA because of thiamine deficiency, for example, only 2 moles of ATP can be generated by anaerobic metabolism from each mole of glucose. Thiamine is also required as a cofactor for Î±-ketoglutarate dehydrogenase, a second enzyme in the Krebs cycle, and for transketolase, an enzyme in the pentose phosphate pathway, in which nicotinamide adenine dinucleotide phosphate (NADPH) is formed for subsequent use in reductive biosynthesis. In addition, thiamine is important in maintaining normal neuronal conduction.[61,76]

Thiamine is available from natural sources, such as organ meats, yeast, eggs, and green leafy vegetables, in a basic form composed of a substituted pyrimidine ring and a substituted thiazole ring connected by a methylene bridge. This connection between the two rings is weak, and the molecule is unstable in an alkaline milieu and in a high temperature environment. In addition, thiamine is highly water soluble, allowing it to leach out of foods that are washed or cooked in water for prolonged times. However, thiamine, which is synthesized as a hydrochloride salt is usually quite stable. Thiamine requirements are determined by total

caloric intake and energy demand, with a minimum daily requirement of 0.5 mg/1000 calories.[61]

Pharmacology

Thiamine is well absorbed from the human gastrointestinal tract by a complex process.[34,53] At low concentrations, thiamine absorption occurs through a saturable mechanism, that is most effective in the duodenum, with absorption occurring to a lesser degree in the large bowel and stomach. As thiamine concentrations increase, however, the majority of absorption occurs through simple passive diffusion. Although more recently synthesized analogs such as thiamine propyl disulfide, benfotiamine, and fursultiamine have enhanced bioavailability, their use remains largely experimental.[21,69] Chronic liver disease, folate deficiency, steatorrhea, and other forms of malabsorption all significantly decrease thiamine's absorption. This malabsorption has even greater clinical relevance in alcoholics.[4,68] In experimental studies, when healthy volunteers were given small amounts of ethanol, a 50% reduction in gastrointestinal thiamine absorption resulted.[68]

Thiamine is eliminated from the body largely by renal clearance, which consists of a combination of glomerular filtration, flow-dependent tubular secretion, and saturable tubular reabsorption.[74] In an animal model, furosemide, acetazolamide, chlorothiazide, amiloride, mannitol, and salt loading all significantly increased urinary elimination of thiamine.[39] This nonspecific flow-dependent elimination was confirmed in humans given small doses of furosemide.[52] Additionally, both furosemide and digoxin appear to inhibit thiamine uptake into myocardial cells.[79]

Thiamine Deficiency

Pathophysiology

Mice develop signs of encephalopathy 10 days after being rendered thiamine deficient. Immunohistochemistry in these animals demonstrates a breakdown of the blood-brain barrier with resultant extravasation of albumin.[24] Similarly, rats develop symptoms after 10 days of thiamine deficiency, and subsequently demonstrate deterioration of the bloodâ€“brain barrier with hemorrhage into the mammillary bodies and other areas of the brain.[11] This pattern is similar to findings described in humans with Wernicke encephalopathy.[49]

The exact cause of Wernicke encephalopathy is unclear. In human autopsy studies, brain samples from alcoholic patients with Wernicke-Korsakoff syndrome demonstrate decreased levels of pyruvate dehydrogenase, Î±-ketoglutarate dehydrogenase, and transketolase when compared to controls.[10] However, a similar decrease in enzyme activity of neuronal tissue was demonstrated in alcoholics who died from hepatic coma without ever manifesting signs of Wernicke encephalopathy.[38] Likewise, the activity of thiamine-requiring Kreb cycle enzymes is reduced in thiamine-replete patients with neurodegenerative diseases.[7] Thus, while thiamine deficiency produces deficits in critical enzymes in humans, it is

unclear whether these deficits are either necessary or sufficient to produce clinical disease.

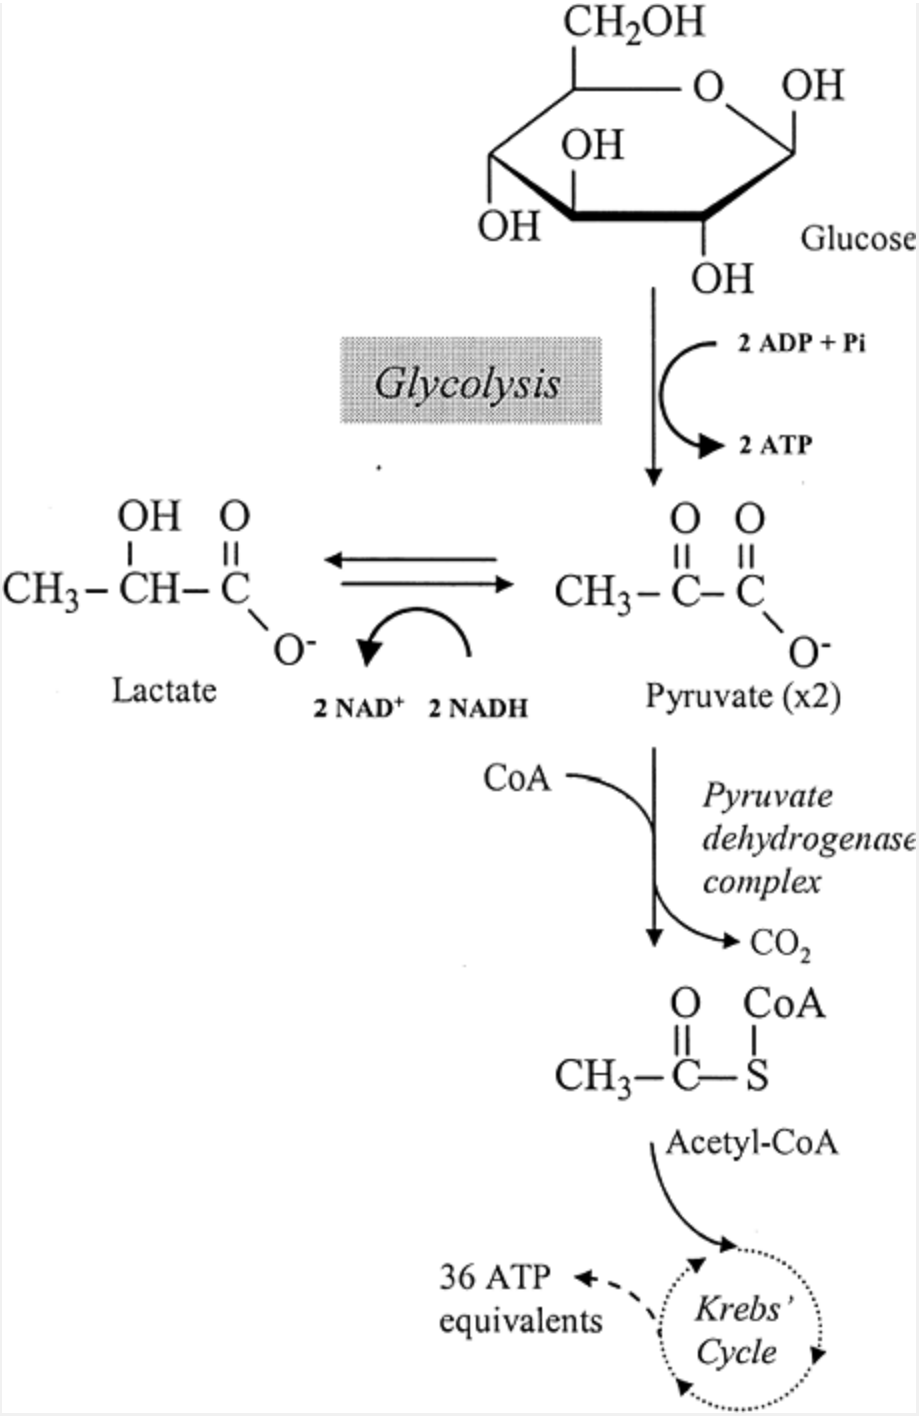


Figure A22-1. Thiamine links anaerobic glycolysis to the Krebs cycle. Anaerobic glycolysis only yields 2 moles of ATP as each mole of glucose is metabolized to 2 moles of pyruvate. To

obtain the 36 additional ATP equivalents that can be derived as the Krebs cycle converts pyruvate to CO_2 and H_2O, pyruvate must first be combined with CoA to form acetyl-CoA and CO_2. This process is dependent on the thiamine-requiring enzyme system known as pyruvate dehydrogenase complex.

Animal models offer insight into the mechanisms involved in developing thiamine-deficient neurologic injury. While the exact chain of events leading to these structural abnormalities is unclear, several models demonstrate key portions of the pathway. Thiamine deficiency in rats produces 200â€“640% increases in levels of glutamate, an excitatory amino acid.[37] This excess of glutamate presumably results from blockade of Î±-ketoglutarate dehydrogenase, which shunts Î±-ketoglutarate, a natural precursor of glutamate away from the Krebs cycle. Rats subsequently develop increases in lactate in vulnerable regions of the brain marked by the induction of the protooncogene c-fos. Both the histochemical lesions and the gene induction can be blocked by the administration of the calcium channel blocker nicardipine.[42] This suggests a strong role for excitatory amino acid-induced alterations in calcium transport in the genesis of thiamine-deficient encephalopathy. In other animal models of thiamine deficiency, neuronal tissues are also directly injured by oxidative stress and lipid peroxidation.[12] Additional lines of investigations demonstrate roles for triggered mast cell degranulation,[20] histamine,[36] and nitric oxide[31] in the generation of neuronal injury. The final common pathway is localized cerebral edema, which may result from altered expression of aquaporin.[16]

Clinical Manifestations

When thiamine is completely removed from the human diet, clinical manifestations of thiamine deficiency typically develop within 2â€“3 weeks, although tachycardia, the first sign of

deficiency, may occur as early as 9 days after cessation of thiamine intake.[76] The clinical symptoms of thiamine deficiency present as two distinct patterns: â€œwetâ€• beriberi or cardiovascular disease, and â€œdryâ€• beriberi, the neurologic disease known as Wernicke-Korsakoff syndrome. Although some patients display symptoms consistent with both disorders, usually either the cardiovascular or the neurologic manifestations predominate. A genetic variant of transketolase activity, combined with low physical activity and low-carbohydrate diet, may predispose to neurologic symptoms, whereas high-carbohydrate diets and increased physical activity lead to cardiovascular symptoms.[6,76] Thus, cardiovascular disease is more common in Asians, and neurologic disease predominates in northern Europeans.

Wet beriberi results from high-output cardiac failure induced by peripheral vasodilation and the formation of arteriovenous fistulae secondary to thiamine deficiency. These patients complain of fatigue, decreased exercise tolerance, shortness of breath, and peripheral edema. The classic triad of oculomotor abnormalities, ataxia, and global confusion defines Wernicke encephalopathy. Other manifestations include hypothermia and the absence of deep-tendon reflexes.[73] Additionally, patients develop a peripheral neuropathy with paresthesias, hypesthesias, and an associated myopathy, all related to axonal degeneration.[61] Laboratory studies may reflect a lactic acidosis brought on by excessive anaerobic glycolysis resulting from blocked entry of substrate into the Kreb cycle.[17,29,30,35,54,73] Korsakoff psychosis, an irreversible disorder of learning and processing of new information characterized by a deficit in short-term memory and confabulation, often occurs together with Wernicke encephalopathy.[71] A 10â€“20% mortality rate is associated with Wernicke encephalopathy, with survivors having an 80% risk of developing Korsakoff psychosis.[51]

Populations at Risk

In the United States, a healthy diet and mandatory thiamine supplementation of numerous food products protect most people from the manifestations of thiamine deficiency. This is, unfortunately, not true in other countries. A survey of the 17 major public hospitals in the Sydney, Australia area, identified more than 1000 cases of either acute Wernicke encephalopathy or Korsakoff psychosis between 1978 and 1993.[40] Similarly, a single Australian hospital identified 32 cases of Wernicke encephalopathy during a 33-month period.[77] In Australia, mandatory supplementation of flour with thiamine in 1991 resulted in a dramatic reduction in hospitalized cases during 1992 and 1993,[40] as well as of those subsequently identified by postmortem studies.[25] Current areas at risk include Ireland and New Zealand where lack of a mandatory supplementation program is correlated with a high prevalence of biochemical evidence of thiamine deficiency.[45]

The alcoholic patient, whose consumption of ethanol is his or her major source of calories, is the best described and most easily recognized patient at risk for thiamine deficiency.[51] Consequential thiamine deficiency is also described in inmates; postoperative patients; in those patients with hyperemesis gravidarum or anorexia nervosa; in those patients receiving parenteral nutrition; in patients with acquired immunodeficiency syndrome (AIDS); in patients with malignancies; in the institutionalized elderly;[34,35] foreign laborers from the Far East; patients

with congestive heart failure on furosemide therapy; and in patients receiving hemodialysis; among others. Thus, despite routine dietary supplementation, many people are still at risk because of dietary limitations, alcohol abuse, or underlying medical conditions.

Thiamine Replacement

Thiamine hydrochloride is included in the initial therapy for any patient with an altered mental status, potentially acting as both treatment and prevention of Wernicke encephalopathy. Many patients with altered levels of consciousness have had or will have a poor nutritional status, or will be hospitalized without oral intake for a number of days because of gastrointestinal disorders or altered mental status. Although thiamine levels can be measured, either directly or functionally, by measuring their erythrocyte transketolase activity at baseline and in response to thiamine diphosphate,[26] these tests are unavailable for clinical use. Likewise, although clinical prediction models have been developed, they are cumbersome and unvalidated.[59] Glucose loading increases thiamine requirements, which can exacerbate marginal thiamine deficiencies or even precipitate coma in the absence of parenteral thiamine supplementation.[51] Although it is commonly believed that acute glucose loading, in the form of a bolus of hypertonic dextrose, can precipitate Wernicke encephalopathy over several hours in normal individuals, there is only evidence to support this effect in patients who already have grave manifestations of thiamine deficiency.[73] Previously healthy patients require prolonged dextrose administration in order to develop Wernicke encephalopathy. Because the morbidity and mortality associated with Wernicke encephalopathy are so severe, and treatment is both benign and inexpensive, thiamine hydrochloride should be included in the initial therapy for all patients who receive dextrose, for all patients with altered consciousness, and for every potential alcoholic or nutritionally deprived individual who presents to the emergency department or other clinical setting.

Initial therapy consists of the immediate parenteral administration of 100 mg of thiamine hydrochloride. This can be given either intramuscularly or intravenously, but the oral route should be

avoided because of its unpredictable absorption. In countries where thiamine propyl disulfide (a lipid-soluble thiamine preparation) is available, the oral route may be considered equally efficacious for the replacement of serious thiamine deficiencies.[4,68,69,2] In some patients, symptoms such as ophthalmoplegia are reported to respond rapidly to as little as 2 mg of thiamine; however, the other neurologic and cardiovascular manifestations of thiamine deprivation may necessitate higher doses and may respond more slowly, if at all. Although virtually every source recommends that daily doses of 100 mg of thiamine are sufficient as preventive therapy, a recent trial suggested improved cognitive function when a daily dose of 200 mg was compared to lower doses.[1] Because of the safety of thiamine hydrochloride, and the urgency to correct the manifestations of thiamine deficiency, up to 1000 mg of thiamine hydrochloride can be used in the first 12 hours if a patient demonstrates persistent neurologic abnormalities.[43]

The practice of requiring the administration of parenteral thiamine prior to hypertonic dextrose in patients with altered consciousness is illogical.[22] Besides the fact that the first dose of dextrose is unlikely to cause thiamine deficiency, thiamine uptake into cells and activation of enzyme systems is slower than that of glucose uptake, which suggests that even pretreatment with thiamine offers little benefit over posttreatment.[66] Despite these limitations it is prudent to administer 100 mg of parenteral thiamine at the time of initial dextrose administration. The biochemical link between dextrose and thiamine is obvious, which demonstrates to the clinician the scientific basis for the administration of thiamine. Although thiamine is unlikely to offer immediate benefits for patients with altered consciousness, it will offer some long-term protection for these individuals at risk and initiate therapy for an uncommon, serious, insidious and easily overlooked disorder.

A supplementary indication for the administration of thiamine hydrochloride occurs in patients with ethylene glycol poisoning. As

shown in Figure 103-2, a minor pathway for the elimination of glyoxylic acid involves its conversion to Î±-hydroxy-Î²-ketoadipate by Î±-ketoglutarate:glyoxylate carboligase, a thiamine and magnesium-requiring enzyme. There are no data to support an increase in Î±-hydroxy-Î²-ketoadipate formation following thiamine administration in ethylene glycol-poisoned animals or humans. However, animal models of primary hyperoxaluria show increases in urinary oxalate during thiamine deficiency, suggesting at least a potential importance of this pathway.[23,65] Because therapy is benign and inexpensive, it is prudent to administer standard doses of thiamine to patients with suspected or confirmed ethylene glycol poisoning. If magnesium supplementation is considered, caution is required because of the potential for renal compromise in ethylene glycol poisoned patients.

Routine thiamine administration should also be considered in patients with congestive heart failure and long-term use of diuretics. Diuretics enhance renal thiamine elimination. In one randomized trial, 200 mg of daily intravenous thiamine was able to increase cardiac ejection fraction by 22% at 7 weeks.[60]

Adverse Events

Very few complications are associated with the parenteral administration of thiamine. The older literature emphasized intramuscular administration because of numerous reports of anaphylactoid reactions associated with intravenous thiamine delivery.[19,50,56,63,75] It is generally believed that these reactions resulted from responses to the vehicle (chlorbutanol) or its contaminants rather than thiamine itself. Despite the availability of purer, aqueous preparations of thiamine, rare adverse reports still occur.[3,41,48,62] Although the intramuscular route is theoretically comparably efficacious in a healthy individual, many patients requiring thiamine may have diminished muscle mass or a

coagulopathy, exacerbating the potential for pain and unpredictable absorption. The safety of thiamine use was evaluated in a large case series in which nearly 1000 patients received parenteral doses of up to 500 mg of thiamine without significant complications.[78] This study suggests that if anaphylaxis to thiamine exists, its occurrence is exceedingly rare, permitting the safe intravenous administration of thiamine to most patients.

Pregnancy Category

Thiamine hydrochloride is listed as pregnancy A and is also considered safe for use in lactating mothers.

Availability

Multiple manufacturers formulate thiamine hydrochloride for intravenous or intramuscular administration. Typical concentrations are either 50 or 100 mg/mL. Although more concentrated solutions are available, their use is usually reserved for preparation of total parenteral nutrition solutions.

Chapter 76
Ethanol Withdrawal

Jeffrey Gold

Lewis S. Nelson

A 46-year-old man with a seizure disorder arrived in the emergency department requesting his daily phenytoin dose after being in police custody for 18 hours. He denied any physical complaints, and simply wanted to be seen and discharged.

His triage vital signs were: blood pressure, 130/80 mm Hg; respiratory rate, 12 breaths/min; pulse, 105 beats/min, without orthostatic changes; and rectal temperature, 99.9Â°F (37.2Â°C). He was well developed, poorly nourished, and appeared older than his stated age. He was garrulous and somewhat anxious, although alert and oriented to time, place, and person. On physical examination he had fine hand and tongue tremors, scattered spider hemangiomata, and hepatomegaly of 14 cm.

Blood was drawn for a complete blood count, serum chemistries, liver function tests, and blood alcohol and phenytoin concentrations. A bedside rapid reagent blood sugar was 70 mg/dL. One liter of 0.9% sodium chloride was administered at 500 mL/h. Multivitamins and

100 mg of thiamine were given intravenously.

One hour later, the patient began to shout at nursing staff that he was being held against his will and that he must leave. He was unable to remember why he asked to be evaluated or who brought him to the hospital. Repeat vital signs were: blood pressure, 130/80 mm Hg; pulse, 130 beats/min; respiratory rate, 12 breaths/min; room air pulse oximetry, 98% saturation; and rectal temperature, 100.3Â°F (37.9Â°C). The patient was diaphoretic with a coarse tremor. The pupils were 5 mm, equal, and briskly reactive.

The patient's clinical condition was unchanged after two separate doses of diazepam 10 mg IV 15 minutes apart. Diazepam was repeated as 10-mg IV boluses to a total of 100 mg, and the patient was placed in 4-point soft restraints after he began to remove his intravenous line and climb off the stretcher. His diaphoresis and tachycardia continued. He picked at the restraints, scratched his skin, and shouted nonsensical words occasionally.

Diazepam administered to a total dose of 220 mg did not improve the patient's agitation; the pulse was 110 beats/min; respiratory rate, 12 breaths/min; and temperature, 101.0Â°F (38.3Â°C). Phenobarbital was administered as 130-mg boluses over 3 minutes and repeated 4 times (520 mg total), following which the patient was calm, and the heart rate was 100 beats/min. The patient was electively intubated, given thiopental, and attached to a mechanical ventilator for airway protection. The patient remained sedated and required an additional 40 mg of diazepam over the next 24 hours. He developed a right lower lobe infiltrate on day 2 of his hospitalization and was treated with ampicillin plus sulbactam. He recovered uneventfully and was extubated 48 hours later.

History and Epidemiology

The medical problems associated with alcoholism and alcohol withdrawal were first described by Pliny the Elder in the 1st century

B.C. In his work *Naturalis Historia*, the alcoholic and alcohol withdrawal were described as follows: â€œâ€¦drunkenness brings pallor and sagging cheeks, sore eyes, and trembling hands that spill a full cup, of which the immediate punishment is a haunted sleep and unrestful nights. â€¦â€• [63] Initial treatments as described by Osler were focused on supportive care, including confinement to bed, cold baths to reduce fever, and judicious use of potassium bromide, chloral hydrate, hyoscine, and, possibly, opium.[62]

Some of the initial large series of alcohol related complications in the early 20th century describe the alcohol withdrawal syndrome (AWS) as a major public health concern. At Bellevue Hospital in New York City, Jolliffe describes 7000â€“10,000 admissions per year for alcohol-related problems from 1902â€“1935, with an estimated rate of 2.5â€“5 admissions/1000 New York City residents.[42] Moore et al describe similar numbers of admissions to Boston City Hospital, with up to 10% of alcoholics admitted with evidence of delirium tremens (DT). The mortality at the beginning of their study among patients with DT was 52% (1912), and DT was the leading cause of death among admitted alcoholics. Over the ensuing 20 years, this rate declined to approximately 10â€“12%, a decrease believed to be secondary to improved supportive care and nursing.[57]

Though widely recognized that alcoholics had a high incidence of delirium and psychomotor agitation, it remained controversial as to whether this was caused by ethanol use, ethanol abstinence, or coexisting psychological disorders. Isbell and colleagues, in 1955, proved that abstinence from alcohol was the cause of this syndrome when they subjected 9 male prisoners to chronic alcohol ingestion for a period of 6â€“12 weeks followed by 2 weeks of abstinence.[40] During this latter period, 6 of the 9 men developed tremor, elevations in blood pressure, heart rate, diaphoresis, and varying degrees of either auditory or visual hallucinations, consistent with the diagnosis of DT.[40] In addition, 2 of the 9 men developed convulsions, further linking alcohol abstinence to seizures. However, it should be noted that the high rate of development of

DT (67%) is atypical and does not represent the true prevalence found in later epidemiologic studies.[12]

Currently, alcoholism and alcohol withdrawal syndromes still represent a major problem in both the inpatient and outpatient setting. In a 10-year epidemiologic study, the prevalence of self-reported symptoms of alcohol withdrawal, including morning tremors and sweating, in the general population was quite low, with only 1â€“3% of men describing 1 or more symptoms of alcohol withdrawal; rates were even lower among women.[12] However, when the population in this study was enriched by those at risk for alcoholism, with at risk being defined as convicted for driving under the influence, nearly 19% met self-reported *Diagnostic and Statistical Manual of Mental Disorders* (4th ed.) (DSM-IV) criteria for alcohol withdrawal. The prevalence was even higher among persons admitted for detoxification, with nearly 80% experiencing 1 or more withdrawal symptom.[12]

Similar results have been obtained in the inpatient setting. Alcohol-related complications accounted for 21% of all medical ICU admissions, with alcohol withdrawal being the most common alcohol-related diagnosis.[54] In one study, 8% of all general hospital admissions, 16% of all postsurgical patients, and 31% of all trauma patients developed AWS.[27,69] The development of AWS in postsurgical and trauma patients can increase the mortality in this population nearly 3-fold.[68,70] Furthermore, alcohol was involved in nearly 86% of homicides, 37% of assaults, and 25â€“35% of nonfatal motor vehicle crashes.[59]

Pathophysiology

Numerous studies over the past 2 decades have provided valuable insight into the mechanism of alcohol withdrawal, allowing for better understanding of both the clinical spectrum of the disorder and potential therapeutic interventions. Alcohol withdrawal is a

neurologic disorder with a continuum of progressively worsening symptoms caused by the effects of chronic ethanol use on the central nervous system, and often exacerbated by the clinical manifestations of alcoholism (eg, nutritional depletion, impaired immunity, anemia, cirrhosis, head trauma).

The effects of chronic alcohol consumption on neurotransmitter function best explains the clinical findings. Persistent stimulation of the inhibitory Î³-aminobutyric acid (GABA) receptor-chloride channel complex by ethanol, leads to downregulation of GABA receptorâ€“chloride channel complex.[11,44] This allows the alcohol user to maintain a relatively normal level of consciousness despite the presence of sedative concentrations of ethanol in the brain. A continued escalation of the steady-state ethanol concentration is required to achieve euphoria (ie, tolerance), which results in progressive desensitization of the GABA receptorâ€“chloride channel complex.[24] The exact mechanism by which this adaptive change occurs is undefined, but may involve substitution of an $\hat{I}\pm_4$ for an $\hat{I}\pm_1$ receptor subunit on the $GABA_A$ receptor (Chap. 15).[13,49] A converse series of events occurs at the *N*-methyl-D-aspartate (NMDA) subtype of glutamate receptor. Binding by ethanol to the glycine binding site of this receptor inhibits the NMDA function, resulting in compensatory upregulation of these excitatory receptors.[33,38] Thus withdrawal of alcohol is associated with both a decrease in GABAergic activity and an increase glutamatergic activity.[33] This phenomenon of a concomitant increased excitation and loss of inhibition results in the clinical manifestations of autonomic excitability and psychomotor agitation.

Repeated episodes of alcohol withdrawal may lead to poorly understood permanent alterations in neurotransmitters and their receptors. In rats, repeated episodes of alcohol withdrawal leads to persistent and progressive EEG abnormalities, with further episodes of withdrawal becoming increasingly resistant to benzodiazepines. Both clinical observation and in vitro data suggest that repeated episodes of alcohol withdrawal leads to permanent dysregulation of

GABA receptors. This understanding may be an explanation for the â€œkindling phenomena,â€• which is the clinical observation of increasing severity of alcohol withdrawal among individual subjects, and the development of benzodiazepine resistant alcohol withdrawal.[10,30,84]

Clinical Syndromes

Alcohol withdrawal is defined in the DSM-IV as the cessation of heavy or prolonged alcohol use resulting, within a period of a few hours to several days, in the development of 2 or more of the clinical findings listed in Table 76-1.[26] Furthermore, these symptoms must have no other organic etiology. Alcohol withdrawal syndromes can be classified both by timing (early vs. late) and severity (complicated vs. uncomplicated). However, there are no adequate or fully accepted criteria by which to define these categories. Furthermore, the clinical course of AWS can vary widely among patients, and progression of individual patients through these different stages is extremely variable. In fact, some heavy alcohol users experience no withdrawal syndrome following the cessation of alcohol consumption. Recognizing these limitations, this conceptual framework still proves helpful in the clinical management of patients with alcohol withdrawal.

Early Uncomplicated Withdrawal

Alcohol withdrawal begins as early as 6 hours after the cessation of drinking. Early withdrawal is characterized by autonomic hyperactivity including tachycardia, tremor, hypertension, and psychomotor agitation. Although these symptoms are uncomfortable, they are not generally dangerous. Most patients who ultimately develop severe manifestations of AWS initially develop these findings, but this is not universal. At this â€œstageâ€• of AWS, the symptoms are still readily amenable to treatment with ethanol, as is done daily by most heavy alcohol users.

TABLE 76-1. DSM-IV Criteria for Alcohol Withdrawal

A. Cessation of (or reduction in) alcohol use that has been heavy and prolonged.
B. Two (or more) of the following, developing within several hours to a few days after criterion A:
   1. Autonomic hyperactivity (e.g., sweating or pulse rate greater than 100)
   2. Increased hand tremor
   3. Insomnia
   4. Nausea or vomiting
   5. Transient visual, tactile, or auditory hallucinations or illusions
   6. Psychomotor agitation
   7. Anxiety
   8. Grand mal seizures
C. The symptoms in criterion B cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
D. The symptoms are not due to a general condition and are not better accounted for by another mental disorder.

Alcoholic Hallucinosis

Nearly 25% of patients with AWS will develop hallucinations, and a subset of these patients will develop alcoholic hallucinosis, a syndrome of persistent hallucinations.[75,78] Although classically these hallucinations are tactile or visual, other types of hallucinations are described. Tactile hallucinations include formication, or the sensation of ants crawling on the skin, which can result in repeated itching and

excoriations. However, as opposed to what is observed with DT, alcoholic hallucinosis is associated with a clear sensorium. The presence of alcoholic hallucinosis is neither a positive or negative predictor of the subsequent development of DT.[39]

Alcohol Withdrawal Seizures

Approximately 10% of patients with AWS develop alcohol withdrawal seizures, or â€œrum fits.â€• For many patients, a generalized alcohol withdrawal seizure may be the first manifestation of the AWS.[76] Approximately 40% of patients with alcohol withdrawal seizures have isolated seizures and 3% develop status epilepticus.[76,77] Alcohol withdrawal seizures may occur in the absence of other signs of alcohol withdrawal and are characteristically brief, generalized, tonicâ€“clonic events with a short postictal period. Rapid recovery and normal mental status belie the seriousness of an alcohol withdrawal seizure. However, for approximately one-third of patients with DT, the sentinel event is an isolated alcohol withdrawal seizure. Alcohol withdrawal seizures occurring in the presence of an elevated ethanol concentration may be a poor prognostic indicator for the development of DT because the relative protection against withdrawal of an elevated ethanol concentration will be lost as the concentration drops.[74] Finally, clinicians should be cognizant that many alcoholics are prescribed anticonvulsant medications because they have a preexisting seizure disorder, often related to repetitive brain trauma.[29] Conversely, the use of anticonvulsants does not unequivocally indicate the presence of a preexisting seizure disorder because of the difficulty in differentiating these seizures from those of alcohol withdrawal.

Delirium Tremens

Delirium tremens is the most serious complication of the AWS, and it generally manifests between 48 and 96 hours after the cessation of drinking.[76] Many of the clinical manifestations of DT are similar to

those of uncomplicated early alcohol withdrawal, differing only in severity, and include tremors, autonomic instability (hypertension and tachycardia), and psychomotor agitation. However, unlike AWS, DT, as defined in DSM-IV, is associated with either (a) disturbance of consciousness (such as reduced clarity of awareness of the environment) with reduced ability to focus, sustain, or shift attention, delirium, confusion, and frank psychosis, or (b) a change in cognition (such as memory deficit, disorientation, language disturbance) or the development of a perceptual disturbance that is not better accounted for by a preexisting, established, or evolving dementia.[26] Unlike the early manifestations of alcohol withdrawal, which typically last for 3â€“5 days, DT can last for up to 2 weeks (Table 76-2).[76]

TABLE 76-2. Diagnostic Criteria for Substance Withdrawal Delirium

A. Disturbance of consciousness (ie, reduced clarity of awareness of the environment) with reduced ability to focus, sustain, or shift attention.
B. A change in cognition (such as memory deficit, disorientation, language disturbance) or the development of a perceptual disturbance that is not better accounted for by a preexisting, established, or evolving dementia.
C. The disturbance develops over a short period of time (usually hours to days) and tends to fluctuate during the course of the day.
D. There is evidence from the history, physical examination, or laboratory findings that the symptoms in criteria A and B developed during, or shortly after discontinuation of substance use.

Risk Factors for the Development of Alcohol Withdrawal

Factors determining whether an individual will develop AWS are not well identified. The strongest predictor for the development of AWS is a history of prior episodes of AWS/DT and/or a family history.[46] The influence of family history on the development of AWS suggests a strong role for genetic factors. Recent studies document a strong association between the A9 polymorphism of the dopamine transporter and the development of AWS/DT.[31] Whether this finding represents a predisposition to greater ethanol consumption because of an enhanced mesolimbic reward system, or some other underlying pathophysiologic effect, is unclear. Similar results are observed with the C allele of the neuropeptide Y gene.[45] Larger and more varied patient cohorts that include both women and nonwhite ethnic groups are required before any definitive conclusions can be drawn.

Because of the subjective nature of many of these findings, we discourage the use of pure clinical descriptors, such as DT, tremors, rum fits, and the like, to classify the severity of alcohol withdrawal in any given patient. Furthermore, the necessity of having a standardized means of classification has enormous implications for epidemiologic, genetic, and treatment studies. One of the more commonly used means for accurately assessing alcohol withdrawal is the Clinical Institute Withdrawal Assessment of Alcohol Scale, Revised (CIWA-Ar) score (Fig. 76-1).[72] This scoring system contains 10 clinical categories and requires less than 5 minutes to complete. Scoring systems are not only essential for symptom-triggered therapy, but provide a basis for comparative analysis of clinical trials in ethanol withdrawal. Greater use of CIWA-Ar or a comparable validated scale will be essential for interpretation of both genetic and treatment trials in the future.

Clinical and Biochemical Predictors

Alcohol concentrations, homocysteine concentrations, and liver function tests are often studied and loosely associated with the development of AWS, with frequently contradictory study results.[8,46] Because many studies are based on small numbers of often highly selected subjects, their generalizability is extremely poor.

Numerous attempts have been made to develop biochemical predictors for the presence and/or severity of alcohol withdrawal. Although consistent abnormalities in readily obtained laboratory values are observed in patients with AWS (eg, aminotransferases, magnesium, erythrocyte parameters), their role in predicting the severity of AWS is poorly described. In one study, an alanine aminotransferase (ALT) >50 U/L (odds ratio [OR] 9.0; 3.5â€“24), a chloride <96 mEq/L (OR 61.5; 54.4â€“69.6), and a potassium <3.6 mEq/L (OR 5.7; 2â€“16.4) were all associated with the development of alcohol withdrawal in patients admitted to a detoxification

center.[81] However, the low specificity of these derangements makes it difficult to assess their predictive value, especially when accounting for other clinical characteristics such as prior history and admission CIWA-Ar score. In addition, there is a negative association between the presence of severe alcohol withdrawal and histopathologic cirrhosis, further clouding the usefulness of routine laboratory testing for prognostication.[3]

Clinical Institute Withdrawal Assessment Of Alcohol Scale, Revised (CIWA-Ar)

Patient:_____ Date: _____Time: _____(24 hour clock, midnight = 00:00)

Pulse or heart rate, taken for one minute: _____ Blood pressure:_____

NAUSEA AND VOMITING: Ask "Do you feel sick to your stomach? Have you vomited?" Observation.
0 No nausea and no vomiting
1 Mild nausea with no vomiting
2
3
4 Intermittent nausea with dry heaves
5
6
7 Constant nausea, frequent dry heaves and vomiting

TREMOR: Arms extended and fingers spread apart. Observation.
0 No tremor
1 Not visible, but can be felt fingertip to fingertip
2
3
4 Moderate, with patient's arms extended
5
6
7 Severe, even with arms not extended

PAROXYSMAL SWEATS: Observation.
0 No sweat visible
1 Barely perceptible sweating, palms moist
2
3
4 Beads of sweat obvious on forehead
5
6
7 Drenching sweats

ANXIETY: Ask "Do you feel nervous?" Observation.
0 No anxiety, at ease
1 Mild anxious
2
3
4 Moderately anxious, or guarded, so anxiety is inferred
5
6
7 Equivalent to acute panic states as seen in severe delirium or acute schizophrenic reactions

AGITATION: Observation.
0 Normal activity
1 Somewhat more than normal activity
2
3
4 Moderately fidgety and restless
5
6
7 Paces back and forth during most of the interview, or constantly thrashes about

TACTILE DISTURBANCES: Ask "Have you any itching, pins and needles sensations, any burning, any numbness, or do you feel bugs crawling on or under your skin?" Observation. 0 none
1 Very mild itching, pins and needles, burning or numbness
2 Mild itching, pins and needles, burning or numbness
3 Moderate itching, pins and needles, burning numbness
4 Moderately severe hallucinations
5 Severe hallucinations

Figure 76-1. Clinical Institute Withdrawal Assessment.

(Reproduced from Sullivan JT, Sykora K, Schneiderman J, et al: Assessment of alcohol withdrawal: The revised Clinical Institute Withdrawal Assessment of Alcohol Scale (CIWA-Ar). Br J Addict 1989;84:1353â€“1357.)

Other investigators have focused on admission ethanol concentration as a predictor for the severity of alcohol withdrawal in at risk subjects. In one study, an admission blood ethanol concentration of >150 mg/dL had a 100% sensitivity and a 57% specificity for the need of acute care for treatment of alcohol withdrawal.[79] At a different treatment facility, an ethanol concentration of >150 mg/dL had an 81% positive predictive value for the need to use more than a single dose of chlordiazepoxide for the treatment of AWS.[79] In addition, admission blood ethanol concentrations in patients with alcohol withdrawal seizures were 2-fold higher than in those without seizures, irrespective of whether or not they had a history of prior withdrawal seizures.[79] However, these results should be interpreted with caution, as other studies yield conflicting results. In one study, an admission ethanol concentration <100 gm/dL was associated with an increased risk of recurrent alcohol withdrawal seizures, and in another study, admission ethanol concentrations failed to predict the development of DT.[18,65] There are many potential explanations, including differences in patient population, differences in cohort size, and the late onset of DT, at a time when ethanol concentrations would be extremely low or nonexistent.[18]

More recently, investigators have looked at the prognostic usefulness of plasma homocysteine concentrations. Numerous reports document hyperhomocysteinemia in alcoholism, presumably caused by a deficiency of dietary folic acid.[21] Furthermore, homocysteine and its metabolites can act as excitatory neurotransmitters at the NMDA receptor and cause seizures and excitatory neuronal death.[51] In one study, plasma homocysteine concentrations were predictive of alcohol withdrawal seizures. However, in this study, there was very

strong correlation (r^2 = 0.7666; P < 0.001) between admission blood ethanol concentrations and homocysteine concentrations, raising doubts as to whether this holds any advantage over blood ethanol concentrations.[8]

Management

Alcohol Withdrawal Seizures

Alcohol withdrawal seizures are perhaps the most rigorously studied complication of AWS. Although alcohol withdrawal seizures are generally self-limited, benzodiazepines are the preferred agent for patients with persistent or recurrent alcohol withdrawal seizures. In a randomized placebo-controlled trial of 229 subjects with alcohol withdrawal seizures, 2 mg of intramuscular lorazepam reduced the risk of recurrent seizure from 24% to 3% (p < 0.001) at 6 hours, and the need for hospital admission from 42% to 29% (p = 0.0222). There is no role for phenytoin in either treatment or prevention of alcohol withdrawal seizures. In multiple trials, phenytoin was ineffective in preventing alcohol withdrawal seizure recurrence.[1,15,64] The most likely explanation for the failure of phenytoin is its inability to regulate GABA or NMDA receptors, the principle mediators of seizures in alcohol withdrawal. One exception to this lack of usefulness occurs in the alcoholic patient with a nonalcohol withdrawal-mediated seizure, or a history of underlying seizure disorders.

Alcohol Withdrawal

In the early stages of alcohol withdrawal, many patients are able to self-medicate with additional ethanol consumption. Among those who seek medical attention, many patients with AWS can be safely managed as outpatients. Outpatient management has significant cost savings with little effect on treatment outcome.[34] In one study, patients who exhibited a lack of intoxication, no history of either DT

or alcohol withdrawal seizures, no comorbid psychiatric or medical disorders, and a CIWA-Ar score of <8, were safely managed as outpatients.[2] Patients not meeting these criteria were referred to inpatient detoxification centers or medical units, depending on the severity of withdrawal and other comorbid conditions.

For all patients with AWS, the initial stages of therapy remain the same, and should include a thorough assessment to identify a coexisting medical, psychiatric, or toxicologic disorder. In particular, an assessment for central nervous system trauma and infection should include the appropriate use of computed tomography and lumbar puncture. Patients with altered cognition and an elevated body temperature should receive antibiotics, pending the results of a lumbar puncture. In concert with this approach, adequate supportive care should be instituted, including maneuvers to normalize any abnormal vital signs such as hyperthermia.

Chronic ethanol consumption leads to severe vitamin and nutritional deficiencies and electrolytes disturbances that should be corrected.[21,37] Specifically, thiamine should be given to all patients to prevent the development of Wernicke encephalopathy. It is generally suggested that thiamine should be given prior to the administration of dextrose to prevent precipitation of Wernicke encephalopathy.[55,80] Although there is little evidence for this approach, the administration of thiamine (see Antidote in Depth: Thiamine Hydrochloride) and dextrose together is a reasonable practice. In addition, there is a high incidence of intravascular volume depletion among alcoholics, so all patients should receive adequate volume resuscitation. Of 39 deaths attributed to DT in which volume status was recorded, all subjects were volume depleted.[57] Finally, for patients with AWS, particularly if severe, prevention of nosocomial complications is paramount for reducing hospital stay. Currently, in addition to adequate volume replacement, we recommend that all patients be kept with the head of the bed elevated to prevent aspiration, and that deep vein thrombosis prophylaxis be given if the patient is bed bound for an extended

period.

The association of severe alcohol withdrawal with severe psychomotor agitation led to early use of sedative hypnotics. One of the first randomized trials compared chlorpromazine to paraldehyde. In both arms there was a 0% mortality, suggesting equivalency of the 2 treatments.[28] Over the ensuing years, numerous trials documented similar efficacy between paraldehyde, benzodiazepines, and antipsychotics.[14,28,73] However, in a landmark study, 547 patients were randomized to 1 of 4 drugs (chlordiazepoxide, chlorpromazine, hydroxyzine, and thiamine) or to placebo for the treatment of alcohol withdrawal.[43] Patients receiving chlordiazepoxide had the lowest incidence of both DT and alcohol withdrawal seizures, establishing benzodiazepines as a first-line agent for treatment of AWS. Of note, use of chlorpromazine, an antipsychotic, was associated with a significant increase in the incidence of seizures in both humans and animal models.[9,43]

Since this study, numerous trials have compared different routes of administration among various sedativeâ€“hypnotic agents, both to each other and to placebo. Because of the historical use noted above, chlordiazepoxide remains widely used in outpatient and inpatient detoxification clinics. Oral benzodiazepine administration is generally effective in patients with early or mild AWS, although initial rapid titration with an intravenous regimen may be more efficient. Benzodiazepines administered intravenously have a rapid onset of action, and have long displaced paraldehyde as the preferred choice for acute control. Among the benzodiazepines, diazepam offers the most rapid time to peak clinical effects, which limits oversedation that may occur following the administration of drugs with slower onset to the peak drug effect, such as lorazepam. Because of the delayed peak clinical effect of lorazepam of approximately 10â€“20 minutes, several doses may be administered in rapid succession with little clinical effect, followed by the appearance of the sedative effect of the cumulative doses. Midazolam may be administered

intramuscularly if intravenous access is not available, but intramuscular injection delays significantly the time to both onset and peak clinical effect. Although no significant differences are observed between benzodiazepines and barbiturates in terms of mortality or the duration of delirium,[2,47] the improved pharmacokinetic profile and ease of administration favor benzodiazepines as the preferred initial agent.

Other pharmacokinetic factors and experience confirm that diazepam is the preferred agent for initial intravenous use in patients with moderate to severe AWS. Diazepam has a long half-life and has an active metabolite (desmethyldiazepam). The prolonged half life (48â€“72 hours) of desmethyldiazepam further extends the effective duration of action of the initial dose of diazepam.[87] A retrospective review reported that the use of a single benzodiazepine rather than multiple benzodiazepines was a marker for treatment success in surgical patients experiencing alcohol withdrawal during surgical admission.[60] These data suggest that it is more important to rapidly sedate the patient with adequate doses of a single benzodiazepine than to use multiple agents in hopes of finding an effective regimen. Finally, it should be noted that in patients with advanced liver disease, the use of diazepam may result in a very prolonged period of sedation because of impaired clearance of the parent compound and its metabolites. Consequently, in these patients, a benzodiazepine without active metabolites, such as lorazepam, may be a better drug.

The initial management of patients with AWS/DT should include rapid titration with intravenous benzodiazepine to achieve sedation. The goal of therapy is to have the patient sedated but breathing spontaneously, with normal vital signs. In many patients, complete sedation may allow for autotitration; that is, as the AWS resolves, the blood concentrations of diazepam and desmethyldiazepam decrease, allowing gradual recovery. In practicality, most patients need periodic redosing with diazepam to maintain adequate sedation. This is particularly important in patients with AWS with an elevated

blood alcohol concentration.

Multiple studies now suggest that if additional doses are required, they should be administered based on symptoms (â€œsymptom triggeredâ€•), as opposed to a fixed dosing schedule. In 2 randomized controlled trials, administration of benzodiazepine in a symptom-triggered fashion reduced both the total amount of benzodiazepine and the duration of treatment.[23,67] In these trials, benzodiazepines were administered every hour as long as the CIWA-Ar score remained >8â€“10. In both trials, symptom-triggered therapy resulted in a 4â€“6-fold reduction in the duration of therapy and a 4â€“5-fold reduction in the total amount of benzodiazepine administered, with no increase in withdrawal seizures or adverse events.[23,67] Symptom-triggered doses in patients with moderate or severe AWS should be diazepam 10â€“20 mg IV or lorazepam 2â€“4 mg.[55] For less-symptomatic patients, oral chlordiazepoxide 50â€“100 mg should be administered. However, it is important to note, that the decision to treat in the symptom-triggered group was made based on CIWA-Ar score (usually >8), which demonstrates the usefulness of standardized scoring and evaluation tools. Finally, it should be noted that in both of these trials, patients had very mild withdrawal symptoms, with mean CIWA-Ar scores of 9â€“11, although experience suggests that this same regimen is also effective in patients with serious withdrawal and/or DT.

Resistant Alcohol Withdrawal and Delirium Tremens

There is a subgroup of patients with AWS who require very large doses of diazepam, or another comparable drug to achieve initial sedation.[50,61,85] This same group often has exceedingly high benzodiazepine requirements to maintain this level of sedation. Subjects with resistant AWS and DT may have benzodiazepine requirements that exceed 2600 mg of diazepam within the first 24 hours, and generally require admission to an intensive care or

stepdown unit.[85] Patients admitted to the Bellevue hospital medical ICU for resistant alcohol withdrawal had very high diazepam requirements, with a mean of 234 mg (range: 10â€“1490 mg) required in the first 24 hours, and individual doses of diazepam that often exceeded 100 mg, to control their agitation. At Bellevue, these patients comprise approximately 5% of all ICU admissions, with nearly 40% of patients requiring mechanical ventilation and a mean ICU length of stay of 5.7 days.

The approach to the management of resistant AWS depends on several factors, including the availability of an intensive care unit bed. In the ICU, despite the perception of failure of high benzodiazepine requirements, we favor administration of benzodiazepines in a symptom-triggered fashion. Patients who receive this therapy generally respond to bolus doses of diazepam ranging from 10â€“100 mg, which results in a brief period of sedation followed by recrudescence of their AWS. This approach was confirmed in a study of patients who developed AWS postoperatively in the ICU.[71] In this study, a symptom-triggered strategy resulted in a shorter length of stay and a lower incidence of mechanical ventilation than did continuous infusion of midazolam.[71] In non-ICU settings, the ability to administer frequent intravenous doses of diazepam is limited, and the use intravenous infusions with secondary sedative agents may be more practical.

In instances of extreme benzodiazepine resistance, patients often receive a second GABAergic drug because of â€œfailureâ€• of benzodiazepine therapy. Phenobarbital, given in combination with benzodiazepine, in intravenous doses of 130 mg, is a reasonable choice. Caution is required to avoid stacking doses of phenobarbital, as the onset of clinical effect takes approximately 20â€“40 minutes.[35,41] Alternatively, propofol in standard doses may be administered. Although propofol has a rapid onset, it is difficult to titrate.[19,56] The main drawback to the use of these drugs is their narrow therapeuticâ€“toxic index, with the potential for profound respiratory depression. This is especially true for propofol, which

should generally only be used in the setting of mechanical ventilation. Both of these agents can act synergistically with benzodiazepines to enhance GABA-induced chloride channel opening. In

addition, propofol uniquely antagonizes NMDA receptors, thus reducing the excitatory component of AWS.

Ethanol

Ethanol consumption is a common and effective means by which alcoholics can self-medicate to treat and/or prevent mild alcohol withdrawal. However, little controlled data exist on the role of ethanol, whether oral or by infusion, for the in-hospital treatment of AWS/DT. In one trial, 39 trauma patients without liver or CNS disease were successfully treated with 10% ethanol infusion for treatment of presumed AWS.[20] Although the authors did not report any adverse effects in this trial, the necessity for frequent blood alcohol monitoring, unpredictable elimination kinetics, potential for significant hepatic complications, and the difficulty in safely administering this therapy makes it inappropriate to recommend this regimen.[25,36,55,82]

Adrenergic Antagonists

Numerous studies have investigated the use of sympatholytics to control the autonomic symptoms of alcohol withdrawal. Both Î²-adrenergic antagonists and clonidine reduced blood pressure and heart rate in randomized, placebo-controlled trials.[4,48,86] However, the inability of these agents to address the underlying pathophysiologic mechanism of AWS, and subsequently control the neurologic manifestations, makes them suboptimal as sole therapeutic agents. There are additional concerns that by altering the physiologic parameters that serve as classic markers for AWS severity, there is a risk of underadministering necessary amounts of

benzodiazepines.[86] Consequently, we do not recommend using these drugs for the treatment of alcohol withdrawal until it becomes clear that other standard therapies have failed.

Magnesium

The benefits of magnesium supplementation are based both on the high prevalence of magnesium deficiency in alcoholics and its usefulness in preventing seizures in other disorders, including eclampsia.[5,37] Furthermore, magnesium deficiency has many clinical similarities to AWS, clouding the differential diagnosis. Numerous studies have evaluated the efficacy of magnesium supplementation. However, in a randomized, placebo-controlled trial, magnesium sulfate had no effect on either severity of alcohol withdrawal or incidence of withdrawal seizures.[83] Consequently, aside from repletion of electrolyte abnormalities, there is no indication for routine administration of magnesium for the treatment of AWS.

Anticonvulsants

Carbamazepine has been used in multiple trials for treatment of mild AWS, more commonly in Europe where an intravenous preparation is available. In animal studies, carbamazepine increases both the central nervous system GABA concentrations and the seizure threshold in alcohol withdrawal.[17] In humans, carbamazepine is superior to placebo and equally efficacious as benzodiazepines for treatment of mild to moderate AWS in both inpatients and outpatients.[7,52,53] Similar data has been obtained with valproic acid, which appears to have a benzodiazepine-sparing effect in patients with mild withdrawal.[66] These drugs may be reasonably recommended as adjuncts, but should not be used as monotherapy.

Newer Agents and Future Directions

There is a constant search for newer agents to treat alcohol

withdrawal, especially for agents that target NMDA receptors. In animal studies, NMDA antagonists have shown benefit in preventing AWS seizure, neurologic damage, and alcohol craving.[6,58] In humans, one NMDA inhibitor, acamprosate, has undergone significant study in the prevention of relapse following alcohol detoxification.[16,32] Its effects on AWS are less clear, although in one study of patients capable of outpatient detoxification, it had no adverse effects on CIWA-Ar scores.[16]

Summary

Alcohol withdrawal is a complex physiologic process involving both enhanced neuronal excitation and reduced inhibition resulting in neuroexcitation. The manifestations of greatest concern are neurologic and include altered mental status and seizure, but the autonomic excess may be clinically consequential. Treatment includes supportive care and sedation with benzodiazepines. When benzodiazepines cannot produce adequate sedation, agents such as phenobarbital or propofol should be added.

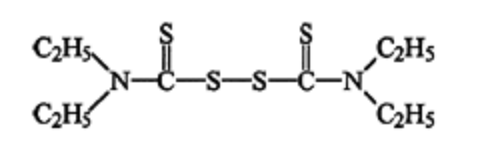
Chapter 77

Disulfiram and Disulfiramlike Reactions

Edwin K. Kuffner



Disulfiram

A 40-year-old woman with a history of depression was found unresponsive by her husband. The husband stated that the patient

had a strange garlic odor on her breath and that she had complained of exhaustion and confusion for several days. The patient's medications included paroxetine, risperidone, and trazodone. The patient also had access to a supply of nonprescription vitamins, herbal preparations, muscle liniments, and an unknown Mexican medication.

Emergency medical personnel transported the patient to the emergency department. Her vital signs were: blood pressure, 178/100 mm Hg; pulse, 56 beats/min; respiratory rate, 32 breaths/min; rectal temperature, 94.8Â°F (34.9Â°C); pulse oximetry on room air, 99%. A bedside rapid reagent blood glucose was 130 mg/dL and therefore dextrose was not administered.

The physical examination revealed an unresponsive patient with a Glasgow Coma Score (GCS) of 6. No evidence of trauma was noted. Pupils were 3 mm and sluggishly reactive to light. Cardiac, pulmonary, and abdominal examinations were unremarkable. Neurologic examination revealed flexion withdrawal to painful stimuli, areflexia, and occasional myoclonic jerks.

The patient's trachea was intubated. Fifty grams of activated charcoal was administered via a nasogastric tube. The 12-lead electrocardiogram (ECG) revealed peaked T waves but was otherwise normal. The serum electrolytes were significant for a bicarbonate of 4 mEq/L, a potassium of 6.0 mEq/L, and an anion gap of 26 mEq/L. The serum lactate was 16.9 mmol/L. Serum blood urea nitrogen (BUN), serum creatinine, and hepatic aminotransferases were normal. Serum acetaminophen, salicylate, and blood ethanol concentrations were undetectable. An arterial blood gas analysis on supplemental oxygen revealed a pH of 7.11, a PCO_2 of 6.7 mm Hg, and a PO_2 of 187 mm Hg. A complete blood count revealed a white blood cell count (WBC) of 15,600/mm^3 (89% neutrophils and 9% lymphocytes) with a normal hematocrit and platelet count. A computed tomography scan of the head, a chest radiograph, and a lumbar puncture were normal.

Blood was sent for determination of ethylene glycol and methanol concentrations and the patient was treated with 50 mg of pyridoxine and 50 mg of folinic acid intravenously. Instead of using fomepizole, which was unavailable, the patient was started on intravenous ethanol. A loading dose of 800 mg/kg of ethanol was followed by a continuous infusion to maintain the blood ethanol concentration between 100 and 120 mg/dL. Shortly after the loading dose of ethanol was administered, the patient developed generalized flushing, tachycardia with a pulse of 120 beats/min, and a systolic blood pressure of 70 mm Hg. The blood pressure did not respond to IV crystalloid, but did respond to norepinephrine. Hemodialysis was performed.

The ethylene glycol and methanol levels were eventually reported as negative. The severe metabolic acidosis was corrected with hemodialysis. Within a few hours of discontinuing the ethanol infusion, the patient's tachycardia and hypotension resolved. Within 24 hours of presentation, the patient's mental status had returned to baseline. The patient later admitted to ingesting a â€œnonprescriptionâ€• Mexican medication for alcoholism that she purchased from a Mexican pharmacist in the United States. The unknown medication was later identified as disulfiram.

A complete understanding of disulfiram toxicity is dependent on understanding the distinction between the different forms of disulfiram toxicity that are associated with acute ingestions, chronic therapy, and disulfiramâ€“ethanol reactions. The preceding case is unique in that it involves both toxicity from an acute overdose of disulfiram and toxicity from an iatrogenic disulfiramâ€“ethanol reaction. This chapter emphasizes the distinctions between these three different forms of disulfiram toxicity.

History and Epidemiology

Disulfiram, tetraethylthiuram disulfide, and related chemicals were used in the rubber industry as catalytic accelerators for the vulcanization (stabilization) of rubber by the addition of sulfur. In the early 1900s, workers exposed to disulfiram were observed to develop adverse reactions when exposed to ethanol, and this suggested that disulfiram might be a useful adjunct in the treatment of alcoholism. In the 1940s, two Danish physicians, Hald and Jacobsen, using disulfiram for its antihelmintic properties became ill after consuming alcohol.[29] Subsequently, disulfiram treatment for alcoholism gained popularity.[3] Although evidence to support the benefit of using disulfiram in a comprehensive alcohol treatment program is equivocal, disulfiram is still prescribed for this purpose today.[36]

Specific epidemiologic information about the three different forms of disulfiram toxicity is difficult to elucidate, even from an analysis of the American Association of Poison Control Centers (AAPCC) (Chap. 130).

Between 1982 and 2003 more than 10,000 patients exposed to disulfiram were reported to the AAPCC. Fewer than 200 of these patients developed major adverse effects. Unlike most xenobiotics reported to the AAPCC, the majority of the disulfiram exposures were in adults. All 12 deaths were adults and most involved a disulfiramâ€“ethanol reaction. In many of the deaths, coingestants other than disulfiram and ethanol were involved.

The best studied and the most commonly reported life-threatening adverse effect of chronic disulfiram therapy is hepatotoxicity. The frequency of disulfiram-related hepatotoxicity is also difficult to determine. As many as 25% of all alcoholics treated with disulfiram develop subclinical elevations in their hepatic aminotransferase levels, and the frequency of disulfiram-induced fatal hepatitis is estimated at 1 in 25,000â€“30,000 patients treated per year.[75]

Pharmacology and Pharmacokinetics of Therapeutic doses of Disulfiram

The effectiveness of disulfiram in discouraging alcohol consumption is aversive in nature, as it is dependent on the patient's fear of developing a disulfiramâ€“ethanol reaction. Disulfiram does not produce central nervous system effects that alter an alcoholic's drinking behavior. Therapeutic doses of disulfiram, used as part of a comprehensive alcohol treatment program, typically range from 125â€“500 mg/d.

Absorption

Disulfiram is highly lipid soluble and very insoluble in water. Following ingestion, disulfiram is either absorbed as the parent compound or converted to diethyldithiocarbamic acid (diethyldithiocarbamate) in the acid environment of the stomach.[13] Diethyldithiocarbamic acid is also very unstable in this acid environment, and either rapidly undergoes absorption and spontaneous decomposition to carbon disulfide and diethylamine, or chelates copper, forming a bis (diethyldithiocarbamate)-copper complex. The bis(diethyldithiocarbamate)-copper complex is more stable than diethyldithiocarbamic acid and also can be absorbed as it passes through the upper gastrointestinal tract. In fact, most disulfiram is absorbed from the small intestine as this bis(diethyldithiocarbamate)-copper complex. Approximately 70â€“90% of an ingested therapeutic dose of disulfiram is absorbed. The bioavailability of disulfiram varies with different preparations. In one study, the mean serum disulfiram concentration in humans following a 250-mg dose was reported to be 0.38 Â± 0.03 Âµg/mL.[22] Peak serum concentrations of disulfiram and its metabolites are achieved 8â€“10 hours following a 250-mg dose.[40]

Distribution

Approximately 96% of disulfiram itself and approximately 80% of disulfiram metabolites are protein bound.[40] Following absorption, disulfiram and its metabolites are uniformly distributed throughout body tissues. A specific volume of distribution for disulfiram is not recognized.

Metabolism

Any absorbed disulfiram is rapidly converted to diethyldithiocarbamic acid by erythrocyte glutathione reductase and endogenous thiols. Diethyldithiocarbamic acid in the blood also reversibly chelates copper, forming a bis(diethyldithiocarbamate)-copper complex. Diethyldithiocarbamic acid is metabolized by a number of different pathways, including glucuronidation, methylation, nonenzymatic degradation, and oxidation. Nonenzymatic degradation of diethyldithiocarbamic acid produces diethylamine and carbon disulfide. Carbon disulfide can be further oxidized to carbonyl sulfide, which, in turn, can be further oxidized to carbon dioxide. Phase II methylation of diethyldithiocarbamic acid, which is mediated by an S-methyltransferase, produces diethyldithiomethylcarbamic acid. Diethyldithiomethylcarbamic acid can be oxidized to diethylthiomethylcarbamic acid. Diethylthiomethylcarbamic acid is further oxidized to sulfoxide and sulfone metabolites and undergoes demethylation to form diethylthiocarbamic acid. Although diethyldithiocarbamic acid can be converted back to disulfiram, and carbon disulfide and diethylamine can be converted back to diethyldithiocarbamic acid, these reactions are not clinically significant[20] (Fig. 77-1).

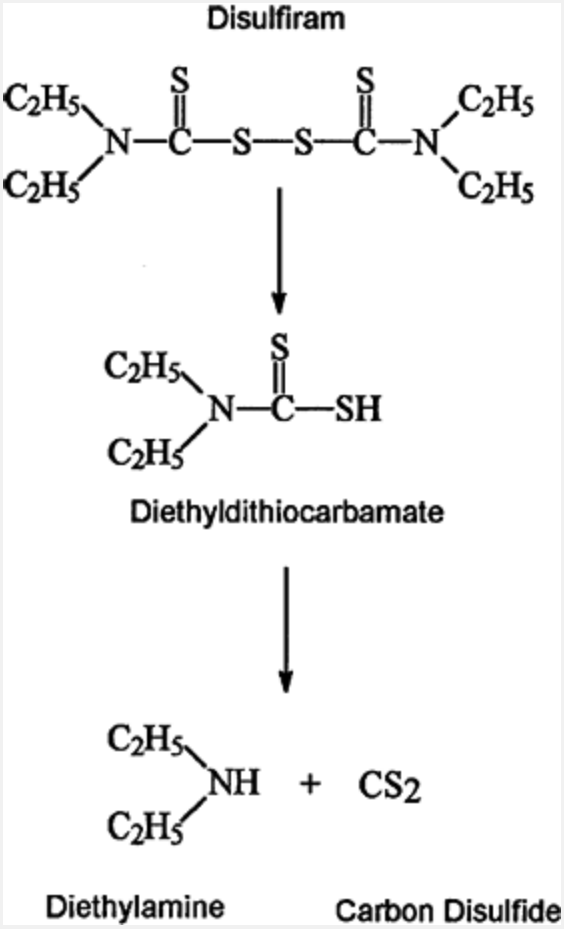


Figure 77-1. Disulfiram metabolism occurs in the liver and in the erythrocyte. The most consequential metabolites are diethyldithiocarbamate and carbon disulfide.

Elimination

Following a 250-mg dose, the half-lives of disulfiram, diethyldithiocarbamate, and carbon disulfide are 7.3 Â± 1.5 hours, 15.5 Â± 4.5 hours, and 8.9 Â± 1.4 hours, respectively. Approximately 20% of disulfiram is excreted unchanged in the

feces and another 20% or more is excreted by the lungs as carbon disulfide. The majority of disulfiram is excreted in the urine as the glucuronidated metabolite of diethyldithiocarbamic acid.[40] At 48 hours after administration of a single 250-mg dose, there is a negligible amount of disulfiram and metabolites detectable in the serum.[22,38]

Disulfiramâ€“Ethanol Reaction

Pharmacology and Pharmacokinetics of Disulfiramâ€“Ethanol Reaction

Understanding the metabolism of ethanol is critical to understanding the mechanism of action of disulfiram as it relates to the disulfiramâ€“ethanol reaction (Fig. 77-2). Disulfiram and its metabolites impair both cytosolic aldehyde dehydrogenase 1 (ALDH 1) and mitochondrial aldehyde dehydrogenase 2 (ALDH 2). The inhibition by disulfiram of ALDH 2 leads to a rise of acetaldehyde levels 5â€“10 times above baseline levels, and a few days of treatment with disulfiram can reduce baseline aldehyde dehydrogenase activity by 50%.[6] Although aldehyde dehydrogenase is present throughout the body, inhibition of hepatic mitochondrial aldehyde dehydrogenase is most important in the disulfiram-ethanol reaction.

The exact mechanism by which disulfiram and its metabolites inhibit ALDH 1 and ALDH 2 is still unclear. Disulfiram may inactivate aldehyde dehydrogenase by causing internal sulfur-sulfur bonds, or by competing for nicotinamide adenine dinucleotide.[97] The metabolites of disulfiram, including diethylthiomethylcarbamic acid and its sulfoxide and sulfone metabolites, may also inhibit aldehyde dehydrogenase.[29,40] Different metabolites may possibly inactivate different isoenzymes of aldehyde dehydrogenase. Diethylthiocarbamic acid is believed to

inactivate ALDH 2. Because aldehyde dehydrogenase inhibition is irreversible, new ALDH must be synthesized to metabolize acetaldehyde.[40] This explains why disulfiram has a longer-lasting effect than would be predicted based upon its half-life.

The duration of the inhibition of aldehyde dehydrogenase by disulfiram is partially dependent on the dose ingested and the route of administration. A 500-mg dose inhibits aldehyde dehydrogenase for up to 4 days, a 1000-mg dose for up to 6 days, and a 1500-mg dose up to 8 days.[29] There are also sustained-release and depot disulfiram preparations, but none are readily available in the United States. A patient reacted to oral ethanol 21 days following the subcutaneous injection of 2 g of disulfiram.[73] Although the severity of the disulfiramâ€“ethanol reaction following subcutaneous disulfiram dosing is reported to be less than that following oral dosing, this has not been proven.

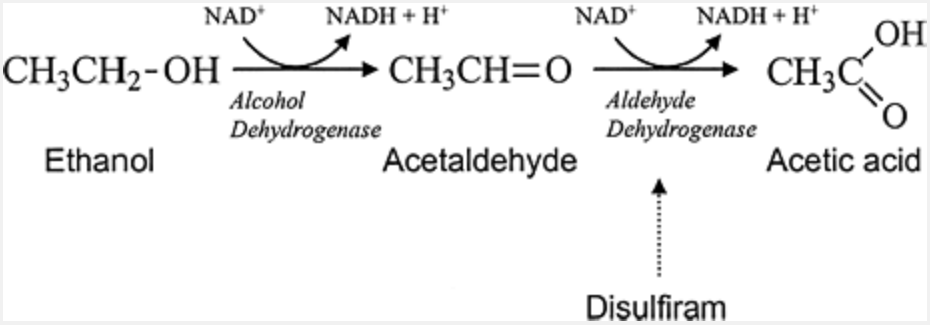

Figure 77-2. The site of action of disulfiram. The irreversible inactivation of aldehyde dehydrogenase results in an increased acetaldehyde level after ethanol is administered.

TABLE 77-1. Common Household Products that Contain Ethanol and May Cause a Disulfiramâ€“Ethanol Reaction

Adhesives
Alcohols: denatured alcohol, rubbing alcohol
Detergents
Foods: liquor-containing desserts, fermented vinegar, some sauces
Nonprescription medications: analgesics, antacids, antidiarrheals, cough and cold preparations, topical anesthetics, vitamins
Personal hygiene products: after-shave lotions, colognes, deodorants, liquid soaps, mouthwashes, perfumes, skin liniments and lotions
Solvents

The accumulation of acetaldehyde, that is normally metabolized rapidly by aldehyde dehydrogenase, is responsible for many of the symptoms produced by the disulfiramâ€“ethanol reaction. In fact, intravenous administration of acetaldehyde to humans produces symptoms similar to those experienced by patients on disulfiram who consume ethanol.[4] Acetaldehyde may increase the release of histamine, which may also be responsible for some of the effects of the disulfiramâ€“ethanol reaction.

Disulfiramâ€“ethanol reactions are reported following exposure to disulfiram by the oral and subcutaneous routes, and to ethanol by any route.[88] Disulfiramâ€“ethanol reactions may follow exposure to the ethanol contained in many products other than alcoholic beverages. Table 77-1 lists some common household products containing ethanol.

Other Enzymes Inhibited by Disulfiram

Disulfiram and its metabolites inhibit other enzymes besides aldehyde hydrogenase, especially those that contain sulfhydryl groups and metalloproteins.[67] Importantly, disulfiram inhibits dopamine Î²-hydroxylase, an enzyme necessary for norepinephrine synthesis.[27,65] The mechanism for this inhibition may be the chelation of copper by diethyldithiocarbamate, which is necessary for dopamine Î²-hydroxylase activity.[81] Disulfiram also decreases urinary concentrations of vanillylmandelic acid in humans.[32] Decreased norepinephrine in the presence of acetaldehyde, a potential vasodilator, may account for the hypotension associated with the disulfiramâ€“ethanol reaction. Increased concentrations of dopamine, as a consequence of dopamine Î²-hydroxylase inhibition, may also explain the psychiatric effects following both acute disulfiram overdose and chronic disulfiram therapy. Although it has been theorized that some of the neurologic effects following both acute disulfiram overdose and chronic disulfiram therapy may be related to the metabolite carbon disulfide, this has not been confirmed in a well-controlled trial.[76]

Disulfiram and the Cytochrome P450 System

Disulfiram and its metabolites are inhibitors of cytochrome P450 (CYP) 2E1.[42] Single doses of disulfiram administered to healthy humans result in 50% inhibition of baseline CYP2E1 activity for at least 3 days, with some inhibition for longer than 1 week.[19,21] Although animal studies suggest that disulfiram alters acetaminophen metabolism, a human study found that disulfiram did not

significantly alter the metabolism of a therapeutic dose of acetaminophen, in either healthy patients or in patients with

alcoholic liver disease.[74] Disulfiram may be an inducer of CYP2B1 and CYP2A1, but it does not appear to affect CYP2C9, CYP2C19, CYP2D6, or CYP3A4 activity.[40,42] Disulfiram inhibits the metabolism and/or decreases the clearance of phenytoin, theophylline and warfarin.[55,67,69,82] The effects of disulfiram on the CYP system may be both dose and time dependent.

Disulfiramâ€“Xenobiotic Interactions

Disulfiram may decrease the clearance of benzodiazepines (chlordiazepoxide, diazepam, and oxazepam),[56] caffeine, phenytoin,[93] theophylline,[14] and some tricyclic antidepressants (desipramine and imipramine).[16] Disulfiram can increase the prothrombin time (international normalized ratio) in patients taking warfarin.[69] Combined therapy of disulfiram with omeprazole can cause catatonia.[28] Isoniazid and metronidazole may potentiate the neuropsychiatric effects of disulfiram, producing confusion and psychosis.[83,100] Patients taking disulfiram therapeutically may develop hypotension following the administration of anesthetic agents.[18] There is a theoretical concern that disulfiram may decrease the metabolism of propylene glycol found in many liquid and parenteral drug formulations, but specific cases of toxicity have not been reported. Although animal studies suggest that disulfiram may increase the carcinogenicity of ethylene dibromide, this has not been substantiated in humans.[103]

Use of Disulfiram as an Antidote

Case reports suggest that disulfiram may be useful for the treatment of nickel dermatitis.[15,41] However, a small double-blind, placebo-controlled study of patients with hand eczema and nickel allergy did not find a clinically significant difference between those treated with disulfiram and those treated with placebo.[41] Because the conditions of some patients have worsened with this therapy,[45] and because some patients treated for nickel dermatitis

have developed disulfiram-induced hepatitis, this therapy is not generally indicated.

Diethyldithiocarbamate, a disulfiram metabolite, is available as the chelator ditiocarb. Although animal data and human case series suggest that diethyldithiocarbamate may be an effective chelator for the treatment of nickel-carbonyl poisoning, no well-controlled human trial has evaluated this therapy. Because disulfiram increases nickel absorption in humans, it is prudent to only use diethyldithiocarbamate in the treatment of nickel-carbonyl poisoning and not for the treatment of elemental or inorganic nickel poisoning.[11,8]

Clinical Manifestations

Most patients taking disulfiram who are exposed to ethanol develop symptoms of the disulfiramâ€“ethanol reaction within 15 minutes. The symptoms usually peak within 30 minutes to 1 hour, and then gradually subside over the next few hours.

Signs and symptoms of a disulfiramâ€“ethanol reaction include facial and generalized body warmth and flushing, conjunctival injection, pruritus, urticaria, diaphoresis, lightheadedness, vertigo, headache, nausea, vomiting, and abdominal pain. Cardiac effects include palpitations, chest pain, and dyspnea. Tachycardia and hypotension, including orthostatic hypotension, are common. Rare complications include shock, myocardial ischemia,[62] hypertension, bronchospasm, and methemoglobinemia.[104] Esophageal rupture and intracranial hemorrhage, secondary to profound vomiting, may occur.[23,64,92,104] Deaths attributed to the disulfiram-ethanol reaction occur but are rare.[5,39,64] There is significant interindividual and intraindividual variation in the intensity and duration of a disulfiramâ€“ethanol reaction.

TABLE 77-2. Xenobiotics Reported to Cause a Disulfiramlike Reaction with Ethanol

Antimicrobials
- Cephalosporins, especially those that contain a methylthiotetrazole (MTT) side chain, such as cefotetan, cefoperazone, cefamandole, and cefmenoxime.
- Metronidazole
- Moxalactam
- Trimethoprim-sulfamethoxazole

Possible reactions with chloramphenicol, griseofulvin, quinacrine, procarbazine, phentolamine, nitrofurantoin

Sulfonylurea oral hypoglycemics
- Chlorpropamide
- Tolbutamide

Chemicals
- Calcium carbimide (citrated)
- Carbon disulfide
- Carbon tetrachloride
- Chloral hydrate
- Dimethylformamide
- Nitrefazole
- Tetraethylthiuram disulfide (disulfiram)
- Tetramethylthiuram disulfide (thiram)
- Thiram analogs (fungicides)
  - Copper, mercuric, and sodium diethyldithiocarbamate
  - Zinc and ferric dimethyldithiocarbamate
  - Zinc and disodium ethylenebis [dithiocarbamate]
- Trichloroethylene

Mushrooms
- *Coprinus* mushrooms including *C. atramentarius, C. insignis, C. variegatus*, and *C. quadrifidus, Boletus luridus, Clitocybe clavipes, Polyporus sulphureus, Pholiota*

squarosa, Tricholoma aurantum, and *Verpa bohemica*

Disulfiramâ€“Ethanollike Reactions

The term *disulfiramlike reaction* is commonly used to describe a presentation similar to the typical disulfiramâ€“ethanol reaction when the patient has not been exposed to both disulfiram and ethanol. Most disulfiramlike reactions involve an exposure to ethanol.[30,51,53,101]

Ingestion of ethanol following ingestion of various *Coprinus* species of mushrooms can cause symptoms of a disulfiramâ€“ethanol reaction (Chap. 113).[80,89]

Many xenobiotics in combination with ethanol also produce symptoms of the disulfiramâ€“ethanol reaction (Table 77-2). Alcohols other than ethanol and organic solvents, including mineral spirits, can also cause symptoms of a disulfiramâ€“ethanol reaction.[87]

Management of Disulfiramâ€“Ethanol Reactions

For most patients experiencing suspected disulfiramâ€“ethanol reactions, it is frequently useful to confirm the presence of ethanol,

either with an exhaled ethanol concentration or by obtaining a blood ethanol concentration. Because only small amounts of ethanol can precipitate a disulfiramâ€“ethanol reaction, some patients, especially those with small ingestions or dermal exposures, may still manifest reactions in the absence of detectable ethanol concentrations at the time of evaluation. Elevated acetaldehyde concentrations in the blood will occur

during a disulfiramâ€“ethanol reaction, but acetaldehyde concentrations are not readily available, and thus are not clinically useful in managing most patients.[31]

Symptomatic and supportive care is the mainstay of treatment. Gastrointestinal decontamination aimed at removing ethanol is unlikely to have any clinically significant effect on limiting the severity or duration of the disulfiramâ€“ethanol reaction, because even small amounts of ethanol can cause toxicity in the presence of disulfiram. Additionally, because nausea and vomiting are common, patients often experience spontaneous gastric emptying. Antiemetics may improve nausea and vomiting, and histamine (H_1) receptor antagonists, such as diphenhydramine, may lesson cutaneous flushing.[91] Most patients with hypotension respond to intravenous crystalloid administration. Symptomatic hypotension refractory to these measures rarely occurs. If hypotension is refractory to crystalloid administration, a vasopressor should be administered. There is a theoretical benefit to administering a direct-acting vasopressor such as norepinephrine, because disulfiram inhibits dopamine Î²-hydroxylase, an enzyme necessary for norepinephrine synthesis. Indirect-acting vasopressors, such as dopamine, that require functioning dopamine Î²-hydroxylase to create a releasable pool of norepinephrine, may be less effective in the setting of disulfiram toxicity. Patients with cardiovascular instability should have an electrocardiogram performed.[62] Most patients with a typical disulfiram-ethanol reaction who have normal vital signs can be safely discharged following resolution of symptoms. More prolonged observation is essential for patients with persistent symptoms, ECG abnormalities, or any potentially life-threatening effect.

Fomepizole, an inhibitor of alcohol dehydrogenase, prevents the metabolism of ethanol to acetaldehyde.[10] Theoretically, by preventing the production of acetaldehyde, fomepizole could limit the effects of the disulfiramâ€“ethanol reaction. A patient on disulfiram experiencing a disulfiramâ€“ethanol reaction was given

fomepizole experimentally, with an almost immediate decrease in the serum acetaldehyde concentration, and a rapid clinical improvement.[54] Fomepizole normalized blood acetaldehyde concentrations and relieved the symptoms of the disulfiramâ€“ethanol reaction in 4 volunteers given calcium carbimide and ethanol.[54] Fomepizole should be considered for patients with life-threatening signs or symptoms of a disulfiramâ€“ethanol reaction who are unresponsive to standard treatment (see Antidotes In Depth: Fomepizole).

Clinical Manifestations

Acute Disulfiram Overdose

Acute overdose of disulfiram is uncommon and typically does not cause life-threatening toxicity. Most patients will develop symptoms within the first 12 hours following ingestion, with resolution of symptoms within 24 hours of ingestion.[79]

Nausea, vomiting, and abdominal pain are common. A spectrum of central nervous system depressionâ€”from drowsiness to comaâ€”may occur.[79] Metabolic acidosis is rare.[57] Dysarthria and movement disorders, including myoclonus, ataxia, dystonia, and akinesia, occur rarely. The movement disorders may be related to direct effects on the basal ganglia.[50,52,57] Sensorimotor neuropathy, subacute weakness, and psychosis are uncommon.[34,44,84,105] Hypotonia may be a prominent feature in children.[6] Persistent neurologic abnormalities, lasting for weeks to months, are reported in both children and adults, but are rare.[11,57,79]

Chronic Disulfiram Therapy

Most of the known adverse effects are derived from case reports. Despite the widespread international use of disulfiram, there are

few well-controlled human trials evaluating chronic disulfiram toxicity. Toxicity from chronic disulfiram therapy correlates poorly with dose, and there is a wide variability in latency period between the time therapeutic dosing is initiated and when symptoms develop. Side effects of chronic disulfiram therapy, unsurprisingly, occur most commonly in alcoholic patients.

Adverse effects most typically involve the liver, the skin, or the central nervous system. Common effects include nausea, drowsiness, dizziness, headache, a metallic taste in the mouth, halitosis, and skin odor described as having a sulfur or garlic smell, decreased libido, impotence, and hypertension.[32,58,98]

Disulfiram therapy causes a spectrum of hepatotoxicity ranging from asymptomatic minor elevations of the aminotransferase levels, to fulminant hepatic failure and death. The hepatotoxicity is clinically indistinguishable from alcoholic hepatitis. The mechanism of disulfiram-induced hepatotoxicity is poorly understood and may be idiosyncratic. Injury may be caused by a hypersensitivity reaction or by direct hepatotoxicity related to a metabolite, or to an immunologic reaction.[25] Histologic patterns of toxicity are predominantly hepatocellular, specifically centrilobular in nature.[8] The onset of hepatotoxicity usually varies from 2 weeks to 6 months after initiation of disulfiram therapy.[8] Although disulfiram-induced hepatotoxicity may be exacerbated by concurrent alcohol consumption, nonalcoholic patients taking disulfiram as a treatment for nickel dermatitis also developed hepatotoxicity.[37,52,43] Elevated aminotransferases are a relative contraindication to disulfiram therapy. They cannot be used to confidently predict which patients will develop disulfiram-induced hepatotoxicity.[86] Dermatoses associated with disulfiram therapy include exfoliative dermatitis, contact dermatitis, urticaria, pruritus, acne, and yellow palms.[59,85] Interestingly, thiram and its analogs, which are found in rubber, are also potent skin sensitizers.[89] Some patients with rubber sensitivity develop localized and generalized dermatitis following ingestion of

disulfiram, whereas other patients can be treated with disulfiram without dermatologic complications.[68,99,101] Disulfiram can also cause exacerbations of nickel and cobalt dermatitis.[45,63] Disulfiram may exacerbate nickel dermatitis because diethyldithiocarbamate complexes with nickel and increases its absorption.[35]

Reported neuropsychiatric side effects include headache, dizziness, confusion,[77] memory impairment,[58] ataxia, parkinsonian symptoms,[52] seizures,[17] optic neuropathy,[1] coma,[58] peripheral neuropathy, psychosis,[7,32] depression, catatonia,[24] and organic brain syndrome.[48,84] Confusion, memory impairment, peripheral neuropathy, and psychiatric diagnoses are common in alcoholic patients who are not taking disulfiram. Alcohol-induced and disulfiram-induced peripheral neuropathy are difficult to distinguish clinically. Disulfiram-induced peripheral neuropathy usually involves motor nerves more than sensory and autonomic nerves, is worse distally, and is usually bilateral. A small prospective study of alcoholics taking therapeutic doses of disulfiram did reveal abnormalities of peripheral

nerve function.[70] Neurologic symptoms may be related to both dose and duration of therapy, but these issues are not well studied.[21] Although case reports suggest an increased incidence of psychiatric complications, one prospective randomized study did not find an increased incidence of psychiatric complications in alcoholic patients taking disulfiram.[12]

Disulfiram therapy may result in increases in serum cholesterol.[60] Although patients with occupational exposures to carbon disulfide, a metabolite of disulfiram, have an increased risk of atherosclerosis and ischemic heart disease, this has not been proven for patients taking disulfiram. One case report suggests that disulfiram may cause thrombocytopenia.[95] Disulfiram is not believed to be teratogenic or carcinogenic.

Diagnostic Testing

Disulfiram serum concentrations are not useful when managing most patients with suspected disulfiram toxicity following an acute overdose, chronic therapy, or a disulfiramâ€“ethanol reaction. When interpreting a disulfiram serum concentration, it is important to note that because of rapid metabolism, only a small proportion of ingested disulfiram appears in the blood as the parent compound. Metabolites of disulfiram, including diethyldithiomethylcarbamic acid and diethylthiomethylcarbamic acid, can also be measured in the serum. Other markers of ingestion of disulfiram include carbon disulfide on the breath and diethylamine in the urine. The activity of hepatic mitochondrial aldehyde dehydrogenase can be determined by liver biopsy, but this is impractical and dangerous. Leukocyte aldehyde dehydrogenase activity correlates most closely with hepatic mitochondrial aldehyde dehydrogenase activity. Decreased erythrocyte ALDH 1 activity and leukocyte ALDH 2 activity are markers of disulfiram exposure, although neither enzyme assay is commonly available.

Chronic Disulfiram Therapy

Monitoring aminotransferase levels, both before the initiation of therapy to establish a baseline and during the course of therapy, is recommended. Unfortunately, no well-controlled trial has specifically addressed the issue of the timing or frequency of routine aminotransferase monitoring. There is indirect evidence that continued use of disulfiram in the face of elevated aminotransferase levels increases the risk of developing life-threatening hepatotoxicity.[25] If an alcoholic patient has increased aminotransferase concentrations from chronic alcohol use, it is appropriate to delay the administration of disulfiram until the aminotransferase concentrations have normalized, as it is never obligatory to emergently initiate therapy. Common, but not

uniform, recommendations for asymptomatic patients include monitoring aminotransferases at 2 weeks following initiation of disulfiram therapy, and at 3â€“6 months intervals thereafter, or as needed.[102] Unfortunately, even conservative monitoring regimens may fail to detect patients who develop hepatitis during the testing intervals, so clinicians should educate patients about the signs and symptoms of hepatitis.

As a method of determining compliance with chronic disulfiram therapy, some authors have advocated using ethanol patch testing to produce cutaneous vasodilation. Studies demonstrate that patch testing is not a reliable measure of compliance with disulfiram therapy. Measuring leukocyte aldehyde dehydrogenase activity, or serum concentrations of disulfiram and/or its metabolites, are better measures of compliance with disulfiram therapy.

Management of Disulfiram Toxicity

Acute Disulfiram Overdose

Symptomatic and supportive care is the mainstay of treatment. There is no antidote for disulfiram toxicity. No studies have specifically addressed gastrointestinal decontamination in the setting of an acute disulfiram overdose. Unless otherwise contraindicated, activated charcoal, 1 g/kg of body weight, should be administered. It would be unusual for a patient with an isolated disulfiram ingestion to require either orogastric lavage or whole-bowel irrigation. Emesis is not indicated, especially because some emetics contain ethanol, which could precipitate a disulfiramâ€“ethanol reaction.

Chronic Disulfiram Toxicity

If a patient on chronic disulfiram therapy develops hepatotoxicity related to disulfiram, the drug should be discontinued. In addition,

patients should be instructed to have their aminotransferase concentrations measured if they develop any signs or symptoms of hepatitis, including anorexia, nausea, vomiting, abdominal pain, generalized weakness, malaise, fever, pruritus, scleral icterus, or jaundice.

If aminotransferase concentrations rise during disulfiram therapy, the drug should be discontinued. Although in some cases rechallenge with disulfiram can confirm the role of disulfiram in causing hepatotoxicity, the benefit is not substantial enough to outweigh the risk.[8] Because the evidence to support the use of disulfiram therapy as part of a comprehensive alcohol treatment program is equivocal using the standards of evidence-based medicine, the risks of continuing disulfiram therapy usually outweigh the benefits. Following discontinuation of disulfiram therapy, hepatic aminotransferase levels usually return to baseline values. Rarely, patients may develop fulminant hepatic failure. Supportive care is the mainstay of treatment for disulfiram-induced hepatic failure. Liver transplantation has been successfully performed for disulfiram-induced hepatic failure.[75]

Summary

Because disulfiram is still used in comprehensive alcohol treatment programs, it is critical to understand the distinction between the different forms of disulfiram toxicity, including toxicity from an acute overdose, from chronic therapy, and from a disulfiramâ€“ethanol reaction. Disulfiram toxicity following an acute overdose is unlikely to be life-threatening unless a massive amount is ingested, an event that usually only occurs in suicidal adults. Although death is reported following disulfiramâ€“ethanol reactions, most patients do not develop life-threatening toxicity. With the recent widespread availability of fomepizole, its role in treating life-threatening disulfiramâ€“ethanol reactions requires further study. The most common adverse effects of disulfiram that

most clinicians, including toxicologists, encounter are secondary to chronic disulfiram therapy. These adverse effects on the liver and the central and peripheral nervous systems are often difficult to distinguish from the effects of chronic alcohol abuse. The effects, including life-threatening disulfiram-induced hepatotoxicity, are rare, and may be limited by closely monitoring patients prescribed disulfiram and by discontinuing disulfiram therapy as soon as any evidence of toxicity develops.

Chapter 78
Î³-Hydroxybutyric Acid

Lawrence S. Quang

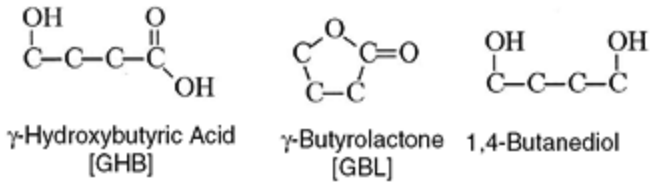

Figure. No Caption Available.

An ambulance was called to provide assistance for a comatose 17-year-old student in a college campus dormitory. The paramedics found the patient completely unresponsive, hypoventilating (4 breaths/min), and lying in a pool of urine and feces. Earlier that same evening the patient had attended a dormitory party where, reportedly, there was â€œheavyâ€• alcohol and â€œliquid Eâ€• consumption.

Physical examination in the emergency department, revealed a minimally responsive young man with the following vital signs: blood pressure, 98/40 mm Hg; pulse, 43 beats/min; respirations, 4 breaths/min; rectal temperature, 95.9Â°F (35.5Â°C). Miosis and intermittent myoclonic

movements of his extremities were also noted. The patient was ventilated by bag-valve-mask. While preparations were made to perform endotracheal intubation, naloxone 0.4 mg IV was administered without effect. The patient was subsequently intubated uneventfully. An electrocardiogram (ECG) demonstrated sinus bradycardia with prominent U waves, and a basic metabolic panel, and serum and urine toxicology screens were unremarkable.

The patient was admitted to the pediatric intensive care unit where he required mechanical ventilation for 4 hours before being extubated. On recovery he admitted to his first experimentation with Î³-hydroxybutyric acid.

Since its scientific discovery as a Î³-aminobutyric acid (GABA) mimetic neurochemical, gamma-hydroxybutyric acid (GHB) has been transformed from an investigational drug with legitimate research applications and lici medical uses to the toxic ingredient in banned nutritional supplements and illicit recreational drugs. GHB and its numerous chemical precursors and structural analogs, most notably Î³-butyrolactone (GBL) and 1,4-butanediol (1,4-BD), represent an emerging group of drugs among the broad class of recreational drugs known as â€œclub drugs.â€• Like most other â€œclub drugs,â€• GHB, GBL, and 1,4-BD are physically and psychologically addictive with acute and chronic toxicity that may be severe or lethal.

GHB, GBL, and 1,4-BD are consumed by a diverse population of acute and chronic abusers, who have misused them as sports supplements with touted anabolic effects; as dietary health supplements, with numerous unsubstantiated â€œnatural health benefitsâ€•, such as sleep and sexua enhancement; or as recreational drugs, with purported euphoriant and psychedelic effects. Despite a federal proscription on GHB since 1990, state and federal legislative efforts to regulate and curb GHB abuse have proven to be more difficult to effect than with other â€œclub drugsâ€• because of the lawful availability of GHB chemical precursors, which are widely used by industry (GBL and 1,4-BD), and because of the unabating supply of alternative GHB analogs that include such drugs as Î³-

valerolactone (GVL), Î³-hydroxyvaleric acid (GHV), and tetrahydrofuran (THF). Perhaps more than any other contemporary drug of abuse, GHB and its analogs heralded the age of electronic drug trafficking, as purveyors exploited the Internet to popularize, market, and distribute GHB and its analogs. Recently, there has been a conspicuous increase in case reports of GHB, GBL, and 1,4-BD use leading to a severe, potentially life-threatening withdrawal syndrome, a clinical feature of toxicity that has not been described with other â€œclub drugs.â€• With the notable exception of ketamine, GHB is one of the only â€œclub drugsâ€• that ha licit medical uses, having recently received approval from the US Food and Drug Administration (FDA) as a therapy for narcolepsy.

History

Before their recent emergence as popular recreational drugs, GHB, GBL, and 1,4-BD had a relatively quiescent history of medical research and lici therapeutic use that spanned more than 6 decades. The toxic effects of GBL were first reported in 1947, when it was noted to completely suppress cortical electroencephalographic

(EEG) activity and cause death from respiratory failure.[35] Simultaneously it was demonstrated that sublethal doses of GBL produced a reversible inhibition of voluntary movements in mice and chickens.

GHB was subsequently discovered in 1960, when it was synthesized as a structural analog of the inhibitory neurotransmitter, GABA, and found to be capable of traversing the bloodâ€“brain barrier after peripheral administration.[53 , 54 , 55] Three years later, GHB was determined to be a naturally occurring neurochemical in the mammalian brain.[5 , 6] In 1966, the first association of the effects of 1,4-BD with GHB were made. Noting the close structural similarity of 1,4-BD with GHB, researchers demonstrated that 1,4-BD could produce an anesthetic response similar t GHB and GBL. In rodents, GHB, GBL, and 1,4-BD all produce anesthesia that is characterized by the loss of voluntary movement, righting reflex, struggle response, and body and limb tone, as well as myoclonic jerking.

EEG tracings of animals treated with GHB, GBL, or 1,4-BD have very similar wave patterns.[95]

As a result of these discoveries, GHB found its first clinical application as an anesthetic in the early 1960s.[53, 54, 55] Several studies in the 1960s, involving a total of 376 patients, confirmed the potential of GHB to serve as an adjuvant to anesthesia.[7, 94] However, those same studies also documented adverse effects, including the occurrence of gross muscular movements when rapidly administered,[7] as well as inadequate analgesia (abrupt rise in systolic and diastolic pressure during surgical incision), emergence delirium, and bradycardia.[94] Although GHB continues to be investigated and used as an anesthetic adjuvant abroad,[50, 51, 52] it has never gained widespread acceptance in the United States for this clinical application.

An important research milestone in GHB history was reached in 1977, when it was reported that GHB use resulted in a significant increase in plasma growth hormone and rapid eye movement sleep in 6 healthy male human subjects.[98] This discovery launched concerted efforts to study and develop GHB as a potential therapeutic agent for sleep disorders such as narcolepsy. However, as an unintended and misappropriated consequence of this and similar studies, GHB became popular as a sports supplement and â€œnaturalâ€• soporific. Subsequently, in the late 1980s, GHB was introduced to the health and dietary supplement market with dubious claims that it could metabolize fat, enhance muscle building, and improve sleep. However, it was quickly associated with severe adverse effects and deaths.[11, 23] Accordingly, the FDA intervened in November 1990 to prohibit further nonprescription sales of GHB in nutritional supplements.[3, 33]

Despite the known dangers from overdoses and FDA regulations, GHB became fashionable and trendy as a recreational drug during the 1990s, as reports of its â€œnaturalâ€• euphoric and hallucinogenic properties popularized its misuse at â€œdance ravesâ€• and nightclubs. The rapid expansion of the Internet during the 1990s helped to fuel the emergence of GHB as a widespread recreational drug. The Internet allowed GHB

purveyors to circumvent the FDA ban on nonprescription sale of GHB-containing products by shifting their distribution from over-the-counter sales to online sales. This FDA ban was further circumvented by substitution of GBL for GHB as the active ingredient in dietary supplements. Soon after its substitution into dietary health supplements, toxic effects similar to GHB, including deaths, were attributed to GBL.[10, 45, 60, 82] Consequently, the FDA issued a voluntary recall of GBL-containing health supplements in February 1999.[31] As was the case with the initial recall of GHB, purveyors of GBL-containing dietary health supplements willingly complied with the FDA order because of the availability of yet another GHB precursor, 1,4-BD. Predictably, the consequences of 1,4-BD misuse and abuse including death were clinically similar to that of GHB and GBL.[14, 24, 87, 90, 110]

In the midst of its emergence as an illicit drug, GHB received both orphan drug and investigational new drug (IND) status from the FDA for clinical trials as a therapeutic drug for narcolepsy. Confounding and nearly preventing its clinical development as a narcolepsy treatment, GHB also developed forensic notoriety as a chemical submission agent used in the commission of drug-facilitated sexual assault. After several highly publicized GHB-related â€œdate rapeâ€• deaths, a federal statute gave GHB dual status as a Schedule III drug for IND use in clinical trials for narcolepsy, and as a Schedule I drug for illicit purposes.[20] Authority was also granted to federal law enforcement agencies to monitor the commercial and industrial sale and distribution of GBL for potential diversionary activity.[19] In response to several deaths in 1999, 1,4-BD was classified by the FDA as a Class I Health Hazard.[31] This FDA categorization recognizes 1,4-BD to be a potentially life-threatening health hazard but does not impose any regulatory actions on its commercial sale or distribution. The current legal status of GHB under federal law has rendered GHB more difficult to obtain, and subsequently increased trafficking and abuse of its chemical precursors and structural analogs.

Epidemiology

Illicit use of GHB and its analogs have primarily occurred in 1 of 4 settings: in the recreational setting of raves or night clubs; in the athletic setting of bodybuilding gyms and fitness centers; in the home consumer setting of individuals seeking its â€œnatural health benefitsâ€•; and in the criminal setting of drug-facilitated sexual assault. Products containing GHB, GBL, or 1,4-BD marketed for these purposes are generally no longer sold because of law enforcement pressure; however, comparable products with similar brand names are available.[31 , 32]

National statistics demonstrate a trend of escalating GHB abuse and poisoning throughout the last decade. In 2002, there were 1386 exposures with GHB and its analogs and precursors reported to the American Association of Poison Control Centersâ€“Toxic Exposure Surveillance System, representing more than a 2-fold increase from approximately 600 GHB cases reported in 1996. Among these, 1181 exposures (85%) required treatment in a healthcare facility and resulted in 272 major outcomes and 3 deaths (Chap. 130).[108] Eighty-five percent of these exposures involved individuals older than age 19 years. According to the Drug Abuse Warning Network, emergency department (ED) mentions related to GHB increased significantly from 1994â€“1999, and GHB mentions increased dramatically from 1997â€“2000.[96] Almost half (46%) of these ED mentions of GHB were attributed to patients age 20 to 25 years, nearly 90% were white, and two-thirds were male. Seventy-four percent of ED visits for GHB toxicity involved another club drug. Alcohol was the most frequently mentioned coingestant in visits with GHB (54%), followed by marijuana (14%) and 3,4-methylenedioxymethamphetamine (ecstasy, 12%). Although most GHB abusers are young adults, adolescents have also abused GHB, and the 2002 â€œMonitoring the Futureâ€• study reported an annual prevalence rate of GHB use of 0.8%, 1.4%, and 1.5% in grades 8, 10, and 12, respectively.[48]

While the illicit use of GHB and its precursors appears to have reached a

plateau in the United States, recent worldwide statistics have reported GHB abuse to be on the rise internationally. For example, in Spain, GHB was responsible for 3.1% of all toxicologic emergencies in an urban publi hospital ED during a 15-month study period, and ranked second in illicit drugs requiring emergency consultation.[72] While European and Asian countries have reported recent rises in acute poisonings from GHB and its chemical precursors and structural analogues, virtually all of the reports of GHB dependence and withdrawal have been from the United States.

Pharmacology

GHB has a dual pharmacologic profile, with the intrinsic neuropharmacology of endogenous GHB being distinct and divergent from that of exogenously administered GHB. The principal difference between their profiles is that the intrinsic neuropharmacologic activity of endogenous GHB appears to be mediated by the GHB receptor, whereas the neuropharmacologic activity of exogenously administered GHB is likel mediated by the $GABA_B$ receptor.

Endogenous GHB

Although the precise physiologic function of endogenous GHB is unknown GHB is a putative neurotransmitter or neuromodulator because it possesses the requisite pharmacologic properties for recognition as such. That is, (a) it has a discrete regional and subcellular distribution in the CNS; (b) it has subcellular systems for synthesis, vesicular uptake, and storage in presynaptic terminals; (c) it is released in a Ca^{2+} -dependent manner following depolarization of neurons; (d) subsequent to neuronal release, GHB binds to GHB-specific receptors and modulates neurotransmitter systems; (e) following neuronal release, GHB activity is terminated by active uptake from the synaptic cleft for metabolism by specific cytosolic and mitochondrial enzymes; and (f) localized applicatior of GHB can produce a response that mimics the action of endogenous GH released by nerve stimulation.

Although GHB is heterogeneously distributed throughout the mammalian CNS, its highest concentrations are found in the hippocampus, basal ganglia, hypothalamus, striatum, and substantia nigra.[64, 66, 103] As shown in Figure 78-1, the subcellular presynaptic synthesis of endogenous GHB involves 3 precursors (GABA, GBL, and 1,4-BD) and 5 enzymes (GABA-transaminase, succinic semialdehyde reductase [SSA reductase], alcohol dehydrogenase [ADH], aldehyde dehydrogenase [ALDH], and serum and peripheral tissue lactonases). The extracellular release of GHB from presynaptic GHB terminals occurs by neuronal depolarization in a Ca^{2+} -dependent manner.[61, 62]

In the early 1980s, three independent studies collectively proposed the existence of a putative GHB-specific receptor.[4, 63, 93] Although the existence of a GHB-specific receptor has been speculated and disputed fo some time, its existence was recently verified by the cloning of a G-proteinâ€“coupled receptor in the rat that is activated by endogenous GHB.[1] This newly cloned receptor exhibits no binding affinity for GABA, baclofen, or glutamate, which have no capacity to displace radioactive GHB from this binding site. In fact, a family of GHB receptors in the brair is now identified.

Activation of the GHB receptor alters second-messenger systems in the hippocampus by increasing cyclic guanosine monophosphate (cGMP) turnover and stimulating inositol phosphate turnover, which subsequently modulate the activity of other neurotransmitter systems.[104] From a toxicologic perspective, perhaps the most important neurotransmitter system altered by GHB binding is the GABA system at the $GABA_B$ receptor. Low-dose GHB inhibits GABA release in the thalamus, which ma implicate a role for GHB in producing absence seizures,[2] and decreases the extracellular GABA concentration in the frontal cortex.[37] However, higher doses of GHB enhance GABA concentrations in the frontal cortex.[3]

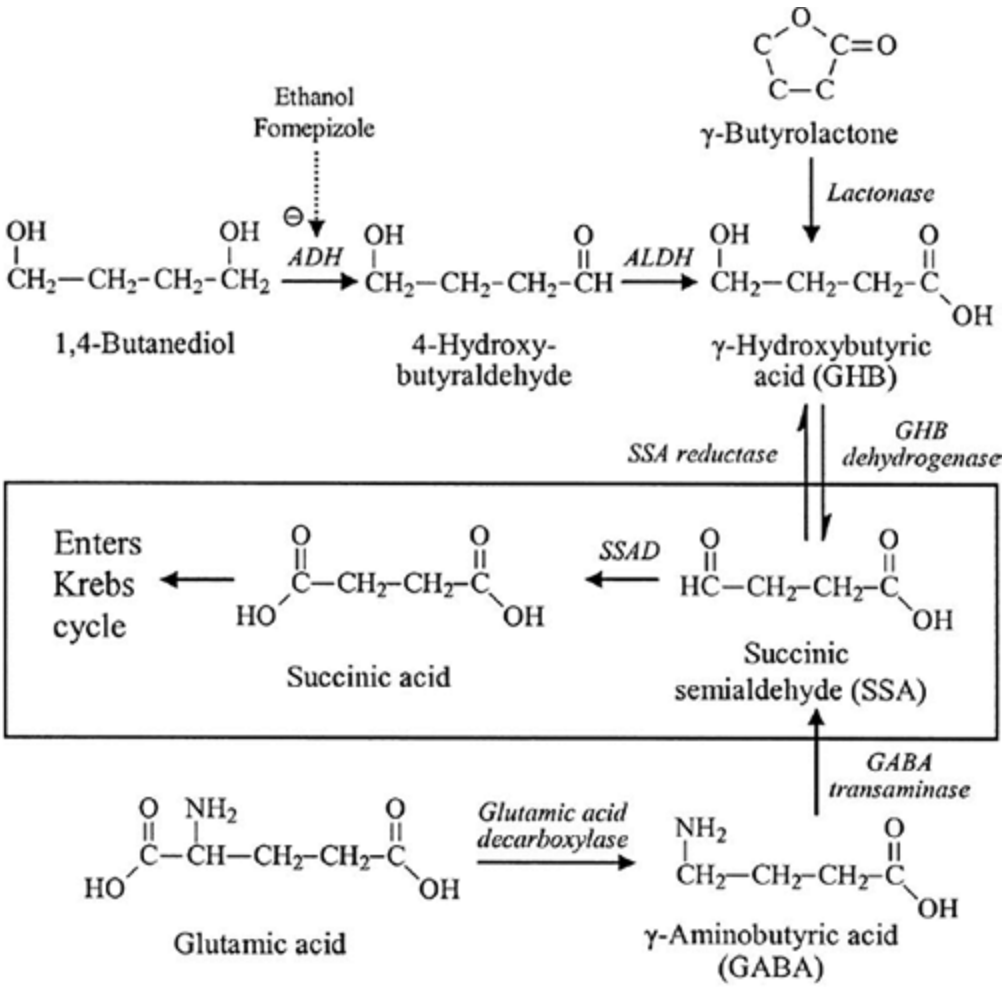

Figure 78-1. The synthesis and metabolism of Î³-hydroxybutyric acid. ADH, alcohol dehydrogenase; ALDH, aldehyde dehydrogenase; SSA reductase, succinic semialdehyde reductase; SSAD, succinic semialdehyde dehydrogenase.

GHB also exerts a prominent modulatory effect on dopamine neurotransmission. Acute administration of GHB inhibits dopamine release and results in the accumulation of dopamine in the presynaptic cells. This effect is mediated by GHB inhibition of dopamine neuron firing in the substantia nigra and mesolimbic regions,[41, 47, 84] and the subsequent autoreceptor-mediated stimulation of tyrosine hydroxylase activity, resulting in increased presynaptic dopamine production.[73, 107] The attenuation of dopamine neurotransmission following GHB administration

may be the pharmacologic basis for the loss of locomotor activity in experimental animals and overdose patients.

Other systems modulated by GHB include the serotonin system, cholinergic system, and opioid system. GHB modulates the serotonin system by increasing its turnover rate, without altering total brain serotonin concentrations, likely by elevating presynaptic tryptophan concentrations.[43, 64, 106] GBL, but not GHB itself, increases total brain acetylcholine concentrations by decreasing firing of cholinergic neurons.[3, 56, 89] Such an increase in brain acetylcholine might underlie the pharmacologic basis for the reported analeptic effect of GHB in narcolepsy. Despite having no binding affinity for opioid receptors, GHB increases the release of endogenous opioids in various brain regions.[30, 38, 41, 57] Furthermore, despite naloxone having no affinity for the GHB receptor, administration of the opioid antagonists naloxone and naltrexone can

attenuate or reverse the electrophysiologic and behavioral actions of GHB on dopamine neuron firing and catalepsy in experimental animals.[29, 92]

After its release from GHBergic presynaptic membranes, GHB activity is terminated by an active vesicular uptake system driven by the vesicular inhibitory amino acid transporter (the same transporter that mediates the vesicular uptake of GABA and glycine) or by an active cellular uptake from the synaptic cleft by means of a high-affinity, Na^+ -dependent, transport protein specific for GHB and its analogs.[3, 40, 75] Once within the cell, the degradation of endogenous GHB in the mammalian brain can occur via 4 pathways, leading to succinic acid (SSA) which enters the tricarboxylic acid cycle, GABA, *trans* -4-hydroxycrotonic acid, or 4,5-dihydroxyhexanoic acid. In the first degradative pathway, which is the most significant quantitatively, GHB is oxidized to SSA by the nicotinamide adenine dinucleotide, phosphate-dependent, high K_m SSR (succinic semialdehyde reductase), which is now commonly referred to as GHB dehydrogenase (GHB-DH) (Fig. 78-1).

Exogenous Î³-Hydroxybutyric Acid

Although accumulating evidence favors the role of endogenous GHB as a neuromodulator, the study of the pharmacologic profile of exogenous GHI is still in its infancy. However, current data suggest that the $GABA_B$ receptor is a major component of the neural substrate mediating the pharmacologic, behavioral, clinical, and toxicologic actions of exogenous GHB and its precursors. When the brain GHB concentration exceeds its physiologic concentration by 2â€“3 orders of magnitude, it will saturate GHB-specific receptors and produce $GABA_B$ receptor-mediated brain perturbations.[59] Similarly, only millimolar concentrations of GHB can mimic the postsynaptic electrophysiologic effects of baclofen on the $GABA_B$ receptor, which can be blocked by $GABA_B$ receptor-selective antagonists but not by GHB receptor-selective antagonists such as NCS 382.[26 , 28] It is theorized that under conditions of excess exogenous administration, GHB may act both directly as a partial $GABA_B$ receptor agonist and indirectly through a GHB-derived GABA pool.[42] GHB itself is a weak $GABA_B$ receptor agonist with an affinity in the mmol/L range, which far exceeds the 1â€“4 Âµmol/L physiologic concentrations of GHB in the brain.[18 , 59 , 69] Therefore, the supraphysiologic concentration of GHB that could accumulate after its exogenous administration may exert its effects through a weak, direct agonistic effect on $GABA_B$ receptor-mediated mechanisms.

GHB and Endogenous Analogs

GHB has several *endogenous* structural analogs (GABA, *trans* -4-hydroxycrotonic acid [T-HCA]) and chemical precursors (GBL, 1,4-BD, Î³-crotonolactone [GCL]), as well as several well *synthetic* structural analog (5-hydroxyvaleric acid, Î³-methyl-GHB, Î³-phenyl-GHB, Î³-(*p* -chlorophenyl)-GHB, Î³-(*p* -methoxyphenyl)-GHB, Î³-benzyl-GHB, *R* -Î³-benzyl-GHB, *S* -Î³-benzyl-GHB, Î³-(*p* -methoxybenzyl)-GHB [NCS 435]), and precursors (GVL, THF). Of these analogs, illicit abuse has only been reported with GBL, 1,4-BD, Î³-methyl-GHB, GVL, and THF.

GHB itself usually exists as either a free acid (a colorless liquid) or as a

sodium salt (generally a white powder). The molecular formulas of GHB for its free acid and sodium salt are $C_4 H_8 O_3$ (molecular weight [MW] 104.11 g/mol) and $C_4 H_7 NaO_3$ (MW 126.09 g/mol), respectively. 4-Hydroxybutyric acid is the chemical name for its free acid, and sodium oxybate is the national nonproprietary name for its sodium salt, which is also a prescription drug. Synonyms for its chemical name are important because illicit GHB products often intentionally list obscure alternative chemical synonyms to conceal the identity of GHB. Synonyms include Î³-hydroxybutyric acid, 4-hydroxybutyric acid sodium salt, Î³-hydroxybutyric acid sodium salt, sodium 4-hydroxybutyrate, and 4-hydroxybutanoic acid.

GBL, the lactone ring precursor analog of GHB, is an endogenous substance in the mammalian brain at concentrations of approximately 10% that of GHB.[17] Chemically, it is most commonly referred to as Î³-butyrolactone, but it also has numerous obscure chemical synonyms, which are often intentionally listed on illicit GBL product labels to conceal the identity of GBL, such as 2(3 H)-furanone dihydro; butyrolactone; 4-butyrolactone; dihydro-2(3 H)-furanone; 4-butanolide; 2(3 H)-furanone; tetrahydro-2-furanone; 4-deoxytetronic acid; butyrolactone-Î³; 4-hydroxbutyric acid lactone; Î³-hydroxybutyric acid lactone; butyryl lactone; butyric acid lactone; butyrolactone; hydroxybutanoic acid lactone; tetrahydro-2-furanone; 1,4-butanolide; and 1,4-lactone. Based on behavioral and analytical observations, GBL is best described as a precursor to the pharmacologically active metabolite GHB. 1,4-BD, the other naturally occurring GHB precursor analog, is usually referred to by the chemical name 1,4-butanediol, but it has several additional chemical synonyms, including 1,4-butylene glycol, 1,4-dihydroxybutane, and 1,4-tetramethylene glycol. CNS depression by 1,4-BD is mediated through metabolism to GHB.[85]

Synthetic Analogs

Numerous pharmacologically active synthetic GHB structural analogs have been produced in the laboratory. In general, lengthening of the GHB carbon chain and introduction of functional groups to the Î³-carbon both

can yield potent compounds with respect to affinity for [^{3} H]GHB-labeled binding sites. Although the list of pharmacologically active GHB structura analogs appears to be ever increasing, only GHV (Î³-methyl-GHB) abuse is reported to date. Nevertheless, the possibility exists for future illicit introduction of these GHB structural analogs, as law enforcement pressur continues to increase for GHB, GBL, and 1,4-BD.

Synthetic Precursor Analogs

GVL and THF have been illicitly used as synthetic precursor analogs of GHV and GBL/GHB, respectively. GVL is the structural analog of GBL produced by the methylation of GBL in the Î³ (4-carbon) position. It has the chemical synonyms 4-hydroxypentanoic acid lactone, 4,5-dihydro-5-methyl-2(^{3} H)-furanone, and Î³-methyl-GHB. When administered, GVL undergoes hydrolysis to yield the GHB structural analog GHV.[67 , 77 , 78] Furthermore, GVL is reported to be used in the illicit synthesis of GHV.[22] THF is the cyclic ether structural analog of GBL. THF can serve as the key precursor ingredient in the illicit synthesis of GBL.[80 , 86] Because THF is a widely employed industrial solvent, human toxicity is generally available in the context of occupational exposure and poisoning, where THF causes nausea, headache, blurred vision, dizziness, narcosis, tinnitus, chest pair and coughing.[9 , 81] Acute poisonings and fatalities from THF are rare; only 2 published references are available. In the first case, a 50-year-old man ingested a drink offered by a stranger and abruptly developed abdominal pain, nausea, and vomiting. He was hospitalized 16 hours postingestion, developed hepatorenal syndrome, and died on hospital day 5. THF was detected in the patient's urine by gas chromatography-mass spectrometry (GC/MS).[76] In the second case, a 55-year-old woman intentionally ingested an organic solvent and psychoactive medications, and presented to an ED with

coma. She required endotracheal intubation, and a chest radiograph was consistent with aspiration pneumonitis. She had a complete recovery on hospital day 4 and was discharged after 8 days, without any sequelae. Toxicologic screening by high-performance liquid chromatography (HPLC)

revealed the presence of zolpidem and fluoxetine. Quantitative nuclear magnetic resonance (NMR) analysis was performed, demonstrating THF and GHB in serum and urine at concentrations of 813 and 850 mg/L, and 239 and 2977 mg/L, respectively. A GC/MS method confirmed the NMR observations.[9]

Pharmacokinetics and Toxicokinetics

GHB is rapidly and near completely absorbed from the gastrointestinal tract with an onset of action of about 15 minutes,[105] and reaches its peal effect by 90â€“120 minutes.[46] The steady-state volume of distribution is approximately 0.58 L/kg.[44] GHB is eliminated very rapidly, with a half-life of 30 minutes.[8] Less than 5% of the parent compound is recovered in the urine. In comparison, GBL is more rapidly absorbed and has a longer duration of action, a result of higher lipid solubility. Because 1,4-BD is metabolized by alcohol dehydrogenase (ADH), coingestion with ethanol can prolong its clinical effects because of competitive inhibition of ADH.[79, 87]

Clinical Manifestations

The clinical manifestations of overdose of GHB and related xenobiotics ca be predicted based on known pharmacologic activity and kinetics. Specifically, effects on the GABA and opioid neurotransmitter symptoms seem to predominate. In volunteers undergoing sleep studies, a clear ora doseâ€“response effect for GHB is noted: 30 mg/kg produces CNS depression and myoclonus, 50 mg/kg produces unconsciousness, and 60 mg/kg produces coma.[33, 65] Again, tolerance has the ability to shift this doseâ€“response curve to the right.

These clinical manifestations of overdose are highlighted by a number of well-documented cases.[23, 24, 90, 99, 110] Although the constellation of signs and symptoms are best reported for GHB, the following is most likely applicable to the entire class of xenobiotics. The onset of action is very rapid, with effects noted as early as 15 minutes postingestion. Vital

signs typically reveal hypotension, bradycardia, bradypnea, and hypothermia. Bradypnea is the most consequential of these effects, and apnea is the most likely cause of death. Pupils are typically miotic and poorly responsive to light. Salivation and vomiting are common, especiall when CNS depression is prominent. These effects compound bradypnea and hypoventilation in that they increase the risk for aspiration.

CNS effects can range from hallucinations, disorientation, and agitation t lethargy, followed by stupor and coma. These findings most likely represent disinhibition of higher cortical areas and are consistent with other sedativeâ€“hypnotics such as ethanol. In contrast to ethanol and other sedativeâ€“hypnotics, however, patients with GHB overdose often have a characteristic violent arousal that accompanies attempts to assess their gag reflex or perform intubation, which is somewhat suggestive of a clonidine overdose (Chap. 60).

Motor abnormalities are also common, and there is debate whether they represent seizures, myoclonus or both. In animal models, GHB can produce seizures, yet EEG monitoring in humans suggests that repetitive movements most likely represent myoclonus.[27] Clinically, these events are often called â€œseizuresâ€• because, in the absence of consciousness or EEG monitoring, it is difficult to distinguish these two disorders.

Other findings include prominent U waves on the ECG.[13] Electrolytes, anion gap, and other standard tests are usually normal.

The duration of effect is characteristically short. Many patients will abruptly awaken within a few hours of presentation and appear completely normal. Even those patients who require endotracheal intubation are usually able to be extubated within 8 hours. As long as aspiration and hypoxia have not occurred, most patients suffer no sequelae.

Diagnostic Testing

The presence of GHB and related xenobiotics can be determined,

quantitatively and qualitatively, in both serum and urine, using a variety of analytical techniques.[39 , 102 , 109] The most important caveat is that appropriate cutoff values must be selected to distinguish use and overdose from endogenous levels.[16 , 25 , 49 , 74] In general, unconsciousness occurs when serum concentrations reach 50 Âµg/mL, an levels above 260 Âµg/mL typically produce deep coma.[90] Attempts to relate concentrations to clinical effects in any individual might not be valid because of the potential for tolerance. Due to rapid metabolism and elimination, concentrations return to endogenous values shortly after nontolerant patients become clinically normal. Most clinical hospital laboratories do not routinely test for the presence of GHB and related xenobiotics, and recovery is typically rapid, so results of analytical testin are not useful for clinical care. They may, however, have forensic implications.

Other routine tests that should be obtained in patients with depressed levels of consciousness include a rapid evaluation of blood glucose, an ethanol concentration, and an ECG. When intentional overdose or self-harm is suspected, a determination of acetaminophen concentration is also indicated. Other studies should be obtained based on the clinical condition of the patient.

Treatment

The provision of good supportive care remains the mainstay of therapy. The decision to perform endotracheal intubation should be made at the bedside and based on a clinical assessment of oxygenation and ventilation. Despite deep coma, many patients will have adequate respirations and airway-protective reflexes. Because the duration of unconsciousness is relatively brief, coma, in and of itself, should not be considered an absolute indication for endotracheal intubation. Hypotension usually responds to fluids, and bradycardia rarely requires pharmacologic intervention. Hypothermia is mild and typically responds t passive rewarming.

Dextrose and thiamine should be given, as clinically indicated. Although

no clinically available GHB antagonists exist, both naloxone and physostigmine have been used. A trial of naloxone is often clinically reasonable in the undifferentiated patient, based on the findings of small pupils and CNS and respiratory depression. Although in animal models some of the effects of GHB are reversed by naloxone, naloxone administration to GHB-toxic humans is largely unsuccessful.[58] Likewise, while

anecdotal reports suggest some utility for physostigmine, a systematic review of available data failed to find any convincing supporting evidence.[101]

There is no role for any form of gastrointestinal decontamination. GHB and related xenobiotics are rapidly absorbed and can produce significant airway compromise. It is unlikely that a significant percentage of the ingested dose will be present in the stomach at the time of presentation, and the use of activated charcoal will only increase the risk of vomiting and aspiration. However, if a coingestant is suspected, appropriate decontamination techniques can be used, as long as there are no contraindications.

GHB Withdrawal

Severe and life-threatening manifestations follow abrupt cessation or reduction in intake of GHB or any of its precursors or analogs.[15, 21, 70, 88, 100] Because GHB and related xenobiotics have a short duration of effect, symptoms usually develop very rapidly and are clinically consisten with sedative hypnotic withdrawal. Patients develop agitation, disorientation, hallucinations, hypertension, tachycardia, hyperthermia, tremor, and seizures, often within hours of their last use.[12, 83]

Treatment principles involve sedation, cooling, volume resuscitation, and a search for other medical and traumatic causes of alterations in behavior. Although benzodiazepines appear to be the safest initial pharmacologic agent to control behavior, excessively large doses may be required. When patients appear resistant to benzodiazepines, either

barbiturates or propofol can be given.[91] Endotracheal intubation is often required when barbiturates or propofol are used.

Summary

GHB is a unique xenobiotic in that it is an endogenous neurotransmitter, licensed pharmaceutical, and a drug of abuse. Complex pharmacologic effects with multiple receptors produce rapid coma with hypotension, bradycardia, respiratory depression, and miosis. Treatment is largely supportive, and because the duration of effect is short, there is essentially no value in attempting to antagonize receptors or enhance elimination. Although fatality is possible, most patients recover rapidly, with no long-standing effects.

Chapter 79
Inhalants

Heather Long

A mother returned home from a parentâ€“teacher conference regarding her 11-year-old daughter; both the parent and the teacher had become concerned about some behavioral changes noted in the girl over the past few months. The mother found her daughter in the bathroom, holding a can of air freshener aerosol spray. Upon discovery, the girl immediately collapsed and lost consciousness. She had some short-lived twitching movements of her extremities that were not rhythmic. On arrival of emergency medical services (EMS), the girl was unresponsive and the electrocardiogram revealed ventricular tachycardia. A white residue was noted around her mouth. EMS initiated resuscitation following the Pediatric Advanced Life Support protocol, which included three stacked, unsynchronized defibrillations at 200, 300, and 360 joules, followed by the administration of intravenous epinephrine (0.01 mg/kg). The patient was endotracheally intubated and given 100% oxygen. Chest compressions were continued throughout transport to the emergency department (ED).

On arrival to the ED, the child was asystolic. Resuscitative efforts,

including chest compressions and the intravenous administration of epinephrine (0.1 mg/kg) and atropine (0.02 mg/kg), were continued in the ED. After approximately 30 minutes, the patient was pronounced dead.

Inhalant abuse is defined as the deliberate inhalation of vapors for the purpose of changing one's consciousness or becoming â€œhigh.â€• It is also referred to as volatile substance abuse and was first described in 1951.[30] Inhalants are appealing to adolescents because they are inexpensive, readily available, and sold legally. Initially, inhalant abuse was viewed as physically harmless, but reports of â€œsudden sniffing deathâ€• began to appear in the 1960s.[6] Shortly thereafter, evidence surfaced of other significant morbidities, including organic brain syndromes and peripheral neuropathy.

Epidemiology

The demographics of inhalant abuse differ markedly from that of other traditional substances of abuse. The 2003 Monitoring the Future Study found that more than 2 million youths between the ages of 12 and 17 years used inhalants at least once in their lifetime.[126] The 2000 National Household Survey on Drug Abuse showed that the number of new inhalan users in the United States increased more than 50%, from 618,000 to 979,000, between 1994 and 2000.[126] Youths ages 12â€“17 years had higher rates of past-year use than did adults ages 18 years and older. Th lifetime prevalence of inhalant use peaked among 8th graders at 15%. The median age of first use is 13 years.[4]

Although long considered to be a problem among boys, there has been a steady increase of inhalant abuse among girls, and their lifetime prevalence now equals that of boys.[8] In the United States, the problem is greatest among children of lower socioeconomic groups; non-Hispanic white adolescents are the most likely and black adolescents the least likely to use inhalants.[80] Although inhalant use is a problem in both urba and rural communities, its prevalence is higher in rural settings.[105] This may relate to the easier access teens in urban areas have to other drugs

of abuse.

Inhalant abuse includes the practices of sniffing, huffing, and bagging. Sniffing entails the inhalation of a volatile substance directly from a container, as occurs with airplane glue or rubber cement. Huffing involves pouring a volatile liquid onto fabric, such as a rag or sock, and placing it over the mouth and/or nose while inhaling. Huffing is the method used by more than 60% of volatile-substance abusers.[80] Bagging refers to spraying a solvent into a plastic or paper bag and rebreathing from the bag several times; spray paint is among the xenobiotics commonly used with this method.

Agents Used

There are myriad xenobiotics abused as inhalants (Table 79-1), most of which are volatile hydrocarbons. Hydrocarbons are organic compounds comprised of carbon and hydrogen atoms and are divided into two basic categories: aliphatic (straight, branched, or cyclic chains) and aromatic. Most of the commercially available hydrocarbon products are mixtures of hydrocarbons; for example, gasoline is a mixture of aliphatic and aromatic hydrocarbons that may consist of more than 1500 compounds. Substituted hydrocarbons contain halogens or other functional groups (eg, hydroxyl or nitrite), other than carbon and hydrogen, that are substituted for hydrogen atoms in the parent structure. Solvents are themselves a heterogeneous group of chemical compounds that are used to dissolve other chemical compounds or provide a vehicle for their delivery.

The most commonly inhaled volatile hydrocarbons are fuels, such as gasoline, and solvents, such as toluene.[105] Other commonly inhaled hydrocarbon-containing products include spray paints, lighter fluid, air fresheners, and glue. In most reported cases of inhalant use, the inhalant is identified not by its chemical name (eg, butane, toluene) but rather by its form (eg, lighter fluid, paint thinner). Because exact components may vary between commercial products, this method is inaccurate and imprecise.

Although volatile alkyl nitrites are technically substituted hydrocarbons, they have pharmacologic and behavioral effects,

as well as patterns of abuse that are distinct from the other volatile hydrocarbons. For this reason, researchers usually classify them as a separate category among abused inhalants. Amyl nitrite is the prototypical volatile alkyl nitrite.[4] Amyl nitrite became popular in the 1960s with the appearance of â€œpoppers,â€• small glass capsules containing the chemical in a plastic sheath or gauze. When crushed, the ampules release the amyl nitrite. When over-the-counter sales of amyl nitrite were restricted in 1968, sex and drug paraphernalia shops began selling small vials of butyl and isobutyl nitrites marketed as room deodorizers or liquid incense.[4 , 75] Because of further restrictions on sales of alkyl nitrites, most of these products now contain chemicals that are not technically alkyl nitrites, such as cyclohexyl nitrite.[4]

Glues/adhesives
Toluene, *n* -hexane, benzene, xylene, trichloroethane, trichloroethylene, tetrachloroethylene, ethyl acetate, methylethyl ketone, methyl chloride
Spray paint
Toluene, butane, propane
Hair spray, deodorants, air fresheners
Butane, propane, fluorocarbons
Cigarette lighter fluid
Butane
Paint thinner
Toluene, methylene chloride, methanol
Gasoline
Aliphatic and aromatic hydrocarbons
Carburetor cleaner
Methanol, methylene chloride, toluene, propane
Dry cleaning agents, spot removers, degreasing agents
Tetrachloroethylene, trichloroethane, trichloroethylene
Typewriter correction fluid
Trichloroethane, trichloroethylene

Nail polish remover
Acetone
Paints, lacquers, varnishes
Trichloroethylene, toluene, n-hexane
â€œPoppersâ€•
Amyl nitrite, isobutyl nitrite
Room deodorizers
Butyl nitrite, isobutyl nitrite, cyclohexyl nitrite
Whipped cream dispensers â€œwhippetsâ€•
Nitrous oxide

Inhalant Chemical

TABLE 79-1. Common Inhalants and the Constituent Chemicals

The most commonly used nonhydrocarbon inhalant is nitrous oxide. Nitrous oxide, or â€œlaughing gas,â€• is used medicinally as an inhalational anesthetic. It is the propellant in supermarket-bought whipped cream canisters, and cartridges of the compressed gas are sold for home use in whipped cream dispensers. These battery-sized metal containers of compressed gas may be used as â€œwhippets,â€• in which the container is punctured using a device known as a â€œcracker,â€• and the escaping gas is either inhaled directly or collected in a balloon and then rebreathed.

Pharmacology

Although chemically heterogeneous, inhalants are generally highly lipophilic and gain rapid entrance into the central nervous system (CNS). Little is known about the cellular basis of the effects of inhalants and it is unclear whether these actually represent a single pharmacologic group. Their effects are probably best represented by the model for ethanol in which multiple different cellular mechanisms explain diverse pharmacologic and toxicologic effects.[4]

Volatile Hydrocarbons

The clinical effects of the volatile hydrocarbons are likely mediated through stimulation of the Î³-aminobutyric acid (GABA) receptor complex the primary system responsible for inhibitory neurotransmission within the CNS. Like ethanol, both toluene and TCE enhance $GABA_A$ receptor-mediated synaptic currents as well as glycine receptor-activated ion function; stimulation of these receptors acts to increase chloride permeability, hyperpolarizing the cell membrane and inhibiting excitability. Despite very different molecular structures, ethanol, enflurane, chloroform, toluene, and 1,1,1-trichloroethane (TCE) compete for binding sites in glycine $Î±_1$ receptors.[9] Additionally, toluene, like ethanol, interferes with glutamate-mediated excitatory neurotransmissior by inhibiting *N* -methyl-D-aspartate (NMDA) receptor-mediated currents i a concentration-dependent manner.[32]

Toluene is the prototypical volatile hydrocarbon and the best studied. In animal models, differences in pharmacologic action are demonstrated between toluene and other alkylbenzenes, and halogenated hydrocarbons such as TCE, and acetone.[17 , 18 , 113] These differences may represent evidence that specific cellular sites for their actions exist. Additionally these differences may explain the variation in their abuse potential or their intoxicating effects.[4] Despite these distinctions, there are marked similarities in the behavioral and pharmacologic effects of the volatile hydrocarbons. Moreover, the clinical effects profile shared by the volatile hydrocarbons, subanesthetic concentrations of general anesthetics, ethanol, and benzodiazepines suggests that they share cellular mechanisms. Shared clinical effects include anxiolytic effects,[19] anticonvulsant effects,[125] impaired motor coordination,[85] and evidence o physical dependence on withdrawal.[36 , 37]

There are scant data on the pharmacokinetics of the inhalants. Most data are derived from studies on occupational and environmental exposures and have limited applicability to the intentional inhalation. More relevant to the understanding of inhalants are the similarities with the inhalationa anesthetic agents, many of which are halogenated hydrocarbons. Factors

determining pharmacokinetic and pharmacodynamic effects of a given inhalational anesthetic include concentration in inspired air; its partition coefficient; interaction with other inhaled substances, alcohol, and drugs; the patient's respiratory rate and blood flow; their percent body fat; and individual variation in drug metabolism (Chap. 65).[46] Whereas the pharmacokinetics of the inhalational anesthetics are extensively studied, the intentional inhalation of variable concentrations of abused inhalants for variable periods of time remains unstudied.

Partition coefficients measure the relative affinity of a gas for two different substances at equilibrium and are used to predict the rate and extent of uptake of an inhaled substance. The blood:gas partition coefficient is most commonly referenced. The higher the number, the more soluble the substance is in blood. Substances with a low blood:gas partition coefficient, like nitrous oxide, are rapidly taken up by the brain and, conversely, are rapidly eliminated from the brain once exposure is ended (Table 79-2).

In a rodent model of inhalation abuse of toluene and acetone,[24] the rapidity of onset and the depth of CNS depression were dependent on the concentration of the solvent inhaled. There was a parallel relationship between brain concentration and pharmacologic effect during induction (inhalation) and postexposure. Brain and liver concentrations dropped rapidly after exposure; concentration in blood decreased at the slowest rate. Elimination was biphasic: rapid elimination during the first step was a result of tissue redistribution,

alveolar ventilation, and metabolic clearance. During the second phase there was a slow decrease in tissue concentrations as a result of the gradual mobilization from adipose tissue with subsequent exhalation or metabolism. Acetone, which is more water-soluble than toluene, is less potent and more slow acting than toluene, but is eliminated much more slowly than toluene and has a much longer duration of action.[24] Positron emission tomography (PET) studies using (^{11}C) radiolabeled toluene in nonhuman primates showed rapid uptake of radioactivity in striatal and frontal regions of the cortex followed by rapid clearance from brain.

Whole-body PET scans in mice showed excretion through the kidneys and liver.[44]

Acetone
243â€“300
Largely unchanged via exhalation 95% and urine 5%
None
n- Butane
0.019
Largely unchanged via exhalation
None
Carbon tetrachloride
1.6
50% unchanged via exhalation; 50% hepatic metabolism and urinary excretion
CYP2E1 to trichloromethyl radical, trichloromethyl peroxy radical, phosgene
n -Hexane
2
10â€“20% exhaled unchanged; hepatic metabolism and urinary excretion
CYP2E1 to 2-hexanol, 2,5-hexanedione, Î³-valerolactone
Methylene chloride
5â€“10
92% exhaled unchanged; hepatic metabolism and urinary excretion
(1) CYP2E1 to CO and CO_2
(2) Glutathione transferase to CO_2 , formaldehyde, and formic acid
Nitrous oxide
0.47
>99% exhaled unchanged
None
Toluene
8â€“16
<20% exhaled unchanged; >80% hepatic metabolism and urinary excretion
CYP2E1 to benzoic acid, then

(1) glycine conjugation to form hippuric acid (68%)
(2) glucuronic acid conjugation to benzoyl glucuronide (insignificant pathway except following large exposure to toluene)
1,1,1-Trichloroethane
1â€“3
91% exhaled unchanged; hepatic metabolism and urinary excretion
CYP2E1 to trichloroethanol, then
(1) conjugated wih glucuronic acid (urochloralic acid) or
(2) further oxidized to trichloracetic acid
Trichloroethylene
9
16% exhaled unchanged; 84% hepatic metabolism and urinary excretion
CYP2E1 to epoxide intermediate (transient); chloral hydrate (transient); trichloroethanol (45%), trichloroacetic acid (32%)

Xenobiotic	Blood:Gas Partition Coefficient (98.6Â°F/37Â°C)	Routes of Elimination	Important Metabolites

TABLE 79-2. Blood: Gas Partition Coefficients, Routes of Elimination and Important Metabolites of Selected Inhalants

The inhalants are eliminated unchanged via respiration, undergo hepatic metabolism or both (Table 79-2). For some the percentage that is metabolized versus eliminated unchanged varies with the exposure dose. Nitrous oxide and the aliphatic hydrocarbons are frequently eliminated unchanged in the expired air. The aromatic hydrocarbons are usually metabolized extensively via the cytochrome P450 (CYP) system, particularly CYP2E1, which has a substrate spectrum that includes a number of aliphatic, aromatic, and halogenated hydrocarbons.[15] Extrahepatic expression of CYP2E1 occurs to a lesser extent but may be of toxicologic significance, particularly in the kidneys and the dopaminergic cells of the substantia nigra.[16 , 56 , 116] In humans, there appears to be no significant gender differences in CYP2E1; however, it is

polymorphic and, as such, allelic distributions vary among different human populations.[15, 103] Moreover, this polymorphism may explain the varying degrees of toxicity exhibited following inhalant abuse.

Although little is known about the cellular actions of the inhalants, even less is known about the reward mechanisms and consequently the abuse potential of inhalants. Animal research on toluene suggests that similar to other drugs of abuse, activation of mesolimbic dopaminergic pathways may play an important role.[13, 44, 96]

Volatile Alkyl Nitrites

Unlike other volatile hydrocarbons, the volatile alkyl nitrites are not thought to have any direct effects on the CNS. Their effects are mediated through smooth muscle relaxation in the central and peripheral vasculature and they share a common cellular pathway with other nitric oxide (NO) donors like nitroglycerin and sodium nitroprusside.[65] A rat model of inhalation of isobutyl nitrite found a half-life of 1.4 minutes with almost 100% biotransformation to isobutyl alcohol. Bioavailability following inhalation was estimated to be 43%.

Nitrous Oxide

The pharmacokinetics and pharmacodynamics of nitrous oxide (N_2O) abuse are derived from its use as an inhalation anesthetic. Anesthetic uptake or induction, as well as emergence with N_2O, is rapid because of its low solubility in blood, muscle, and fat.[107] There is no appreciable metabolism of N_2O in human tissue.[38] An animal study found N_2O significantly inhibited excitatory NMDA-activated currents and had no effect on GABA-activated currents.[57] N_2O is also known to stimulate dopaminergic neurons, but the significance of this in mediating its anesthetic effects remains unclear.[62, 86]

Animal studies suggest the analgesic effects (or more accurately the antinociceptive effects because it refers to animals) of N_2O appear to be mediated through opioid peptide release in the midbrain. These

antinociceptive effects can be reversed by the opiate antagonist naloxone.[12] However, the anesthetic effects are not attenuated by naloxone, and, in humans, the subjective and psychomotor effects of N_2O are not extinguished by even high doses of naloxone.[104, 127]

Clinical Manifestations

Signs and symptoms of inhalant use may be subtle, tend to vary widely among individuals, and generally resolve within two hours

of exposure. Following acute exposure, there may be a distinct odor of the abused inhalant on the patient's breath or clothing. Depending on the inhalant used and the method, there may be discoloration of skin around the nose and mouth. Mucus membrane irritation may cause sneezing, coughing, and tearing. Patients may complain of dyspnea and palpitations. Gastrointestinal complaints include nausea, vomiting, and abdominal pain. After an initial period of euphoria, patients may have residual headache and dizziness.

Volatile Hydrocarbons

The central nervous system is the intended target of the inhalants and is most susceptible to adverse effects. Initial CNS effects include euphoria and hallucinations (both visual and auditory) as well as headache and dizziness. As toxicity progresses, CNS depression worsens and patients may develop slurred speech, confusion, tremor, and weakness. Transient cranial nerve palsies are reported.[111] Further CNS depression is marked by ataxia, lethargy, seizures, coma, and respiratory depression. These acute encephalopathic effects generally resolve spontaneously and associated neuroimaging abnormalities are not reported.[40]

As can be expected given the high lipophilicity of most inhalants, toxicity from chronic use is manifested most strikingly in the central nervous system. Toluene leukoencephalopathy, characterized by dementia, ataxia, eye movement disorders, and anosmia, is the prototypical manifestation

of chronic inhalant neurotoxicity. Patients with toluene leukoencephalopathy display characteristic neurobehavioral deficits reflecting white matter involvement: inattention, apathy, and impaired memory and visuospatial skills with relative preservation of language.[40] Autopsy studies reveal white matter degeneration including cerebral and cerebellar atrophy and thinning of the corpus callosum.[66, 97] On microscopy, there is diffuse demyelination with relative sparing of the axons. Abundant perivascular macrophages containing coarse or laminar myelin debris found in areas of the greatest myelin loss is a characteristic pathologic feature.[40] This targeting of myelin, which is 70% lipid, may be explained by toluene's lipophilicity.[40] As myelination continues at least through the second decade of life, the typical toluene abuser who begins inhaling during adolescence may be particularly susceptible to its toxic CNS effects.[39] Advances in magnetic resonance imaging with gadolinium, which allow enhanced visualization of the cerebral white matter, demonstrate that the extent of white matter injury in the brain directly corresponds to the clinical severity of toluene leukoencephalopathy.[40] It is postulated that reactive oxygen species generated either by toluene or its metabolite benzaldehyde induce lipid peroxidation.[77, 78] Genetic polymorphisms and host susceptibility among chronic abusers are also hypothesized to play a role.[49]

Acute cardiotoxicity associated with hydrocarbon inhalation is manifested most dramatically in â€œsudden sniffing death.â€• In witnessed cases, sudden death occurred when sniffing was followed by some physical activity. Examples include running or wrestling or a stressful situation like being caught sniffing by parents or police.[6] It is thought that the inhalant â€œsensitizes the myocardiumâ€• by blocking the potassium current (I_K), thereby prolonging repolarization.[88] This produces a substrate for dysrhythmia propagation; the activity or stress then causes a catecholamine surge that initiates the dysrhythmia (Chap. 23).[88] Cardiac dysrhythmias following the inhalation of hydrocarbons were documented with the halogenated inhalational anesthetics in the early 1900s, and this association was subsequently confirmed in both animal and human studies.[42, 112] Multiple case reports of ventricular fibrillation follow

intentional inhalation of other hydrocarbons as well, such as butane fuel,[51, 123] Freon (Dupont trade name for fluorinated hydrocarbons), and Glade Air Freshener (SC Johnson), which contains a mixture of short-chain aliphatic hydrocarbons.[71] Although cardiotoxic effects of inhalant abuse are generally acute, dilated cardiomyopathy is reported with chronic abuse of toluene and with trichloroethylene.[81, 124] Microscopy reveals evidence of chronic myocarditis with fibrosis.[124]

The typical clinical presentation of a patient with hydrocarbon cardiotoxicity includes palpitations, shortness of breath, syncope, and ECG abnormalities, including atrial fibrillation, premature ventricular contractions, QTc prolongation, and U waves.

The primary respiratory toxicity complication of inhalational substance abuse is hypoxia, which is either caused by rebreathing of exhaled air, as occurs with bagging, or displacement of inspired oxygen with the inhalant reducing the FiO_2 . Direct pulmonary toxicity associated with inhalants is most often a result of inadvertent aspiration of a liquid hydrocarbon (Chap. 102). Aspiration injury is associated with acute lung injury and the acute respiratory distress syndrome, a continuum of lung injury characterized by increased permeability of the alveolar-capillary barrier and the resulting influx of edema into the alveoli, neutrophilic inflammation, and an imbalance of cytokines and other inflammatory mediators.[119] Reports of asphyxiation initially ascribed to inhalant abuse were later found to be caused by suffocation by a plastic bag, mask, or container pressed firmly to the face, and not specifically by toxicity of the inhaled vapor.[6, 27, 118]

Irritant effects on the respiratory system are frequently transient, but patients may develop chemical pneumonitis. This syndrome is characterized by tachypnea, fever, tachycardia, rales/rhonchi, leukocytosis, and radiographic abnormalities, including perihilar densities bronchovascular markings, increased interstitial markings, infiltrates, and consolidation. Rebreathing of exhaled air, as occurs with bagging, may lead to hypercapnia and hypoxia. Acute eosinophilic pneumonia following abuse of a fabric protector containing 1,1,1-trichloroethane, is also

reported.[63] Barotrauma presents as pneumomediastinum or subcutaneou emphysema.[100]

Hepatoxicity is associated with exposure to halogenated hydrocarbons, particularly carbon tetrachloride, but also chloroform, trichloroethane, trichloroethylene, and toluene.[76] Intentional inhalation of carbon tetrachloride is rarely reported, but its toxic metabolite, the trichloromethyl radical, created by the cytochrome CYP2E1, can covalentl bind to hepatocyte macromolecules and cause lipid peroxidation.[95] The resultant depletion of glutathione and the potentially fatal centrilobular necrosis mimic acetaminophen toxicity and have led to a postulated role for *N* -acetylcysteine (NAC) in preventing carbon tetrachloride hepatoxicity. Animal studies on the efficacy of NAC in preventing carbon tetrachloride-induced hepatoxicity have yielded mixed results.[31 , 33 , 34] There are no clinical trials in humans, but case series suggest a protectiv role for NAC.[98] Two cases of centrilobular hepatic necrosis following inhalation of trichloroethylene are reported. Inhalation of either toluene or one of the many halogenated hydrocarbons is associated with elevated liver enzymes and hepatomegaly that generally return to baseline within weeks of abstinence.[3 , 55 , 60 , 70 , 87 , 89]

Renal toxicity is most frequently described following inhalation of toluene Traditionally, prolonged toluene inhalation was said to cause a distal rena tubular acidosis (RTA), resulting in hypokalemia. However, distal RTA is associated classically with a hyperchloremic metabolic acidosis and a normal anion gap, and

toluene abuse may be associated with an increased anion gap. Production of hippuric acid, a toluene metabolite, plays a more important role in the genesis of the metabolic acidosis than was previously thought.[28] Hippurate excretion, usually expressed as a ratio to creatinine, rises dramatically with toluene inhalation.[82] The excretion of abundant hippurate in the urine unmatched by ammonium mandates an enhanced rate of excretion of sodium and potassium cations. Continued loss of potassium in the urine leads to hypokalemia. Toluene is rapidly metabolized to hippuric acid, and the hippurate anion is swiftly cleared by

the kidneys, leaving the hydrogen ion behind. This prevents the rise in anion gap that would normally occur with an acid anion other than chloride, generating a normal anion gap. In some cases, the loss of sodium causes extracellular fluid volume contraction and a fall in the glomerular filtration rate, which may transform the metabolic acidosis with a normal anion gap into one with a high anion gap caused by the accumulation of hippurate and other anions.[28] Through unclear mechanisms, other renal abnormalities occur with toluene inhalation, including hematuria, albuminuria, and pyuria. Glomerulonephritis associated with hydrocarbon inhalation is also reported and is a result of antiglomerular basement membrane antibody-mediated immune complex deposition.[115 , 128]

Toluene-abusing patients may present with profound hypokalemic muscle weakness. In a study of 25 patients admitted to the hospital following inhalant abuse, 9 presented with muscle weakness. The mean serum potassium concentration was 1.7 mEq/L and 6 of these patients had elevated creatine phosphokinase concentrations, ranging from 118â€“4350 IU/L (normal: <50 IU/L in women and <85 IU/L in men). Four patients were quadriplegic on presentation and of these, 2 were initially diagnosed erroneously with Guillain-BarrÃ© syndrome. The patients had inhaled toluene 6â€“7 hours per day for 4â€“14 days prior to presentation.[108]

Acute dermatologic and upper airway toxicity is associated with the inhalation of Freon, a previously widely used refrigerant. Vesicular lesions resembling frostbite and massive, potentially life-threatening edema of the oropharyngeal, glottic, epiglottic, and paratracheal structures are reported.[1 , 67] This is caused by the cooling of the gas associated with its rapid expansion once it is released from its pressurized container. With chronic abuse of volatile hydrocarbons, patients may develop severe drying and cracking around the mouth and nose as a consequence of a defatting dermatitis known as â€œhuffer's eczema.â€• Other manifestations of chronic irritation include recurrent epistaxis, chronic rhinitis, conjunctivitis, halitosis, and ulceration of the nasal and oral mucosa.[82]

Methylene chloride (dichloromethane), most commonly found in paint removers and degreasers, is unique among the halogenated hydrocarbons in that it undergoes metabolism in the liver by CYP2E1 to carbon monoxide.[90] In addition to acute CNS and cardiac manifestations, inhalation of methylene chloride is associated with delayed onset and prolonged duration of signs and symptoms of carbon monoxide poisoning. The CO metabolite is generated 4â€“8 hours after exposure and its half-life is 13 hours, significantly longer than that of CO following inhalation (Chap. 120).[5 , 109]

Methanol toxicity is reported following intentional inhalation of methanol-containing carburetor cleaners.[43 , 72 , 79] Significant findings may include hyperemic discs on funduscopic examination, metabolic acidosis, and CNS and respiratory depression (Chap. 103). Methanol-containing carburetor cleaners may also contain significant amounts of toluene (43.8%), methylene chloride (20.5%), and propane (12.5%). These xenobiotics may potentiate CNS depression and contribute to the toxicity associated with these products.

Chronic inhalation of the solvent *n* -hexane, a petroleum distillate and a simple aliphatic hydrocarbon found, for example, in rubber cement, can cause a sensorimotor peripheral neuropathy. Toxicity is mediated via a metabolite, 2,5-hexanedione, that interferes with glyceraldehyde-3-phosphate dehydrogenase-dependent axonal transport, resulting in axonal death.[35] Numbness and tingling of the fingers and toes is the most common initial complaint; progressive, ascending loss of motor function with frank quadriparesis may ensue.[29] Sural nerve biopsy shows axonal swelling and axonal loss, with secondary loss of myelin, probably as a result of retraction by axonal swelling, and accumulation of neurofilaments.[68] Nerve conduction studies show marked conduction slowing and conduction block (Chap. 19).[29 , 68]

Reports of polyneuropathy associated with chronic gasoline inhalation date to the 1960s and describe a symmetric, progressive, sensorimotor neuropathy with occasional superimposed mononeuropathies.[25 , 61] Initially these deficits were attributed to the presence of tetraethyl lead

as an â€œantiknockingâ€• agent in gasoline, but cases following abuse of unleaded gasoline are also reported.[25, 101] *n* -Hexane is present in gasoline in concentrations up to 3% and is thought the likely mediator of gasoline neuropathy.[120]

Teratogenicity

Fetal solvent syndrome (FSS) was first reported in 1979.[114] The authors described a 20-year-old primigravida with a 14-year history of solvent abuse defined as â€œdailyâ€• and â€œheavyâ€• who gave birth to an infant exhibiting facial dysmorphia, growth retardation, and microcephaly a constellation of findings that resembles fetal alcohol syndrome (FAS).[10] Since then a number of cases and case series have been reported.[103, 104, 105, 106] A general limitation of these case series is their reliance on self-reporting of substance abuse. In a number of cases included for analysis of teratogenic effects, mothers admit to use during pregnancy of other potential teratogens, including ethanol, cocaine, heroin, and phenobarbital.[104, 105] Cases purported to represent inhalant abuse in the absence of other drug abuse, particularly ethanol, are not verified by laboratory testing. A small study of infants born to mothers with a self-reported history of chronic solvent abuse found 16% had major anomalies, 12.5% had facial features resembling FAS, and 3.6% had cleft palate.[99] Craniofacial abnormalities common to both FAS and FSS include small palpebral fissures, thin upper lip, and midfacial hypoplasia. Features of FSS that distinguish it from FAS include micrognathia, low-set ears, abnormal scalp hair pattern, large anterior fontanelle, and downturned corners of the mouth.[114] Hypoplasia of the philtrum and nose are more characteristic of FAS.[92] Compared to matched controls, infants born to mothers who report inhalant abuse are more likely to be premature, to be low birth weight, to have smaller birth length, and to have small head circumference.[2, 122] Followup studies of these infants show developmental delay when compared to children matched for age, race, sex, and socioeconomic status.[2, 53] A rat model of toluene-abuse embryopathy found a significant reduction in the number of neurons within each cortical layer, as well as abnormal neural migration.[47] In

another animal model of inhalant abuse, mice exposed in utero to either toluene or TCE gained less weight and performed worse on behavioral tests than controls.[58, 59]

Withdrawal

Observed similarities in the acute effects of inhalants compared with other CNS depressants have suggested similar patterns of tolerance and withdrawal. Rodent models of inhalant abuse with toluene and TCE show evidence of physical

dependence that manifest as an increase in handling-induced seizures on cessation of inhalation.[37, 121] Additionally, these studies demonstrate cross-tolerance of the benzodiazepine diazepam with the motor-stimulating effects of TCE and, to lesser degree, with toluene. Inhalant abusers have themselves described tolerance with weekly usage in as little as 3 months.[22, 50] Withdrawal symptoms, including sleep disturbances, nausea, tremor, and irritability, lasting 2â€“5 days after last use are described.[22] Whether this represents a true withdrawal syndrome or residual effects of the inhalant is unclear.

Volatile Alkyl Nitrites

Methemoglobinemia caused by inhalation of amyl, butyl, and isobutyl nitrites is well reported.[20, 48, 74] Nitrites are strong oxidants that may induce hemoglobin oxidation from the ferrous (Fe^{2+}) to the ferric (Fe^{3+}) state. Patients may present with signs and symptoms of methemoglobinemia including shortness of breath, cyanosis, tachycardia, and tachypnea (Chap. 122). Eye pain and transient increased intraocular pressure are reported following use of amyl nitrite.[91]

Nitrous Oxide

Reported deaths associated with abuse of nitrous oxide (N_2O) appear to be caused by secondary effects of N_2O, including asphyxiation and motor

vehicle collisions while under the influence, and not to direct toxicity.[110] [118] Investigations following deaths associated with N_2O have found many of the dead were discovered with plastic bags over their heads, in an apparent attempt to both prolong the duration of effect and increase the concentration to heighten the effect.[51] Autopsy findings in these cases were consistent with asphyxiation: acute lung injury, cardiac petechiae, and generalized visceral congestion.[110, 118] Laboratory simulation of a reported death in which the victim was found with a plastic bag over his head with a belt fastened loosely around his neck and a spent whipped cream canister within the plastic bag showed nitrous oxide displaces oxygen in a closed space.[118] Additionally, N_2O concentrations in this simulation were greater than 60%; at concentrations of nitrous oxide greater than 50%, the normal hypoxic response is diminished.[118] The combined effects of displaced oxygen and a blunted hypoxic drive may increase the risk of asphyxia.

Chronic abuse of nitrous oxide is associated with neurologic toxicity mediated via irreversible oxidation of the cobalt ion of cobalamin (vitamin B_{12}). Oxidation blocks formation of methylcobalamin, a coenzyme in the production of methionine and *S*-adenosylmethionine, required for methylation of the phospholipids of the myelin sheaths. Additionally, cobalamin oxidation inhibits the conversion of methylmalonyl to succinyl coenzyme A. The resultant accumulation of methylmalonate and propionate can result in synthesis of abnormal fatty acids and their subsequent incorporation into the myelin sheath (Chap. 65).[93] Case reports and small case series in humans following self-reported chronic, heavy abuse of N_2O found development of myeloneuropathy resembling the subacute combined degeneration of the dorsal columns of the spinal cord of classic vitamin B_{12} deficiency.[14, 26, 69, 73, 117] Presenting signs and symptoms reflect varying involvement of the posterior columns, the corticospinal tracts and the peripheral nerves. Numbness and tingling of the distal extremities is the most common presenting complaint. Physical examination may reveal diminished sensation to pinprick and light touch, vibratory sensation and proprioception, gait disturbances, the Lhermitte sign (electric shock sensation with neck flexion), hyperreflexia, spasticity

urinary and fecal incontinence, and extensor plantar response.[26,93] Among reported patients with nitrous oxide-associated neurotoxicity who had documented levels of vitamin B_{12}, approximately 50% had low vitamin B_{12} serum concentrations.[14,26,69,73,106,117] In the few patients who underwent Schilling tests, results were normal.[54,69,106] Nerve conduction studies and electromyography typically revealed a distal, axonal sensorimotor polyneuropathy.[26,54,69,117]

Laboratory and Diagnostic Testing

Routine urine toxicology screens are unable to detect inhalants or their metabolites. Most volatile inhalants can be detected using gas chromatography after exposure; likelihood of detection is limited by the dose, time to sampling, and method of specimen storage. Blood is the preferred specimen, but urinalysis for metabolites and hippuric acid (for toluene) may extend the time until the limit of detection is reached.[23] Specimens should be stored at a temperature between 23Â°F (â€“5Â°C) and 39.2Â°F (4Â°C).[23] Testing is not readily available at most institutions and the need to send the specimen to a reference laboratory limits the clinical usefulness in most situations. A thorough history and physical examination and careful questioning of the patient's friends and family are probably more helpful in cases of suspected inhalant abuse.

Depending on the patient's signs and symptoms, additional diagnostic testing may be indicated, including an electrocardiogram, chest radiograph, serum electrolytes, liver enzymes, and serum pH. The patient's presenting complaint(s) should guide decisions regarding furthe diagnostic testing.

Some inhalants present with unique diagnostic considerations (Table 79-3). The potassium concentration should be analyzed in patients manifestin muscle weakness and decreased deep tendon reflexes for suspected toluene-induced hypokalemia. A carboxyhemoglobin concentration should be determined following methylene chloride exposure. A methemoglobin concentration analysis might be indicated following exposure to amyl, butyl, or isobutyl nitrites. Liver function tests might be indicated followin

exposure to toluene, trichloroethylene, and TCE. A methanol concentration might be indicated following inhalation of methanol-containing carburetor cleaners.

Nerve conduction studies and electromyography can be useful in cases of suspected peripheral neuropathy. Routine laboratory testing, including cerebrospinal fluid analysis, is unremarkable in patients with inhalant-induced leukoencephalopathy. A CT scan of

the head is generally normal until late in the disease, when diffuse hypodensity of white matter becomes evident. T2-weighted magnetic resonance imaging with its superior resolution of white matter is the diagnostic study of choice. Standard MRI does not detect initial changes caused by toluene leukoencephalopathy; measurement of *N* -acetyl aspartate (NAA), a marker of CNS axons, with magnetic resonance spectroscopy (MRS) may assist with earlier detection. A decrease in NAA concentration, usually expressed as ratio of NAA to creatinine (NAA:Cr), may serve as a marker of axonal damage.[40]

Toluene
Hypokalemia; hepatotoxicity; leukoencephalopathy (chronic)
1,1,1-Trichloroethane, trichloroethylene
Hepatotoxicity
Methylene chloride
Carbon monoxide poisoning
Alkyl nitrites (amyl, butyl, isobutyl)
Methemoglobinemia
n -Hexane
Peripheral neuropathy (chronic)
Nitrous oxide
Myeloneuropathy (chronic)

Agent Special Considerations

TABLE 79-3. Inhalants, Common Sources, Special Considerations

Management

Management begins with assessment and stabilization of the patient's airway, breathing, and circulation (the â€œABCsâ€•). The patient should be connected to a pulse oximeter and cardiac monitor. Oxygen should be administered and the patient should be treated with nebulized albuterol i wheezing. Early consultation with a regional poison control center may assist with identification of the xenobiotic and patient management.

Cardiac dysrhythmias associated with inhalant abuse carry a significantly poor prognosis. Sudden death following use is not limited to new users and there appears to be no premonitory signal to the user.[6 , 94] Life-threatening electrolyte abnormalities must be considered early and corrected in the patient presenting with dysrhythmia. Patients with nonperfusing rhythms should be managed following standard managemen with defibrillation. There are no evidence-based treatment guidelines for the management of inhalant-induced cardiac dysrhythmias, but Î²-adrenergic antagonists are thought to offer some cardioprotective effects to the sensitized myocardium.[88] Propranolol and esmolol have both been used successfully in treatment of ventricular dysrhythmias following inhalant abuse.[45 , 84]

Fluid and electrolyte abnormalities should be sought and corrected early. Other complications, including methemoglobinemia, elevated carboxyhemoglobin, and methanol toxicity, should be managed with the appropriate antidotal therapy. Patients with respiratory symptoms that persist beyond the initial complaints of gagging and choking should be evaluated for hydrocarbon pneumonitis and treated supportively (Chap. 102).

With abstinence, behavioral and neuroimaging changes associated with toluene-induced leukoencephalopathy may be partially reversible early on; beyond a poorly defined period, changes are irreversible.[40] Cessation of abuse is the most important therapeutic intervention in patients with *n*-hexaneâ€“induced neuropathy and nitrous oxide-induced

myeloneuropathy; limited anecdotal evidence supports the coadministration of vitamin B_{12} (1000 Âµg intramuscularly) and methionine (1 g orally) in cases of nitrous oxide-induced myeloneuropathy.[26, 106]

Agitation, either from acute effects of the inhalant or from withdrawal, is safely managed with a benzodiazepine. In the vast majority of patients, symptoms resolve quickly and hospitalization is not required. The potential toxicity of inhalants should be reinforced and patients should be referred for counseling. Subsets of users, meeting the criteria for inhalant dependence and inhalant-induced psychosis, require inpatient psychiatric care. Pharmacotherapy with carbamazepine or the antipsychotics haloperidol or risperidone appears beneficial to some patients with an inhalant-induced psychotic disorder.[52, 83] Drug use treatment programs for inhalant abuse are scarce and few providers have special training in this area.[7]

Summary

Inhalants are a heterogeneous group of agents that include the volatile hydrocarbons, the alkyl nitrates, and nitrous oxide. Incidence of abuse is greatest among adolescents. The central nervous system is the intended target for the inhalant users; early effects include euphoria, hallucinations, headache, and dizziness. Acute cardiotoxicity is manifested most dramatically in â€œsudden sniffing death.â€• Unique consideration and toxicity are associated with specific agents (Table 79-3). Diagnosis is largely clinical; further diagnostic testing should be guided by the patient's presenting complaint. Management begins with basic life support and care is generally supportive. Cessation of use is the only known treatment for many manifestations of chronic toxicity.

Chapter 80 Hallucinogens

Kavita M Babu

Robert P. Ferm

A 17-year-old boy was taken to the emergency department (ED) by his friends because he was acting bizarrely on the way home from school. He told a friend that he had â€œdropped acidâ€• after school and now could not stop staring at the bright lights. He encouraged his friends to enjoy the â€œpeace of the lights.â€• Physical examination revealed that the patient was agitated, and staring at the overhead lights. Vital signs were: blood pressure, 150/100 mm Hg; pulse, 112 beats/min; respiratory rate, 28 breaths/min; oral temperature, 100.4Â°F (38Â°C); and room air pulse oximetry 97%. A rapid bedside blood glucose was 120 mg/dL. His skin was moist and pale. Examination of the eyes revealed slowly reactive 6-mm pupils without nystagmus. He had occasional faint, scattered end-expiratory wheezes. Cardiac auscultation was normal. The abdomen was soft and nontender with hyperactive bowel sounds. There was no clubbing, cyanosis, or edema. Neuropsychiatric examination revealed that the patient was oriented, but was frightened by the visual hallucinations, and was â€œhearing purple and blueâ€• from the overhead lights. The remainder of the

neurologic examination was intact except for the presence of a fine tremor. The patient stated that he had previously taken lysergic acid diethylamide (LSD), although this was the first time that he had used it while alone. He understood that he was experiencing drug effects; however, he was extremely anxious and afraid of â€œlosing his mind.â€• The patient was moved to a quiet location with minimal stimuli and an intravenous line was inserted. He received diazepam 10 mg via slow IV push, and had some subsequent improvement of his anxiety. After approximately 8 hours of observation, the patient returned to his baseline functional status, without hallucinations or anxiety. After obtaining permission from the patient regarding disclosure, the ED staff notified his pediatrician and parents. A referral was made for drug counseling, and the patient was discharged to home with family members.

Epidemiology

Hallucinogens are a diverse group of xenobiotics that alter and distort perception, thought, and mood without clouding the sensorium. They have been used for thousands of years by many different cultures, largely during religious ceremonies. The ancient Indian holy book *Rig-Veda* , written more than 3500 years ago, describes a sacramental xenobiotic called Soma both as a god and as an intoxicating xenobiotic. Although debated for many years, the source of Soma is now believed to be the juice of the mushroom *Amanita muscaria* .[84 , 90] The Aztecs used the psilocybin-containing teonanacatl (flesh of the gods) and Ololiuqui (morning glory species) in their religious ceremonies. To this day, the Native American Church uses peyote in religious ceremonies.

Synthetic hallucinogen use is often said to have begun with the discovery of lysergic acid diethylamide (LSD). The synthesis of LSD resulted from extensive research on the ergot alkaloids derived from the fungus *Claviceps purpurea.* From medieval times through recent years, several large-scale epidemics of vasospastic ischemia, gangrene, and hallucinations (collectively called ergotism) have

resulted from *C. purpurea* contamination of cereal crops.[117] *C. purpurea* is suggested as the cause of the mass hysteria leading up to the Salem Witch trials. Many of these adverse effects after ingestion of *C. purpurea* are attributed to its serotonergic agonist effects.[35]

In 1938, Albert Hofmann, a Swiss chemist, synthesized LSD-25, the 25th substance in a series of lysergic acid derivatives being researched as new arousal, or analeptic, agents. These lysergic acid compounds were based on ergot extracts from *C. purpurea.* Five years later, LSD-25 was â€œtestedâ€• when Hofmann had an unintentional exposure in his laboratory, and subsequently developed hallucinations.[54 , 98] Soon thereafter, Sandoz laboratories began marketing LSD under the trademark name Delysid as an adjunct for analytic psychotherapy. In the 1950s, a small number of psychiatrists began using LSD to release the repressed memories of patients, and as an experimental model for schizophrenia.[103] The Central Intelligence Agency reportedly experimented with using LSD as a tool for interrogating suspected communists and as a mind-control agent.[23 , 98]

In the 1960s, the concept of the â€œfifth freedomâ€• emerged. As individuals explored this â€œrightâ€• to alter their consciousness as they saw fit, LSD (also called â€œacidâ€•) became a fashionable recreational drug. In one of the most famous slogans of the 1960s, Dr. Timothy Leary popularized LSD with the phrase, â€œTune in, Turn on, Drop out.â€•[98] By 1966, federal law banned the use of LSD.[80] Initial reports of LSD-induced chromosomal damage appeared in the 1960s, although further studies of pregnant women who had taken LSD did not demonstrate an increased risk of abortions or birth defects.[29 , 39 , 56 , 64 , 67]

LSD use diminished in the late 1970s and early 1980s, perhaps because of users' concerns regarding potential health risks of brain damage, â€œbad trips,â€• and flashbacks.[83] In the meantime, there was a rise in the use of the â€œdesignerâ€• hallucinogens. Exploiting a loophole in drug enforcement laws, these synthetic tryptamine and amphetamine hallucinogens were chemically similar to, but legally

distinct from, their outlawed counterparts.

A resurgence in LSD use was reported among high school teens in the late 1990s, with more prevalent use in the suburbs than

the inner city.[4,81,91] In 1997, two studies of adolescents showed a lifetime prevalence of LSD use at 13 and 14%.[57,83] However, in 2000, DEA agents seized an LSD-production lab and apprehended two men involved in massive production of LSD in the United States. Their incarceration resulted in a more than 90% decrease in LSD availability nationwide.[107]

The use of contemporary hallucinogens has grown in venues like all-night dance clubs and â€œrave parties.â€•[14] While the impact of these parties and clubs on the growth of hallucinogen use in the United States is unclear, many of the newer hallucinogens have been christened â€œclub drugsâ€• because of this association.[48] In addition, the Internet has developed as a vehicle for the rapid and facile sharing of information on the synthesis of emerging drugs, user experiences, and adverse effects.[21]

Specific Hallucinogens

The term *hallucination* can be defined as false perception that has no basis in the external environment. The term is derived from the Latin â€œto wander in mind.â€• A hallucination is distinct from an illusion, which refers to mental impressions derived from the misinterpretation of an actual experience. Hallucinogenic substances may also have illusogenic effects. Although the term *psychedelic* has been used for years to refer to the recreational and nonmedical effects of hallucinogens, other terms, like entheogen, and entactogen, frequently appear in Internet discussions. Entheogens are â€œsubstances which generate the god or spirit within,â€• whereas entactogens create an awareness of â€œthe touch within.â€•[37]

Hallucinogens can be categorized by their chemical structures, and

further divided into natural and synthetic members of each family (Table 80-1). The major structural classes of hallucinogens include the lysergamides, indolealkylamines (tryptamines), phenylethylamines (amphetamines), arylhexamines, cannabinoids, harmine alkaloids, and the tropane alkaloids. In addition, there are several unique hallucinogens, such as Salvinorin A. This chapter focuses on lysergamides, tryptamines, phenylethylamines, and Salvinorin A. Further discussion of the other classes of hallucinogens can be found in Chaps. 73 and 81 .

Lysergamides

Lysergamides are derivatives of lysergic acid, a substituted tetracyclic amine based on an indole nucleus (Fig. 80-1). Naturally occurring lysergamides are found in several species of morning glory (*Rivea corymbosa* , *Ipomoea violacea*) and Hawaiian baby wood rose (*Argyreia nervosa*).[52] Morning glory seeds contain multiple alkaloids, including lysergic acid hydroxyethylamide and ergonovine. The morning glory seeds were called Ololiuqui in ancient Mexico, where Aztecs and other indigenous populations used them in religious rites.[101] However, in one volunteer study, Ololiuqui use predominantly caused sedation rather than hallucinations.[55]

Lysergamides
- D-Lysergic acid diethylamide (LSD)
- Lysergic acid hydroxyethylamide
  - *Ipomoea violacea* (morning glory)
  - Ololiuqui (South American morning glory)
- Ergine
  - *Argyreia* (Hawaiian baby wood rose)

Indolalkylamines/Tryptamines
- 5-Methoxy-*N,N* -dimethyltryptamine
- *N,N* -Dimethyltryptamine
- Psilocin
- Psilocybin

Phenylethylamines
- Mescaline
- MDMA (3,4-methylenedioxymethamphetamine)
- 2CB
- 2CT-7

Tetrahydrocannabinoids
- Marijuana
- Hashish

Belladonna alkaloids
- Jimsonweed (*Datura stramonium*)
- Henbane (*Hyoscyamus niger*)
- Deadly nightshade (*Atropa belladonna*)
- *Brugmansia* species

Miscellaneous
- *Salvia divinorum*
- *Ketamine*
- Phencyclidine (PCP)

TABLE 80-1. Xenobiotics Classified as Hallucinogens

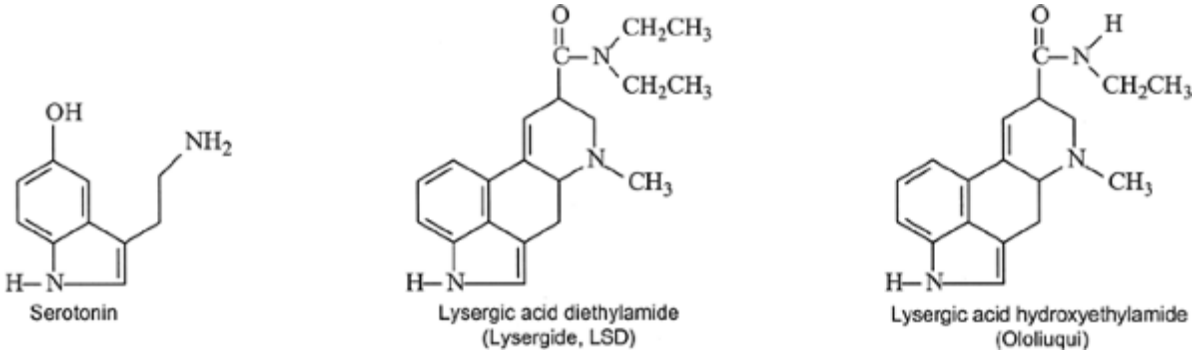

Figure 80-1. Hallucinogens of the lysergamide class and their chemical similarity to serotonin.

Ingestion of 200â€“300 morning glory seeds is required to achieve hallucinogenic effects. Hawaiian baby wood rose seeds contain ergine, and only 5â€“10 seeds are required to produce hallucinations. Ten

seeds may cost as little as 2 dollars. After ingestion of wood

rose seeds, the effects typically last for 6â€“8 hours, and produce tranquility without marked euphoria.[6] Both morning glory and Hawaiian baby wood rose seeds can be purchased legally in garden stores and on the Internet.

The synthetic lysergamide, LSD, is derived from an ergot alkaloid of the fungus *C. purpurea.* Although four LSD isomers exist, only the *d* isomer is active. Lysergic acid diethylamide is a water-soluble, colorless, tasteless, and odorless powder. Currently, LSD is typically sold as liquid-impregnated blotter paper, microdots, tiny tablets, â€œwindow paneâ€• gelatin squares, liquid, powder, or tablets.[91] Although LSD use has been reported via intravenous and intramuscular routes, ingestion of blotter paper is the most common route of abuse. The minimum effective oral dose is 25 Âµg.[60] The Drug Enforcement Administration reports that the current street dose of LSD ranges from 20â€“80 Âµg, which is lower than the 100â€“200 Âµg quantities reported during the 1960s and early 1970s.[32] The onset of effects may occur 30â€–60 minutes after exposure, with a duration of 10â€–12 hours after ingestion. LSD users typically experience heightened awareness of auditory and visual stimuli with size, shape, and color distortions. Auditory and visual hallucinations may occur, as well as synesthesia, a confusion of the senses, where users may describe â€œhearing colorsâ€• or â€œseeing sounds.â€• Other more complex perceptual effects may include depersonalization and a sensation of enhanced insight or awareness. A â€œbad tripâ€• may occur with any dose of LSD, and produce anxiety, bizarre behaviors, and combativeness.

LSD is classified as a Schedule I agent, with a high abuse potential, a lack of established safety even under medical supervision, and no known use in medical treatment.[110]

Indolealkylamines (Tryptamines)

Indolealkylamines, or tryptamines, represent a class of natural and synthetic compounds that structurally share a substituted monoamine group (Fig. 80-2). Endogenous tryptamines include serotonin and melatonin. Naturally occurring exogenous tryptamines include psilocybin, bufotenine, and dimethyltryptamine (DMT). Psilocybin is found in three major genera of mushrooms: *Psilocybe, Panaelous* , and *Conocybe* .[90] Other hallucinogenic mushrooms include *A. muscaria* and *A. pantherina* , which contain ibotenic acid, muscimol, and muscazone.[52] Toxic and hallucinogen mushrooms are discussed at length in Chapter 113 . Psilocybin-containing mushrooms, or â€œmagic mushrooms,â€• grow in the Pacific Northwest and the southern United States, usually in cow pastures. The mushroom may be recognized by a green-blue color that it assumes after bruising, but misidentification is common.[12] In the gastrointestinal tract, psilocybin is converted to psilocin, the active hallucinogen.[50] The effects of psilocin are similar to LSD, but with a shorter duration of action of about four hours.

DMT is a potent short-acting hallucinogen. It is found naturally in the bark of the Yakee plant (*Virola calophylla*), which grows in the Amazon basin and is used by shamans as a hallucinogenic snuff to â€œcommunicate with the spirits.â€•[90] DMT is also found in the hallucinogenic tea, Ayahuasca, which is used by indigenous healers in the Amazon Basin. In Ayahuasca, dimethyltryptamine-containing plants (eg, *Psychotria viridis*) are combined with plants containing harmine alkaloids (eg, *Banisteriopsis caapi*) that inhibit hepatic monoamine oxidases to increase the oral bioavailability of DMT (Chap. 69).[73] For current recreational purposes, DMT is typically smoked, snorted, or injected. By this route, its hallucinogenic effects peak in 5â€“20 minutes, with a duration of 30â€“60 minutes. This short duration of action has earned DMT the nickname â€œbusinessman's trip.â€•

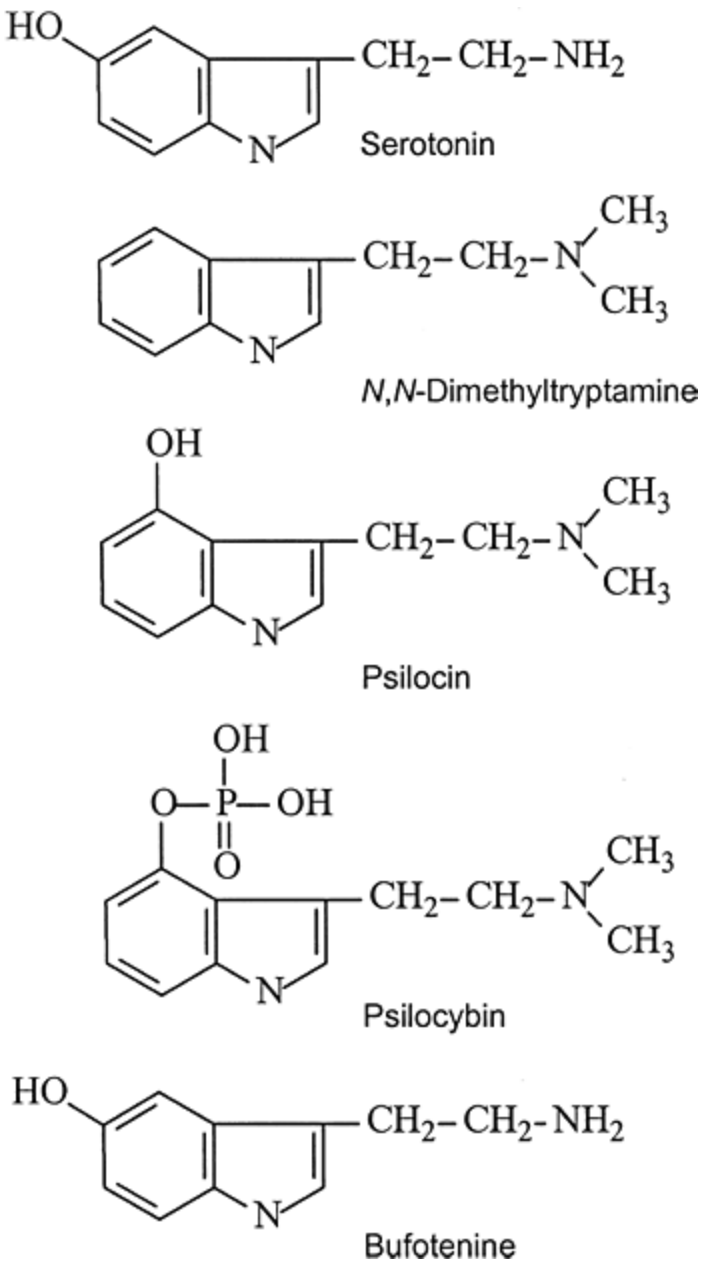

Figure 80-2. Hallucinogens of the indolalkylamine class and their chemical similarity to serotonin.

The use of toads in religious ceremonies and witchcraft dates back thousands of years. All species of the toad genus *Bufo* have parotid glands on their backs that produce a variety of xenobiotics, including dopamine, epinephrine, and serotonin.[70] Many of these toads produce

bufotenine, a tryptamine, which causes hypertension, but does not cross the bloodâ€“brain barrier. Interest in bufotenine grew out of reports of a toad-licking fad in the 1980s, in which individuals would reportedly lick toads for recreational purposes.[69] However, further review suggests that bufotenine is not the hallucinogenic substance found in toad secretions. Instead, 5-methoxydimethyl tryptamine (5-MeO-DMT), has been identified as the psychoactive substance.[116] 5-MeO-DMT is only found in one species of toad, *Bufo alvarius* (Sonoran Desert toad or Colorado River toad).[69] Although bufotenine is currently classified as a Schedule I substance by the United States Drug Enforcement Administration, 5-MeO-DMT is not scheduled.[77 , 105] Like DMT, 5-MeO-DMT is rapidly metabolized by intestinal monoamine oxidase enzymes; licking or ingesting toads skins would thus have limited potential as a route of recreational use.[21] Methods for extracting and drying *B. alvarius* secretions for smoking are available and on the Internet. The toad venom glands also produce cardioactive steroids, called bufadienolides, which may cause cardioactive steroid toxicity (Chap. 62), and in some species, can secrete tetrodotoxin.[75 , 119] Death has resulted from wrongful use of *Bufo* secretions for purposes of aphrodisia.[28 , 49]

Two of the more important synthetic tryptamines include *N,N* -diisopropyl-5-methoxytryptamine (5-MeO-DiPT, Foxy Methoxy), and Î±-methyltryptamine (AMT, IT-290). Since 2001, law enforcement authorities in more than 10 states have seized large amounts of 5-MeO-DiPT and AMT.[106] These xenobiotics are often sold surreptitiously as methylenedioxymethamphetamine (MDMA).

5-MeO-DiPT is usually ingested, but it can be smoked or insufflated. Effects begin 20â€“30 minutes after ingestion, and include disinhibition and relaxation. There is a dose-dependent response and at higher doses symptoms may be similar to LSD or MDMA, with mydriasis, euphoria, auditory and visual hallucinations, nausea, diarrhea, and jaw clenching.[79 , 95] The hallucinogenic effects are reported to last from 3â€“6 hours.[74 , 95 , 106] Other substances, such as sildenafil, Î³-

hydroxybutyrate, benzodiazepines, and marijuana, may be used to heighten or prolong the hallucinogenic effects of 5-MeO-DiPT.[68] 5-MeO-DiPT received Schedule I status in 2004.[109]

AMT is a monoamine oxidase inhibitor that was initially marketed as an antidepressant in the former Soviet Union.[94 , 106] AMT is available as a white powder that can be ingested, smoked, or insufflated. Despite its chemical similarity to DMT, the effects of AMT may last from 12â€“16 hours.[66] AMT was given Schedule I status by the DEA in September 2004.[109]

Phenylethylamines (Amphetamines)

Endogenous phenylethylamines include dopamine, norepinephrine, and tyrosine. Exogenous phenylethylamines are known for their ability to stimulate catecholamine release and cause a variety of physiologic and psychiatric effects, including hallucinations. Substitution on the phenylethylamine structure has important effects on both the hallucinogenic and stimulant potential of the xenobiotic. The presence of a methyl group in the side chain of the phenylethylamines is associated with a higher degree of hallucinogenic effect (Fig. 80-3).[59] MDMA, amphetamine and methamphetamine are well-known members of this family and are discussed in detail in Chap. 73 .

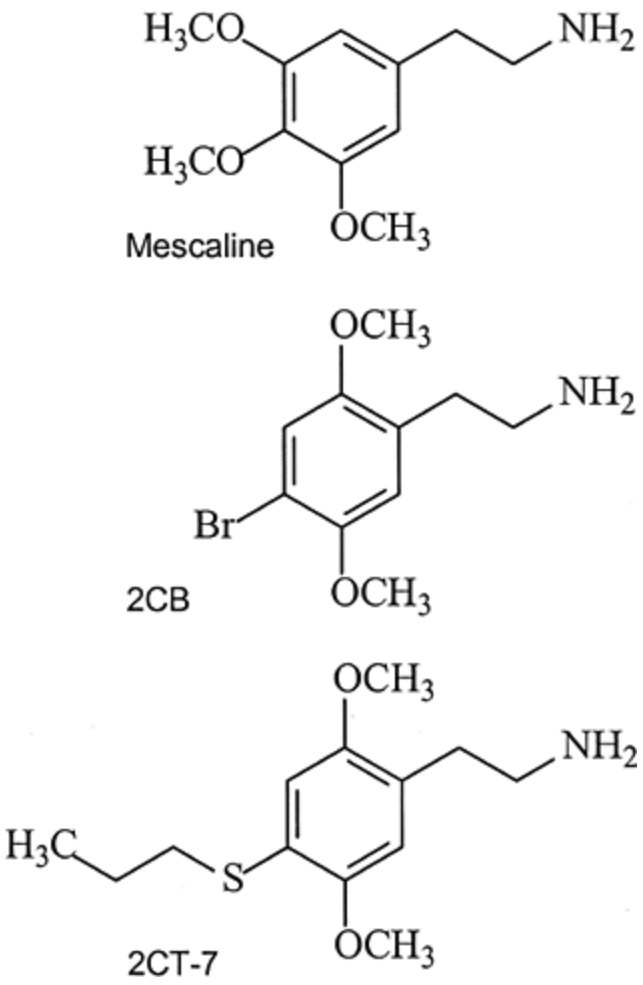

Figure 80-3. Hallucinogens of the phenylethylamine class.

The best recognized of the naturally occurring phenylethylamines is mescaline. Mescaline is found in peyote (*Lophophora williamsii*), a small, blue-green spineless cactus that grows in dry and rocky slopes throughout the southwestern United States and northern Mexico. Peyote buttons are the round, fleshy tops of the cactus that have been sliced off and dried. The bitter-tasting buttons are eaten whole or can be dried and crushed into a powder, which is reconstituted into a tea.[52] Nausea, vomiting, and diaphoresis often precede the onset of hallucinations. Six to 12 peyote buttons, or 270â€“540 mg of mescaline, are commonly required to produce hallucinogenic effects.[89] The legal use of peyote in the United States is restricted to the Native

American Church, where peyote buttons are used in religious ceremonies, and for medical treatment of physical and psychological ailments.[24, 26]

Other nonindigenous cactus species containing significant amounts of mescaline include the San Pedro cactus (*Trichocereus pachanoi*) and Peruvian torch cactus (*Trichocereus peruvianus*). These plants can be purchased in garden stores and on the Internet for ornamental purposes.[52]

However, the synthesis and effects of hundreds of other congeners of amphetamine have been described.[93] The best known of these synthetic hallucinogenic amphetamines are 4-bromo-2,5-dimethoxyphenethylamine (2CB, Nexus, Bromo, Spectrum), and 2,5-dimethoxy-4-*N*-propylthiopheneethylamine (2CT-7, Blue Mystic).

During the 1980s, 2CB gained popularity as a legal alternative to MDMA. When 2CB was given Schedule I status in 1995, 2CT-7 emerged as another legal designer amphetamine.[11] In March 2004, 2CT-7 also received Schedule I status.[31] Low doses of 2CB and 2CT-7 can produce hypertension, tachycardia, and visual hallucinations, while elevated doses are associated with shifts in color perception, enhanced auditory and visual stimulation, and even morbid hallucinations.

Salvia divinorum

Salvia divinorum is a perennial herb classified as a member of the mint family or *Labiatae.* Although there are more than 500 species of *Salvia*, *S. divinorum* is most recognized for its hallucinogenic properties. The plant is characterized by a height greater than 1 m, large green leaves, hollow square stems, and white flowers with purple calyces.[111] *S. divinorum* is a native to areas of Oaxaca, Mexico, and grows well in sunny, temperate climates (Fig. 80-4).

Since the 16th century, the Mazatec Indians have employed *S. divinorum* in religious rites as a means of producing visions.[111] The Mazatecs continue to revere *S. divinorum* as an incarnation of the

Virgin Mary, referring to the plant as Ska Maria Pastora. *S. divinorum* may be chewed, smoked, or ingested as tea. Hallucinations occur immediately after exposure to the xenobiotic and are typically quite vivid. Synesthesia, a confusion of the senses, like hearing colors or smelling sounds, has been reported among *Salvia* users.[33] However, this effect is not specific to *S. divinorum* , and has been reported with multiple other hallucinogens. Hallucinogenic effects after *S. divinorum* use are typically brief, lasting only 1â€“2 hours.

Currently, the Controlled Substances Act does not prohibit use of *S. divinorum* or its active ingredients. Nationwide regulation of this xenobiotic exists in Australia, and there is local legislation in some midwestern towns where use among teenagers is rampant.[108] There is widespread marketing of this hallucinogen on the Internet as a â€œlegal hallucinogen.â€•[33] Plants, leaves, and extracts may be purchased online, and tips for cultivation of plants are easily accessible.

Pharmacokinetics

LSD is the most studied hallucinogen, and there is extensive information about its pharmacokinetics. Ingestion is the most common route of exposure, and the gastrointestinal tract rapidly absorbs LSD. Other routes of administration include intranasal, parenteral, sublingual, smoking, and conjunctival instillation. Plasma protein binding is greater than 80% and volume of distribution is 0.28 L/kg. It is concentrated within the visual cortex, as well as the limbic and reticular activating systems. LSD is metabolized in the liver via hydroxylation and glucuronidation, and excreted predominantly as a pharmacologically inactive compound. LSD has an elimination half-life of about 2.5 hours. Only small amounts are eliminated unchanged in the urine.

Tolerance to the psychological effects of LSD occurs within 3 days with daily dosing, but rapidly dissipates if the xenobiotic is withheld for 2

days. Psychological cross-tolerance among mescaline, psilocybin, and LSD is reported in humans.[15] There is no evidence for physiologic tolerance, physiologic dependence, or a withdrawal syndrome with LSD. Limited tolerance is demonstrated between psilocybin and cannabinoids such as marijuana.[22]

There is little information about 2CB and 2CT-7 in the medical literature. Both drugs may be used via oral, intranasal, and intrarectal routes. Both 2CB and 2CT-7 exert their hallucinogenic effects within 1 hour of use, and physiologic and psychologic effects may persist for 6â€“10 hours. While specific pharmacokinetic data on 2CB and 2CT-7 are not available, the pharmacokinetics of other phenylethylamines may be similar. Amphetamine, methamphetamine, and MDMA are well absorbed through the GI tract. The elimination half-life ranges from 8â€“30 hours for members of this class, and is dependent on urine pH.[13,30] Amphetamines are weak bases, and undergo more rapid elimination in an acidic urine environment.[92] The volume of distribution ranges from 3â€“5 L/kg for amphetamine, 3â€“4 L/kg for methamphetamine, and is likely more than 5 L/kg for MDMA.[13,30,65,92] Elimination of other amphetamines occurs through multiple mechanisms including aromatic hydroxylation, aliphatic hydroxylation, and *N* -dealkylation.[65] Tolerance has been demonstrated in chronic amphetamine users.[61]

Pharmacokinetic data for *S. divinorum* have been described in one volunteer study. Psychoactive effects were typically experienced 5â€“10 minutes after absorption of Salvinorin A via the buccal mucosa, reaching a plateau during the first hour after exposure, and resolving within 2 hours. Vaporization and inhalation of Salvinorin A led to more rapid effects at 30 seconds after exposure. These effects would plateau at 5â€“10 minutes, and typically subside after 20â€“30 minutes. In this study, ingestion of *S. divinorum* leaves did not produce the same effects as buccal or inhalational administration, leading to the theory that gastrointestinal deactivation of Salvinorin A occurs after ingestion.[96] The pharmacokinetic characteristics of hallucinogens are summarized in Table 80-2 .

TABLE 80-2. Pharmacokinetic Classification of Hallucinogens

Pharmacology

Although the lysergamide, indolealkylamine, and phenylethylamine hallucinogens are structurally distinct, the similarities in their effects on cognition have led scientists to postulate a shared mechanism of action. Studies support a common site of action on central serotonin receptors.[5, 20, 25, 53, 102] Serotonin (5-HT) modulates many psychological and physiologic processes, including mood, personality, affect, appetite, motor function, sexual activity, temperature regulation, pain perception, sleep induction, and antidiuretic hormone release. There are more than 14 known 5-HT receptor subtypes; differing affinity for these subtypes occurs based on the structure of the hallucinogen, and may account for the subtle differences between their effects.

Another theory held by hallucinogen researchers was that the common site of action within the brain itself would involve the cerebral cortex, the area of the brain responsible for higher functions like cognition and mood. Alternatively, hallucinogens could affect subcortical areas, like the locus coeruleus found in the upper pons. The locus coeruleus is the part of the brain that responds to new stimuli and has projections throughout the entire cortex which affect cortical functioning.[72]

The lysergamide, indolealkylamine, and phenylethylamine hallucinogens all bind to the 5-HT_2 class of receptors. There is a good correlation between the affinity of both indolealkylamine and phenylethylamine hallucinogens for 5-HT_2 receptors in vitro and hallucinogenic potency in humans in vivo.[5, 46, 82, 102] Of the multiple subtypes of 5-HT_2 receptors, 5-HT_{2A} receptors are found with highest density in the cerebral cortex, making the 5-HT_{2A} receptor the most likely common site of hallucinogen action.[72] This theory is bolstered by an animal study that shows that a selective 5-HT_{2A} antagonist can inhibit the effects of LSD and a phenylethylamine, 2,5-dimethoxy-4-iodo-amphetamine (DOI). The response to high doses of LSD and DOI suggest that both lysergamides and phenylethylamines are partial agonists at cortical 5-HT_{2A} receptors.[47, 72, 87]

Although the majority of investigation has focused on the role of

serotonin for drug-induced hallucinations, other neurotransmitters are involved. Stimulation of 5-HT_{2A} receptors enhances release of glutamate in the cortical layer V pyramidal cells.[5, 10] LSD and other lysergamides stimulate both D_1 and D_2 dopamine receptors.[9, 45, 115] In animal models, LSD and phenylethylamine hallucinogens modulate *N*-methyl-D-aspartate (NMDA) receptor-mediated effects, and may have a protective effect against neurotoxicity secondary to phencyclidine (PCP) and ketamine.[10, 38] Another theory that incorporates these other neurotransmitters revolves around â€œthalamic filtering.â€• The thalamus receives input and output from the cortex and reticular activating system, and functions to filter relevant sensory input. This theory has been explored as an explanation for organic psychosis and the effects of hallucinogens. Multiple neurotransmitters, including dopamine, acetylcholine, Î³-aminobutyric acid (GABA), and

glutamate, exert their actions on the thalamus. Increased excitatory or decreased inhibitory neurotransmitter in this region of the brain may lead to â€œsensory overload,â€• which manifests itself clinically as symptoms of psychosis.[44]

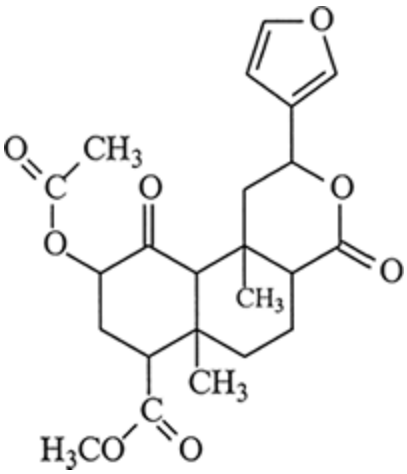

Figure 80-4. Salvinorin A.

The psychological effects of hallucinogens seem to represent a complex and elusive interaction between different neurotransmitters, including

the serotonergic and dopaminergic systems.

Based on this serotonergic mechanism, serotonin syndrome could theoretically occur after the use of any of the lysergamide, indolealkylamine, or phenylethylamine hallucinogens. Animal studies have documented LSD and tryptamine-induced serotonin syndrome.[97, 112] Case reports have linked phenylethylamine use to fatal serotonin syndrome in recreational users.[78, 114]

Salvinorin A, the psychoactive component of *S. divinorum*, is thought to be one of the most potent natural hallucinogens. The effect of Salvinorin A occurs via binding at the Î´ opioid receptor, making it structurally and mechanistically unique (Fig. 80-4).[86, 118] The Î´ opioid receptor is distinct from the Âµ opioid receptor, which generally mediates euphoria and analgesia (Chap. 38).

Clinical Effects

Physiologic changes accompany and often precede the perceptual changes induced by lysergamides, tryptamines, and phenylethylamines. The physical effects may be caused by direct drug effect or by a response to the disturbing or enjoyable hallucinogenic experience. Sympathetic effects mediated by the locus coeruleus include mydriasis, tachycardia, hypertension, tachypnea, hyperthermia, and diaphoresis. They may occur shortly after ingestion and often precede the hallucinogenic effects. Other reported clinical findings include piloerection, dizziness, hyperactivity, muscle weakness, ataxia, altered mental status, coma, and hippus, a rhythmic dilation and constriction of the pupils.[62] Nausea and vomiting often precede the psychedelic effects produced by psilocybin and mescaline.

Potentially life-threatening complications, such as hyperthermia, coma, respiratory arrest, hypertension, tachycardia, and coagulopathy, were described in a report of 8 patients with a massive LSD overdose.[58] Sympathomimetic effects are generally less prominent in LSD ingestion than in phenylethylamine toxicity. Similar sympathetic symptoms have

been described after the use of 2CB and 2CT-7. Three deaths are associated with 2CT-7 use; anecdotal reports suggest that 1 death may have resulted from seizures or aspiration.[31 , 36 , 104]

The vast majority of morbidity from hallucinogen use stems from trauma. Hallucinogen users frequently report lacerations and bruises sustained during their â€œhigh.â€• Additionally, dysphoric reactions may drive patients to react to stimuli with unpredictable, and occasionally aggressive, behaviors. Many Internet sites advise readers to take hallucinogens only while under the supervision of a â€œsitter.â€•

The psychological effects of hallucinogens are dose-related and affect changes in arousal, emotion, perception, thought process, and self-image. The response to the xenobiotic is related to the user's mindset, emotions, or expectations at the time of exposure, and can be altered by the group or setting.[2] A person experiencing the effects of a hallucinogen is usually fully alert, oriented, and aware that he or she is under the influence of a drug. Euphoria, dysphoria, and emotional lability may occur.

Perceptual distortions are common, typically involving distortion of body image and alteration in visual perceptions. Hallucinogen users may display acute attention to details with excessive attachment of meaning to ordinary objects and events. Usual thoughts seem novel and profound. Many people report an intensification of their sensory perceptions such as sound magnification and distortion. Colors often seem brighter with halolike lights around objects. Frequently, hallucinogen users relate a sense of depersonalization and separation from the environment, commonly called an â€œout-of-bodyâ€• experience. Synesthesia, or sensory misperception, occurs frequently and may include â€œhearingâ€• color or â€œseeingâ€• sounds. True hallucinations may occur and can be visual, auditory, tactile, or olfactory.

Acute adverse psychiatric effects of hallucinogens include panic reactions, true hallucinations, psychosis, and major depressive

dysphoric reactions. Acute panic reaction, the most common adverse effect, presents with frightening illusions, tremendous anxiety, apprehension, and a terrifying sense of loss of self-control.[46] These psychiatric effects may cause patients to seek care in the emergency department.

Differential Diagnosis

Hallucinosis is the abnormal organic mental condition of persistent hallucinations. The major causes of hallucinosis can be divided by etiology into structural, infectious, functional, and toxicâ€“metabolic. The diagnosis of hallucinogen exposure often must be established on the basis of history and physical examination alone. The person who has ingested hallucinogens typically is oriented and will often give a history of hallucinogen use. This stands in stark contrast to patients with xenobiotic-induced delirium, in whom orientation is, by definition, altered.

Xenobiotics such as amphetamine, cocaine, PCP, and anticholinergics produce delirium or psychosis at doses capable of producing hallucinations. Psychiatric or â€œfunctionalâ€• causes of perceptual changes, such as schizophrenia, typically present with auditory hallucinations. Patients with central anticholinergic toxicity usually present with disorientation, combative behavior, and incoherent mumbling, and may be unaware that the hallucinations are drug-induced.[60] The presence of marked hyperthermia, uncontrollable behavior, or extreme agitation should suggest phenylethylamine use, or an alternative drug exposure, such as cocaine or PCP.

Evaluation for other causes of altered mental status and hallucinations should include early exclusion of hypoglycemia, meningitis, intracerebral hemorrhage, thyrotoxicosis, sepsis, decompensated

psychiatric disease, withdrawal states and other toxic exposures. A lumbar puncture and computed tomography of the head are adjunctive tests that may be required in a case where the history of hallucinogen

exposure is unclear.

Laboratory

Routine drug-of-abuse screens do not detect LSD or other hallucinogens. Although LSD exposure can be detected by radioimmunoassay, confirmation by high-performance liquid chromatography or gas chromatography is necessary. These tests are rarely used in the clinical setting, but are much more common for forensic matters.[15, 34] False-positive urine testing for LSD has been reported after exposure to several medications including fentanyl, sertraline, haloperidol, and verapamil.[42, 85]

Depending on their structure, phenylethylamines may cause positive qualitative urine testing for amphetamines. However, amphetamine drug testing is associated with numerous false-positive results, particularly after the use of cold medications that contain ephedrine, pseudoephedrine, or phenylpropanolamine.[99] Gas chromatography-mass spectrometry testing methods for detection of 5-MeO-DiPT, DMT, AMT, 2CT-7, and 2CB have been described.[113]

There is currently no information on laboratory drug testing for *S. divinorum.*

Treatment

Most hallucinogen users do not seek medical attention because they experience only the desired effect of the drug. For any hallucinogen user who does present to the ED, initial treatment must begin with attention to airway, breathing, circulation, level of consciousness, and abnormal vital signs. Even when hallucinogen exposure is suspected, the basic approach to altered mental status should include dextrose, naloxone, and oxygen therapy as indicated, along with a vigorous search for other etiologies.

Hallucinogens rarely produce life-threatening toxicity. Sedation with benzodiazepines is usually sufficient to treat hypertension, tachycardia,

and hyperthermia. Benzodiazepines remain the cornerstone of therapy, as the sedating effect can diminish both endogenous and exogenous sympathetic effects.[76] Autonomic instability and hyperthermia may be a feature of phenylethylamine use, as well as tryptamine use or massive LSD overdose.[41 , 58 , 76] Hyperthermia resulting from agitation or muscle rigidity requires urgent sedation with benzodiazepines and rapid cooling. While CNS depression is unlikely to be severe enough to require endotracheal intubation in a patient with a pure hallucinogen exposure, intubation and paralysis may be required in the patient with intractable hyperthermia.[18] Seizures may occur with tryptamine or phenylethylamine use, and can be initially treated with benzodiazepines. Morbidity and mortality typically result from the complications of hyperthermia including rhabdomyolysis and myoglobinuric renal failure, hepatic necrosis, and disseminated intravascular coagulopathy. For the most part, however, hydration, sedation, a quiet environment, and meticulous supportive care will prove adequate to prevent mortality in recreational use or overdose.[27]

The patient with a dysphoric reaction can be placed in a quiet location with minimal stimuli. A nonjudgmental advocate should attempt to reduce the patient's anxiety, provide reality testing, and remind the individual that a drug was ingested and the effect will wear off in a couple of hours.[100] Significant agitation, dysphoria, or a â€œbad trip,â€• combined with signs of autonomic instability, can usually be treated by the administration of a benzodiazepine.[1] The role of antipsychotics in controlling hallucinogen-induced agitation is unclear. Haloperidol, risperidone, and ziprasidone may help control the acutely agitated patient. However, haloperidol and risperidone may worsen panic and visual symptoms, and increase the incidence of hallucinogen persisting perception disorder.[3] The safety of ziprasidone in hallucinogen users has not yet been reported. Although further study on these xenobiotics is required, prolonged psychosis may require treatment with long-term antipsychotic therapy.

Gastrointestinal decontamination with activated charcoal may be considered for asymptomatic patients with recent ingestions, but is

probably not helpful after clinical symptoms appear, and attempts may lead to further agitation. Excessive physical restraint should be avoided out of concern for hyperthermia and rhabdomyolysis.

Serotonin syndrome may occur after hallucinogen use, and has been described after LSD, tryptamine, and phenylethylamine use.[35, 78, 97, 112] Diagnosis begins with early identification of serotonin syndrome based on the constellation of symptoms. Treatment is largely supportive and symptomatic, and includes the avoidance of further administration of serotonergic medications. Specific therapy with agents like cyproheptadine may be warranted (Chap. 70).[19]

In comparison to the other hallucinogens, the high produced by *S. divinorum* is relatively mild. Symptoms severe enough to require treatment in the emergency department are uncommon, but may include agitation and confusion. Gastrointestinal decontamination with activated charcoal may be considered if presentation is early after ingestion or if coingestants are suspected. Agitation may be managed through administration of benzodiazepines. To date, no significant toxicity or death from *S. divinorum* use or overdose has been reported.

Long-Term Effects

Long-term consequences of LSD use include prolonged psychotic reactions, severe depression, and exacerbation of preexisting psychiatric illness.[51, 88] When LSD was initially popularized, some patients were noted to behave in a manner similar to schizophrenia and required admission to psychiatric facilities. In volunteer studies, panic reactions, hallucinogen persisting perception disorder, and extended psychoses were noted. When the xenobiotic was used for alleviation of anxiety and personality abnormalities, flashbacks and extended psychosis were reported.[40] Several authors have suggested that individuals who reacted this way to hallucinogen use may have had preexisting, compensated psychological disturbances.[5, 71]

Flashbacks have been reported in up to 80% of LSD users.[7]

Anesthesia, alcohol intake, and medications can precipitate flashbacks.[43] These abnormal perceptions can be triggered during times of stress, illness, and exercise, and are often a virtual recurrence of the initial hallucinations.

Hallucinogen-persisting perception disorder (HPPD) is a chronic problem associated with LSD abuse. According to the *Diagnostic and Statistical Manual 4th Edition* , the diagnosis of HPPD requires the recurrence of perceptual symptoms that were experienced while intoxicated with the hallucinogen that causes functional impairment and is not caused by a medical condition.[8] The etiology of HPPD is still unknown, and the reported incidence varies widely.

Symptoms are primarily visual, and reality testing is typically intact in HPPD. Common perceptual and visual disturbances in HPPD include geometric forms; false, fleeting perceptions in the peripheral fields; flashes of color; intensified color; and halos around objects.[71] One finding described after LSD use is palinopsia, or â€œtrailing,â€• which refers to the continued visual perception of an object after it has left the field of vision. Interestingly, these visual perceptions are associated with normal ophthalmologic examinations and abnormal EEG evaluations, suggesting a cortical etiology for the visual symptoms.

Although many drugs have been tried to treat patients with HPPD, most have not proven beneficial. However, there have been no randomized trials to compare the efficacy of different pharmacologic interventions in HPPD. Clonazepam reportedly improved symptoms of LSD-induced HPPD in one study of 16 patients.[63] Haloperidol and risperidone are associated with an exacerbation of panic and visual symptoms.[3 , 7] Clonidine may also be a therapeutic option for HPPD. Patients being treated with tricyclic antidepressants or selective serotonin reuptake inhibitors have an inconsistent response to therapy.[16 , 17]

Summary

Hallucinogens are a diverse group of xenobiotics that alter and distort

perception, thought, and mood without clouding the sensorium. The lysergamide, phenylethylamine, and tryptamine hallucinogens share a serotonergic mechanism of action; however, other neurotransmitters may be responsible for the complex effects of these hallucinogens. Salvinorin A, a novel hallucinogen, exerts its effects via the Î´ opioid receptor. Acute adverse psychiatric effects of hallucinogens include panic reactions, true hallucinations, psychoses, and major depressive dysphoric reactions. Hallucinogens rarely produce life-threatening problems, but have been known to cause autonomic instability, seizures, and hyperthermia, particularly in overdose. Meticulous supportive care with attention to abnormal vital signs is often the only therapy required. Long-term consequences of LSD use may include prolonged psychotic reactions, severe depression, exacerbation of preexisting psychiatric illnesses, and hallucinogen-persisting perception disorder.

Chapter 81
Cannabinoids

Michael McGuigan

A 25-year old man was arrested for erratic driving on a city street. He was not involved in a crash or injured. On initial questioning the man stated that he was not drinking or using any other mind-altering substances. The police noted inappropriate smiling and atypical answers to their battery of standard questions. Although the man claimed that he was not intoxicated he was asked by the police to take a breath alcohol test, which was negative. However, his behavior was of sufficient concern to the police that they brought him to the emergency department (ED).

In the ED the patient was alert, oriented, and compliant with all requests. He stated that he had no medical problems and took no medication. He mentioned that he had used marijuana infrequently in the past, but that it had been at least 6 months since his last use. He denied the use of other drugs.

The patient had normal vital signs, including temperature. His pupils were normal and reactive, extraocular movements were intact, there was no nystagmus, and his sclera were minimally injected. He had a

supple neck and clear lungs. His neurologic examination including his gait, was normal. A bedside rapid glucose was 95 mg/dL.

At the request of the police, the patient's urine was sent to the hospital laboratory for analysis for drugs of abuse. The analysis results were positive for cannabinoids and negative for all other drugs assayed. The patient was charged with driving under the influence of drugs.

In court, the man was convicted of the charges on the grounds that in his deposition testimony he reiterated his claim that he had not used drugs for 6 months, yet had a positive urine toxicology test. Even if he was a heavy marijuana user, this 6 months was too long for an assay to remain positive. The man sued the hospital. See Chapter 135 for further discussion.

Cannabis is a collective term referring to the bioactive substances from *Cannabis sativa.* The *C. sativa* plant contains a group of more than 60 chemicals (C21 group) called cannabinoids. In this chapter, the term *cannabis* encompasses all cannabis products. The major cannabinoids are cannabinol, cannabidiol, and tetrahydrocannabinol. The principal psychoactive cannabinoid is Î”^{9}-tetrahydrocannabinol (THC). Marijuana is the common name for a mixture of dried leaves and flowers of the plant. Hashish and hashish oil are the pressed resin and the oil expressed from the pressed resin, respectively. The concentration of THC varies from 1% in low-grade marijuana up to 50% in hash oil. Pure THC and a synthetic cannabinoid are available as prescription drugs with the generic names of dronabinol and nabilone, respectively.

History and Epidemiology

Cannabis has been used for more than 4000 years. The earliest documentation of the therapeutic use of marijuana is the 4th century B.C. in China.[74] Cannabis use spread from China to India to North Africa, reaching Europe around 500 A.D.[63] In colonial North America,

cannabis was cultivated as a source of fiber.

Marijuana was used as an intoxicant from the 1850s until the 1930s when the US Federal Bureau of Narcotics began to portray marijuana as a powerful, addicting substance. Despite this, marijuana was listed in the *United States Pharmacopoeia* from 1850 to 1942. In 1970, The Controlled Substances Act classified marijuana as a Schedule I drug.

Currently, marijuana is the most commonly used illicit drug in the United States. A recent study by the Substance Abuse and Mental Health Services Administration[107] reported that 95 million persons age 12 years and older (40% of that population) had tried marijuana at least once. Of these, 94.6% were age 18 years and older. Approximately 14.6 million persons used marijuana in the month prior to the survey, 4.8 million of whom used it on 20 or more days in the month prior to the survey. The number of first-time users was estimated to be 2.6 million in 2001. These incidence figures have remained essentially unchanged since 1995.

Medical Uses

Cannabinoids are proposed for use in the management of many clinical conditions (Table 81-1), but have only been approved for the control of chemotherapy-related nausea and vomiting that are resistant to conventional antiemetics, for breakthrough postoperative nausea and vomiting, and for appetite stimulation in HIV patients with anorexia-cachexia syndrome. The claims of benefit in the other medical conditions in Table 81-1 are not supported by robust evidence.[5,36,56,120]

Pharmacology and Pathophysiology

Î”^{9}-THC (sometimes referred to in the literature as Î”^{1}-THC) was isolated in 1964. In the early 1990s, two specific cannabinoid-binding receptors were identified: CB1 (or *Cnr1*) and CB2 (or *Cnr2*).

Subsequent research identified endogenous cannabinoid receptor ligands (anandamide, palmitoylethanolamide), as well as cannabinoid receptor agonists and antagonists.[27,42,108]

CB1 receptors are distributed throughout the brain with high densities in the basal ganglia, substantia nigra, globus pallidus, cerebellum, hippocampus, and cerebral cortex (particularly the frontal regions). CB2 receptors are located peripherally in immune system tissues (splenic macrophages), peripheral nerve terminals, and the vas deferens. Both receptors inhibit adenylyl cyclase and stimulate potassium channel conductance.[88] CB1 receptors are located on the presynaptic side of central nervous system synapses and their activation inhibits the release of acetylcholine, L-glutamate, Î³-aminobutyric acid, noradrenaline, dopamine, and 5-hydroxytryptamine.[52,57,99] CB2 receptors are believed to participate in the regulation of immune responses and inflammatory reactions.

TABLE 81-1. Medical Conditions Proposed for Cannabinoid Use

Anorexia-cachexia syndrome secondary to HIV infection[a]
Asthma
Glaucoma
Nausea and vomiting (resistant)[a]
Neurologic disorders
Anxiety
Depression
Epilepsy
Head injury
Insomnia
Migraine headaches
Multiple sclerosis

	Muscle spasticity and spasms Pain Parkinson disease Tourette syndrome
[a]	FDA approved use.

The neuropharmacologic mechanisms by which cannabinoids produce their psychoactive effects have not been fully elucidated.[43,52,88] Nevertheless, activity at the CB1 receptors is believed to be responsible for the clinical effects of cannabinoids,[10,27,52,108] including the regulation of cognition, memory, motor activities, nociception, and nausea and vomiting. Chronic administration of a cannabinoid agonist reduces CB1 receptor density in several regions of the rat brain.[11]

Pharmacokinetics and Toxicokinetics

The pharmacokinetics of cannabinoids have been extensively reviewed.[35]

Absorption

The rate and completeness of absorption of cannabinoids depend on the route of administration and the type of cannabis product.

Inhalation of smoke containing THC results in the onset of psychoactive effects within minutes. From 10â€“35% of available THC is absorbed during smoking and peak plasma concentrations of THC occur an average of 8 (range: 3â€“10) minutes after the onset of smoking marijuana. Peak plasma levels depend on the dose; a marijuana cigarette containing 1.75% THC produces a peak plasma THC concentration of approximately 85 ng/mL.[46]

Ingestion of cannabis results in an unpredictable onset of

psychoactive effects in 1â€“3 hours. Because of THC's instability in acidic gastric fluid and first-pass hepatic clearance,[85] 5â€“20% of available THC reaches the systemic circulation following ingestion. Peak plasma concentrations of THC usually occur 2â€“4 hours after ingestion but delays up to 6 hours are described.[31,64] The therapeutic serum concentration of THC for the treatment of nausea and vomiting is greater than 10 ng/mL.[17]

Dronabinol has an oral bioavailability of approximately 10% with high interindividual variability.[35,85] Peak plasma concentrations occur 2â€“3 hours after ingestion. Nabilone has an oral bioavailability estimated to be greater than 90% and reaches peak plasma concentrations 2 hours after ingestion.[98]

Distribution

THC has a steady-state volume of distribution of approximately 2.5â€“3.5 L/kg.[35] Previous estimates of up to 10 L/kg are considered erroneous because of inaccuracy of the quantitative method used. THC is 98% bound, primarily to plasma lipoproteins. Cannabinoids are lipid soluble and accumulate in fatty tissue in a biphasic pattern. Initially, THC is distributed to highly vascularized tissues (eg, liver, kidneys, heart, muscle). Following smoking or intravenous administration, the distribution half-life is less than 10 minutes.[46,85] After the initial distribution phase, THC accumulates more slowly in less vascularized tissues and body fat. Repeated administration of Î”^{8}-THC (an isomer of Î”^{9}-THC) to rats over 2 weeks resulted in steadily increasing concentrations of Î”^{8}-THC in body fat and liver, but not in brain tissue. Once administration of Î”^{8}-THC stopped, the cannabinoids were slowly released from fat stores as adipose tissue turned over.[84]

THC crosses the placenta and enters the breast milk. Concentrations in fetal serum are 10â€“30% of maternal concentrations. Daily marijuana smoking by a nursing mother resulted in concentrations of THC in breast milk that are 8-fold higher than concomitant maternal

serum concentrations; THC metabolites do not accumulate in breast milk.[90]

Metabolism

THC is nearly completely metabolized by hepatic microsomal hydroxylation and oxidation by the cytochrome P450 (CYP) system (primarily CYP2C).[35] The primary metabolite (11-hydroxy-Î”^{9}-THC or 11-OH-THC) is active and is subsequently oxidized to the inactive 11-nor-Î”^{9}-THC carboxylic acid metabolite (THC-COOH) and many other metabolites.[1,3,93]

The plasma concentrations of THC and its metabolites change over time. Smoking a marijuana cigarette results in peak plasma concentrations of THC before finishing the cigarette. In 6 volunteers, peak plasma concentrations of THC occurred at 8 (range: 6â€“10) minutes after onset of smoking, of 11-OH-THC at 13 (range: 9â€“23) minutes, and of THC-COOH at 120 (range: 48â€“240) minutes[46] (Fig. 81-1). Approximately 1 hour after beginning to smoke a marijuana cigarette, the THCâ€“toâ€“11-OH-THC ratio is 3:1 and the THCâ€“toâ€“THC-COOH ratio is 1:2; at approximately 2 hours the ratios are 2.5:1 and 1:8, respectively; at 3 hours the ratios are 2:1 and 1:16, respectively.[46]

Ingestion of cannabis results in much more variable concentrations and time courses of THC and metabolites (Fig. 81-1). Nonetheless, at 2â€“3 hours postingestion the ratios are similar to those after smoking: THCâ€“toâ€“11-OH-THC is 2:1 and THCâ€“toâ€“THC-COOH ranges from 1:7 to 1:14.[31,116]

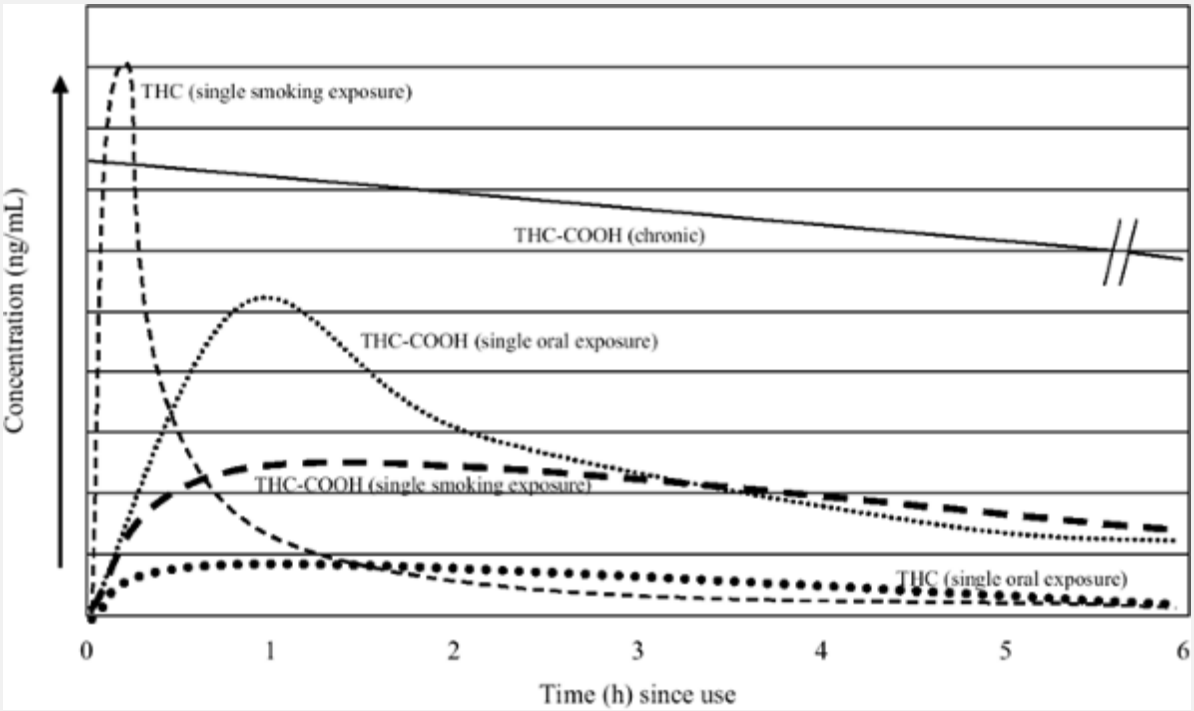

Figure 81-1. Estimated relative time course of THC and its major metabolite based on the route of exposure.

----------THC (single smoking exposure);----------THC-COOH (single smoking exposure);

----------THC (single oral exposure);----------THC-COOH (single oral exposure);

----------THC-COOH (chronic exposure).

Excretion

Reported elimination half-lives of THC and its major metabolites vary considerably. Following intravenous doses of THC, the mean elimination half-life ranges from 1.6â€“57 hours.[35] Elimination half-

lives are expected to be similar following inhalation.[35,46] The elimination half-life of 11-OH-THC is 12â€“36 hours and the elimination half-life of THC-COOH ranges from 1â€“6 days.[58,116]

THC and its metabolites are excreted in the urine and the feces. In the 72 hours following ingestion, approximately 15% of a THC dose is excreted in the urine and roughly 50% is excreted in the feces.[1,15,116] Following intravenous administration, approximately 15% of a THC dose is excreted in the urine and only 25â€“35% is excreted in the feces.[116] Inhalation is expected to produce results similar to intravenous administration.[35,46] In 5 days, 80â€“90% of a THC dose is excreted from the body.[40,50]

Cannabinoids were measured in the urine following smoking a marijuana cigarette containing 27 mg of THC[70] (Fig. 81-1). THC urine concentrations peaked at 2 hours (mean: 21.5 Âµg/L; range: 3.2â€“53.3 Âµg/L) after smoking and were undetectable (<1.5 ng/mL) in 5 of the 8 subjects by 6 hours after smoking. Urine concentrations of 11-OH-THC peaked at 3 hours (77.3Â± 29.7 Âµg/L). The primary urinary metabolite is the glucuronide conjugate of THC-COOH.[119] THC-COOH urine concentrations peak at 4 hours (179.4 Â± 146.9 Âµg/L)[70] and it has an average urinary excretion half-life of 2â€“3 days (range: 0.9â€“9.8 days).[35] Both 11-OH-THC and THC-COOH remained detectable in the urine of all 8 subjects for the 8 hours of the study.[70]

Following discontinuation of use, metabolites may be detected in the urine of chronic users for several weeks.[26,53] Factors such as age, weight, and use more than once a day only partially explained the long excretion period.[26]

Clinical Manifestations

The clinical effects of THC use, including time of onset and duration of effect, vary with the dose, the route of administration (ingestion is slower in onset than inhalation), the experience of the user, the

user's vulnerability to psychoactive effects, and the setting in which the drug is used. The concomitant use of central nervous system depressants such as ethanol, or stimulants such as cocaine, alters the psychological and physiologic effects of cannabis.

Psychological Effects

Use of cannabis produces variable psychological effects.[33] The variation, which occurs both between and within users, may be a result of drug tolerance, level or phase of intoxication, physical and social settings, or user expectations or cognitive set. The most commonly self-reported effect is relaxation. Other commonly reported effects are perceptual alterations (heightened sensory awareness, slowing of time), a feeling of well-being (including giddiness or laughter), and increased appetite.[33]

Physiologic Effects

Use of cannabis is associated with physiologic effects on cerebral blood flow, the heart, the lungs, and the eyes.

In a controlled double-blind positron emission tomography study,[71] intravenous THC increased cerebral blood flow, particularly in the frontal cortex, insula, cingulate gyrus, and subcortical regions. These increases in cerebral blood flow occurred 30â€“60 minutes after dosing and were still elevated at 120 minutes.[72] Similar blood flow changes result from smoking marijuana.[87]

Common acute cardiovascular effects of cannabis use include increases in heart rate and decreases in vascular resistance.[55,104] Cannabis produces dose-dependent increases in heart rate within 15 minutes of starting a marijuana cigarette (from a baseline mean of 66 beats/min to a mean of 89 beats/min) that reach a maximum (mean: 92 beats/min) 10â€“15 minutes after peak plasma THC concentrations. These changes last for 2â€“3 hours.[7] Increases in

blood pressure may occur with cannabis use. In a study of 6 subjects, an increase in blood pressure from a baseline mean of 119/74 mm Hg to a mean of 129/81 mm Hg occurred, but was not statistically significant.[7] In a double-blind, controlled study of ten men being investigated for angina pectoris, smoking a marijuana cigarette resulted in statistically significant changes in blood pressure from a baseline mean of 123/79 mm Hg to a peak mean of 132/84 mm Hg.[94] In contrast, repeated THC ingestions resulted in significant slowing of heart rate (from a mean of 68 beats/min to a low of 62 beats/min) and lowering of blood pressure (from a mean of 116/62 mm Hg to a low of 108/53 mm Hg).[8] Decreased vascular tone may cause postural hypotension accompanied by dizziness and syncope.

THC administered through inhalation or ingestion produces a dose-related short-term decrease in airway resistance and an increase in airway conductance in both normal and asthmatic individuals,[110] although the mechanism is not clear. Smoking marijuana results in an immediate increase in airway conductance, which peaks at 15 minutes and lasts 60 minutes; ingestion of cannabis produces a significant increase in airway conductance at 30 minutes, which peaks at 3 hours and lasts 4 to 6 hours.[111,112]

The principal ocular effects of cannabis are conjunctival injection and decreased intraocular pressure. Cannabinoids, applied topically to a rabbit eye, resulted in hyperemia of the conjunctival blood vessels 2 hours after application.[77] Inhaled, ingested, or intravenous cannabis causes a fall in intraocular pressure in 60% of users[34] by acting on CB1 receptors in the ciliary body.[92] The mean reduction in intraocular pressure is 25% and lasts 3â€“4 hours.

Acute Toxicity

In addition to the physiologic and psychological effects described above, acute toxicity may include decreases in coordination, muscle strength, and hand steadiness. Lethargy, sedation, postural

hypotension, inability to concentrate, slurred speech, and slow reaction time also may occur.[83,117]

In young children, the acute ingestion of cannabis is potentially life-threatening.[54,73] Ingestion of estimated amounts of 250â€“1000 mg of hashish resulted in obtundation in 30â€“75 minutes. Tachycardia (>150 beats/min) was found in one-third of the children. Less commonly reported findings include apnea, cyanosis, bradycardia, hypotonia, and opisthotonus.

Acute Adverse Reactions

Cannabis users occasionally may experience distrust, dysphoria, fear, or panic reactions. Transient psychotic episodes are associated with cannabis use. Commonly reported adverse reactions to the prescribed dose of dronabinol or nabilone include postural hypotension, dizziness, sedation, xerostomia, abdominal discomfort, nausea, and vomiting.

One case of acute pancreatitis (serum amylase up to 3200 IU/mL) following a period of heavy cannabis use is reported, but the causal relationship is unclear.[32]

Life-threatening ventricular tachycardia (200 beats/min) has been reported.[95] In 6 individuals with acute cardiovascular deaths, postmortem whole-blood THC concentrations ranged from 2â€“22 Âµg/L (mean: 7.2 Âµg/L; median: 5 Âµg/L).[4] While the temporal association is clear, causality is less clear because 3 of the 6 people had significant preexisting cardiac pathology. The risk of myocardial infarction is increased 5 times over baseline in the 60 minutes after marijuana use, but subsequently declines rapidly to baseline risk levels.[78] Atrial fibrillation with palpitations, nausea, and dizziness was temporally associated with smoking marijuana in 3 patients.[62,105]

Chronic Use Adverse Effects

Long-term use of cannabis is associated with a number of adverse effects.

Immune System

Cannabinoids affect host resistance to infection by modulating the secondary immune response (macrophages, T and B lymphocytes, acute phase and immune cytokines). However, an immune-mediated health risk from using cannabis has not been documented.[60]

Respiratory System

Smoking marijuana delivers more particulates to the lower respiratory tract than does smoking tobacco[122] and marijuana smoke contains carcinogens similar to tobacco smoke. Case reports and a hospital-based case-control study suggest that cancers of the respiratory tract (mouth, larynx, sinuses, lung) are associated with the regular smoking of marijuana, although exposure to tobacco smoke and ethanol may be confounding factors.[16,110,113] A recent cohort study with 8 years of followup demonstrated no association between marijuana smoking and smoking-related cancers,[38] and a recent population-based case-control study found that marijuana use was not associated with an increased risk of developing oral squamous cell carcinoma.[97]

Reproductive System

Reduced fertility in chronic users is a result of oligospermia, abnormal menstruation, and decreased ovulation.[13]

Cannabis is a Class C drug in pregnancy[12] and affects birthweight and length but does not cause fetal malformations. Statistically significant reductions in birthweight (mean: 79 g less than nonusers) and length (mean: 0.5 cm shorter than nonusers) are reported in women who had urine assays positive for cannabis during pregnancy.[123] The results of three other studies are difficult to

interpret because marijuana use in pregnancy was poorly documented.[39,42,121] Epidemiologic studies based on self-reporting of cannabis use do not support an association between the use of cannabis during pregnancy and teratogenesis.[61,67,121,123]

The effect of maternal use of cannabis during pregnancy on neurobehavioral development in the offspring has been studied. No detrimental effects are reported in children born to heavy marijuana users in rural Jamaica.[24] Tremors and increased startling are reported in infants younger than 1 week of age whose mothers used cannabis during pregnancy.[29] There were no abnormalities in the children of heavy users (>5 joints per week) in Ottawa, Canada

at 12, 24, and 36 months of age, but lower scores in verbal and memory domains at 48 months are reported.[28,40] The results of studies evaluating the effect of in utero exposure to cannabis on postnatal neurobehavioral development are equivocal because of methodologic concerns regarding exposure assessment and control of covariates,[23] including the continued parental use of cannabis during the postnatal and early childhood periods. The role of postnatal and early childhood secondhand exposure to cannabis in the development of neurobehavioral problems has not been evaluated.

Endocrine System

In experimental animals, cannabis exposure is associated with suppression of gonadal steroids, growth hormone, prolactin, and thyroid hormone; in addition, cannabis alters the activity of the hypothalamicâ€“pituitaryâ€“adrenal axis.[13] In human studies, the results are inconsistent, long-term effects have not been convincingly demonstrated, and clinical consequences are undefined.[13]

Neurobehavioral Effects

There is a concern that chronic cannabis use results in deficits in

cognition and learning that last well after cannabis use has stopped. Neuropsychological tests administered to 10 cannabis-dependent adolescents, 8 adolescent noncannabis drug abusers, and 9 nondrug users showed significant differences that persisted for the duration of the study (6 weeks of abstinence) between the cannabis group and the other groups in a visual retention test and a memory test.[102] In a study of 3 experienced marijuana smokers, cannabis impaired arithmetic and recall tasks up to 24 hours after smoking.[41] Adults who were heavy cannabis users (more than 7 uses/wk) had impairments in math skills, verbal expression, and memory retrieval processes; light and intermediate users showed no impairments.[9] After 1 day of abstinence, 65 heavy marijuana users (median: use on 29 of past 30 days) showed greater impairment than light marijuana users (median: use on 1 day of past 30 days) on neuropsychological tests of attention and executive functions.[91] The authors were uncertain whether this difference was caused by residual xenobiotic in the brain, a withdrawal effect from the drug, or a direct neurotoxic effect of cannabis.

An â€œamotivationalâ€• syndrome is attributed to cannabis use. The syndrome is a poorly defined complex of characteristics such as apathy, underachievement, and lack of energy.[19,101] The association of the syndrome with cannabis use is based primarily on anecdotal uncontrolled observations.[44] Anthropologic field studies, evaluations of US college students, and controlled laboratory experiments have failed to identify a causal relationship between cannabis use and the amotivational syndrome.[44] A study evaluating the role of depression in the amotivational syndrome found significantly lower scores on â€œNeed for Achievementâ€• scales in heavy users (median: daily use for 6 years) with depressive symptoms compared to heavy users without depressive symptoms and light users (median: several times per month for 4.5 years) with or without depressive symptoms.[82] These data suggest that symptoms attributed to an amotivational syndrome are caused by depression, not cannabis. Another study found that behavior that could be interpreted as amotivation was

inversely related to the perceived size of the reward.[19]

Abuse, Dependence, and Withdrawal

The *Diagnostic and Statistical Manual of Mental Disorders, 4th Edition*[2] defines marijuana abuse as repeated instances of use under hazardous conditions; repeated, clinically meaningful impairment in social/occupational/educational functioning; or legal problems related to marijuana use. Marijuana dependence is defined as tolerance, compulsive use, impaired control, and continued use despite physical and psychological problems caused or exacerbated by use. The prevalence of marijuana use disorders increased significantly between 1992 and 2002 among black men and women and among young Hispanic men.[21]

The amount, frequency, and duration of cannabis use required to develop dependence are not well established.[18,109] Much of the support for cannabis dependence is based on the existence of a withdrawal syndrome. In animals repeatedly given cannabis, the administration of a CB1 receptor antagonist produced signs of withdrawal.[66,106] In humans, chronic users experience unpleasant effects when abstaining from cannabis. The time of onset of withdrawal symptoms is not well characterized.[13,106] The most reliably reported effects are irritability-restlessness-nervousness and appetite and sleep disturbances.[106] Other reported acute withdrawal manifestations include tremor, diaphoresis, fever, and nausea. These symptoms and signs are reversed by the oral administration of THC.[37] The duration of withdrawal manifestations, without treatment, is not clearly established.[14,106]

Cannabis and Driving

The perceptual alterations caused by cannabis suggest that its recent use should be associated with automobile crashes. However, neither experimental nor epidemiologic studies have provided definitive answers about the effects cannabis use has on driving ability. The

published analytical studies of the relationship between cannabis and driving behavior/motor vehicle crashes have been reviewed.[6] In experimental driving studies, cannabis impairs driving ability but cannabis-using drivers recognize their impairment and compensate for it by driving at slower speeds and increasing following distance. However, the slower reaction time caused by cannabis results in impaired emergency response behavior.

The epidemiologic studies evaluating the association of cannabis use and traffic crashes provide no evidence that cannabis alone increases the risk of causing fatal crashes or serious injuries.[6,86] Studies of 2500 drivers injured in multiple vehicle crashes found that those with blood tests positive for THC had no higher culpability rate than xenobiotic-free drivers.[68,69] A recent study comparing past driving records of subjects entering a drug treatment center with controls found that a self-reported history of cannabis use was associated with a statistically significant increase in adjusted relative risk for all crashes (relative risk 1.49, 95% confidence interval 1.17â€“1.89) and for â€œat faultâ€• crashes (relative risk 1.68, 95% confidence interval 1.21â€“2.34).[20]

The results of studies evaluating the effect of a combination of cannabis and ethanol are contradictory.[6] One study supported potentiation of effects,[114] one could not evaluate the role of xenobiotics other than ethanol,[118] and one did not support potentiation.[51]

Diagnostic Testing

Cannabinoids can be detected in plasma or urine. Enzyme-multiplied immunoassay technique (EMIT) and radioimmunoassay (RIA) are routinely available; gas chromatography-mass spectrometry (GC/MS) is the most specific assay and is used as the reference method.

EMIT is a qualitative urine test that is often used for screening purposes. EMIT identifies the metabolites of THC. In these tests, the

concentrations of all metabolites present are additive. For the Emit II Cannabinoid 20-ng Assay, the cutoff level for distinguishing positive from negative samples is 20 ng/mL. A positive test means that the total concentration of all the metabolites present in

the urine was at least 20 ng/mL. A positive urine test for cannabis only indicates the presence of cannabinoids, it does not identify which metabolites are present or in what concentrations. Qualitative urine test results do not indicate or measure intoxication or degree of exposure. The National Institute on Drug Abuse guidelines for urine testing specify test cut-off concentrations of 50 ng/mL for screening and 15 ng/mL for confirmation.

Variables affecting the duration of detection of urinary metabolites include dose, duration of use, acute versus chronic use, route of exposure, and sensitivity of the method. In addition, factors affecting the quantitative values of urine THC and metabolites include urine volume, concentration, and pH. Using GC/MS, metabolites may be detected in the urine up to 7 days following a single marijuana cigarette.[48,49]

The length of time between stopping cannabis use and a negative EMIT urine test (<20 ng/mL) depends on the severity of use. Release of THC from adipose tissue is important in drug testing because chronic users may release cannabinoids in quantities sufficient to result in positive urine tests for several weeks. In addition, vigorous exercise may stimulate the release of cannabinoids from fat depots. In light users being tested daily under observed abstinence, the mean time to the first negative urine test is 8.5 days (range: 3â€“18 days) and the mean time to the last positive urine is 18.2 days (range: 7â€“34 days).[26] In heavy users (mean: 9 years of using at least once a day) being tested under the same conditions, the mean time to the first negative urine test result (EMIT assay <20 ng/mL) was 19.1 days (range: 3â€“46 days) and the mean time to the last positive urine sample was 31.5 days (range: 4â€“77 days).[26]

Standard laboratory analyses identify THC and its metabolites but cannot identify the source of the THC (eg, marijuana, hashish, dronabinol). EMIT will not identify nabilone because it is not THC; however, nabilone can be specifically identified using high-performance liquid chromatography-tandem mass spectrometry.[96]

Immunoassays may give false-negative and false-positive test results (Table 81-2). To help identify evidence tampering, negative urine immunoassays should be accompanied by examining the urine for clarity and measuring urinary specific gravity, pH, temperature, and creatinine.[103,115]

TABLE 81-2. Xenobiotics or Conditions Purported to Produce Inaccurate Screening Test Results

False Negative[a]	False Positive
Bleach (NaOCl)	Dronabinol
Citric acid	Efavirenz
Detergent additives	Ethacrynic acid
Dettol[b]	Hemp seed oil
Dilution	NSAIDs
Glutaraldehyde	Promethazine
Lemon juice	Riboflavin

Potassium nitrite (KNO_3)	
Salt (NaCl)	
Tetrahydrozoline	
Vinegar (acetic acid)	
Water	

[a] Xenobiotics producing false-negative urine tests are usually added to a urine sample, not ingested.
[b] Dettol is an antiseptic containing isopropyl alcohol (8â€“11%), pine oil (8.4%), and chloroxylenol (4.8%).

Passive Inhalation

Studies of passive exposure to marijuana smoke and the urinary excretion of cannabinoids have used enclosed spaces with nonsmokers present during and after active smoking.[22,65,80,81,89]

In an unventilated 6.9 Ã— 8.2 Ã— 7.9-foot room (12,225.8 L of air), 5 adult volunteers were exposed to the sidestream smoke of 4 or 16 marijuana cigarettes (THC 25 mg/cigarette) smoked simultaneously over 1 hour on each of 6 consecutive days.[22] After being exposed to 4 marijuana cigarettes, 4 of the volunteers had at least 1 positive urine by EMIT assay (cut-off: 20 ng/mL) at some unspecified time during the 6 study days; exposure to 16 marijuana cigarettes resulted in positive EMIT assays only after the second day's exposure.

In a car (1650 L of air), 3 adult volunteers were exposed to the

smoke from 12 marijuana cigarettes smoked by 2 people over 30 minutes.[80] EMIT analyses of urine samples from 1 passive inhaler were positive at time 0â€“4 hours and on days 2 and 3; a second passive inhaler had 1 positive urine test at time 4â€“24 hours after exposure.

Three adult volunteers in a 10 Ã— 10 Ã— 8-foot unventilated room (21,600 L of air) were exposed to the sidestream smoke of 4 marijuana cigarettes (THC 27 mg/cigarette) smoked simultaneously over 1 hour.[81] The concentrations of cannabinoids in urine samples taken 20â€“24 hours after exposure were less than 6 ng/mL when analyzed using RIA methodology.

Another study used an unventilated room (total volume of 27,950 L) containing 3 desks and a filing cabinet.[65] Over 10â€“34 minutes, each of 6 volunteers smoked a marijuana cigarette (THC 17.1 mg/cigarette) and left the room. Four nonsmoking adult males were in the study room for 3 hours from the start of smoking. The door was opened and closed 18 times during the study. The maximum urine cannabinoid concentration (measured by RIA) in the nonsmokers was 6.8 ng/mL at 6 hours after the start of smoking.

Another study used a closed 8 Ã— 8 Ã— 10-foot room (15,500 L of air) with each of 4 subjects smoking 2 marijuana cigarettes containing 2.5% THC on one occasion and 2.8% THC on a second occasion.[89] On each occasion, 2 nonsmoking subjects were in the room for 1 hour from the onset of smoking. None of the nonsmokers' urine samples (from 0â€“24 hours) from either exposure period tested positive on an EMIT assay with a cut-off of 20 ng/mL. An identical experiment in a closed car (approximately 3500 L of air) resulted in 1 of 23 urine specimens testing positive at 6 hours.

Saliva

Saliva samples may be used to establish the presence of cannabinoids and time of cannabis consumption. Cannabinoids (THC,

THC-COOH, 11-OH-THC) in saliva may be from the smoke of the marijuana or hashish or from a preliminary metabolism in the mouth.[100] Saliva THC concentrations above 10 ng/mL are consistent with recent use and correlate with subjective intoxication and heart rate changes.[75]

Hair

Hair sample analysis is not useful in identifying THC or its metabolites. Only small quantities of nonâ€“nitrogen-containing substances, such as cannabinoids, are found in hair pigments.[25,59,76]

Sweat

The analysis of perspiration to test for cannabinoids is a recent development. Perspiration deposits drug metabolites on the skin and

these are renewed even after the skin is washed. Detection threshold is reported to be 10 ng/mL but forensic confirmation by alternative means is required.[59]

Estimating Time of Exposure

A measurable serum concentration of THC is consistent with recent exposure and intoxication but there is poor correlation between serum THC concentrations and degree of intoxication.[45]

The ratio of THC to THC-COOH has been used to estimate time of smoking marijuana. Similar concentrations of each indicate cannabis use within 20â€“40 minutes and imply intoxication. In naive users, a concentration of THC-COOH that is greater than THC indicates that use probably occurred more than 30 minutes ago. Serum THC-COOH concentrations >40 ng/mL suggest chronic cannabis use.[79] The high background concentrations of THC-COOH in habitual users make estimations of time of exposure unreliable in this population.

Serum concentrations of THC and THC-COOH were used in a logarithmic equation to predict the time since smoking a marijuana cigarette.[70] The ratio provided acceptable results up to 3 hours after smoking (predicted time of exposure averaged 27 minutes longer than actual exposure time) but more than 3 hours after smoking the predicted exposure time was overestimated by 3 hours. Mean overestimations of predicted exposure time of 2.5â€“4.2 hours for smoking and of 1.6 hours for ingestions are reported when serum samples are taken more than 4 hours after exposure.[47]

Chronic use or oral administration of cannabis increases the concentration of 11-OH-THC relative to the concentrations of THC or THC-COOH. In these cases, estimating time of exposure based on relative concentrations is problematic. In 4 subjects, ingestion of cannabis produced total metabolite plasma concentrations less than 20 times the plasma concentration of THC for 3 hours after ingestion, suggesting that a ratio of this magnitude is consistent with recent oral consumption.[64]

Management

Gastrointestinal decontamination is not recommended for patients who ingest cannabis products, nabilone, or dronabinol because clinical toxicity is rarely serious and responds to supportive care. In addition, a patient with a significantly altered mental status, such as somnolence, agitation, or anxiety, has risks associated with gastrointestinal decontamination that outweigh the potential benefits of the intervention.

Agitation, anxiety, or transient psychotic episodes should be treated with quiet reassurance and benzodiazepines (lorazepam 1â€“2 mg IM or diazepam 5â€“10 mg IV) or antipsychotics (haloperidol, ziprasidone) as needed. There are no specific antidotes for cannabis. Coingestants, such as cocaine or ethanol, should be identified and their effects anticipated and treated as indicated.

Summary

Cannabis is a commonly used and widely available xenobiotic. Common manifestations of acute cannabis toxicity include relaxation, perceptual alterations, sedation, tachycardia, postural hypotension, inability to concentrate, slurred speech, and slow reaction times. Feelings of distrust, fear, or panic may occur. Obtundation, apnea, bradycardia, hypotonia, and opisthotonus are reported in young children following ingestion of cannabis. THC or its metabolites can be identified in blood or urine, but treatment is not guided by drug concentrations. Treatment of an overdose, a high degree of toxicity, or an acute adverse reaction is symptomatic and supportive.

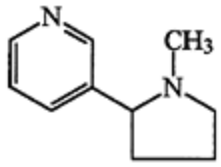
Chapter 82
Nicotine and Tobacco Preparations

Morton E. Salomon



MW = 162 daltons

Nicotine

At 8:15 A.M. an 11-month-old boy was found eating cigarette butts out of an ashtray. The parents cleaned his lips and mouth with cold water. Twenty minutes later the child vomited 3 times. The parents contacted their regional poison center, which advised them to bring the child immediately to an emergency department (ED). En route, via ambulance, the child vomited again. On presentation to the ED at 9:00 A.M., the child was noted to be tremulous and diaphoretic with excessive salivation. He had a glassy-eyed look and did not interact with his parents. His vital signs were: blood pressure, 128/78 mm Hg; pulse, 150 beats/min; respiratory rate, 28 breaths/min; and temperature, 99.7Â°F (37.6Â°C). Pulse oximetry measured 96% saturation on room air.

Pupils were 3 mm and reactive to light. The skin was pale without rashes or bruises. The anterior fontanel was appropriately open (1 cm) and flat. The mouth was clear of particulate matter. Examination of the chest, heart, and abdomen were normal, as were his pulses. The neurologic examination was nonfocal; however, at 9:10 A.M., approximately 1 hour after the ingestion, the child had a generalized seizure lasting less than 15 seconds. There was no incontinence, eye rolling, or focal neurologic findings. The ED staff placed a 28-French orogastric tube into the child's stomach and lavaged with 100-mL aliquots of 0.9% sodium chloride. Lavaging produced a scant amount of brown particulate material along with other stomach contents. After the stomach contents were cleared, 10 g of activated charcoal with sorbitol were delivered through the orogastric tube, which was then replaced by a nasogastric tube. Over the next 30 minutes, the child became increasingly lethargic. Neurologic examination demonstrated progressively more hypotonia, and his deep tendon reflexes became undetectable. The blood pressure decreased to 76/50 mm Hg, the pulse decreased to 84 beats/min and his respiratory rate decreased to 18 breaths/min. His skin was mottled and cool. The pulse oximeter registered 88â€“89% on room air. An arterial blood gas analysis done prior to placing the child on oxygen showed: pH 7.44; PCO_2 , 46 mm Hg; and PO_2 , 57 mm Hg. By 9:45 A.M. the child was intubated and placed on a ventilator. Copious clear secretions were noted from both the mouth and endotracheal tube and the child was given 0.2 mg of atropine intravenously. The complete blood count (CBC), electrolytes, glucose, calcium, magnesium, and renal function tests done at the time of admission were all within normal limits.

Four hours after presentation, the child was more alert and breathing more effectively and began fighting the ventilator. He was sedated with a continuous midazolam infusion, and was gradually weaned from the respirator and extubated 11 hours after the ingestion. He was discharged home 48 hours after ingestion in stable condition and his parents were counseled regarding poison prevention. Followup examination 15 days later revealed no apparent sequelae.

Fifty million Americansâ€”25% of the adult populationâ€”smoke cigarettes despite antismoking public education campaigns, widespread knowledge of its health consequences, and decreasing social acceptance.[6 , 78] In the United States, 350,000 deaths annually are attributable to cigarette smoking, making it the single most important cause of preventable premature mortality.[57] It is now widely accepted that tobacco use is addictive and that nicotine is the component primarily responsible for dependency.[72]

Nicotine is a tertiary amine, that is a colorless, bitter-tasting, and a highly water-soluble volatile liquid that is weakly alkaline (pK_a = 8.0â€“8.5).[6] The principal source of nicotine is the tobacco plant, *Nicotiana tabacum* , from which nicotine was first isolated in 1826.[13] Nicotine also can be isolated from multiple plant species in the Solanaceae family. *N. tabacum* is not the only tobacco plant in this family. The first tobacco to be brought back from the New World to

Europe was *N. rustica* , which contains a much higher concentration of nicotine (approximately 18%) and which is still found in â€œTurkish tobacco.â€• [39] Nicotine is also found in small concentrations in plants outside the *Nicotiana* genus, and even in plants outside the Solanaceae family. In addition, there are a number of alkaloids with chemical structures and physiologic activity similar to that of nicotine in tobacco plants and botanical species related to tobacco.[39]

Nornicotine, anabasine, and anabatine are structurally similar alkaloids also found in tobacco. Anabasine is the principal alkaloid found in *N. glauca* .[65] Lobeline, derived from *Lobelia inflata* , or â€œIndian tobacco,â€• is frequently used as a nicotine substitute.[32] Cystisine, found in mescal beans, is used for its mind-altering properties. Coniine, the lethal alkaloid in â€œpoison hemlock,â€• is also chemically related to nicotine.

History and Epidemiology

The principal sources of nicotine exposure and poisoning are tobacco

products: cigarettes, cigars, pipe tobacco, chewing tobacco, and snuff. Nicotine is also the essential component of smoking-cessation products such as nicotine gum, nicotine patches, nicotine nasal and oral sprays, and nicotine lozenges. Nicotine had a brief application as an animal tranquilizer and was used extensively as an agricultural insecticide in the 1920s and 1930s; formulations of this product are still used by â€œorganicâ€• gardeners.

Sources and Uses of Nicotine

Cigarettes

Cigarettes are the most widely used tobacco products in Western culture and the most likely to be implicated in nicotine poisoning. When a cigarette is burned, the smoker inhales both gaseous and particulate matter. Nicotine is found in the particulate phase of cigarette smoke, along with tar. The total nicotine content of a â€œregularâ€• American cigarette varies between 13 and 20 mg. â€œLow nicotineâ€• cigarettes contain half this amount, and many European cigarettes contain up to 30 mg of nicotine.[8 , 20 , 70] When a cigarette is smoked, more than half the nicotine escapes in the sidestream smoke and a large fraction remains in the butt and filter.[2] As a result, a typical cigarette delivers 0.5â€“2.0 mg of nicotine (average: 1.0 mg) to the smoker.[32] This amount depends on the total nicotine content of the cigarette as well as the individual's smoking technique. The nicotine content written on a cigarette package is determined by burning cigarettes on mechanical smoking machines in a standardized manner.[45] A smoker, on the other hand, extracts variable amounts of nicotine from a cigarette to maintain a steady blood nicotine concentration. Smokers vary the degree of nicotine extraction by altering the rate of puffing, the puff volume, the depth and duration of inhalation, and the size of the residual butt.[6 , 45] African Americans extract, on average, 30% more nicotine per cigarette smoked than whites.[58] When smokers switch from â€œregularâ€• to â€œlow-tarâ€• cigarettes, they often maintain a similar nicotine intake by increasing

the number of cigarettes they smoke and by puffing in a more vigorous manner (Table 82-1).[45]

Not all cigarettes are made from pure tobacco. It is common, especially in Asia, to create cigarettes out of a mixture of tobacco and other products. â€œKreteksâ€• are cigarettes composed of 60% tobacco and 40% ground clove. In the United States, they are especially popular with adolescents because of their pleasant odor and euphorigenic effect. Unfortunately, kreteks are more addicting than tobacco alone.[39] Moreover, eugenol, the major active ingredient in cloves, is believed to be the probable cause of the severe lower respiratory complications of acute lung injury and hemorrhage that occur in some users.[39]

Smokeless Tobacco

Smokeless tobacco, especially snuff, has regained popularity in the United States. Because smoking is not involved, and with the present laws in many states making it illegal to smoke in public places, the public generally believes that smokeless tobacco is more socially acceptable and less of a health risk.[23,39] In fact, in comparison to nonsmokers, there is as much as 48 times the risk of oropharyngeal cancers among longtime users of smokeless tobacco, in addition to other oral and nonoral health hazards.[12,13,39]

Smokeless tobacco comes in two varieties: chewing tobacco and snuff. Snuff is a finely cut tobacco powder packaged dry or moist. In Europe, especially Great Britain, small pinches of dry snuff are inhaled through the nostrils. In the United States, dry and wet snuff are usually â€œdipped.â€• This involves placing a bite-size amount of tobacco (a â€œquidâ€•) between the mucous membranes and the gums. Chewing tobacco is generally packaged as â€œtwistsâ€•â€”leaf tobacco twisted into ropelike portionsâ€”or â€œplugsâ€•â€”shredded tobacco pressed into cakes. These forms are chewed or simply placed in the gingival recess. Generally, the nicotine from smokeless tobacco dissolves in the saliva and is absorbed through the mucous membranes of the mouth. However, approximately one-third of smokeless tobacco users swallow their saliva, absorbing additional nicotine in the intestinal tract.[12,13,

[69] Snuff contains approximately 14 mg of nicotine per gram of tobacco. A typical quid contains 1.5â€“2.5 g of tobacco, which the user â€œdipsâ€• for 20â€“30 minutes. Ten percent of the available nicotine crosses the oral mucosa, producing a total nicotine dose of 2.0â€“3.5 mg/dip. Tobacco chewers use approximately 7 g of tobacco at a time. The nicotine content of a typical â€œchawâ€• is 7.8 mg/g of tobacco. Only 8% of this nicotine is absorbed through the oral mucosa, because the pH of chewing tobacco is only 6.5. Ultimately, the tobacco chewer gets approximately the same dose of nicotine or slightly more than the tobacco snuffer.[11] The smokeless tobacco user who takes 8â€“10 dips or chaws per day gets a nicotine dose equivalent to 30â€“40 cigarettes per day, and cotinine (nicotine metabolite) concentrations found in their urine are similar to those found in the urine of smokers.[5 , 11]

Less Common Sources

Although poisoning from smokeless tobacco usually occurs by ingestion in children, 1 case report of nicotine poisoning occurred when a child licked the contents of a spittoon.[21] Another unusual source of nicotine poisoning is tobacco enemas, where tobacco is soaked in water and the juice of this extract is added to enemas for the treatment of pinworm. This practice has produced at least 1 reported case of severe nicotine poisoning.[20]

Green-leaf tobacco sickness occurs when a tobacco harvester handles dew-laden tobacco leaves. The nicotine dissolves in the water and is absorbed through the worker's skin, if cutaneous precautions are not taken.[6 , 39] Transcutaneous nicotine poisoning is also reported in smugglers who hide tobacco leaves under their clothing.[39]

Nicotine salts, such as nicotine sulfate, were popular pesticides in the 1920s and 1930s. These compounds generally contain 40% nicotine; when they come in contact with moist skin, significant doses of nicotine are absorbed. Several cases of severe nicotine poisoning from skin exposure or ingestion, including deaths, have occurred.[9 , 39 , 55]

Although industrial scale manufacture of nicotine insecticides was discontinued by 1950, these products are available through catalogues and web sites catering to the organic gardener.

Gum

Nicotine is prepared in the form of gum to assist abstinent smokers with withdrawal symptoms. Nicotine resin gum is packaged in 2 strengths: 2 mg and 4 mg per stick. It is designed to be chewed slowly and intermittently. When used correctly, blood concentrations of nicotine are less than those achieved through cigarette smoking, even when 4-mg gum is chewed. Because of alkaline buffers, approximately 53â€“72% of the nicotine in the gum is absorbed through the buccal mucosa. Additional amounts can be absorbed through swallowed saliva.[6] However, when the gum is chewed rapidly and vigorously, nicotine concentrations in the blood can rise rapidly, producing adverse effects, especially in children.[70] Severe nicotine poisoning in a 20-month-old child occurred from the use of nicotine gum.[68] Moreover, adverse effects are reported in adults who have used the gum while continuing to smoke.[50 , 70] If the gum is swallowed, it is less likely to be toxic because the nicotine is released in an acidic milieu resulting in an ionized state and absorbed slowly during GI transit, producing low blood concentrations.[6]

Patches

There are currently four nicotine-releasing adhesive patches available to aid in the treatment of smoking cessation. These patches, designed for 16â€“24 hours of use, vary in size and nicotine release rates, and contain 8.3â€“114 mg of nicotine per patch. Only a portion of the total nicotine load of the patch is actually absorbed during the cutaneous application.

Nasal Spray and Inhaler

In 1996, a nicotine nasal spray was released in the United States as

another treatment modality for withdrawal symptoms during smoking cessation. The metered-dose inhaler contains 100 mg of nicotine in a concentration of 10 mg/mL, and is designed to deliver 200 equivalent puffs. Each puff contains 0.5 mg of nicotine of which slightly more than half will pass into the circulation through the nasal mucosa.[49] Absorption is diminished slightly by rhinitis and delayed by the use of Î±-adrenergic decongestants.[40] The recommended dose is 2 sprays (1 mg)â€”1 in each nostrilâ€”every 30â€“60 minutes. The user titrates the dosing frequency to withdrawal symptoms, using a maximum of 40 doses (80 puffs) per day and creating a steady-state serum nicotine concentration of 6â€“18 ng/mL.

A nicotine metered-dose oral inhaler for smoking cessation is now available. The device is designed to mimic smoking by providing airway stimulation as well as nicotine replacement. Absorption of nicotine occurs primarily through the buccal and pharyngeal mucosa, but slow, deep inhalation can redirect some nicotine into the pulmonary tree and achieve absorption there. Typical use achieves an average steady-state serum nicotine concentration of 7 ng/mL.[41]

Absorption
Lungs, oral mucosa, skin, intestinal tract, gastric acidity inhibits absorption
Volume of distribution
1 L/kg
Protein binding
5â€“20%
Metabolism
80â€“90% hepatic, remainder in lung and kidney; principle metabolites are cotinine, nicotine-â€²-*N* -oxide
Half-life
1â€“4 h, shorter in smokers (average, 2h); half-life of cotinine is 19 h
Elimination
2â€“35% excreted unchanged in urine

TABLE 82-2. Pharmacologic Characteristics of Nicotine

Pharmacology and Pharmacokinetics

Table 82-2 summarizes the pharmacologic characteristics of nicotine.

Absorption

The typical cigarette smoker will adjust his or her use of cigarettes and pattern of smoking to maintain an average nicotine concentration of 30 ng/mL.[6] Nicotine is readily absorbed from the buccal mucosa, respiratory tract, intestinal tract, and skin. The usual site of absorption is the lungs. Inhaled nicotine from cigarette smoke reaches the brain in approximately 8 seconds, with central nervous system (CNS) concentrations of nicotine rising rapidly and then declining rapidly as the drug is redistributed to other tissues.[6 , 32] The cigarette smoker achieves a serum nicotine concentration of 5â€“30 ng/mL after a single cigarette.[6]

Nicotine from cigar and pipe tobacco, as well as from chewing tobacco, snuff, and nicotine resin chewing gum, is generally absorbed through the buccal mucosa. Pipe and cigar tobacco are air-cured to achieve an alkaline pH of 8.5. Smokeless tobaccos and nicotine gum are buffered. The alkaline pH of all of these products enhances buccal absorption.[6] Smokeless tobacco users generally achieve nicotine concentrations comparable to those of cigarette smokers. Pipe and cigar smokers usually average lower nicotine concentrations, unless they inhale the smoke from these products.[6]

Nicotine generally achieves a volume of distribution of 1 L/kg. It readily crosses the placenta and is also transmitted in small concentrations in breast milk.[6]

Metabolism and Elimination

Habitual tobacco users generally metabolize 80â€“90% of their nicotine intake, excreting 10â€“20% in urine unchanged. Metabolism takes place primarily in the P450 system of the liver, but also, to a lesser extent, in the kidney and lung.[9,32] The two major oxidative metabolites of nicotine are cotinine and nicotine-1-*N*-oxide. Both of these compounds are pharmacologically inactive and are excreted primarily by the kidney.[6,32] The half-life of nicotine is 1â€“4 hours but generally averages 2 hours in chronic users.[6,32] Because nicotine metabolism in the liver is an inducible transformation, smokers metabolize the drug more rapidly than nonsmokers. The elimination half-life of cotinine is approximately 19 hours, making cotinine levels in the urine a better marker of recent tobacco use and total tobacco exposure.[6,32] Clearance of cotinine is slower in African Americans than in whites.[58]

Î²-Adrenergic antagonists
Nicotine
Benzodiazepines
Opioids
Caffeine
Phenacetin
Cyclic antidepressants
Theophylline
H_2-histamine antagonists

TABLE 82-3. Xenobiotics with Enhanced Metabolism in Smokers

Renal excretion of unchanged nicotine can vary from 2â€“35% of the total dose,[6] depending on urine flow and urine pH. Experimentally, acidification of the urine traps nicotine ions and enhances direct elimination.[6,20] Nonsmokers eliminate a larger proportion of nicotine unchanged in the urine because of their slower hepatic metabolism.[35]

Drug Interactions

A number of studies demonstrate that smokers have altered metabolism of many commonly used xenobiotics. Smokers metabolize via autoinduction the xenobiotics listed in Table 82-3 more quickly than do nonsmokers.[32, 35] Nicotine itself is metabolized more rapidly in smokers. The therapeutic effectiveness of opioids, benzodiazepines, nifedipine, and Î²-adrenergic antagonists is diminished in smokers.[32] Smokers with peptic ulcer disease are also more likely to fail treatment with H_2 antagonists and antacids.[6] The presumed mechanism for this change in drug metabolism is induction of microsomal enzyme systems. However, because there are 3000 components to tobacco smoke, it is difficult to know exactly which components affect metabolism. In all likelihood, nicotine is not responsible for the induction. For example, IV nicotine does not affect theophylline metabolism in humans.[6] It is more likely that polycyclic aromatic hydrocarbons (PAH), released by the combustion of tobacco, are responsible for the induction of P448 microsomal enzymes in the liver.[35] Xenobiotics whose metabolism is affected by smoking are in part metabolized by this system. In contrast, xenobiotics using the P450 system exclusively are not affected by chronic smoking.[35] This conclusion would be further supported by demonstrating the absence of xenobiotic interactions in users of smokeless tobacco, nicotine gum, and transdermal nicotine patch users. Nicotine and ethanol are frequently used concurrently, and animal studies demonstrate that pretreatment with ethanol exaggerates cardiovascular responses to IV nicotine. Heart rate and blood pressure increase in an additive way. Smokers are more apt to suffer from dysrhythmias and sudden death during alcohol use. It is likely that this is the result of increased oxygen demand triggered by additive cardiovascular stimulation.[7] Because ethanol does not influence the rate of nicotine metabolism, the etiology of this additive response is unclear.

Pathophysiology

Nicotine binds stereospecifically to select acetylcholine receptors, generally referred to as nicotine receptors (Chap. 14).[6, 32] There are nicotine receptors throughout the body, particularly in the autonomic

ganglia, adrenal medulla, central nervous system, spinal cord, neuromuscular junctions, and chemoreceptors of the carotid and aortic bodies.[6 , 32] In the CNS, the highest density of nicotine receptors can be found in the limbic system, midbrain, and brainstem.[6] The physiologic effects on the CNS are multiple, complex, and dose-dependent. At doses commonly encountered with tobacco use there is stimulation of the reticular activating system and an alerting pattern on electroencephalogram (EEG).[32 , 68] There is a facilitation of memory and attention, with a decrease in aggression and irritability.[32] Although nicotine might reduce skeletal muscular tone and decrease deep-tendon reflexes, its central and neuromuscular stimulatory effects can also produce tremor.[32 , 65] At very high doses, nicotine induces seizures. Studies in mice suggest that nicotine-induced seizures can be controlled by the neuroinhibitory agent 5-Î±-pregnan-3Î±-ol-20-one. It is therefore postulated that nicotine produces seizures at high doses by a CNS disinhibition mechanism at CNS nicotine receptor synapses.[42]

Gastrointestinal effects are probably mediated by nicotine stimulation of vagal centers in the medulla oblongata. Even at low doses, nicotine exposure produces nausea and vomiting in the naive tobacco user. Nicotine also increases gastroesophageal reflux, probably by either lowering sphincter pressure or increasing acid secretion.[62] Diarrhea can be stimulated by larger doses of nicotine, which is probably mediated by both central and parasympathetic excitation.[20 , 32]

Nicotine exerts a number of endocrinologic effects either by acting directly on nicotine receptors in the endocrine gland or by stimulating neurohumoral pathways in the CNS. It enhances the release of catecholamines, and stimulates the production of vasopressin (antidiuretic hormone), growth hormone, adrenocorticotropin, cortisol, prolactin, serotonin, and Î²-endorphins. It also affects pancreatic exocrine functions in rats. In rats pretreated with nicotine doses comparable to exposures that moderate smokers receive there is an increase in amylase, trypsin, and chymotrypsin activity.[15] With repeated exposure, tolerance develops to many of these effects.[6]

Nicotine is an anorexiant, especially to sweet foods, while increasing basal energy expenditures. It also causes moderate increases in serum glucose by reducing insulin sensitivity.[51] These effects explain why nicotine promotes weight loss. Smokers weigh, on average, 6â€“10 lbs less than nonsmokers. With repeated exposure, tolerance develops to many of these effects.[6, 32] Habitual use of nicotine also decreases estrogen levels in female smokers, probably by promoting hydroxylation of estradiol. As a result, women who smoke are at increased risk for osteoporosis.

Clinical Manifestations

More than 60% of reported nicotine exposures produce no toxicity and only 1% produced moderate to major toxicity. This low proportion of serious poisoning is not surprising, because 98% of these exposures are unintentional and more than 90% occur in children younger than 6 years of age (Chap. 130).[8] Nonetheless, serious exposures do occur, even in young children, and seem to be dose related. In one report, 23 (45%) of 51 childhood exposures to nicotine resulted in some degree of symptomatology. Only 8 (16%) of these 51 children required evaluation by a physician and only 4 children (8%) developed significant symptoms of lethargy, unresponsiveness, and limb jerking.[70] Similarly, another study reported that only 1 (5%) of 20 children who ingested nicotine became moderately ill and required 24 hours of hospitalization.[8] Most unintentional exposures in small children result from the ingestion of tobacco products. The tobacco itself usually induces spontaneous vomiting, which limits its own absorption.

Early (15â€“60 min)
Abdominal pain
Bronchorrhea
Hypertension
Agitation/anxiety

Gastrointestinal Respiratory Cardiovascular Neurologic

TABLE 82-4. Signs and Symptoms of Acute Nicotine Poisoning

A child who ingests 1 or more cigarettes or 3 or more cigarette butts has a 90% chance of becoming symptomatic. Conversely, ingestion of smaller amounts will produce symptoms only half the time.[78] In a retrospective review of cigarette ingestions by 10 children, each of the 4 children who became severely poisoned had ingested at least 2 whole cigarettes.[44] One-half piece or more of 2-mg nicotine chewing gum usually produces symptoms in a child.[70]

Table 82-4 outlines the symptoms associated with acute nicotine exposure. Clinical signs of low concentrations of nicotine, such as those occurring routinely in smokers, include tremor and increased heart rate, respiratory rate, blood pressure, and alertness.

In marked contrast to these relatively mild effects associated with cigarette smoking, when nicotine is taken in â€œtoxicâ€• quantities, as in an insecticide exposure, for example, the effects are more severe. The symptoms may follow a biphasic pattern in which there is initial stimulation followed quickly by inhibition.[65] Early symptoms of toxicity often include nausea, vomiting, diaphoresis, and increased salivation. Cardiovascular signs include tachycardia, hypertension, and pallor secondary to vasoconstriction. Early neurologic manifestations include headache, dizziness, ataxia, and, in moderately severe cases, confusion as well as visual and auditory distortions.[8,65]

In the most severe exposures, these generally mild symptoms can be quickly overshadowed by signs of more extreme stimulation, such as seizures, muscle fasciculations, and atrial fibrillation.[8,65,68] Although seizures do occur, there are no reports of nicotine-induced status epilepticus in nonexperimental conditions. These symptoms are often succeeded by signs of multisystem depression, such as bradycardia and hypotension, and a curarelike neuromuscular blockade that leads to muscle paralysis, particularly respiratory paralysis.[55,65,68] Death is generally attributable to respiratory depression or paralysis of the intercostal muscles complicated by increased bronchial secretions or to cardiovascular collapse.[9,55,65] Timely and adequate respiratory and

cardiovascular support generally leads to full recovery without sequelae.[9 , 55]

Vomiting is the most common symptom of nicotine poisoning, occurring in more than 50% of symptomatic patients. However, it is not a reliable sign of toxicity.[70] Patients can present with lethargy and respiratory depression without prior vomiting or any other signs of CNS stimulation.[9] Moreover, nicotine chewing gum ingestions in children produce vomiting less frequently (20% incidence) than do cigarette ingestions.[70]

Following the ingestion of tobacco products, children usually manifest symptoms within 30â€“90 minutes. When children chew nicotine gum, symptoms are usually apparent within 15â€“30 minutes, a result of more rapid absorption through the buccal mucosa.[68 , 70] When death occurs, it usually occurs within 1 hour of exposure, however with mild poisonings, symptoms generally last only 1â€“2 hours after exposure. With severe toxicity, however, full recovery might take 48â€“72 hours.[68]

As little as 1 mg of nicotine can produce symptoms in a young child. Four to 8 mg of nicotine might produce symptoms in an adult, especially a nonhabituated victim.[20] Nicotine doses of 0.8â€“1.0 mg/kg are considered to be lethal dose in adults.[20 , 21 , 44] In a prospective study of nicotine ingestions in children, the 3 most severely poisoned infants ingested a minimum of 1.4 mg/kg. The 25 asymptomatic children ingested a mean of 0.5 mg/kg, and all asymptomatic children ingested less than 1 mg/kg.[70] These numbers indicate a very narrow range between nontoxic and significantly toxic doses.

Green-leaf tobacco sickness generally produces a mild to moderate illness consisting of nausea, vomiting, headaches, dizziness, pallor, and diaphoresis.[6 , 39] However, in two recent outbreaks of green-leaf tobacco sickness in Kentucky, nearly 25% of the affected tobacco workers required hospitalization. A significant portion of these poisoned workers were younger than age 18 years.[3 , 48]

One study exposed dogs transdermally and orally to 3 different

commercially available nicotine patch systems. The topical administration provided 1â€“2 mg/kg over 24 hours, producing serum concentrations as high as 43 ng/mL. Two of 12 topical applications elicited salivation and vomiting. Oral exposure up to 13 mg/kg produced maximal serum concentrations of 73 ng/mL, with only vomiting in 2 of 12 oral challenges.[47]

Published reports from a 2-year postmarketing surveillance study by 34 poison centers describe toxicity from misuse or from unintentional exposure to transdermal nicotine patches. Transdermal application of 2â€“20 transdermal nicotine patches in 9 adults resulted in very serious toxicity. Eight patients were admitted to intensive care; 4 had refractory seizures; and 4 required assisted ventilation. However, 7 of the 9 patients ingested cointoxicants in suicide attempts, and the maximum nicotine level recorded was only 27 ng/mL.[81] Thirty-six exposures in children were less severe. Half the children had topical exposures and half had bitten, chewed, or swallowed the patches. Nearly 40% developed symptoms, but only 27% required medical evaluation and only 5% were hospitalized for 24 hours or more.[80] It seems, therefore, that unintentional exposure to nicotine patches has not yet produced serious toxicity.

Diagnostic Testing

Toxicologic assay for nicotine or its metabolites is of limited value in the management of a patient with an acute poisoning. The presence

of nicotine or cotinine in the urine might reflect coincidental active or passive smoke exposure and therefore does not confirm nicotine as the cause of poisoning.[68] Serum nicotine levels must be determined shortly after exposure and are difficult to interpret. A serum nicotine level greater than 50 ng/mL generally predicts serious toxicity, but lower levels can also be significant in the nontolerant patient.[65]

Management

Unintentional ingestions of nicotine in small children almost invariably involve small amounts, with spontaneous vomiting providing adequate decontamination. Thus many patients do not need medical evaluation. Individuals who ingest 1 or more whole cigarettes or 3 or more cigarette butts, who acquire their exposures from a more toxic source (a nicotine insecticide or a tobacco enema), who develop symptoms other than vomiting, or who are potentially suicidal should be referred to an ED without delay. Patients with mild symptoms and no complicating circumstances can generally be observed for 4 hours in the ED and released if symptoms have resolved.[65]

Initial Management

The patient with a significant recent oral exposure, who has not vomited prior to presentation, should be decontaminated by orogastric lavage. Emesis induced by syrup of ipecac should be avoided because nicotine poisoning may cause unexpected seizures or respiratory depression.[9, 70] Activated charcoal effectively binds nicotine and should be used to reduce absorption in gastrointestinal (GI) exposures. Pharmacokinetic studies indicate that nicotine appears in the GI tract, even when administered intravenously.[70] Because this suggests that nicotine undergoes enteroenteric or enterohepatic circulation, multiple-dose activated charcoal should be considered in patients with serious exposures.

In cases of skin exposure to wet tobacco leaves, concentrated nicotine liquid, or nicotine pesticide powder, the patient's clothing should be promptly removed, bagged, and not returned to the patient and the skin thoroughly washed with soap and water. The medical staff must wear impervious gloves and gowns during these procedures to avoid secondary exposure.

Symptom-Directed Treatment

Because of the variety of stimulatory and depressant effects in the

neuromuscular, sympathetic, parasympathetic, and central nervous systems, treatment of nicotine toxicity is a complex therapeutic problem. Treatment is based on a symptom analysis with primary emphasis on respiratory support. Seizures are usually treated with a benzodiazepine. Loading the patient with longer-acting anticonvulsants is generally unnecessary.[9 , 44 , 65] Cardiovascular compromise is treated with atropine for symptomatic bradycardia and fluids for hypotension.[65] If hypotension does not respond to fluids, a vasopressor such as dopamine or norepinephrine is recommended.[68] By reversing bradycardia with atropine, there is some risk of further exacerbating the vasoconstrictive effects. For this reason, some authors also suggest using concomitant phentolamine, an Î±-adrenergic antagonist, in the treatment of nicotine overdose.[20 , 65] Such combined therapy is unnecessary, however, as adrenergic stimulation is rarely life-threatening in nicotine poisoning, and adrenergic antagonism can exacerbate hypotension in the delayed phase. Respiratory compromise, caused by respiratory depression is generally treated with oxygen, intubation, and positive pressure ventilation as indicated.

Enhancing Elimination

Although nicotine is a weak base (pK_a = 8.0â€“8.5) and excretion can theoretically be enhanced by acidification of the urine, this approach is to be condemned,[9 , 65] because the potential risks of acidification in a patient with seizures and possible rhabdomyolysis outweigh any of the theoretical benefits.[65] Furthermore, because the symptoms in nicotine poisoning are generally short-lived, acidification is unnecessary. Fluid diuresis may also enhance elimination and is safer but also is unnecessary because of the limited urinary elimination.[9]

Antidotes

There is no specific antidote for nicotine poisoning. Pempidine and mecamylamine demonstrate both competitive and noncompetitive antagonism to the central effects of nicotine,[46] and hexamethonium, a

ganglionic blocker, prevents nicotine-induced seizures in animals.[65] None of these blockers has been reported as used, either experimentally or clinically, to treat overdoses in humans. Although their application is theoretically of interest, new approaches with these blockers are unlikely to be developed because severe nicotine poisoning is rare and nonspecific supportive measures are almost always adequate when initiated in a timely manner.

Nicotine Withdrawal and Treatment

Tobacco use meets all of the World Health Organization (WHO) definitions of addiction. There is an overpowering compulsion to continue taking the drug. There is a tendency to develop tolerance to its effects and therefore to keep increasing the dosage. Psychological and physical dependency develops, and the absence of tobacco produces discomfort in the smoker. Finally, tobacco has detrimental consequences for both the individual user and society at large.[52]

Tobacco addiction occurs with other forms of tobacco besides cigarettes, especially with smokeless tobacco. Of course, many smokeless tobacco users switch to this product to wean themselves from cigarettes.[52 , 59]

Individuals dependent on tobacco, like any other substance-dependent individuals, go through multiple cycles of quitting and relapsing. While spontaneous quitting without any special treatment program is the most common route to abstinence, the achievement rate by this method is only 1% of users per year.[6 , 36] Women cigarette smokers have a lower rate of quitting success than men.[56]

Smokers are much more likely than nonsmokers to have other substance dependencies.[36] Conversely, 80â€“95% of alcohol and drug abusers also smoke cigarettes. It has been suggested that nicotine use promotes the release of endogenous endorphins. Therefore, withdrawal from nicotine might have a strong biochemical resemblance to withdrawal from opioids.[16] In fact one study was able to precipitate withdrawal symptoms in nicotine-dependent rats with subcutaneous naloxone and then reverse

the abstinence symptoms with morphine sulfate.[43] On the other hand, nicotine's neurochemical effects on the brain, and on other neurotransmitters

such as dopamine, closely resemble that of other psychostimulants. (For an in-depth discussion of the physiology of withdrawal see Chap. 15 .)

With so many substances involved in cigarette smoking, it is quite likely that tobacco dependency is a complex addiction, involving both psychological components, such as oral gratification, and physical dependency. It is now widely accepted that the primary addictive component of tobacco is nicotine,[53 , 59 , 78] but this is the subject of some controversy and is supported primarily by indirect evidence.

Clinical Manifestations of Nicotine Withdrawal

Manifestations of nicotine withdrawal can occur within 2â€“8 hours of the last cigarette. In fact, most moderate to heavy smokers experience some withdrawal symptoms as they wake up each morning. Withdrawal reaches maximum intensity at 24â€“48 hours, and then diminishes over a 2-week period of abstinence. After 1 month, symptoms are gone, except for the cravings for cigarettes and an increase in appetite.[6 , 66] Approximately 80% of smokers experience withdrawal symptoms when quitting, and withdrawal is nearly universal among smokers using 20 or more cigarettes per day.[6] Nicotine withdrawal is not confined to cigarette smokers alone. The same syndrome is reported in smokeless tobacco users and chronic users of nicotine chewing gum.[6 , 52]

Most of the symptoms associated with tobacco withdrawal are subjective, leading to an overall feeling of dysphoria. These manifestations, widely described in the literature, are summarized in Table 82-5 .[14 , 27 , 32 , 38 , 52] The most dramatic and intense symptom of tobacco abstinence is a craving for cigarettes, which can continue for months to years.[6] Cravings for cigarettes are less intense and diminish

more quickly in people who are totally abstinent, as compared to those who are only partially abstinent.[66]

One study evaluated 7 smokers in a battery of computerized performance tasks over a 24-hour period of abstinence. With increasing abstinence, the smoker's responses showed increased latencies and decreased accuracy.[71] Moreover, EEG studies evaluating smokers in withdrawal show a decrease in high-frequency activity and an increase in low-frequency activity, consistent with diminished arousal.[32]

Anger/aggression/hostility
Decreased arousal pattern on EEG
Anxiety
Decreased blood pressure
Blurred vision
Decreased heart rate
Confusion
Diminished psychomotor performance
Constipation
Impaired short-term memory
Craving for cigarettes
Reduced plasma catecholamines
Drowsiness
Weight gain
Gastrointestinal upset
Headache
Hunger
Impaired concentration
Irritability/impatience
Moodiness
Restlessness
Sleep disturbance

Subjective Objective

TABLE 82-5. Clinical Manifestations of Nicotine Withdrawal

The most common objective physical manifestation of nicotine abstinence is a decrease in heart rate by a mean of 9 beats/min within the first day of abstinence; it is a unique feature of nicotine withdrawal syndrome.[27] This decrease remains constant when measured over the next 5 weeks of abstinence, suggesting that heart rate reduction in tobacco abstinence reflects the absence of stimulation from nicotine, rather than withdrawal symptomatology.[79] Concentrations of epinephrine and norepinephrine also decrease in abstinent smokers. This is probably another manifestation of the absence of nicotine effect and undoubtedly contributes to the reduction in mean heart rate.[17]

Management of Acute Nicotine Withdrawal

In clinical practice, nicotine withdrawal syndrome is encountered when tobacco users attempt to quit in the interest of their long-term health or when acute illness forces abstinence. The discomfort is a primary obstacle to smoking cessation and contributes significantly, but not solely, to the low success rate of attempts to quit smoking. Therefore, any treatment approach that lessens nicotine withdrawal symptoms, without reinitiating the use of tobacco products, is more likely to aid the effort to quit, which in turn will have many long-term health benefits. An in-depth discussion of smoking cessation management falls outside the purview of a textbook on toxicologic â€œemergencies.â€• Physician counseling, behavioral interventions, nicotine replacement therapies, and select antidepressants raise cessation rates. A brief overview is included because of the current medical and public health significance of this subject.

Nicotine Replacement Therapy

One approach to the treatment of nicotine abstinence syndrome is to provide nicotine without tobacco. This therapy offers nicotine in a safer,

more clinically controllable form that minimizes nicotine withdrawal symptoms. After the patient breaks the smoking habit, the nicotine replacement agent is gradually tapered.[63]

Nicotine gum is the oldest of the nicotine substitution therapies. It ameliorates many symptoms of nicotine withdrawal, especially feelings of irritability, aggression, and dysphoria. However, it seems less effective in eliminating cigarette craving and increased hunger.[10]

The effectiveness of nicotine chewing gum in promoting long-term smoking abstinence has been extensively studied.[33, 74, 75] A meta-analysis of all these studies, with special emphasis on double-blind, randomized, placebo-controlled trials with 1 or more years of followup study, indicates that nicotine chewing gum in conjunction with a formal program of behavioral therapy can produce 1-year abstinence rates of 29â€“49%.[1, 6, 77] On the other hand, when nicotine gum is used in general medical practice, without structured behavioral interventions, improvement in smoking abstinence is short-lived and smoking cessation rates at 6â€“12 months are similar to those of placebo-treated patients.[4, 6, 33]

Unfortunately, many smokers who use nicotine gum to quit develop dependency on the gum itself. As an adjuvant to smoking cessation, nicotine gum should be used for a *maximum* of 3 months. However, several studies have reported continued use of the gum at 1-year followup (6â€“38% of users).[6, 25, 26] Self-administration of the gum may reinforce some of the behavioral patterns that sustain smoking. It can be argued that the behavioral components of the

addictive process must be decisively interrupted for successful treatment of the addiction.[59]

Transdermal nicotine patches have supplanted chewing gum as the preferred nicotine-replacement therapy. Because nicotine patches are easier to use, requiring only once-a-day application, compliance is better. The dose of nicotine delivered to the patient is more predictable, nicotine steady-state concentrations are higher, and different dose

patches make tapering easier to control. Finally, because no specific behavioral action is required of the patient, other than putting the patch on in the morning, a transdermal nicotine patch does not require self-administration of nicotine by the user and therefore does not mimic oral smoking behavior.[59 , 63]

There are four patch systems currently available, each of which comes in several different doses of nicotine. Three of the patch systems are designed for 24-hour use, and the newest is made for 16-hour use to approximate more closely nicotine intake patterns of the smoker.[54] The patches generally deliver steady-state nicotine serum concentrations of 10â€“15 ng/mL, which are maintained throughout the application of the patch.[24]

Several double-blind, placebo controlled studies have demonstrated that, at 6â€“12-month follow-up, transdermal nicotine patch users achieve abstinence 2â€“4 times more frequently than placebo users.[14 , 19 , 22 , 77 , 78] Many studies have demonstrated that long-term efficacy is present even with little or no formal behavioral intervention accompanying the program.[1 , 14 , 77]

The most consistent adverse effect of the transdermal nicotine patch is skin irritation at the site of the patch. In one trial, approximately 5% of patients withdrew from the study because they could not tolerate the cutaneous irritation.[1]

Both nicotine nasal spray and nicotine oral inhaler reduce withdrawal symptoms and promote abstinence more effectively than placebo.[41 , 73 , 76] Both treatment modalities are based on the belief that airway stimulation will mimic smoking more closely and therefore be more effective in reducing cigarette cravings. Furthermore, the application of nicotine to mucous membranes provides a rapid transient rise in serum nicotine and thus reduces cigarette cravings more promptly than slower forms of nicotine delivery.[30] Although these characteristics are probably real, the replication of smoking's airway sensations might actually make long-term abstinence more difficult to achieve.

To date there have been no head-to-head comparisons of any of the nicotine-replacement therapies. Both transdermal nicotine patch and nicotine nasal spray seem to be more effective than nicotine gum in reducing cigarette craving and increased appetite.[30 , 63] A meta-analysis of 103 nicotine-replacement therapy trials, with data from more than 30,000 patients, concluded that all nicotine-replacement therapy modalities were better than placebo in promoting abstinence at 6 or more months. Abstinence odds ratios were highest for nicotine nasal spray and lowest for nicotine gum.[67]

Clearly, nicotine replacement therapies are moderately effective in promoting smoking cessation, especially in the short term. To be successful, the patient must eventually face the inevitableâ€"withdrawal from nicotine itself. Theoretically, if other treatment modalities promote tobacco abstinence effectively without the use of nicotine replacement, they would have a substantial advantage.

Antidepressant Therapy

Antidepressant medications such as bupropion offer an encouraging alternative to nicotine replacement in smoking cessation. The idea of using antidepressants for smoking cessation grows out of the observations that nicotine has antidepressive effects; that anxiety and depression are frequent comorbid conditions in nicotine-addicted patients; that dysphoria is a common symptom of nicotine withdrawal; and that women have a more difficult time with nicotine abstinence.[31]

In a randomized double-blinded placebo-controlled comparison study of sustained-release bupropion, smoking abstinence at 52 weeks was 12% in the placebo group and 23% in the 300-mg per day bupropion group.[31] A subsequent trial, compared bupropion SR and nicotine patch, and both together, for smoking cessation efficacy in 893 subjects. The 1-year cessation rate was 16% in the patch groupâ€"roughly equivalent to placeboâ€"but was 30% in the bupropion group and 35% in the bupropion-plus-patch group. The bupropion-plus-patch group also had the smallest weight gain.[34] Another study of 211 adolescent smokers

also showed modest benefit from the combination of bupropion plus patch compared with patch alone.[37]

The sustained-release bupropion dose currently recommended is 150 mg twice a day. Patients should be started on treatment at least 1 week prior to their smoking quit date and continued on treatment for 8 weeks. There is an increased seizure risk with bupropion, but generally not at the doses recommended for smoking cessation unless patients are otherwise prone to seizures.[34]

Other antidepressants, including monoamine oxidase inhibitors and selective serotonin reuptake inhibitors, have no proven long-term benefit in smoking cessation.[28]

Summary

Nicotine, a tertiary amine from *N. tobacum* and other tobacco plants, is found commercially in a number smoking products and smoking-cessation treatment pharmaceuticals. It is commonly absorbed through the buccal mucosa or respiratory epithelium of the lungs, but can also be absorbed from the skin and intestine. Up to 90% of a nicotine â€œdoseâ€• is metabolized by an inducible P450 hepatic biotransformation, producing 2 inactive metabolites that are slowly excreted by the kidneys. It exerts its physiologic effects on selective acetylcholine receptors, primarily in neural tissue. Although the vast majority of reported nicotine exposures are unintentional and occur in children and produce mild or no toxicity, severe poisoning and even death can result, and there is a narrow range between nontoxic and significantly toxic doses. Clinical manifestations of consequential poisoning are complex but can be characterized as biphasic, with initial excitation followed quickly by inhibition. Management is symptom directed with special emphasis on seizure control and respiratory support.

In terms of smoking cessation management, it should be noted that although several xenobiotics will reduce the severity of nicotine

withdrawal, long-term smoking cessation is more difficult to achieve. In many approaches to smoking treatment, the overall mean 6â€“12-month success rate seems to be approximately 25%.[59] This is, of course, much better than the spontaneous abstinence rate of 1%, but as many as 70% of patients who achieve initial abstinence will be smoking again after 1 year.[16] Whatever approach is taken to treat tobacco abstinence, it seems the patient must start with a strong desire to quit, avoid unusually stressful situations, and have a social support network that encourages the effort to stop smoking. The most successful programs are multimodality treatments that combine counseling or other behavioral therapies with one or more pharmacologic interventions.

Chapter 83
Phencyclidine and Ketamine

Ruben Olmedo

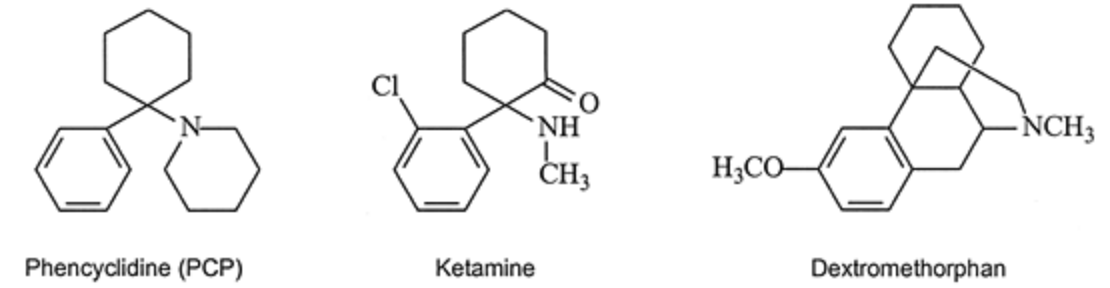

Figure. No Caption Available.

A 17-year-old boy was brought to the emergency department (ED) by his school supervisor and 2 police officers. The boy was extremely agitated, but having transient periods of blank staring

and myoclonic movements of both arms. It took several members of the ED staff to keep him on a stretcher.

Initially, no history was obtainable from the patient, who responded to verbal stimuli with inappropriate physical gestures and a few nonsensical words. The school supervisor reported that the boy had become suddenly agitated and had created a disturbance in the lunchroom, throwing chairs about the room.

His vital signs were: blood pressure, 130/90 mm Hg; pulse, 110 beats/ min; respiratory rate, 18 breaths/min; and temperature, 99.9Â°F (37.2Â°C). He was well developed and well nourished, anicteric, and acyanotic. The head and neck examination were normal. His breath sounds were clear to auscultation. He had a normal heart exam. His abdomen was soft and nontender and his bowel sounds were normal. The skin was cool and diaphoretic. Conjunctivae were normal; extraocular movements were intact, but there was persistent vertical and horizontal nystagmus; pupils were equal at 4 mm and reactive to light; fundi were normal. The patient moved all extremities, had good strength and normal, symmetric deep-tendon reflexes; muscle tone seemed increased and there were periodic myoclonic jerks; plantar flexion was elicited; a sensory examination could not be performed because of the patient's lack of response and agitation.

Blood was drawn for initial laboratory tests and an intravenous infusion of 5% dextrose in 0.45% sodium chloride solution was started at 200 mL/h. Fifty milliliters of 50% dextrose and 100 mg of thiamine were given IV. He was placed on 6 L of oxygen via nasal cannula. Fifty grams of activated charcoal were given together with 50 g of sorbitol by mouth.

The initial laboratory data, including complete blood count, electrolytes, arterial blood gas analysis, and urinalysis, were all normal. An ECG revealed a sinus tachycardia at 110 beats/min and was otherwise normal.

By the time the physical examination and laboratory tests were completed, the patient had become calm and cooperative. He related that while at lunch, one of his friends had put mustard on his sandwich and that it tasted â€œterrific.â€• He recalled finishing the sandwich and then slowly â€œfreaking outâ€• and losing control of his mind and body.

By the time the patient's mother arrived in the ED, his clinical condition had significantly improved. Within 3 hours after the patient's arrival, he was cooperative and his neuropsychiatric examination was entirely normal. Because he had no prior history of drug abuse, he was discharged home and arrangements were made for a followup examination with his pediatrician.

History and Epidemiology

Phencyclidine (PCP) was discovered in 1926, but it was not developed as a general anesthetic until the 1950s. At the time, the Parke Davis drug company was searching for an ideal intravenous anesthetic that would rapidly achieve analgesia and anesthesia with minimal cardiovascular and respiratory depression.[36] It was marketed under the name Sernyl because it rendered an apparent state of serenity when administered to laboratory monkeys. Its surgical

use began in 1963, but PCP was rapidly discontinued when a 10â€“30% incidence of postoperative psychoses and dysphoria was documented over the subsequent 2-year period.[79] By 1967 the use of PCP was limited exclusively to veterinary medicine as a tranquilizer marketed under the name Sernylan.

Simultaneously, in the 1960s, PCP was developing as a San Francisco street drug called â€œthe PeaCe Pill.â€•[66] Numerous street names have been given to phencyclidine: on the West Coast it was called â€œAngel Dust, PCP, crystal, crystal joints (CJs)â€•; Chicago called it â€œTHCâ€• or â€œTACâ€•; the East Coast

opted for â€œthe sheets,â€• â€œHog,â€• or â€œelephant tranquilizer.â€•[120] Ironically, the drug was initially unpopular with drug users because of its dysphoric effects and unpredictable oral absorption.[154] With time, however, its use spread in a similar geographic pattern to that of marijuana and lysergic acid diethylamide (LSD), from the coastal United States to the Midwest region.[66]

Phencyclidine abuse became widespread during the 1970s.[25] The relatively easy and inexpensive synthesis coupled with the common masking of PCP as LSD, mescaline, psilocybin, cocaine, amphetamine, and/or â€œsynthetic THCâ€• (tetrahydrocannabinol) added to its allure and consumption.[120] By the late 1970s PCP abuse had reached epidemic proportions.[7] The Drug Abuse Warning Network (DAWN) reported that the number of PCP related emergencies and deaths more than doubled in the two years from 1975 to 1977. In 1978 the National Institute of Drug Abuse reported that of the young adults (18â€“25 years old), 13.9% had used PCP.[50] The manufacture of phencyclidine was ultimately prohibited in 1978 when the drug was added to the list of federally controlled substances. Classifying PCP as a Schedule II drug led to its decrease in availability and, consequently, a decrease in its use. Although the 1980s brought about a cocaine epidemic that eclipsed PCP, PCP has remained consistently available on the streets, primarily regionalized to large cities in the northeastern United States and in the Los Angeles area,[103] where PCP use continues to rise and fall with societal trends. Because many of the PCP congeners made during the manufacturing process were being abused in place of PCP, the Controlled Substance Act of 1986 made these derivatives illegal and established that the use of PCP's precursor, piperidine, necessitated mandatory reporting. With this new law in place, those possessing similar but not identical illegal substances could be prosecuted. This led to a further decline in the popularity of phencyclidine. Beginning in 1984, the overall use of PCP remained

flat, reaching a nadir in 1994.[182] Since 1994, however, there has been an increase of reported PCP abuse. DAWN reported that the number of PCP-related emergencies increased 28% in the years between 1995 and 2002. According to the 2002 the National Survey on Drug Use and Health (NSDUH), lifetime use of PCP was highest among those 26 years of age and older (3.5%) compared with people ages 18â€“25 years (2.7%) and those ages 12â€“17 years (0.9%).[182] In the 2003 NSDUH report, the number of PCP users remained at approximately 200,000.[183]

Laboratory investigation of phencyclidine derivatives led to the discovery of ketamine, a chloroketone analog. Ketamine was introduced for general clinical practice in 1970 and was marketed as Ketalar, Ketaject, and, for veterinary use, Ketavet. Because ketamine has approximately 5â€“10% of the potency of PCP and a much shorter duration of action, it provides greater control in clinical use. Thirty-five years of clinical experience have established that ketamine provides adequate surgical anesthesia, a rapid recovery, and less prominent emergence reactions than does PCP.[56,81,157,195] Because of the simplicity and efficacy of its use it is regularly employed in operating rooms, emergency departments, and throughout the developing world where little clinical monitoring is available during surgical and emergency procedures.[53,78,79,80,81,82,158,194]

Abuse of ketamine was first noted on the West Coast in 1971.[168] During the 1980s there were reports of its abuse internationally, as well as among physicians.[3,68] The nonmedical use of dissociative anesthetics has continued to increase throughout the 1990s, and into the 2000s in spite of the common complications associated with their use.[181] At present, ketamine, methylenedioxyamphetamine (MDA), and methylenedioxymethamphetamine (MDMA) have regained popularity with today's youth. The same pharmacologic qualities that made ketamine more popular than PCP clinically are also responsible for its nonmedical popularity. Ketamine is regularly

consumed at all-night â€œrave partiesâ€• and in nightclubs because of its â€œhallucinatoryâ€• and â€œout-of-bodyâ€• effects, relatively inexpensive price, and short duration of effect (a single snort lasting between 15 and 20 minutes).[11,44,92,96,196]

The use of ketamine is not limited to the inner city. In the past decade, the media reports police arrests in affluent suburban communities for possession and sale of ketamine, as well as more in-depth and frequent reporting of the effects of its toxicity among users.[44,92,155,196] In contrast to PCP, ketamine is not manufactured illegally, but rather, diverted illicitly from legitimate medical, dental, and veterinary sources. Additionally, with the advent of the Internet, its availability has dangerously grown nationwide; a sham â€œbiotechâ€• Internet company was seized by New York City police in the year 2000 for selling so-called date-rape drugs, including ketamine.[131]

Adverse reactions do occur, although, there are few reports of fatalities secondary to ketamine during this period of increased use.[72,111,136] Because of its abuse potential, ketamine was placed in Schedule III of the Controlled Substance Act in 1999.[157] In 2002, DAWN reported that there was a dramatic rise (more than 2000%) of ketamine-related ED visits between 1994 and 2001. Despite any clear reason, after a peak of 679 ketamine-related ED visits in 2001, there was a decline to 260 visits in 2002.[183]

Pharmacology

Chemistry

Phencyclidine's chemical name 1-(1-phenylcyclohexyl) piperidine provided the basis for its street acronym PCP. During its unlawful chemical synthesis, numerous analogs are made which have similar effects on the central nervous system (CNS) and which have been used as PCP substitutes. These â€œdesignerâ€•

arylcyclohexylamines are aliphatic- or aromatic-substituted amines, ketones, or halides, and appear similar to the parent compound. More than 60 psychoactive analogs are mentioned in the medical literature and the following salient points of the 5 most prevalent compounds are worth mentioning. TCP and PCC are piperidine derivatives. Piperidine, the synthetic precursor, was formerly easily purchased for manufacturing PCP and its derivatives. TCP, a thiophene analog (1-[1-(2-thienyl)cyclohexyl] piperidine), produces even more intense effects than PCP. An intermediate of PCP synthesis, PCC (1-piperidino-cyclohexanecarbonitrile) was a constituent of up to 22% of illicit drug preparations analyzed for phencyclidine. This most likely resulted from a poor manufacturing process.[14,167] PCC degrades to piperidine, which is recognizable by its strong fishy odor. The presence of its carbonitrile group adds to its toxicity by generating cyanide when smoked.[12,14,174,175] The pyrrolidine derivative, PHP (phencycloclohexylpyrrolidine), is comparable clinically to PCP and is not detected by many of the available drug-screening methods.[27,89] More potent than PCP, PCE (1-phenyl-cyclohexylethylamine) was commonly available on the street as a white powder indistinguishable from PCP.[167]

Ketamine and tiletamine, two legal congeners of PCP, are used clinically for sedation and anesthesia. In large quantities, both are also used in veterinary medicine for animal sedation. Ketamine (Ketaset and Ketalar) is the only dissociative anesthetic product manufactured for human use for the purpose of anesthesia, conscious sedation, and the treatment of bronchospasm. The development of a mechanistic approach to pain therapy in the last 15 years has brought a renewed interest in the use of ketamine as an adjuvant to multimodal pain treatment. Ketamine is used prophylactically and therapeutically in children and adults in the management of postoperative pain. For the treatment of pain ketamine is administered intravenously (median dose: 0.4 mg/kg;

range: 0.1â€“1.6), orally, intramuscularly, rectally, subcutaneously, intraarticularly, caudally, epidurally, transdermally, intranasally, or added to a patient-controlled analgesia device.[61,90,107,160]

The molecular structure of ketamine [2-(ortho-chlorophenyl)-2-methylaminocyclohexanone] contains a chiral center, producing a racemic mixture of 2 resolvable optical isomers or enantiomers, the D(+)-isomer and L(â€“)-isomer. Commercially available preparations of ketamine contain equal concentrations of the 2 enantiomers. These 2 molecules differ in their pharmacodynamic effects. In a randomized, double-blind evaluation of patients undergoing surgery, the D(+)-isomer of ketamine was a more effective anesthetic, but manifested a higher incidence of psychotic emergence reactions than the L(â€“)-isomer. In other studies, the D(+)-isomer causes a greater increase in both blood pressure and pulse than the D(â€“)-isomer, as well as more bronchodilating effects.[158,195]

Pharmacokinetics and Toxicokinetics

Phencyclidine is a white, stable solid that is readily soluble in both water and ethanol. It is a weak base with a pK_a between 8.6 and 9.4 with a high lipid-to-water-partition coefficient. It is rapidly absorbed from the respiratory and the gastrointestinal tracts; as such, it is typically self-administered by oral ingestion, nasal insufflation, smoking, or intravenous and subcutaneous injection.

The effects of PCP are dependent on routes of delivery and dose. Its onset of action is most rapid from the intravenous and inhalational routes (2â€“5 minutes) and slowest (30â€“60 minutes) following gastrointestinal absorption.[42,43] Sedation is commonly produced by doses of 0.25 mg intravenously, whereas oral ingestion typically requires 1â€“5 mg to produce similar sedation. Signs and symptoms of toxicity usually last 4â€“6 hours, and large overdoses generally resolve within 24â€–48 hours, but

effects may persist in a chronic user.[16,54,57,119,141,154] However, in the PCP-intoxicated patient, the relationships between dosage, clinical effects, and serum levels are not reliable or predictable.

There are several explanations for PCP's protracted CNS effects. It has a large volume of distribution of 6.2 L/kg.[42,200] Its high lipid solubility accounts for its entry and storage in adipose and brain tissue. Also on reaching the acidic CSF, PCP becomes ionized, producing CSF concentrations approximately 6â€“9 times greater than those of serum.[133]

PCP undergoes first-order elimination over a wide range of doses. It has an apparent terminal half-life of 21 Â± 3 hours under both control and overdose settings.[42,95] More prolonged toxicity has been reported in patients who â€œbody-packâ€• PCP in plastic bags.[95,203] Ninety percent of PCP is metabolized in the liver and 10% is excreted in the urine unchanged. Evidence indicates that PCP undergoes hepatic oxidative hydroxylation into 2 monohydroxylated and 1 dihydroxylated metabolites. All 3 compounds are conjugated to the more water-soluble glucuronide derivatives and then excreted in the urine.

Urine pH is an important determinant of renal elimination of PCP. In acidic urine, PCP becomes ionized and then cannot be reabsorbed. Acidification of the urine increased renal clearance of PCP from 1.98 Â± 0.48 L/h to 2.4 Â± 0.78 L/h.[42] Additional studies have found a much higher renal clearance (8.04 Â± 1.56 L/h) if the urine pH was decreased to <5.0.[10] Although this may account for a 23% increase in the renal clearance, it only represents a 1.1% increase of the total drug clearance.

Similarly, ketamine is water soluble but also has a high lipid solubility that enables it to distribute to the CNS readily. It has a pK_a of 7.5 and a volume of distribution of 1.8 Â± 0.7 L/kg. Ketamine has approximately 10% of the potency of PCP,[81,97] and human trials demonstrate that its clinical effects, similar to PCP, are both route and dose dependent.[46,49,56,176] Peak

concentrations occur within 1 minute of IV administration and within 5 minutes of a 5-mg/kg IM injection.[195,204] Ketamine distributes immediately into the CNS with the duration of its hypnotic and anesthetic effects being principally caused by its redistribution from the brain to other tissues.[195] Recovery time averages 15 minutes for IV administration, but it is prolonged to between 30 and 120 minutes for intramuscular administration. Oral or rectal doses are not well absorbed and undergo substantial first-pass metabolism.[158,195] In contrast to oral administration of ketamine where symptoms last 4â€“8 hours, symptoms after nasal administration last for 45â€“90 minutes.

Ketamine is extensively metabolized in the liver by the cytochrome P450 (CYP) isozyme CYP2B6 and to a lesser extent by CYP3A4 and CYP2C9.[202] Its biotransformation is complex with numerous metabolites described.[2,158,195] The major pathway involves its *N*-demethylation to norketamine, a metabolite with one-third the anesthetic potency of ketamine. Norketamine is hydroxylated at different sites within its hexanone ring, producing varying second chiral centers. The majority of these diastereoisomers are glucuronidated to more water-soluble derivatives that are then excreted in the urine.[81,158] Ketamine also undergoes ring hydroxylation prior to *N*-demethylation as a minor metabolic pathway. The elimination half-life, which reflects both metabolic and excretory phases, is 2.3 Â± 0.5 hours and is prolonged when xenobiotics requiring hepatic metabolism are coadministered.[117] Because of the enzymatic hepatic metabolism, both tolerance, and enzyme induction are reported following chronic administration.[81,158]

Available Forms

PCP is available on the street in a variety of forms, including powder, liquid, tablets, leaf mixtures, and rock crystal. Because of its uncontrolled illegal manufacture, the contents of PCP sold vary

considerably, with powder often the purest form, containing approximately 5 mg per dosage.[153] Leaf mixtures are made by sprinkling approximately 1â€“10 mg of phencyclidine onto parsley, oregano, mint, tobacco, or marijuana. A typical PCP joint (known as â€œcrystal joint,â€• â€œKJ,â€• or â€œsupergrassâ€•) is developed for smoking and contains about 1 mg per 150 mg of plant product.[7] Mentholated cigarettes dipped into liquid PCP are known as â€œsupercools.â€•

Since PCP's inclusion in the federal Controlled Substance Act of 1970, PCP has been infrequently incorporated into marijuana cigarettes. Currently, there are reports of marijuana cigarettes again being adulterated with PCP. These are being sold on the street under varying names like â€œIllyâ€• in Connecticut, â€œHydroâ€• in New York City, â€œDipâ€• in New Jersey, â€œWetâ€• in Philadelphia, and â€œFryâ€• in Texas.[91] The cigarettes are treated with â€œembalming fluid,â€• which

allegedly enhances the drug's euphoric effects. Embalming fluid, which contains formalin (formaldehyde in methanol), is used as a medium to allow a uniform distribution of PCP in these cigarettes.[91] It is difficult to discern whether this â€œenhancedâ€• mixture is purchased intentionally or is placed in these cigarettes surreptitiously.

On the street and on the Internet, ketamine is known as â€œvitamin K,â€• â€œSpecial K,â€• â€œSuper K,â€• â€œKet,â€• or simply â€œK.â€• It is available in a liquid form that is dried into a pure-white crystalline powder and is typically self-administered by ingestion or insufflation in a fashion similar to PCP. It is rarely injected intravenously or intramuscularly in liquid form.

When used by injection there is an observed demographic and behavioral difference among those who initiate drug injection use with ketamine and those who initiate injection use with another

drug and later transition into ketamine injection.[114]

Ketamine is primarily sold as tablets, capsules, or powder. These formulations are often adulterated with substances such as caffeine, MDMA, ephedrine, methamphetamine, heroin, and cocaine (a mixture known as CK or Calvin Klein).[59,161] In fact, other than alcohol, MDMA (39%), heroin (17%), and cocaine (14%) are the most frequently mentioned substances used with ketamine.[185] Exemplifying the commercial growth of ketamine, some of the tablets are even found to contain a â€œKâ€• logo.[59] Common sedating doses are 75â€“300 mg orally (30â€“75 mg for insufflation). Higher doses, ranging between 300 and 450 mg orally (100â€–250 mg for insufflation), result in substantial CNS toxicity. These manifestations are similar to the clinical emergence reactions that patients experience with ketamine anesthesia.

Pathophysiology

The arylcyclohexylamines, of which PCP and ketamine are prototypes, are a group of anesthetics that functionally and electrophysiologically â€œdissociateâ€• the somatosensory cortex from higher centers.[46,194] The precise mechanisms by which PCP and ketamine achieve these effects are complex and not fully understood; however, investigation of the nature of PCP-induced psychosis has led to a substantial identification of the various sites of PCP activity.

Most studies demonstrate that PCP and ketamine bind with high affinity to sites located in the cortex and limbic structures of the brain.[122] They block the *N*-methyl-D-aspartate (NMDA) receptors at serum concentrations encountered clinically.[190,205] Analogs of PCP (TCP, PCE, PHP, ketamine) and dizocilpine or MK-801 also interact with the NMDA receptor in a doseâ€“response manner that corresponds appropriately to their neurobehavioral effect.[26,164,197] These xenobiotics bind to the NMDA receptor at a site independent of glutamate.[97,102,122,199] As such they antagonize glutamate's

action on this channel noncompetitively and block Ca^{2+} influx (Fig. 14-14).

PCP and ketamine bind to the biogenic amine reuptake complex with 10â€“20% of the affinity to which they bind to the NMDA receptor. Binding occurs at physiologic concentrations that normally take place after subanesthetic doses.[4,149] This weak inhibition of the catecholamine and dopamine reuptake accounts for the respective sympathomimetic and psychomotor effects. An increase in blood pressure and heart rate is induced. Rapid intravenous infusion produces a more pronounced effect than by intramuscular injection, with the D(+)-isomer having a greater effect than the D(â€“)-isomer.[195]

In significant overdoses, PCP and ketamine also stimulate Ïƒ receptors at concentrations generally associated with coma, although with lower affinity than NMDA receptors.[177,198] Both D_2 and Ïƒ receptors have an inhibitory effect on the cholinergic receptor pathways.[198] At the higher concentrations typically associated with death, PCP and ketamine also bind to the nicotinic, opioid, and muscarinic cholinergic receptors.[189]

Data indicate that NMDA antagonists produce effects on behavior, sensation and cognition that resemble aspects of endogenous psychoses, particularly schizophrenia.[98,146] The behavioral abnormalities were first observed in studies in the late 1950s when PCP, administered to healthy volunteers, generated a form of organic psychosis that mimicked schizophrenia. When the drug was administered to schizophrenic patients it uniformly intensified their primary symptoms of profound disorganization, some of these symptoms lasted for weeks.[119] PCP psychosis is so similar to schizophrenia that many psychiatrists cannot distinguish them without a prior indication of drug abuse history.[173]

Current interest in the role of excitatory neurotransmitter systems in the pathophysiology of schizophrenia has led to similar observations in patients after ketamine administration.

Subanesthetic doses of ketamine administered to both healthy and schizophrenic volunteers induced a mild, dose-related, short-lasting increase in psychotic symptoms. Although the normal and schizophrenic volunteers had different levels of baseline psychosis, the magnitude, time course, and doseâ€“response changes in positive symptoms were similar across the two populations. Both groups experienced thought disorganization, such as concreteness and loose association, hallucinations and delusions along a gradient of intensity.[109,111,112,113]

There is a connection between PCP psychosis and sensory processing. PCP and ketamine inhibit sensory perception in a dose-dependent manner. This processing in sensory information corresponds to their relative affinities to the NMDA receptor and not to the Ïƒ receptor.[6,149] Clinically, the impairment of sensory input produced by PCP resembles that of patients who are deprived of sensory stimulation.[132] When external stimulation was reduced by environmental sensory deprivation, the psychotomimetic effects of PCP were diminished,[40] giving credence to the theory that it may not be anxiety that causes perceptual dysfunction in schizophrenia, but the converse.

Many of the NMDA antagonists, including PCP and ketamine, have a negative effect on cognition and memory. There is substantial animal evidence, including primates, that repeat administration of PCP and ketamine result in cognitive and memory impairement.[87,100] Both impair concentration, recall, learning, and retention of new information.[13,30,52,54,73,86,87,88,109,126,135,143] In humans, ketamine selectively impairs explicit,[72] episodic,[51,138,139] and procedural memory,[138] as well as disrupts frontal cortical function as measured by the Wisconsin Card Sorting Task and verbal fluency[109,126] in a doseâ€“dependent manner. In addition, the frequent use of ketamine produces long-lasting impairments in many aspects of memory.[52,139] Learning and memory impairments in volunteers who were administered subanesthetic doses of ketamine (0.65 mg/kg) are independent of the subject's attention

and related psychosis.[126] Accordingly, it is presumed that the NMDA receptor antagonists interfere with those functions that integrate interoceptive and exteroceptive input in which goal-directed action becomes possible, similar to the organic psychosis in schizophrenia.

It was discovered that hypofunction of the NMDA receptor causes neuroanatomical and neurobehavioral toxicologic effects.

Animals exposed to NMDA antagonists such as PCP and dizocilpine, transiently demonstrated neuronal vacuolar degeneration in the retrosplenial cortex and the posterior cingulate areas of the brain.[144,145] Single high doses or repeated exposure to NMDA receptor antagonists are associated with a higher incidence of cellular death.[45,62,63,144] This injury seems to be related to the induction of selective expression of individual heat shock proteins in this anatomical area.[166] The major function of cingulate cortical neurons is to mediate affective responses to pain.[191]

Excitatory amino acids are neurotransmitters responsible for mediating seizure activity in the brain. As NMDA inhibitors, the anticonvulsant properties of PCP and ketamine are inconclusive. Animals administered PCP or PCP analogs progress through dose-related clonic activity followed by tonicâ€“clonic convulsions, as is typical of classic convulsant compounds.[149] Animal research also demonstrates wide interspecies variability of the EEG effects of PCP.[57] In a murine seizure model, ketamine possessed selective anticonvulsant properties.[31] In addition, ketamine preserves learning proficiency in rats when administered shortly after onset of status epilepticus, an effect that may prove useful in the clinical setting when combined with conventional antiepileptic medications.[178]

In humans, although these dissociative xenobiotics induce excitatory activity in the thalamus and limbic areas, they do not affect cortical regions.[48,49,56,69] Excitation, muscle twitching,

posturing,[134] and tonicâ€“clonic motor activity with or without EEG changes are reported with these subcortical EEG alterations.[34,47,69,134] In the clinical setting, many report ketamine to possess anticonvulsant properties at clinical doses that may be explained by an NMDA inhibitory effect.[34,47]

The NMDA receptor is also responsible for the development of the neuronal organization of the central nervous system.[93,94,169,170] It is linked to hypoxicâ€“ischemic brain injury by mediating calcium influx, a final pathway in cell death. The uninhibited firing of NMDA afferent neurons secondary to brain injury causes their death, as well as the death of efferent neurons downstream. In neonatal rats, ketamine increases the rate of neuronal apoptosis.[163] NMDA antagonists such as PCP block hypoxic brain injury from stroke and trauma.[17,118] In a rat model of ischemic stroke, PCP had a protective effect on the brain, demonstrated by a decreased rate of seizure activity.[17] This effect is transient and has not been studied in human subjects.

PCP induces modest tolerance in rats and squirrel monkeys. The development of tolerance is mostly secondary to PCP's pharmacologic effect rather than to biodispositional changes. Dependence was also observed in monkeys who self-administered PCP (10 mg/kg/d to serum concentrations of 100â€“300 ng/mL) over 1 month by the appearance of dramatic withdrawal signs when access was denied. Signs included vocalizations, bruxism, oculomotor hyperactivity, diarrhea, piloerection, difficulty remaining awake, tremors, and, in 1 case, convulsions.[15] These signs appeared within 8 hours of abstinence and were most severe at about 24 hours. When either PCP or ketamine (2.5 mg/kg/h) was readministered to the animals, PCP withdrawal symptoms were reversed, indicating cross-dependence from PCP to ketamine.[20,172]

Physiologic dependence in humans has not been studied formally. It is implied to occur by the observation that 68 chronic PCP users

developed depression, anxiety, irritability, lack of energy, sleep disturbance, and disturbed thoughts after 1 day of abstinence from drug use.[156] Additionally, neonates whose mothers used PCP developed jitteriness, vomiting, and hypertonicity that lasted for at least 2 weeks.[180] These symptoms may represent PCP withdrawal or intrinsic teratogenic effects on neurologic development.[76,93] Although there are no controlled studies observing the physiologic symptoms of withdrawal in humans who chronically use PCP or ketamine, there is a definite psychological dependence on the sensations experienced during recreational use of the drugs.[168] There are few case reports of ketamine dependency in the medical literature where patients report a need to use an increased quantity of drug to get the same effect.[137,150] In addition, ketamine impairs response inhibition, which is found to be related to increases in subjective ratings of desire for the drug.[138]

Clinical Manifestations

The reported signs and symptoms of patients presenting to the emergency department with PCP toxicity are variable. The variations are a result of differences in dosage, the multiple routes of administration, concomitant drug use, and other associated medical conditions. In addition, individual differences in susceptibility to the drug's effects, the development of tolerance in chronic users, as well as contaminants in the drug manufacture, may account for erratic clinical findings.

Vital Signs

Body temperature is rarely affected directly by PCP and ketamine. In one large series, only 2.6% of patients demonstrated hyperthermia (temperature >101.8Â°F [38.8Â°C]).[129] In an experimental animal model, PCP failed to increase body temperature.[36,57] When hyperthermia does occur, all the known

complications, including encephalopathy, rhabdomyolysis, myoglobinuria, electrolyte abnormalities, and liver failure, occur (Chap 16).[8,19,39,151]

Most PCP- and ketamine-toxic patients demonstrate mild sympathomimetic effects. PCP consistently increases both the systolic blood pressure (SBP) and diastolic blood pressure (DBP) in a dose-dependent fashion.[36,57] (Doses of 0.06 mg/kg of PCP IV increased the SBP and DBP by 8 mm Hg, whereas 0.25 mg/kg produce a 26 and 19 mm Hg increase in SBP and DBP, respectively.) PCP also increases the heart rate, although inconsistently.[84] Likewise, ketamine produces mild increases in blood pressure, heart rate, and cardiac output via this same mechanism.[49,121,176,186,195]

Cardiopulmonary

Rarely are cardiovascular catastrophes encountered in PCP toxicity.[60,130] These complications may result from direct vasospasm of blood vessels,[5,35] causing severe systemic hypertension[61] and cerebral hemorrhage.[22] Hypertension, abnormal behavior, and miosis in children strongly suggest PCP poisoning.[105]

The effect of PCP and ketamine on cardiac rhythm is controversial. Dysrhythmias are only observed in animals poisoned with very large doses of PCP. Ketamine is observed to both enhance and diminish epinephrine-induced dysrhythmias in animals.[21,58,85,106] The considerable experience in the use of ketamine anesthesia on humans undergoing surgery or cardiac catheterization has not demonstrated prodysrhythmic effects.[65,142]

As these dissociative anesthetics were designed to retain normal ventilation, hypoventilation is uncommon. In clinical studies, PCP increased the minute ventilation, tidal volume, and respiratory rate of volunteers.[84] Clinically, in PCP-toxic patients, irregular

respiratory patterns occur with tachypnea much more often than

with bradypnea.[8,129] Hypoventilation, when present, is usually secondary to the use of particularly high doses of PCP. Pulmonary edema secondary to respiratory depression is also a rare occurrence. Large doses of PCP (20 mg/kg) administered to laboratory animals produced respiratory depression.[36] Although respiratory depression in humans is an extremely rare event, it has been reported with fast or high-dose infusions of ketamine.[77,195] In fact, ketamine has been used successfully to prevent intubation in patients with refractory asthma.[71,159,181,195]

Neuropsychiatric

The majority of patients with PCP and ketamine toxicity who are brought to medical attention manifest diverse psychomotor abnormalities.[12,18,28,68,100,188] As dissociative anesthetics, these drugs produce a lack of response to external stimuli by dissociating various elements of the mind. Consciousness, memory, perception, and motor activity appear dissociated from each other. This dissociation prevents the user from attaining cognition and properly assembling all this information to construct a reality. Clinically the person may appear inebriated, either calm or agitated, and sometimes violent. In large overdoses, the drug's anesthetic effect causes patients to develop stupor or coma. In recreational use, â€œdissociativesâ€• are not taken for these effects, but rather for so-called out-of-body experiences. In addition patients often have disordered thought processes (including disorientation as to time, place, and person) or amnesia, paranoia, and dysphoria.[67]

The manifestations of PCP and ketamine toxicity are better illustrated by the results of their effects in controlled human studies. Volunteers who took oral PCP doses of up to 7.5 mg/d, or ketamine 0.1 mg/kg, exhibited inebriation, but higher doses (PCP

>10 mg/d; ketamine 0.5 mg/kg) generally caused a more severe impairment of mental function.[57,109] Intravenous doses of 0.1 mg/kg of PCP[16,54,119,141,162] or 0.5 mg/kg of ketamine[109,149] causes diminution in all sensory modalities (pain, touch, proprioception, hearing, taste, and visual acuity) in a doseâ€“dependent fashion. Both drugs also cause feelings of apathy, depersonalization, hostility, isolation, and alterations in body image.[16,54,70,109,119,149] The deficits in sensory modalities are evident prior to the development of the psychological effects of PCP, with pain perception disappearing first. This alteration in analgesic perception is caused by a blocking action on the thalamus and midbrain (Fig. 83-1).[141]

Abnormal stereognosis and proprioception occur in a doseâ€“dependent manner. This disturbed perception results in body image distortions described as â€œnumbness,â€• â€œsheer nothingness,â€• and â€œdepersonalization.â€• The decrease of proprioceptive sensation to gravity probably gives the sensation of â€œtrippingâ€• or â€œflying.â€• Because all sensory modalities are affected, visual, auditory, and tactile illusions and delusions are common. Hallucinations are typically auditory rather than visual, which are more common with LSD use. Ketamine's hallucinogenic effects on healthy human volunteers are linearly related to steady-state concentrations between 50 and 200 ng/mL.[23] The majority of ketamine users report experiencing a â€œk-hole,â€• a slang term to the intense psychological and somatic state experienced while under the influence of ketamine. This experience varies with the individual, but can include buzzing, ringing or whistling sounds, traveling through a dark tunnel, intense visions and out-of-body or near-death sensations.[55]

The reaction to the misperceived or disconnected reality may result in unintentional actions and violent behavior. The hallmark of PCP toxicity is the recurring delusion of superhuman strength and invulnerability resulting from both the anesthetic and dissociative properties of the drug. There are case reports of

patients presenting with trauma either from jumping from high altitudes, fighting large crowds or the police, or self-mutilation. The true extent and incidence of violence is probably less than previously suggested.[24]

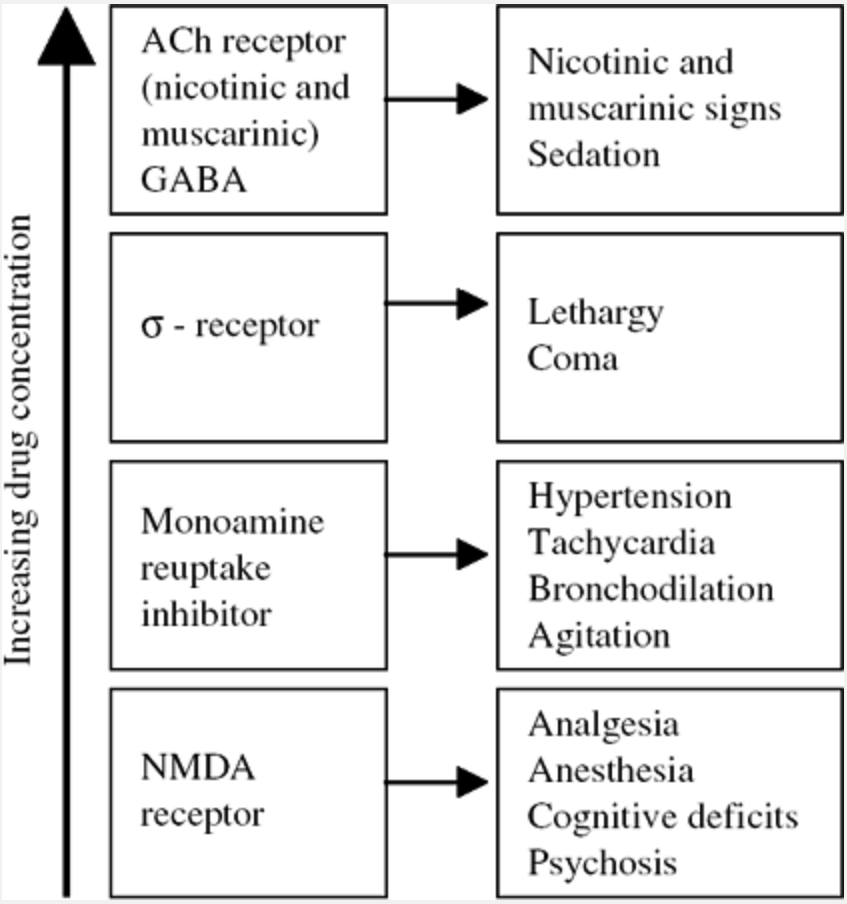

Figure 83-1. Clinical effects of phencyclidine and ketamine. Phencyclidine and ketamine bind to different receptors in the CNS with varying degrees of affinity; that is an increasing concentration is necessary to achieve the consequential clinical effects. ACh = acetylcholine.

Typically, neurologic signs include rotatory nystagmus, ataxia, and

altered gait. Initially, except for ataxia, motor movement is not impaired, until the patient becomes unconscious. On physical examination, use of dissociative agents typically produces relatively small pupils and (horizontal, vertical, and/or rotatory) nystagmus, and diplopia. In the largest case series reported to date, nystagmus and hypertension were noted in 57% of patients who had taken PCP.[129] Smaller and more limiting studies have found an incidence of nystagmus of 89% or higher.[18] Other cerebellar manifestations were also encountered, most notably dizziness, ataxia, dysarthria, and nausea. A pooled data compilation of 35 reports demonstrated that emesis occurred 8.5% of the time.[81] In fact, Internet chat groups devoted to substance abuse commonly direct users to â€œmix dissociatives with marijuanaâ€• for its antiemetic effect.

Larger doses of PCP produce loss of balance and confusion, the latter characterized by inability to repeat a set of objects, frequent loss of ideas, blocking, lack of concreteness, and disordered linguistic expression.[51,57,109,119,162] Similarly, ketamine users report a high incidence of incoordination, confusion, unusual thought content and an inability to speak.[55] In general, dissociative anesthetics stimulate the central nervous system but seizures rarely occur, except at high doses. The largest case series of PCP-toxic patients detected a 3.1% incidence of seizures.[129]

Although PCP- and ketamine-toxic patients also present with motor disturbances, it is not clear to what extent PCP and ketamine are actually responsible for these manifestations. The most common of the reported disturbances are dystonic reactions: opisthotonos, torticollis, tortipelvis, and risus sardonicus (facial

grimacing). Myoclonic movements, tremor, hyperactivity, athetosis, stereotypies, and catalepsy also occur.[12,29,68,129] A slight increase in muscle tone results from a dopaminergic effect.[119] Laryngospasm requiring intubation has been reported after the use of ketamine anesthesia. The incidence of this

complication is less than 0.017%.[81] In comparison, the incidence of laryngospasm following traditional general anesthesia is 2%.[147]

Emergence Reaction

The acute psychosis, observed during the recovery phase of PCP anesthesia, limits its clinical use. This bizarre behavior, characterized by a confused state, vivid dreaming, and hallucinations, is termed an â€œemergence reaction.â€• These reactions occur most frequently in middle-age males, with a reported incidence of 17â€“30%.[84,104] The most violent emergence reactions follow an intravenous dose of approximately 0.25 mg/kg (total: 20 mg) of phencyclidine.[57] The mildest degrees of agitation produced by phencyclidine resemble the effects of ethanol intoxication. These same postanesthetic reactions also limit the clinical use of ketamine. The incidence of emergence reactions following ketamine administration may approximate 50% in adults and 10% in children.[81] Patients older than age 10 years, females, and persons who normally dream frequently and/or have a prior personality disorder incur the greatest risk.[81] The incidence of the occurrence of emergence reactions appears to be exacerbated when the drugs are rapidly administered intravenously, and in those patients who are exposed to excessive stimuli during recovery. Although it has not been proved in a controlled study, reducing external stimuli during the recovery phase might reduce emergence reactions.

Both cholinergic and anticholinergic clinical manifestations occur in the PCP- or ketamine-toxic patient. Miosis, mydriasis, blurred vision, profuse diaphoresis, hypersalivation, bronchospasm, bronchorrhea, and urinary retention occur.[12,18,116,128,129] Clinically, ketamine stimulates salivary and tracheobronchial secretions; both of which are equally and effectively inhibited by atropine and glycopyrolate.[137] Furthermore, in a randomized, double-blind trial, after infusion of 1.5 mg/kg of ketamine in

healthy volunteers, physostigmine decreased nystagmus, blurred vision, and the time to recovery.[185]

Ironically, the very characteristics that were thought to make phencyclidine ideal for anesthesiaâ€”the preservation of muscle tone and cardiopulmonary functionâ€”magnify the difficulties in managing an individual who manifests dysphoria after an overdose. The course of delirium, stupor, and coma associated with PCP and ketamine is extremely variable, although the manifestations are much milder and shorter acting following ketamine use.

Diagnostic Testing

Most hospital laboratories do not perform quantitative analysis of PCP, but many can do a qualitative urine test for the presence of the drug. Qualitative testing is more important than a quantitative determination as serum concentrations do not correlate closely with the clinical effects. PCP may not be part of a routine toxicologic screening and it therefore may be necessary to request a specific analysis if confirmation is required.

When a routine toxicologic screen is reported as negative this result should not lead to the erroneous conclusion that PCP exposure has been excluded. If it is necessary to confirm the suspicion that PCP is the offending agent, urine is most commonly used for analysis, although serum, and possibly gastric contents, can be employed. Rarely is it essential to make this determination.

PCP is qualitatively detected by an enzyme immunoassay at a sensitivity of 10.00 ng/mL. High-affinity antibodies were once studied as specific PCP antagonists that may reverse PCP-induced toxicity.[148,187] The detection of PCP is thus dependant on the concentration of PCP in the body fluid tested and the affinity of the antibody for the PCP molecule. As such, the immunoassay antibody binding to a molecule similar to PCP can anticipate false-positive

reactions. Metabolites of PCP, such as PCE, PHP, TCP and its pyrrolizidine derivative TCPy, cross-react with the immunoassay at concentrations 30 times higher than those used to detect PCP. Because of its similar structure to PCP, dextromethorphan and its metabolite dextrorphan, also cross-react with Syva enzyme-multiplied immunoassay and fluorescence polarization PCP assays (Chap. 7).[92]

Although nonspecific, laboratory findings resulting from PCP use can include leukocytosis, hypoglycemia, and elevation of muscle enzymes, myoglobin, BUN, and creatinine.[129] The EEG reveals diffuse slowing with Î¸ and Î´ waves, which may return to normal before the patient improves clinically.

There is no commercially available immunoassay for ketamine. When necessary, ketamine is detected by gas chromatography and mass spectroscopy. The increase in popularity in ketamine use in certain parts of the world has led to the development of rapid-detection urine assays that are sensitive, specific, and accurate.[37,192] There is anecdotal evidence that ketamine also cross-reacts with the urine PCP immunoassay because of their structural similarity.[165] Other authors, including the manufacturer who tests the reactivity of the commercially available PCP immunoassay with ketamine, do not find such results.[32,188]

Management

Agitation

Conservative management is indicated for PCP and ketamine toxicity and includes maintaining adequate respiration, circulation, and thermoregulation. The psychobehavioral symptoms observed during acute dissociative reactions and during the emergence reaction are similar. To treat the symptoms of agitation and alteration of mental status of acutely toxic PCP patients, it is

helpful to recognize that both pharmacologic[1,33,38,41,64,81,82,123,127] and behavioral[40,41,81,110] modalities have been employed to diminish agitation and emergence phenomena during conscious sedation with ketamine. To prevent self-injury, a common form of PCP-induced morbidity and mortality, the patient must be safely restrained, initially physically, and then chemically. An intravenous line must be established and blood drawn for electrolytes, glucose, BUN, and creatinine determinations. The use of 0.5â€“1.0 g/kg of body weight of dextrose and 100 mg of thiamine HCl intravenously should be considered if indicated.

Psychomotor agitation from PCP toxicity may cause hyperthermia and should be identified early on. Treatment should be accomplished immediately with adequate sedation to control motor activity. Physical restraint should only be used temporarily, if necessary, until chemical sedation is achieved. Rapid immersion in an ice water bath may be necessary because body temperatures greater than 106Â°F (41.1Â°C) place the patient at a great risk for end-organ injury. These patients will need volume repletion and

electrolyte supplementation because hyperthermia increases fluid loss from sweat.

In the pharmacologic treatment of emergence reactions, butyrophenones and benzodiazepines have been employed with benzodiazepines demonstrating the most success. A benzodiazepine such as diazepam, administered in titrated doses of up to 10 mg intravenously every 5â€“10 minutes until agitation is controlled, is usually safe and effective. Numerous studies demonstrate the benefits of benzodiazepines, although under certain conditions,[38,81] they may prolong recovery time. Midazolam may be more effective than diazepam under certain circumstances.[33,127] In contrast, phenothiazines may lower the seizure threshold, and both phenothiazines and butyrophenones may cause acute dystonic reactions. Phenothiazines may also

cause significant hypotension, worsen hyperthermia, and exacerbate any anticholinergic effects from these drugs.

Some behavioral modalities have also been implemented in the treatment. Early studies demonstrated that the psychotomimetic effects of PCP were diminished when external stimulation was reduced by environmental sensory deprivation.[40] The practice of placing patients in a quiet room with minimal sensory stimulation is recommended by many, but has never been formally studied in a double-blind, controlled trial. Conversely, it is observed in patients undergoing ketamine anesthesia that emergence reactions are less violent when patients are talked to or when music is played.[110,171]

Although it is always important to ask the patient the names, quantities, times, and route of all drugs taken, the information obtained from such a patient is notoriously unreliable. Even when the patient is trying to cooperate and give an accurate history, many street psychoactive xenobiotics are drug mixtures whose contents are unknown to the patient. Consequently, pharmacologic management is complex and often sign- or symptom-dependent. Although some authors have attempted to define the appropriate therapy for specific PCP congeners and for ketamine-induced psychosis, no single approach has been consistently efficacious.[73,108,124]

Decontamination

Patients with a history of recent oral use of PCP are candidates for gastrointestinal decontamination, but they should be considered too unstable for induced emesis, as uncontrolled agitation or respiratory compromise can rapidly develop. Although there is rarely, if ever, an indication, if congestion is suspected, orogastric lavage may be initiated but the patient may need to be sedated. Activated charcoal, 1 g/kg, should be administered as soon as possible, and repeated every 4 hours for several doses. Activated

charcoal will effectively adsorb PCP and increase its nonrenal clearance; even without prior gastric evacuation this approach is usually adequate.[155] Unless there are specific contraindications, a single dose of a cathartic, such as sorbitol, can be given.

Theoretically, xenobiotics that are weak bases, such as PCP, can be eliminated more rapidly if the urine is acidified. Although urinary acidification with ammonium chloride was previously recommended,[9] we do not recommend this approach. The risks associated with acidifying the urineâ€”simultaneously inducing a systemic acidosis, thereby potentially increasing urinary myoglobin precipitationâ€”outweigh any perceived benefits (Chap. 10).

As opposed to the problems in applying ion-trapping to renal excretion, ion-trapping results in the active mobilization of PCP into gastric secretions. Phencyclidine is in a substantially ionized (and therefore nonâ€“lipid-soluble) form in the acid of the stomach and can be absorbed only when it reaches the more alkaline intestine. As a result, gastric suction can remove a significant amount of the drug, as well as interrupt the gastroenteric circulation (by which the drug is secreted into the acid environment of the stomach only to be reabsorbed again in the small intestine).[9] Continuous gastric suction, however, can also be dangerous and unnecessary. It should be considered only in comatose patients. Continuous suction may result in trauma to the patient as well as in fluid and electrolyte loss, which can further complicate management and possibly interfere with the efficacy of activated charcoal. For these reasons the administration of multiple-dose activated charcoal rather than continuous nasogastric suction appears to be the safest and most effective way of removing ion-trapped drug from the stomach.

Most patients rapidly regain normal CNS function anywhere from 45 minutes to several hours after using these drugs. However, those who have taken exceedingly high doses or who have an underlying psychiatric disorder may remain comatose or exhibit

bizarre behavior for days, or even weeks, before returning to normal. Those who regain normal function rapidly should be monitored for several hours and then, after a psychiatric consultation, should receive drug counseling and any additional social support available. Patients whose recovery is delayed should be treated supportively and monitored carefully in an intensive care unit.

Many patients become depressed and anxious during the â€œposthighâ€• period, and chronic users may manifest a variety of psychiatric disturbances.[201] These individuals typically present with repeated drug use, hospitalizations, and poor psychosocial functioning in the long term.

The major toxicity of PCP appears to be behaviorally related: self-inflicted injuries, injuries resulting from exceptional physical exertion, and injuries sustained as a result of resisting the application of physical restraints are frequent. Patients appear to be unaware of their surroundings and sometimes even oblivious to pain because of the dissociative anesthetic effects. In addition to major trauma, rhabdomyolysis and resultant myoglobinuric renal failure account in large measure for the high morbidity and mortality associated with PCP intoxication. If significant rhabdomyolysis[39,151] has occurred, myoglobinuria may be present. Early fluid therapy should be used to avoid deposition of pigment into the kidneys, leading to renal failure. Urinary alkalinization as part of the treatment regimen for rhabdomyolysis would potentially increase PCP reabsorption and deposition in fat stores, but this is only theoretical and is not recommended.

Although the clinical experience with recreational use of ketamine is limited, toxic manifestations appear to be similar, yet milder and shorter-lived, when compared to PCP. In a study of 20 patients who presented with acute ketamine toxicity, all were treated conservatively and successfully with intravenous hydration, and sedation with benzodiazepines.[188]

Summary

As â€œdissociativeâ€• anesthetics became clinically available, their abuse potential was also discovered. The popularity of PCP and ketamine results from their ability to produce an â€œout-of-body experienceâ€• with seemingly hallucinatory effects. The action of these drugs is largely mediated by the NMDA receptor. Their toxicity, in great part neuropsychiatric in nature, is managed by supportive

care. The popularity of ketamine may be related to its lesser toxicity and milder distortion of the personality.

Normal concentrations
Serum
=
0.8â€“3 Âµg/L
Urine (24 hour)
=
0.5â€“6.2 Âµg/L
Urine (24 hour)
=
35 Âµg/g creatinine
A 19-year-old Hispanic man with a history of alcoholism presented to the

(ED) complaining of 1 day of repeated vomiting, diarrhea, and abdominal history was significant for multiple failed attempts to achieve alcohol abst help him attain sobriety, his parents sent him an aversive medication fro â€œSoluto Vital.â€• On the day prior to admission the patient ingested t of the bottle that was labeled to contain tartar emetic and small amounts *Strophanthus.* The normal dose was listed as 20â€“25 drops. His estimate was 500 mg. Approximately 30 minutes after ingestion he experienced ab vomited multiple times. Massive diarrhea rapidly ensued.

Physical examination revealed a young man in distress with the following pressure, 104/71 mm Hg; pulse, 96 beats/min; respirations, 18 breaths/ 96.6Â°F (35.9Â°C). The remainder of the examination was remarkable fo a clear chest, and a normal heart examination. His abdomen was tender but there was no rebound tenderness or guarding. Neurologic examination was no indication of suicidality. His stool tested negative for occult blood

An intravenous line was inserted, and the patient was resuscitated with (solution. Specimens were sent for a complete blood count, electrolytes, a enzymes. An electrocardiogram was interpreted as normal. In the ED, the episodes of vomiting despite antiemetic therapy. His diarrhea also contin studies were consistent with volume loss and possibly renal injury (blood creatinine, 2.4 mg/dL; hematocrit, 60%; urinalysis, 2+ protein) the patien hospital.

The vomiting gradually subsided and a single dose of 50 g of activated c without a cathartic. By 12 hours after admission, his creatinine had impro total urine output was only 500 mL for the first 24 hours. The following d was discharged. Subsequently, his 24-hour urine reported an antimony c or 682 Âµg/g creatinine. The patient never returned for followup care.

Chemistry

Antimony (Sb) is located in the same group on the periodic table as arsen shares many chemical, physical, and toxicologic properties. Because it can nonmetal, antimony is classified as metalloid (Chap 12).[77] Pure antimony white, brittle, hard metal that is easily pulverized.[61 , 89] However, becaus

rapidly converted to either antimony oxide or antimony trioxide, it is ext

rare to find isolated elemental antimony in nature. It has been suggested originates from *anti monon* (enmity to solitude) because antimony is almo other metal.[59] Thus, for the purposes of this chapter, the term *antimony* nature, antimony can be found in more than 100 different minerals,[59, 49] cervantite, valentine, and kermesite.[30] The sulfide ore (stibnite) is the m Bolivia and South Africa are among the leading producers.[89] Like arsenic, both organic and inorganic compounds with trivalent and pentavalent oxi inorganic trivalent antimony compounds include antimony trioxide (SbO_3 (SbS_3), antimony trichloride ($SbCl_3$), antimony potassium tartrate (C_8 H (SbH_3). Antimony pentasulfide (Sb_2 S_5) and pentoxide (Sb_2 O_5) are pe compounds that can act as oxidizing agents.[40] From an industrial perspec application of antimony is the use of antimony oxychloride (Sb_6 O_6 Cl_4)

Tartar emetic (antimony potassium tartrate) is an odorless trivalent antim potent emetic effect[40] and a sweet metallic taste.[41] Antimony potassium t one of the most toxic antimony compounds, with minimal lethal doses rep and 1200 mg.[59] There are large species variations of the LD_{50} (median le subjects) in experimental animals, with a reported range of 115 mg/kg in mg/kg in mice. In comparison, because of a low water solubility, antimor practically, to be nontoxic, with an LD_{50} >20,000 mg/kg.[32]

History

In spite of the fact that antimony and its compounds are regarded as am remedies in the practice of medicine, they remain unfamiliar to most peo discovered during exploration of old Mesopotamian civilization (3rd and 4 suggested that both the Sumerians and the Chaldeans were able to produ The reference to eye paint in the Old Testament suggested the use of an thousand years, Asian and Middle Eastern countries used antimony sulfide cosmetics, including rouge and black paint for eyebrows, also known as k Because of the scarcity of antimony sulfide, lead replaced antimony as a modern cosmetic preparations.

One of the first monographs on metals, written in the 16th century, inclu

antimony.[84] The medicinal use of antimony for the treatment of syphilis, dates to the medieval period. Paracelsus (1493â€“1541) was credited wi compounds as therapeutic agents and increasing their popularity. In spite potential, many of the disciples of Paracelsus enthusiastically continued th Various antimony compounds were used also as topical preparations for t leprosy, mania, and epilepsy.[89] Orally administered tartar emetic (antimo used for treatment of fever, pneumonia, and inflammatory conditions, bu of its significant toxicity.[11 , 27 , 39] Historically, the therapeutic dose rang tartrate was from 20 mg every 10 minutes (until vomiting occurred) to 4(

The use of antimony as a homicidal poison[80] was recognized, and this pra the 20th century (Chap 1).

The current medical use of antimony is limited to the treatment of leishm kala-azar, and schistosomiasis, and to sporadic use as aversive therapy f Pentavalent compounds are used because they are better tolerated. In sp in vitro,[27] there is no current oncologic use of antimony.

Some contemporary homeopathic[35] and anthroposophical[75] practices still antimonial compounds as home remedies; however, these practices are r

Because of its poor physical properties (eg, inflexible metal), the element very few industrial uses. In contrast, its alloys with copper, lead, and tin applications. Industrial and occupational exposure to antimony occurs mai dust or fumes during the processing or packaging of antimony compounds also be occupationally exposed to antimony.[34] Antimony concentrations in from 10â€“60 mg/kg.[34 , 63] This may be an additional factor contributing concentrations of antimony found in workers' lungs.[34]

In developed countries, antimony poisoning rarely occurs following intent preparations.[89]

Toxicokinetics

Absorption

Antimony may be absorbed by inhalation, ingestion, or transcutaneously.

gastrointestinal tract begins immediately on ingestion, and the oral bioav ranges from 15â€“50%.[33, 85] This poor gastrointestinal absorption in hum concomitant emesis, necessitates parenteral administration of many ant pharmaceuticals. Pulmonary absorption of many inorganic antimony compo limited by low solubility.[59] In contrast, animal data suggest that inhaled absorbed from the lung, distributed to various organs, and subsequently urine.[26]

Distribution

Distribution apparently depends on the oxidation state of antimony. In an trivalent antimony is incorporated into the red blood cells within 2 hours similar time frame, 90% of pentavalent antimony will still be found in the administered intravenously or orally, antimony is predominantly distribute organs, including liver, kidneys, thyroid, and adrenals.[66, 89] Uptake by t mechanisms of diffusion and saturable binding. Repeated exposures cause independent of the concentration in red cells.[74] In a hamster model, follo organic antimonials, the greatest concentration of antimony was found in inhalation, antimony accumulates predominantly in red blood cells, and to extent in liver and spleen.[26, 28] The fact that elevated urine and serum are measured more than 2 years after the treatment suggests that antimo for a prolonged period of time.[58]

Excretion

Although antimony and arsenic share many toxicokinetic properties, unlik trivalent antimony is not methylated in vivo.[3] Trivalent antimony is excret conjugation with glutathione. A significant proportion of excreted antimo recirculation.[3] The remainder is excreted in urine. The overall elimination 10% of a given dose cleared in the first 24 hours, 30% in the first week, antimony is still detected in the urine 100 days after administration.[57, 8 much more rapidly excreted by the kidneys than trivalent antimony (50â€ 24 hours).[89] In workers, urine concentrations of pentavalent antimony co intensity of exposure.[3]

Pathophysiology

Elemental antimony is considered to be more toxic than its salts, but bec elemental form is relatively uncommon, this fact is of limited clinical rele metals, antimony binds to sulfhydryl groups to inhibit a variety of metab Trivalent antimony compounds are more toxic than the pentavalent comp higher affinity for erythrocytes and sulfhydryl groups.[54] Tartar emetic and also considered local irritants of the gastrointestinal tract. One proposed activation of enterochromaffin cells that are located in the gastrointestinal secrete serotonin. Released serotonin acts on the 5-HT_3 receptors, stimul and activating the vomiting center.[38 , 87] In addition, there is apparent action, particularly after administration of higher doses of antimony.[89] Fr perspective, trivalent antimony compounds also inhibit phosphofructokinas energy for schistosomes.[14 , 89]

Clinical Manifestations

Data on human toxicity of antimony are very limited, and are largely ext occupationally exposed patients and from the reports of adverse effects leishmaniasis with antimony. There are very few case reports of intentio For didactic purposes, we recognize three distinct populations that may p toxicity.

Workers with occupational exposures usually present with subtle clinical toxicity develops slowly over time. It is important to recognize that antim concentration of arsenic as impurity, making it difficult to distinguish whe are caused by contaminants or by the antimony. Therapeutic side effects may have a somewhat subacute to acute clinical picture, as some patient require prolonged treatment with antimony to achieve cure,[82] exposing th large cumulative doses.

Patients with oral ingestions present with acute symptoms mimicking the other metal salts. Several cases were described after the use of old porc use of antimony compounds as home remedies.[1 , 53 , 62 , 79]

Local Irritation

The majority of antimony toxicity is based on local irritation. In sufficien acts as an irritant to the eyes, skin, and mucosa. Chronic exposure can [72] Irritation of the upper respiratory tract can lead to pharyngitis.

Systemic

Gastrointestinal in acute exposures, antimony can rapidly produce nausea pain, and diarrhea. Some patients may report a metallic taste in the mou gastrointestinal irritation can progress to hemorrhagic gastritis. Workers antimony dusts have a much higher incidence of gastrointestinal ulcers ir (63 per 1000 vs. 15 per 1000).[12] A large series of patients developed ch pancreatitis following treatment with pentavalent antimonial agents.[31] Be cases improved despite continuation of treatment, the authors presumed direct toxicity. In another series, several patients with HIV who were trea meglumine antimonate developed severe pancreatitis and died.[24]

Cardiovascular

In animals, antimony decreases myocardial contraction, decreases corona producing decreased systolic pressure,[89] and causes bradycardia.[23] The cardiac effects are related to changes on the electrocardiogram (ECG). Pr interval, inversion or flattening of T waves, and ST segment changes are during treatment of visceral leishmaniasis with pentavalent antimonial co stibogluconate and meglumine antimonate).[18 , 90] Torsades de pointes wa treated with pentavalent antimonial preparations.[65 , 81] In patients with disease (eg, cardiomyopathy), ECG changes can occur even with antimony considered to be therapeutic.[37] These changes are not necessarily associ cardiac function.[44] However, it is important to recognize that pentavalent the treatment of leishmaniasis are associated with sudden deaths, probably development of ventricular dysrhythmias.[16 , 78]

Thrombophlebitis is common after IV use of antimony, but has been repo occurs orally.[55]

Respiratory

Local irritation from antimony trioxide can produce laryngitis, tracheitis, lung injury was reported after acute exposure to antimony pentachloride.

Although antimony oxides are capable of causing metal fume fever,[29] this comparison to exposure to zinc oxide.[2 , 29] Antimony metal fume fever is concentrations below 5 mg/m^3 .[20]

Renal

Patients treated with sodium stibogluconate can develop varied manifesta ranging from renal cell casts, proteinuria, and increased blood urea nitro renal failure.[4 , 70] Some patients can also develop renal tubular acidosis[4] necrosis.[71]

Hematologic

Severe anemia was reported in HIV-positive patients during the treatmen stibogluconate, with documented transient severe bone marrow dyseryth complete recovery on discontinuation of the therapy.[46]

Patients treated with sodium stibogluconate for visceral leishmaniasis oc thrombocytopenia.[9 , 45 , 51] Rare cases of epistaxis are described during t unclear if they are associated with thrombocytopenia.[52] Visceral leishma

itself is known to be associated with pancytopenia, probably as a result o peripheral blood cells.[69] It may be difficult to determine whether this phe disease itself or is secondary to the treatment, although some authors su immune thrombocytopenia.[69]

Leukopenia is frequently observed in patients treated with antimonial co authors speculate that antimony-induced lymphopenia is associated with herpes zoster in HIV patients.[91]

Dermatologic

Antimony spots[76] are papules and pustules that develop around sweat an

may resemble varicella. A similar skin rash was described in the 18th cer application of antimony tartrate for medicinal use.[59] Interestingly, these interpreted as a sign of cure.[39]

Neurologic

A patient with cutaneous leishmaniasis who was treated with sodium sti antimony) developed a reversible, peripheral sensory neuropathy in temp treatment.[13] The authors suggested that neuropathy may be the result c antimony.

Reproductive

In animal studies, antimony exposure causes ovarian atrophy, uterine m conception.[7] Limited information from the Russian literature describes an spontaneous abortion and premature births in women who were occupatic salts. Antimony was found in the blood, urine, placenta, amniotic fluid, an women.[7]

Carcinogenicity

Initial studies in female rats reported lung tumors after inhalational expo trioxide.[36 , 86] Likewise, a survey among antimony smelter workers sugge cancer, with a latency of 20 years, in comparison to a nonexposed popul concomitant exposure to arsenic and its effects could not be excluded and inadequately controlled for workers' smoking habits.[50]

Patients with schistosomiasis have an increased incidence of bladder tum compounds are considered to be one potential cause.[89]

Stibine

Antimony compounds can react with nascent hydrogen forming an extrem (SbH_3), which resembles arsine (AsH_3) (Chap. 85). Stibine is probably compound. It is a colorless gas with a very unpleasant smell that rapidly temperatures above 302Â°F (150Â°C).[43 , 89] Historically, stibine release

charging of lead storage batteries.[89] In addition to GI symptoms that inc abdominal pain, stibine has strong oxidative properties capable of produc (Chap. 24). Similar to arsine,[73] severe stibine exposure may result in h and death. Maintenance workers are advised to avoid use of drain cleane capable of releasing hydrogen in situations where antimony may be prese

Diagnostic Testing

Standard laboratory testing to help identify volume depletion and renal in patients with acute antimony toxicity. A complete blood count, electrolyte and a urinalysis should be obtained. When there is a known or suspected additional studies should include tests for hemolysis, such as determinatio haptoglobin. Blood should also be obtained for a blood type and cross-ma likely to be required.

An ECG should be obtained to evaluate for QTc prolongation and other ch myocardial disease should have more frequent monitoring of cardiac funct

Antimony concentration in a 24-hour urine collection can be used for asse exposure to either trivalent or pentavalent antimony.[3] A normal urinary nonexposed patients is reported in the range of 0.5â€“6.2 Âµg/L.[58 , 88] T US population is 0.128 Âµg/L, with concentrations of the 95th percentile serum antimony concentration is impractical because it cannot be determi However, it is suggested that normal serum concentration of antimony is Âµg/L,[58] although some laboratories use higher values.[64]

Treatment

Decontamination

Following a significant acute ingestion, the majority of the patients devel emesis is unlikely to offer any additional benefit. In contrast, gastric lava especially if performed before the onset of spontaneous emesis. Although antimony is adsorbed to activated charcoal, based on experience with sal mercury, administration of activated charcoal seems reasonable. Additiona a documented enterohepatic circulation, multiple-dose activated charcoal r

patients exposed to stibine, decontamination involves removal from the e administration of high-flow oxygen. Theoretically, severe stibine exposure transfusion for removal of stibineâ€“hemoglobin complex.[73]

Supportive Care

The mainstay of treatment for antimony poisoning is good supportive car anticipate massive volume depletion and begin rehydration with isotonic Electrolytes and urine output should be followed closely. A central venous required in patients with cardiovascular instability. Antiemetics are indicat comfort and to facilitate the administration of activated charcoal. Followir hematocrit should be followed closely and blood should be transfused bas

Chelation

Human experience with regard to chelation of antimony is rather limited l serious toxicity and the rarity of instances when patients have received c available data are based on animal experimentation. Dimercaprol, succim dimercaptopropane-sulfonic acid (DMPS) all improve survival of experime One animal study that compared survival after treatment with multiple c

concluded that the most effective antidotes were DMPS and succimer.[6]

A single case series documented survival in 3 of 4 patients exposed to ta intramuscular dimercaprol at a dose of 200â€“600 mg/d. All 4 patients h excretion of antimony.[55] In another case report, a patient survived after but without evidence of enhanced antimony excretion in urine.[3] Although are difficult to make, it is reasonable to begin therapy with intramuscular certain that antimony is removed from the gastrointestinal tract, at which switched to oral succimer. Because chelation doses for antimony poisonin chelators should be administered in doses and regimens that are determin effective for other metals (see Antidotes in Depth: Dimercaprol [British A Antidotes in Depth: Succimer [2,3-Dimercaptosuccinic Acid]).

Summary

Antimony is an element whose physical, chemical, and toxicologic proper arsenic. Although uncommon, antimony toxicity does occur. The hallmarks gastrointestinal manifestations leading to profound volume depletion and Electrocardiographic findings may assist in the identification of this xenol supportive, although chelation may be indicated in life-threatening cases.

Chapter 85
Arsenic

Marsha Ford

Arsenic (As)

Atomic number = 33

Atomic weight = 74.92

Normal concentrations

Whole blood = < 5Âµg/L(0.665 Âµmol/L)

Urine (24 hour) = <5Âµg/L (< 6.65 Âµmol/L)

Urine (24 hour) = <100 Âµg/g creatinine

A 55-year-old woman was hospitalized for diarrhea, nausea, vomiting, and weakness of unknown etiology. The patient had type II diabetes mellitus and had been in her usual state of health until 5 weeks earlier when, after eating noodle paste, she and her husband developed persistent nausea, vomiting, and diarrhea. Both were

admitted with dehydration and hypokalemia and treated for 1 week. On discharge the patient's weakness necessitated the use of a cane for walking. Approximately 3 weeks later, the patient's husband complained of weakness, then vomited and had a syncopal episode. He was resuscitated with intravenous (IV) fluids and admitted to the hospital. The following day he suddenly became hypotensive, had a cardiopulmonary arrest, and died. Four days later, the patient again developed nausea, vomiting, diarrhea, and weakness. She also noted numbness in her hands and feet, described as â€œpins and needles.â€• She distinguished this from the numbness in her toes, previously ascribed to diabetic neuropathy. The patient had also been bedridden for the past 10 days because of weakness and an inability to walk. There were no further neurologic complaints.

Her past medical history revealed type II diabetes mellitus for 3 years, hypertension, and an episode of an unknown cardiac dysrhythmia. Her medications included NPH insulin, digoxin, ranitidine, multivitamins, and thiamine. There was no history of alcohol abuse. Review of systems was pertinent for a 20-lb weight loss over the past month and diffuse tissue swelling. Physical examination revealed a weak woman lying in bed. Vital signs were: blood pressure, 120/75 mm Hg; pulse, 90 beats/min; respirations, 20 breaths/min; and temperature, 100.4Â°F (38Â°C). Examination of the head, ears, eyes, nose, and throat demonstrated periorbital edema and bilateral carotid bruits. Lungs were clear to auscultation, and the cardiac examination revealed normal rate with a 2/6 systolic ejection murmur radiating to the aortic region. Abdominal examination revealed mild distension with bowel sounds present, and no tenderness or organomegaly. Pulses were 1+ in all the extremities. Neurologic examination revealed orientation to time, place, and person; cranial nerves IIâ€“XII were intact; muscle strength was 4â€“5/5, except for quadriceps and iliopsoas strength of 3/5 bilaterally; deep-tendon reflexes were 1+ at the biceps and 0 at the brachioradialis, knees, and ankles. Plantar reflexes were normal. Sensory examination revealed abnormal position sense

decreased in the upper extremities and absent in the lower extremities, and vibration and position sense decreased in both upper and lower extremities.

During the next 3 days the patient's muscle strength diminished in a caudal-to-rostral pattern, and she was transferred to the ICU, with a presumptive diagnosis of Guillain-BarrÃ© syndrome. Review of the records from the first hospitalization revealed a prolonged QTc interval on routine ECG, and a finding of mild hypotension requiring 6 days of intravenous crystalloid infusions, an unusual requirement for the presumed diagnosis of gastroenteritis. In the ICU, laboratory examination revealed a hemoglobin (Hb) of 8.1 g/dL with a mean corpuscular volume (MCV) of 93.3 Âµm^3 and a white blood cell (WBC) count of 2400 cells/mm^3. Other laboratory tests were within normal limits, including serum iron, cortisol, vitamin B_{12}, folate, and thyroid function tests. Westergren sedimentation rate was normal at 19 mm/h. Her ECG demonstrated a normal sinus rhythm, QRS axis of 60Â°, and a prolonged QTc interval of 610 msec. Lumbar puncture measured a normal opening pressure of 135 mm H_2O, and the CSF contained 5 WBC/mm^3, 0 red blood cells (RBC)/mm^3, protein 42 mg/dL, and glucose 98 mg/dL. Radiopaque material was noted on a plain abdominal radiograph. The toxicologic consultant ordered a stat spot urine for arsenic, which measured 16,422 Âµg/L. The patient underwent chelation therapy until the urinary arsenic was less than 50 Âµg/L. During recovery the patient experienced extreme pain, even with light touch to the extremities. Ten months later the patient had gradually recovered from her peripheral neuropathy to the point that she could feed herself. An investigation was unsuccessfully pursued.

The therapeutic use of arsenic (arsenic trioxide) for acute promyelocytic leukemia (APL), as well as its emergence as a significant environmental toxin, has renewed interest in its pharmacology and toxicology.[167] The role of arsenic in our pharmacopeia may expand; its efficacy in treating various other

leukemias, lymphomas, and multiple myeloma is being studied.[115] This chapter discusses the properties and toxicity of inorganic arsenic, the most prevalent toxic form.

TABLE 85-1. Sources of Arsenic

Inorganic
Occupational/Manufacturing
Animal feed (additive)
Brass/bronze
Ceramics/glass
Computer chips
Dyes/paints
Electron microscopy
Fireworks (Chinese)
Fossil fuel combustionâ€”coal
Herbicides
Insecticides/pesticides
Metallurgy
Mining
Rodenticides
Semiconductors (gallium arsenide)
Smeltingâ€”copper, lead, zinc, sulfide minerals
Soldering
Wood preservatives
Medicines/Contaminated Drugs
Chemotherapy (acute promyelocytic leukemia)
Depilatory
Herbals/alternative medicines
Homeopathic remedies
Kelp
â€œMoonshineâ€• ethanol
Opium

Other
Contaminated well water
Contaminated foods/candies, eg, licorice
Organic
Melarsoprol (trypanocidal)
Parasitic therapy (veterinary)
Seafood (arsenobetaine)

TABLE 85-2. Arsenic

Enviromental	
MCL	50 ppb
Occupational standards	
ACGIH	
TLV-TWA (elemental, inorganic compounds, arsenous acid, arsenic acid)	0.01 mg/m^3
TLV-STEL	Not established
BEI (inorganic plus methylated metabolites in urine)	35 Âµg arsenic/L
OSHA	

PEL-TWA	
• Organic compounds • Inorganic compounds	0.5 mg/m^3 0.01 mg/m^3
PEL-STEL	Not established
NIOSH	
REL-TWA	Not established
REL-STEL (inorganic compounds)	0.02 mg/m^3 (15 min ceiling)

ACGIH = American Conference of Governmental Industrial Hygienists; BEI = biologic exposure index (urine sampling occurs at end of workweek); MCL = maximum contaminant level of drinking water, United States Environmental Protection Agency; MW = molecular weight; NIOSH = National Institute for Occupational Safety and Health; OSHA = Occupational Safety and Health Administration; PEL = permissible exposure limits, REL = recommended exposure limits; STEL = short-term exposure limit; TLV = threshold limit values; TWA = time-weighted average.

Arsenic is a metalloid that exists in multiple forms: elemental, gaseous (arsine), organic, and inorganic [(As^{3+} [trivalent, or arsenite] and As^{5+} [pentavalent, or arsenate])]. Tables 85-1 and 85-2 list sources of, and facts about arsenic. Additional trivalent arsenicals include tetra-arsenic tetrasulfide (realgar; As_4S_4) and diarsenic trisulfide (orpiment; As_2S_3). Realgar and orpiment have

been used by the Chinese to treat malignancies, diarrhea, and infections of the chest and liver.[99] Arsenic metal is considered nonpoisonous because of its insolubility in water and bodily fluids.[141] The toxicity of exogenous organic forms is low. The gaseous form, which is highly toxic, is discussed in Chap. 24.

History and Epidemiology

Arsenic poisoning can be unintentional, suicidal, homicidal, occupational, environmental, or iatrogenic.[74,75,101,120] Mass poisonings have occurred. Nearly 400 residents of Hong Kong fell ill after eating contaminated bread from the Esing Bakery in 1857; two bakery foremen were thought to have tampered with the recipe. The 1900 Staffordshire Beer Epidemic in England saw 6000 beer drinkers fall ill and 70 die from beer brewed with sugar made with arsenic-contaminated sulfuric acid. In Wakayama, Japan, 70 people were poisoned by eating intentionally contaminated curry at a festival in 1998. In 2003, the largest recent outbreak of arsenic poisoning in the United States occurred in New Sweden, Maine, when adulterated church coffee resulted in the death of one parishioner and the hospitalization of an additional 15 victims. Hydroarsenicism from contaminated groundwater has resulted in mass environmental poisonings for the past 4 decades. Arsenic trioxide reemerged as a treatment for promyelocytic leukemia in the 1990s after physicians in Harbin, China found a high remission rate in patients given Ailing-1, a crude arsenic trioxide infusion.[88,188] Adverse drug effects can occur but the majority of infusions are tolerated without discontinuing therapy.[116,138]

Contaminated soil, water, and food are the primary sources of arsenic for the general population. Pentavalent arsenic is the most common inorganic form in the environment.[38] The primary form of arsenic in fish and shellfish is arsenobetaine. Although arsenosugars can be found in crustaceans, seaweed, and algae,[94] less than 1% is inorganic arsenic.[44] Inorganic arsenic can be found in larger amounts

in other foodstuffs, such as rice and produce, along with smaller amounts of its methylated metabolites.[142,181]

In the past 2 decades, consumption of contaminated water has emerged as the primary cause of large-scale outbreaks of chronic arsenic toxicity. Arsenic leaches from various minerals and ores, as well as from industrial waste.[108] In Bangladesh, millions of people have been poisoned by drinking water from tube wells contaminated with arsenic leached from ground minerals.[21] Ironically, the wells were dug to obtain safer groundwater. Hydroarsenicism has also been reported in Chile, Taiwan, Thailand, India, Mexico, and Argentina. In 2001, the United States Environmental Protection Agency decreased the maximum contaminant level of arsenic in drinking water to 10 parts per billion (ppb, or 0.010 mg/L), after statistical modeling indicated an increased risk of lung and bladder cancer from water contaminated

with arsenic at the formerly acceptable level of 50 ppb.[25,46] The World Health Organization also recommends a level of 10 ppb.

Pharmacology

Arsenic trioxide (As_2O_3; Trisenox) is administered therapeutically in doses of 0.15â€“0.16 mg/kg/d by either the intravenous or oral route.[88,147] At this dose its beneficial effects in acute promyelocytic leukemia (APL) occur predominantly by initiating cellular apoptosis when arsenic concentrations reach 0.5â€“2.0 Âµmol/L. Apoptosis is triggered by several mechanisms. The trivalent arsenic ion binds to mitochondrial membrane sulfhydryl (SH) groups, damaging mitochondrial membranes and collapsing membrane potentials. Cytochrome c is released from the damaged mitochondria with subsequent activation of caspases 9, 3, and 8, and initiation of apoptosis. Cells may be more susceptible to arsenic-induced apoptosis if the intracellular levels of catalase and glutathione peroxidase (H_2O_2 scavenging enzymes) and glutathione-*S*-

transferase (responsible for conjugating glutathione to xenobiotics) are reduced.[28,54,76,136] Arsenic trioxide also facilitates apoptosis by downregulating gene expression of BCL2, a prosurvival protein that protects against apoptosis.[26] Finally, arsenic trioxide can arrest cells early in mitosis, leading subsequently to apoptosis.[64]

Low-dose arsenic trioxide treatment (0.08 mg/kg/d) beneficially promotes cell differentiation of APL cells when arsenic concentrations reach 0.1â€“2.0 Âµmol/L. This differentiation is impaired by the promyelocytic leukemia-retinoic acid receptor Î± (PML-RARÎ±) oncoprotein. This oncoprotein results from the APL-defining translocation of chromosomes 15 and 17. The PML portion of this oncoprotein plays a key role in leukemogenesis by interfering with RARÎ± activity that is essential for normal myeloid cellular development. Trivalent arsenic degrades this PML portion, freeing RARÎ± to facilitate cell differentiation.[28,111]

Melarsoprol (*Mel B;* ARSOBAL), the arsenoxide derivative of an organic arsenical, is used to treat the meningoencephalitic stage of West African (Gambian) and East African (Rhodesian) trypanosomiasis. The drug concentrates in trypanosomes via a purine transporter. Its target is trypanothione, the primary reducing agent in trypanosomes. Melarsoprol binds to trypanothione to produce *Mel T*, a competitive inhibitor of trypanothione reductase that is responsible for maintaining adequate levels of trypanothione. The resulting decrease in trypanothione leads to a loss of reducing capacity with subsequent lysis of the parasite.[158]

Pharmacokinetics and Toxicokinetics

Absorption

Inorganic arsenic is tasteless and odorless and is well absorbed by the gastrointestinal, respiratory, intravenous, and mucosal routes. *Gastrointestinal* absorption is facilitated by increased solubility and

smaller particle size, and occurs predominantly in the small intestine, followed by the colon. Poorly soluble trivalent compounds such as arsenic trioxide (As_2O_3) are less-well absorbed than more soluble trivalent and pentavalent compounds that, in aqueous solution, have an oral bioavailability greater than 90%. However, when placed in an aqueous solution, As_2O_3 is more toxic than an identical dose of undissolved As_2O_3 eaten in food.[164] A rodent experiment demonstrated approximately 70% GI absorption of dimethylarsinic acid (cacodylic acid). Systemic absorption via the *respiratory* tract depends on the particulate size, as well as the arsenic compound and its solubility. Large, nonrespirable particles are cleared from the airways by ciliary action and swallowed, allowing GI absorption to occur. Respirable particles lodging in the lungs can be absorbed over days to weeks or remain unabsorbed for years.[19,174] *Dermal* penetration of arsenic through intact skin does not pose a risk for acute toxicity but potentially may be problematic with chronic application. H_3AsO_4 applied to intact skin in Rhesus monkeys resulted in absorption of a mean of 2.0â€“6.4% of the applied dose.[175] Skin irritation and damage may increase systemic absorption.[53,135]

Pharmacokinetics

Intravenous administration of a single 10-mg dose of As_2O_3 to 8 patients, followed by data collection for 24 hours, showed mean pharmacokinetic values as follows: maximum plasma concentration (Cp_{max}) of 6.85 Âµmol/L, Î± elimination half-life ($t_{1/2}$ Î±) of 0.89 Â± 0.29 hours, and Î² elimination half-life ($t_{1/2}$ Î²) of 12.13 Â± 3.31 hours. Nail and hair levels increased during As_2O_3 administration. In 6 patients, 1â€“8% of the daily dose was eliminated in a 24-hour urine. Repeat pharmacokinetic studies on day 30 of treatment were not statistically different.[145] Another study of patients receiving a single dose of 5 mg of As_2O_3 intravenously demonstrated mean pharmacokinetic values as follows: Cp_{max} of 2.636 Âµmol/L, $t_{1/2}$ Î± of 1.413 hours, $t_{1/2}$ Î² of 9.411 hours, serum clearance of 1.987 L/h,

and area under the plasma drug concentration versus time curve (AUC) of 12.706 Âµmol/L/h. A single dose of 10 mg intravenously showed a Cp_{max} of 6.799 Â± 0.314 Âµmol/L.[144] Arsenic trioxide 10 mg given orally for APL demonstrated total plasma and blood AUC values that were 99% and 87%, respectively, of the corresponding values reported for a 10-mg intravenous dose administered in the same 9 patients.[87]

A study in humans receiving intravenous radioarsenic isotope (^{74}As) showed arsenic clearing from the blood in three phases:

- *Phase 1 (2â€“3 hours)*â€”Arsenic is rapidly cleared with a $t_{1/2}$ of 1â€“2 hours; more than 90% may be cleared during this phase.
- *Phase 2 (3 hours to 7 days)*â€”A more gradual decline occurs, with an estimated $t_{1/2}$ of 30 hours; by 10 hours postinfusion the arsenic is concentrated in red blood cells (RBCs) by a 3:1 ratio compared to plasma.
- *Phase 3 (10 or more days)*â€”Clearance continues slowly with an estimated $t_{1/2}$ of 300 hours.[110]

The rapid clearance in phases 1 and 2 explains why blood testing for arsenic is unreliable, except early in acute poisoning.

Initial distribution is predominantly to liver, kidney, muscle, and skin. The skin is rich in sulfhydryl groups; the skin's elimination $t_{1/2}$ of arsenic was estimated to be 1 month in a rabbit study.[42] Distribution to brain also occurs quickly. In the ^{74}As study, 0.30% of the administered dose was found in biopsy samples in the first hour postinfusion. This peak declined to 0.16% by day 7.[110] Ultimately, arsenic distributes to all tissues. Arsenic crosses the placenta and accumulates in the fetus,[100] but is not appreciably excreted in breast milk.[35]

Metabolism, by adding methyl groups, occurs primarily in the liver, but also occurs in the kidneys, testes, and lungs (Fig. 85-1). If the

arsenic is pentavalent, approximately 50â€“70% will first be reduced to trivalent arsenic.[151,165] This bioactivation step requires the oxidation of glutathione[39] and can begin within 15 minutes of

exposure.[165] *S*-adenosylmethionine (SAM) is the primary methyl donor. Nonenzymatic methylation has also been demonstrated in an in vitro study using human liver cytosol; here, methylcobalamin (methyl B_{12}) was the methyl donor.[185] Dietary and vitamin deficiencies, as well as high doses of inorganic arsenic, may diminish the ability to methylate arsenic.[169] Addition of one methyl group produces monomethylarsonic acid (MMA^V); adding a second methyl group produces dimethylarsinic acid (DMA^V). Production of a trivalent intermediate in this reaction, monomethylarsonous acid (MMA^{III}), is catalyzed by MMA^V reductase. In rabbits this is the rate-limiting enzyme in the biotransformation pathway; however, no data exist to confirm a similar role in human metabolism.[167,186] Conversion of MMA^V to DMA^V is catalyzed by a methyltransferase.

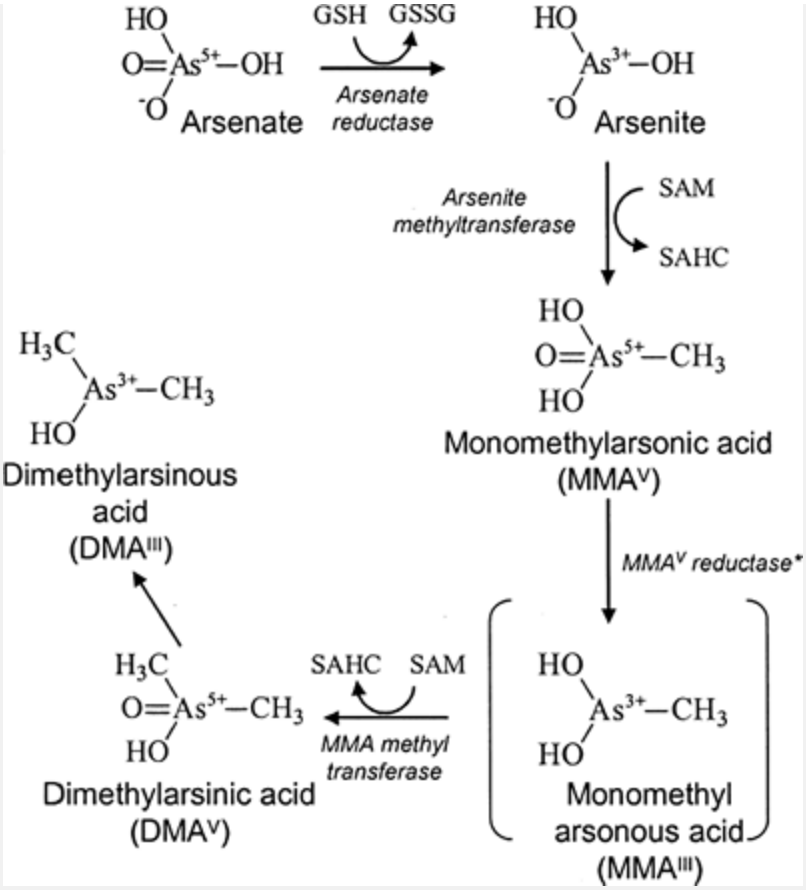

Figure 85-1. Metabolism of arsenate [As^{5+}] and arsenite [As^{3+}]. DMA = dimethylarsinic acid; GSH = glutathione; MMA = monomethylarsonic acid; SAHC = *S*-adenosylhomocysteine; SAM = *S*-adenosylmethionine. The asterisk (*) denotes MMA^V reductase, the rate-limiting enzyme in rabbit studies of arsenic metabolism; the analogy to humans is unknown.

These monomethylation and dimethylation steps were previously thought to detoxify As^{3+}. Estimated human LD_{50} (median lethal dose for 50% of test subjects) doses were reported to be arsenic trioxide, 1.43 mg/kg; MMA^V 50 mg/kg; and DMA^V 500 mg/kg. However, it is important to note that the doses cited for MMA and DMA apply to arsenic existing in the pentavalent form (As^{5+}). Studies in animals

and cell cultures indicate that MMA^{III} may be more toxic than As^{3+}.[104,124,125] Cytotoxicity studies in human hepatocytes revealed descending toxicity of arsenic and its metabolites as follows: MMA^{III} > arsenite > arsenate > MMA^{V} = DMA^{V}. Thus, toxicity increases with the formation of MMA^{III}.

Urinary elimination of unchanged arsenic and its methylated metabolites occurs via glomerular filtration and tubular secretion; active reabsorption does occur.[161] Human studies demonstrate renal arsenic elimination of 46â€“68.9% within the first 5 days postingestion.[20,77,126] Approximately 30% is eliminated with a half-life of greater than 1 week, while the remainder is slowly excreted with a half-life of greater than 1 month.[20,109] Fecal elimination is considerably less, with reported amounts ranging from 0.21â€“6.1% in humans.[110,154]

Arsenobetaine is also well absorbed and is excreted unchanged in the urine.[165] Elimination occurs more rapidly than with inorganic arsenic. In a study involving human volunteers, 25% was excreted within 2â€“4 hours, 50% by 20 hours, and 70â€“83.7% after 166 hours. A two-component exponential model shows nearly 50% of the arsenobetaine eliminated, with a first component $t_{1/2}$ of 6.9â€“11.0 hours and a second component $t_{1/2}$ of 75.7 hours.[77]

Pathophysiology

Investigations of the pathophysiologic effects induced by toxic doses of arsenic, in contradistinction to therapeutic doses, have elucidated the toxic mechanisms discussed below. The apoptotic mechanisms thought to be responsible for some therapeutic effects of arsenic trioxide have not been studied in toxicity models.

Trivalent Arsenic

The primary biochemical lesion of As^{3+} is inhibition of the pyruvate dehydrogenase (PDH) complex (Fig. 85-2). Normally,

dihydrolipoamide is recycled to lipoamide, a necessary cofactor in the conversion of pyruvate to acetyl-coenzyme A (CoA). As^{3+} binds the sulfhydryl groups of dihydrolipoamide, blocking lipoamide regeneration.[131] Acetyl-CoA is a central molecule in metabolism, and the resulting decrease leads to several deleterious effects:

- Decreased citric acid cycle activity and thus decreased adenosine triphosphate (ATP) production. Disruption of oxidative phosphorylation leads to production of hydrogen peroxide and oxygen radicals.
- Decreased gluconeogenesis that can worsen hypoglycemia. Pyruvate carboxylase catalyzes the conversion of pyruvate to oxaloacetate (initial step in gluconeogenesis), and this reaction requires the carboxylation of biotin, a CO_2 carrier attached to pyruvate carboxylase. Biotin cannot be carboxylated unless acetyl-CoA is attached to the enzyme.[132,152]

In the citric acid cycle, oxidation of Î±-ketoglutarate to succinyl-CoA uses an Î±-ketoglutarate dehydrogenase complex that contains the same cofactors as the PDH complex, including lipoamide. Arsenic also blocks the dihydrolipoamideâ€“lipoamide recycling in this complex, thus interfering with citric acid cycle activity at a second point. Succinyl-CoA is necessary for production of porphyrins and amino acids, and deficiency may contribute to the anemia and wasting seen with chronic arsenic poisoning. Arsenic inhibition of thiolase, the catalyst for the final step in fatty acid oxidation, also impairs ATP production. Diminished fatty acid oxidation results in decreased acetyl-CoA, in the loss of the reduced form of nicotinamide adenine dinucleotide (NADH) and the reduced form of flavin adenine dinucleotide ($FADH_2$) (electron carriers reduced during fatty acid breakdown whose subsequent oxidation yields ATP). Trivalent arsenic also inhibits glutathione synthetase, glucose 6-phosphate dehydrogenase (required to produce nicotinamide adenine dinucleotide phosphate [NADPH]), and glutathione reductase.[5] These

inhibitions result in decreased levels of reduced glutathione, which is required to facilitate arsenic metabolism, protect RBCs from oxidative damage, maintain

hemoglobin in the ferrous state, and scavenge hydrogen peroxide and other organic peroxides.

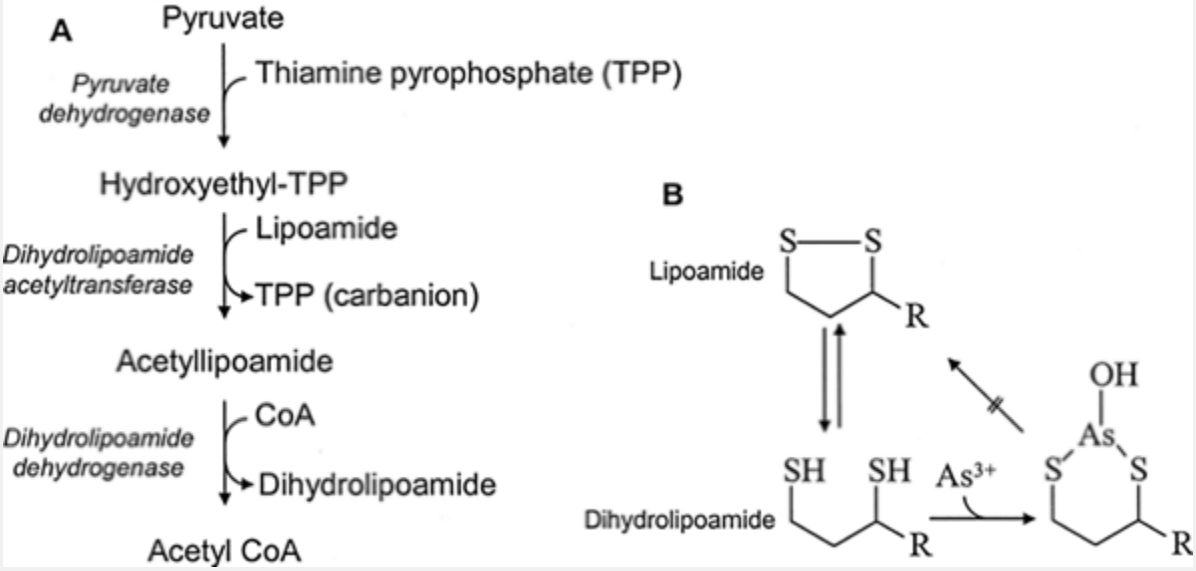

Figure 85-2. Effect of trivalent arsenicals (As^{3+}) on pyruvate dehydrogenase (PDH) complex. A. The PDH complex is composed of the three enzymes, which use thiamine pyrophosphate (TPP) and lipoamide as cofactors to decarboxylate pyruvate and form acetyl CoA. B. Arsenic interferes with the regeneration of lipoamide from dihydrolipoamide, thereby altering the function of the PDH complex.

Arsenic affects cardiac repolarization currents. When toxicity occurs, the result is ventricular dysrhythmias, including torsades de pointes. An in vitro study of cells exposed to As^{3+} demonstrated blockade of the delayed rectifier channels I_{Ks} and I_{Kr}. Interestingly, activation of

$I_{K\text{-}ATP}$, a weak inward rectifier channel, also occurred; this activation could potentially counteract some of the effects of As^{3+} on the I_{Ks} and I_{Kr} channels.[41]

Animal experiments with phenylarsine oxide, a trivalent arsenical, demonstrate inhibition of insulin-induced glucose transport involving vicinal sulfhydryl groups, as well as Î²-cell damage in pancreatic islets attributed to inhibition of the Î±-ketoglutarate dehydrogenase complex.[17] These findings support a link between exposure to arsenic and the development of diabetes mellitus.[91,128] The impaired glucose transport, plus the inhibited gluconeogenesis (discussed above), can lead to glycogen depletion and hypoglycemia.[133] Several animal experiments indicate improved central nervous system (CNS) glucose content[132] and an increase in survival time with glucose treatment.[34,166]

Pentavalent Arsenic

Several mechanisms can cause toxicity from As^{5+}; pentavalent arsenic can be transformed to As^{3+}.[73,168] Pentavalent arsenic also resembles phosphate chemically and structurally, may share a common transport system for cellular uptake with phosphate,[73] and can uncouple oxidative phosphorylation by substituting for inorganic phosphate (P_i) in the glycolysis reaction catalyzed by glyceraldehyde 3-phosphate dehydrogenase (Fig. 85-3). The resulting unstable product, 1-arseno-3-phosphoglycerate, spontaneously hydrolyzes to 3-phosphoglycerate, so glycolysis continues, but the ATP normally produced during conversion of 1,3-bisphosphoglycerate to 3-phosphoglycerate is lost. Uncoupling may also occur if adenosine diphosphate (ADP) forms ADP-arsenate, instead of ATP, in the presence of As^{5+}. The ADP-arsenate rapidly hydrolyzes, thus uncoupling oxidative phosphorylation.

Effects on RBCs include decreased membrane fluidity and ATP depletion.[177] Chronic arsenic exposure is associated with vascular disease; in vitro studies demonstrate inhibition of endothelial cell

proliferation and glycoprotein synthesis in addition to lipid peroxidation.[27] A study or rodent and human platelets demonstrates increased platelet aggregation and arterial thrombosis.[95] Noncirrhotic hepatic portal fibrosis can develop. In a controlled study where mice chronically ingested water containing equal parts As^{3+} and As^{5+} for up to 15 months, the development of portal fibrosis was preceded by decreased hepatic glutathione (GSH), increased lipid peroxidation, and diminished levels or activities of numerous enzymes involved in regenerating GSH or scavenging free radicals.[139] Proposed mechanisms by which arsenic induces cancer include DNA damage induced by a dimethyl sulfide (DMS)-derived peroxyl radical, gene amplification, replacing phosphate in DNA during replication, and increased cell proliferation.[80,180] Experimental evidence and human studies support a number of etiologic or contributing factors for skin keratosis and cancer,[1] including chronic stimulation of keratinocyte-derived growth factors such as transforming growth factor-Î± (TGF-Î±); impaired methylation; mutation in the p53 tumor-suppressor gene; inhibition of poly(ADP-ribose) polymerase vital for DNA repair; and interference with mitotic spindle and microtubular function.[56,72,179]

Pigmentary changes also occur, and hyperpigmentation is attributed to increased melanin.

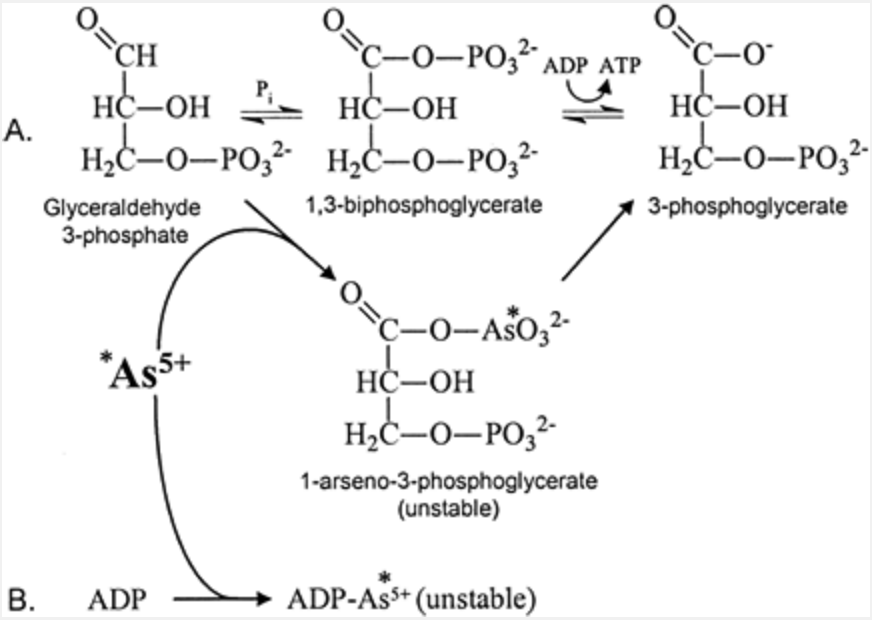

Figure 85-3. Pathophysiologic effects of pentavalent arsenic (As^{5+}). A. As^{5+} substitutes for inorganic phosphate (*), bypassing the formation of 1,3-bisphosphoglycerate (1,3-BPG), and thus losing the ATP formation that occurs when 1,3-BPG is metabolized to 3-phosphoglycerate. B. Energy loss also occurs if As^{5+} substitutes for P_i and blocks the formation of ATP + AMP from two ADPs. ADP = adenosine diphosphate; AMP = adenosine monophosphate; ATP = adenosine triphosphate.

Clinical Manifestations

Toxic Effects: Inorganic Arsenicals

Toxic manifestations vary, depending on the amount and form of arsenic ingested, as well as the chronicity of ingestion. Other influencing factors include individual variations in methylation and excretion. Larger doses of a potent compound, such as arsenic

trioxide, will rapidly produce manifestations of acute toxicity, whereas chronic ingestion of substantially lower amounts of pentavalent arsenic in groundwater will slowly result in a different clinical picture. Manifestations of subacute toxicity can develop in patients who survive acute poisoning, as well as in patients who are slowly poisoned environmentally. To avoid misdiagnosis, the physician must be aware of these differences.

Acute Toxicity

Gastrointestinal signs and symptoms of nausea, vomiting, abdominal pain, and diarrhea, which occur 10 minutes to several hours following ingestion, are the earliest manifestations of acute poisoning by the oral route. The diarrhea has been compared to that seen with cholera and may resemble â€œrice water.â€• Severe multisystem illness can ensue in the extensive exposure. Cardiovascular signs, ranging from sinus tachycardia and orthostatic hypotension to shock, can develop. Reported cases have mimicked myocardial infarction or systemic inflammatory response syndrome, with intravascular volume depletion, capillary leak, myocardial dysfunction, and diminished systemic vascular resistance.[10,14,16,60,78,143] Acute encephalopathy can develop and progress over several days, with delirium, coma, and seizures attributed to cerebral edema and microhemorrhages.[22,50,143] Seizures may be secondary to dysrhythmias, and the underlying cardiac rhythm should be assessed. In 3 cases, seizures secondary to torsades de pointes associated with a prolonged QTc interval developed 4 days to 5 weeks after acute arsenic ingestion.[14,58,149] Acute lung injury, acute respiratory distress syndrome and respiratory failure, hepatitis, hemolytic anemia, acute renal failure, rhabdomyolysis, other ventricular dysrhythmias, and death can occur.[16,48,63,112,153] Three people died after suddenly developing bradycardia, followed by asystole.[16,78,101] Fever may develop, misleading the practitioner to diagnose sepsis.[43,78] Hepatitis can occur and may be a result of altered intrahepatic heme metabolism causing an increased synthesis of

bilirubin or a result of altered protein transport between hepatocytes.[3] Acute renal failure may be secondary to ischemia caused by hypotension, tubular deposition of myoglobin or hemoglobin, renal cortical necrosis, and direct renal tubular toxicity.[18,55,140,162] Glutathione depletion may be contributory.[70] Unusual complications include phrenic nerve paralysis, unilateral facial nerve palsy, pancreatitis, pericarditis, and pleuritis.[11,187] Fetal demise has been reported, with toxic arsenic levels found in the fetal organs.[16,100]

Acutely poisoned patients with less severe illness may experience gastroenteritis and mild hypotension that persist despite antiemetic and intravenous crystalloid therapies. Hospitalization and continued intravenous fluids may be required for several days.[93] The prolonged character of the gastrointestinal symptoms is atypical for most viral and bacterial enteric illnesses and should alert the physician to consider arsenic poisoning, especially if there is a history of repetitive gastrointestinal illnesses. A metallic taste or oropharyngeal irritation can occur; the latter can mimic pharyngitis.[16,67] The garlicky breath odor attributed to inorganic arsenicals has also been reported with exposure to arsine gas. Gastrointestinal ulcerative lesions and hemorrhage have been reported.[50,60] Toxic erythroderma and exfoliative dermatitis result from a hypersensitivity reaction to arsenic.[155]

Subacute Toxicity

In the days and weeks following an acute exposure, prolonged or additional signs and symptoms in the nervous, gastrointestinal, hematologic, dermatologic, pulmonary, and cardiovascular systems can occur. Encephalopathic symptoms of headache, confusion, decreased memory, personality change, irritability, hallucinations, delirium, and seizures may develop and persist.[43,52] Sixth cranial nerve palsy and bilateral sensorineural hearing loss are reported.[33,58] Peripheral neuropathy typically develops 1â€“3 weeks

after acute poisoning, although in one series 9 patients developed maximal neuropathy within 24 hours of exposure.[33,67,93] Sensory symptoms develop first, and diminished to absent vibratory sense may be present. Progressive signs and symptoms include numbness, tingling, and formication with physical findings of diminished to absent pain, touch, temperature, and deep-tendon reflexes in a stocking-glove distribution. Superficial touch of the extremities may elicit severe or deep, aching pains, a finding that also occurs with thallium poisoning. Motor weakness may then develop. The most severely affected patients manifest an ascending flaccid paralysis that mimics Guillain-BarrÃ© syndrome.[33,67,93] Respiratory problems can include dry cough, rales, hemoptysis, chest pain, and patchy interstitial infiltrates.[67,123] These findings may be misinterpreted as viral or bronchitic disease. Leukopenia, and less commonly anemia and thrombocytopenia, occur from days to 3 weeks after an acute exposure, but resolve as bone marrow function returns.[74,97]

Dermatologic lesions can include patchy alopecia, oral herpetiform lesions, a diffuse pruritic macular rash, and a brawny nonpruritic desquamation. Diaphoresis and edema of the face and extremities can develop. Mees lines (transverse striate leuconychia of the nails) are 1â€“2-mm-wide horizontal nail bands that represent disturbed nail matrix keratinization. (See ILMEESUNES in the Image Library at http://www.goldfrankstoxicology.com) They are uncommon in arsenic poisoning. In one series of 74 patients with acute and chronic toxicity, Mees lines were found in only 5% of the patients. Mees lines are also reported with thallium poisoning, chemotherapy, Hodgkin disease, helminthic infections, renal failure, and systemic lupus erythematosus.[1,179] A minimum of 30 days after exposure is required for the lines to extend visibly beyond the nail lunulae. Contact dermatitis has been reported from topical exposure in an occupational setting. Other possible toxic manifestations of subacute inorganic arsenic toxicity include nephropathy, fatigue, anorexia with weight loss, torsades de pointes, and persistence of gastrointestinal symptoms.[10,105]

Chronic Toxicity

Chronic low-level exposure to inorganic arsenicals typically occurs from occupational or environmental sources. Malignant and nonmalignant skin changes, hypertension, diabetes mellitus, peripheral vascular disease, and several internal malignancies are associated with drinking water containing arsenic that is consumed by study populations.[121,183] The skin is very susceptible to the toxic effects of arsenic; multiple dermatologic lesions have been reported in populations suffering from hydroarsenicism.[108,183] Alterations in pigmentation occur first, with hyperpigmentation being the most common. Hypopigmentation (â€œraindropâ€• pattern) can also occur. (See ILARSENIC1 in the Image Library.) Hyperkeratoses typically develop on the palms and soles, but can be diffuse. (See ILARSENIC2 in the Image Library.) Squamous and basal cell

carcinomas and Bowen disease may occur. Bowen disease usually proliferates in multiple sites, especially on the trunk, and is noted for developing on sun-protected areas. Latency periods for developing keratoses, Bowen disease, and squamous cell carcinoma were 28, 39, and 41 years, respectively, in 17 patients chronically exposed to environmental or medicinal arsenic.[178] Gastrointestinal symptoms of nausea, vomiting, and diarrhea are less likely but can occur. Hepatomegaly was present in 190 of 248 patients with hydroarsenicism; liver biopsy in 69 cases revealed a noncirrhotic portal fibrosis in 91.3%.[139] Portal hypertension and hypersplenism have occurred. Hepatic angiosarcomas have been linked to arsenic exposure.[32,79,92] Population studies in areas of Bangladesh and Taiwan with arsenic contaminated water show an increased prevalence of diabetes mellitus.[128,160] Restrictive lung disease was reported in 9 of 17 patients, and a restrictive plus obstructive pattern occurred in another 7 cases.[108] Aplastic anemia and agranulocytosis are documented in patients exposed to arsenic.[43] A doseâ€“response relationship between arsenic exposure and vascular

disease is reported in several populations. After adjusting for age, sex, hypertension, diabetes mellitus, cigarette smoking, and alcohol consumption, a significant relationship was observed with cerebrovascular disease in a region of Taiwan.[31] Blackfoot disease, an obliterative arterial disease of the lower extremities, occurring in Taiwan, is linked to chronic arsenic exposure,[159] as is ischemic heart disease.[23] Incidence of Raynaud phenomenon and vasospasm was reported to be increased in smelter workers exposed to arsenic compared to a control group.[90] Encephalopathy and peripheral neuropathy are the neurologic manifestations most commonly reported.[13,66] Electromyographic studies of 33 patients with chronic ingestion of arsenic-contaminated water revealed 10 patients with findings consistent with sensory neuropathy. The minimum time for exposure was 2 years. Interestingly, 3 patients consumed water with an arsenic concentration that slightly exceeded the contaminant level of 50 ppb that was previously permissible in the United States.[69] Arsenic is classified as a definite carcinogen by the International Agency for Research on Cancer (IARC, Group 1) and the National Toxicology Program (NTP). Cancers known to develop include lung (adenocarcinomas and oat cell carcinomas) and skin. Bladder carcinoma is strongly associated; transitional cell carcinoma was the most common type in one large epidemiologic study.[30] Suprisingly perhaps, a critical literature review of animal and human studies found that exposure to environmental arsenic was unlikely to cause reproductive or developmental toxicity.[40]

Melarsoprol

The therapeutic use of melarsoprol can produce many of the toxic effects that occur with inorganic arsenic, including fever, encephalopathy, and acute cerebral edema with seizures and coma. Whether these effects are caused by drug toxicity or by an immune reaction elicited by trypanosomal antigens is unknown.[122,158] Other adverse effects include vomiting, abdominal pain, peripheral neuropathy with hypersensitivity reactions, hypertension, myocardial

damage, and albuminuria. Hemolysis can occur in patients with glucose-6-phosphate dehydrogenase deficiency, and erythema nodosum in patients with leprosy. In a study of the usefulness of melarsoprol as a treatment for refractory or advanced leukemia, reported adverse effects included fatigue, vomiting, diarrhea, vertigo, fever, seizures, headache, back pain, and injection site pain.[148]

Adverse Drug Effects: Arsenic Trioxide

The most common adverse effects are *dermatologic* (skin dryness, pigmentary changes, maculopapular eruptions with or without pruritus), *gastrointestinal* (nausea, vomiting, anorexia, diarrhea and dyspepsia), *hematologic* (leukemoid reactions), *hepatic* (elevation of aminotransferase concentrations typically â‰¤10 times the upper limit of normal values; with a reported incidence of 20% with low-dose and 31.9% with conventional-dose therapy[144]), *cardiac* (prolonged QTc interval in 40â€“63% of patients, first-degree atrioventricular block, ventricular ectopy, monomorphic nonsustained ventricular tachycardia, torsades de pointes, sudden asystole, and death),[138,144,147,163,176] *facial edema*, and *neurologic* (paresthesias, peripheral neuropathy, and headache). All of these effects occurred more commonly in one case series with conventional-dose therapy (0.16 mg/kg/d) when compared to low dose therapy. They are usually treated symptomatically without discontinuing As_2O_3 treatment. Leukemoid reactions, defined as white blood cell counts greater than 10 Ã— 10^9/L, develop in approximately 50% of patients between 14 and 42 days of beginning treatment. Such patients are at risk for intracerebral hemorrhage or infarction and for the APL syndrome. This syndrome is similar to the retinoic acid syndrome; the remission induction treatment phase is the period of greatest risk.[145] Approximately 20â€“25% of patients will develop one or more signs or symptoms of this syndrome, including pulmonary interstitial infiltrates and/or pleural effusions, dyspnea, tachypnea, fluid retention, myalgias, arthralgias, fever, and weight

gain.[106,116,138,144,145]

Diagnostic Testing

Timing of testing for arsenic must be correlated with the clinical course of the patient and whether the poisoning is acute, subacute, chronic, or remote with residual clinical effects. To properly interpret laboratory measurements, confounding factors, such as food-derived organic arsenicals or accumulated arsenic (DMA and arsenobetaine) in patients with chronic renal failure, must be considered.[37,189,190] Failure to understand potential confounders, as well as the time course of arsenic metabolism, clearance, and effect on laboratory parameters, can complicate the assessment of possible arsenic poisoning.

Urine and Blood

Diagnosis ultimately depends on finding an elevated urinary arsenic concentration. In an emergency, a spot urine may be sent prior to beginning chelation therapy. A markedly elevated arsenic concentration verifies the diagnosis in a patient with characteristic history and clinical findings, whereas a low level does not exclude arsenic toxicity.[171] In 9 acutely symptomatic patients, initial spot urine arsenic levels ranged from 192 to 198,450 Âµg/L.[81] Because urinary excretion of arsenic is intermittent, definitive diagnosis hinges on finding a 24-hour urinary concentration equal to or greater than 50 Âµg/L, 100 Âµg/g creatinine, or 100 Âµg total arsenic. All urine should be collected in metal-free polyethylene containers; acid-rinsed containers are no longer necessary. If testing is performed by an outside reference laboratory, specimens from acutely ill patients should be sent via express transportation with a request for a rapid result.

When interpreting slightly elevated urinary arsenic levels, laboratory findings must also be correlated with the history and clinical findings,

because seafood ingestion is reported to transiently elevate urinary arsenic excretion up to 1700 Âµg/L.[9] When seafood arsenic is a consideration, speciation of arsenic can be accomplished

by high-performance liquid chromatography (HPLC) separation, followed by inductively coupled plasma-mass spectrometry (ICPMS), HPLC via ion-pair chromatography coupled with hydride-generation atomic-fluorescence spectrometry (HGAFS), or by hydride generation coupled with cold-trap gas chromatography-atomic absorption spectrometry. These techniques separate arsenobetaine (AsB), As^{3+}, As^{5+}, MMA, and DMA.[47] Arsenobetaine can also be directly measured by silica-based cation-exchange separation, followed by atomic absorption spectrometry.[117] Two other methods, selective hydride-generation atomic-absorption spectrometry (HGAAS) and resin-based ion-exchange chromatography, do not directly measure AsB; instead, they indirectly derive this value by subtracting the sum of all measured arsenic species from the total arsenic concentration.[117] If arsenic speciation cannot be done, the patient can be retested after a 1-week abstinence from fish, shellfish, and algae food products.

Conditions under which urine is stored can affect total arsenic recovery, as well as proportionality of the species. The various arsenic speciesâ€”arsenate (As^{5+}), arsenite (As^{3+}), MMA, DMA, and AsBâ€”remain stable for 2 months in urine stored without preservatives at either â€“4Â°F (â€“20Â°C; freezer) or 39.2Â°F (4Â°C; refrigerator); AsB is stable for 8 months under these conditions. Storage for longer than 2 months can alter the recovery of various species. Addition of 0.1% hydrochloric acid (HCl) facilitates reduction of arsenate to arsenite and also decreases MMA and DMA levels. Acid-washed collection containers should not be used if measurement of the various arsenic species is planned. Total arsenic recovery can be diminished by any of the following: specimen storage for greater than 2 months, acidification, or testing using the HPLC-ICPMS and HPLC-HGAFS methods, in which samples are filtered prior to undergoing HPLC separation.[47]

Diagnostic evaluation of chronic toxicity should include laboratory parameters that may become abnormal within days to weeks following an acute exposure. Tests should include a complete blood count, renal and liver function tests, urinalysis, and 24-hour urinary arsenic determinations. Complete blood count findings can include a normocytic, normochromic, or megaloblastic anemia; an initial leukocytosis followed by development of leukopenia, with neutrophils depressed more than lymphocytes, and a relative eosinophilia; thrombocytopenia; and a rapidly declining hemoglobin, indicative of hemolysis or a gastrointestinal hemorrhage.[89] Basophilic stippling of RBCs can be seen; this can occur in other toxic and clinical disorders. Karyorrhexis, a rupture of the RBC cell nucleus with chromatin disintegration into granules that are extruded from the cell, and dyserythropoiesis are reported in both lead- and arsenic-toxic patients. Both findings are caused by arsenic-induced inhibition of DNA synthesis and damage to the nuclear envelope.[45] The karyorrhexis can occur within 4 days and resolve by 2 weeks after poisoning, and may be an early indication of arsenic toxicity.[89] Elevated serum creatinine, aminotransferases, and bilirubin, as well as depressed haptoglobin concentrations, may develop. Urinalysis may reveal proteinuria, hematuria, and pyuria. Cerebrospinal fluid examination in patients with CNS findings can be normal or exhibit mild protein concentration elevation, measured at 26.5 mg/dL in one case.[67] Urinary arsenic excretion in subacute and chronic cases varies inversely with the postexposure time period, but low-level excretion can continue for months after exposure. In a study of 41 cases of arsenic-induced peripheral neuropathy, most patients with a neuropathy of 4â€“8 weeks duration had total 24-hour urinary arsenic measurements of 100â€“400 Âµg.[67]

Hair and Nail Testing

In cases of suspected arsenic toxicity, in which the urinary arsenic measurements fall below accepted toxic levels, analysis of hair and nails may yield the diagnosis. Arsenic can be detected in the

proximal portions of hair within 30 hours of ingestion.[184] Inorganic arsenic is the form best absorbed by these tissues and the form most commonly found in human poisoning cases; small amounts of methylated metabolites may also be detected.[127] Arsenobetaine has not been found in hair and tissues in human and animal studies.[181,182] Hair grows at rates varying from 0.7â€“3.6 cm per month, with a mean rate of 1 cm per month.[173] The Society of Hair Testing has made the following recommendations for collection of hair specimens, in the context of testing for drugs of abuse: (a) collect approximately 200 mg of hair from the posterior vertex region of the scalp using scissors to cut as close to the scalp as possible, and (b) tie the hairs together, wrap in aluminum foil to protect from environmental contamination, and store at room temperature.[173] Nails grow approximately 0.1 mm per day. Total replacement of a fingernail requires 3â€“4 months, whereas toenails require 6â€“9 months of growth. These facts, plus the frequency of hair cutting, should be considered when estimating the usefulness of measuring arsenic levels in these tissues. The normal values of the testing laboratory should be used to determine whether arsenic levels are elevated. In cases of remote toxicity, hair and nail arsenic measurements may or may not be elevated, depending on the time elapsed since exposure. Sequential hair analysis to assess the time(s) of exposure can be performed by solid sampling graphite furnace atomic absorption spectrophotometry, or by x-ray fluorescence spectrometry.[82,156,157]

Challenge Testing

The role of challenge testing is unclear. In a study of people chronically exposed to elevated levels of arsenic in groundwater, a baseline urine was collected at â€“2 to zero hours in an exposed group (whose groundwater contained arsenic 510â€“660 Âµg/L), and in a control population (whose groundwater contained arsenic 0â€“21 Âµg/L). Sodium 2,3-dimercapto-1-propane sulfonate (DMPS) 300 mg was then administered, and urines were collected in 2-hour aliquots

for the next 6 hours. Total concentrations of inorganic arsenic, MMA, and DMA were elevated in the post-DMPS aliquots in both groups, more so in the exposed group. On a percentage basis, MMA levels were elevated the most.[8] It is unknown whether a DMPS challenge could assist in diagnosing an acute or a remote exposure with non-diagnostic urine, hair, and nail measurements.

Other Tests

Abdominal radiographs might demonstrate radiopaque material in the gastrointestinal tract soon after an ingestion;[2,29,60,61,68] however, even after an acute ingestion the absence of radiopaque materials on abdominal radiographs is reported.[36] The incidence of positive radiographs after an ingestion is unknown, and a negative radiograph should not eliminate arsenic as a diagnostic consideration. Electrocardiographic changes reported include QRS widening, QTc prolongation, ST segment depression, T-wave flattening, ventricular premature contractions, nonsustained monomorphic ventricular tachycardia, and torsades de pointes.[12,119,147,163] Nerve conduction studies (NCS) can confirm or diagnose clinical or subclinical axonopathy. Both the sensory nerve action potential

(SNAP) and the motor compound muscle action potential (CMAP) measure the number of axons that can conduct impulses. However, the sensory studies are more sensitive than motor studies in detecting axonal degeneration and demyelination; decreased SNAP measurements can indicate subclinical neuropathy. In motor nerve studies, the amplitude (height of the CMAP) is a more sensitive measure of the number of axons that can conduct impulses than is the conduction velocity; this can be explained by the pattern of axonal destruction. Nerve biopsies have confirmed disintegration of both axons and myelin in patients with arsenic-induced peripheral neuropathy; the axonal loss begins distally in the lower extremities and is initially scattered. Thus, conduction along the remaining functional axons can be sufficient to produce normal or only slightly

decreased conduction measurements on NCS.[57,67,83,93,114,118]

Management

General

Acute arsenical toxicity is life-threatening and mandates aggressive treatment. Advanced life support monitoring and therapies should be initiated when necessary, but with a few caveats. Careful attention to fluid balance is important because cerebral and pulmonary edema may be present. Xenobiotics that prolong the QTc, such as the class IA, class IC, and class III antidysrhythmics, should be avoided. Potassium, magnesium, and calcium concentrations should be maintained within normal range to avoid exacerbating a prolonged QTc. Glucose concentrations and glycogen stores should be maintained parenterally with dextrose and hyperalimentation solutions, or with enteral feedings, in view of their beneficial effects, in experimental models of arsenic poisoning.[98,132,133,152] Arsenic poorly adsorbs to activated charcoal, cholestyramine, and bentonite. Activated charcoal should be administered in the presence of significant ingestions. If radiopaque material is visualized in the gastrointestinal tract, whole-bowel irrigation can be administered until the radiopaque material is no longer seen on repeat abdominal radiograph. Continuing nasogastric suction may be important in removing arsenic resecreted in the gastric or biliary tract. Arsenite was still detectable in the gastric aspirate in 3 patients 5â€“7 days following an ingestion.[103] There is no clinical experience with the use of *N*-acetylcysteine to increase glutathione levels; an animal experiment suggested a protective effect.[129]

In cases of chronic toxicity, patients should be removed from the arsenic source and gastric decontamination should be performed if there is evidence of arsenic in the gastrointestinal tract. Arsenic can be readily removed from skin with soap, water, and vigorous scrubbing. In all cases, when homicidal intent is suspected, patients

should be advised against accepting food or drink from anyone who might be responsible. Also, the hospital visitors should be closely monitored and outside nutritional products should be forbidden.

Chelation Therapy

The decision to initiate chelation therapy should depend on the clinical condition of the patient as well as the laboratory results for arsenic in urine, hair, or nails. A severely ill patient with known or suspected acute arsenic poisoning should be chelated immediately, prior to laboratory confirmation. In a series of 33 patients who had coma, seizures, or both, 24 patients were treated with British anti-Lewisite (BAL) within 6 hours (mean: 1 hour) and 75% survived, compared with a survival rate of 45% of 9 patients who were treated later (range: 9â€“72 hours; mean: 30 hours).[43] Cases of subacute and chronic toxicity can await rapid laboratory confirmation prior to beginning chelation, unless the clinical condition deteriorates.

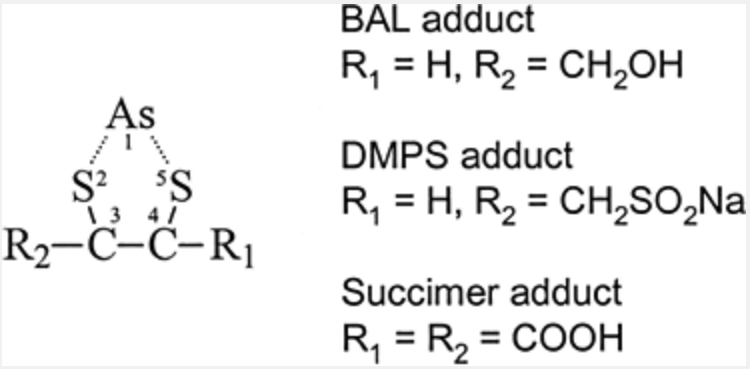

Figure 85-4. 1,2,5-Arsadithiolane adducts with BAL, DMPS, and DMSA.

Specific

Chelators

Dimercaprol (BAL) and 2,3-dimercaptosuccinic acid (succimer) are the 2 chelators available in the United States. A third drug, DMPS, is distributed by Heyl, a German pharmaceutical company, as Dimaval, but it is not approved or marketed in the United States (see Antidotes in Depth: Succimer [2,3-Dimercaptosuccinic Acid]). All contain vicinal dithiol moieties that bind arsenic to form stable 1,2,5-arsadithiolanes (Fig. 85-4), and all are most effective when administered in doses equimolar to the arsenic burden.[113] Dosing regimens and adverse effects are listed in Table 85-3.

TABLE 85-3. Chelators

Dosage	Adverse Effects
BAL 3â€“5 mg/kg every 4â€“6 h	Hypertension; febrile reaction; diaphoresis; nausea; vomiting; salivation; lacrimation; rhinorrhea; headache; painful injection; injection site sterile abscess; hemolysis in G6PD-deficient patients; chelation of essential metals (prolonged course)
SUCCIMER 10 mg/kg/dose every 8 h for 5 d, then 10 mg/kg/dose every 12 h	Nausea; vomiting; diarrhea; abdominal gas and pain; transient elevations of hepatic aminotrans-ferases and alkaline phosphatase; rash; pruritus; sore throat; rhinorrhea; drowsiness; paresthe-sias; thrombocytosis; eosinophilia

DMPS Dose: 5 mg/kg/dose IM, administered as a 5% solution Day 1: q6â€“8h Day 2: q8â€“12h Day 3 and thereafter: q12â€“24h	Allergic reactions; increased copper and zinc excretion; nausea; pruritus; vertigo; weakness, toxic epidermal necrolysis
End point: for chelation is a 24 hour urinary arsenic of < 50 Âµg/L	

In the United States, BAL remains the initial chelating drug for acute arsenical toxicity.[113] It is the only intracellular and extracellular chelator available in the United States. BAL is administered parenterally and thus is not affected by the patient's gastrointestinal motility. Its therapeutic-to-toxic ratio is narrow, with adverse effects likely to occur in patients receiving doses of 4 mg/kg or greater. It is administered intramuscularly in peanut oil; the injections are painful and can lead to sterile skin abscesses. In a cellular study of glucose uptake impaired by a lipophilic arsenical, BAL was superior to succimer and DMPS in restoring cellular equilibrium.[113] A human case series found increased survival with early use of BAL and improvement in encephalopathy within 24 hours of initiating therapy.[43] However, other acute cases treated promptly with BAL developed peripheral neuropathy.[93] In a study of subacute cases with peripheral neuropathy, BAL accelerated neurologic recovery but did not affect the overall recovery rate.[33] Despite starting BAL therapy 8 hours postexposure, a man who had ingested 2.15 g of arsenic

developed severe toxicity and neurologic deficits.[49] Most concerning are the animal experiments indicating that BAL shifts arsenic into the brain and testes, two organs that have bloodâ€“organ barriers susceptible to this lipophilic drug.[7,71,85] It is clear that BAL has limitations, and that we need a safer, more effective intracellular/extracellular parenteral chelator.

Succimer is an oral hydrophilic analog of BAL and is the chelator of choice for subacute and chronic toxicity. It has proven effective in animal studies and in reported human cases.[7,84,96,102,146] In mice exposed to sodium arsenite, succimer was more effective than either DMPS or BAL in decreasing lethality, and more potent than BAL in restoring activity in the pyruvate dehydrogenase complex.[7] It is equal or superior to BAL in speeding arsenic elimination.[113] Liver function tests and essential metal levels should be monitored in patients requiring prolonged therapy.[51,62]

DMPS is also a water-soluble analog of BAL. Although not approved for use in the United States, it has been used on an investigational basis in a few cases (Karen Simone, PharmD, and Anthony Tomassoni, MD, personal communication). It can be administered by the oral, intravenous, and intramuscular routes. It is eliminated from the body more slowly than succimer and has the advantage of intracellular as well as extracellular distribution.[4] It predominantly binds MMA^{3+} and possibly removes the MMA^{3+} from endogenous ligands. The DMPSâ€“MMA^{3+} complex is eliminated in the urine.[6,8,59] It may also work by synergistically increasing the nonenzymatic methylation of As^{3+}.[185] Two brothers ingested nearly pure arsenic trioxide (1 and 4 g each) and were treated with intravenous and oral DMPS. The brother who ingested 4 g developed hypotension, renal failure, respiratory insufficiency, and asystolic cardiac arrest. DMPS was started 32 hours postingestion, and the patient survived with normal renal function and no neurologic dysfunction. His sibling had a milder course; DMPS was started 48 hours postingestion, and there were no neurologic sequelae on followup examination.[112] DMPS significantly increased biliary excretion of arsenic in a guinea pig

model, but did not increase fecal excretion. The latter is most likely a result of enterohepatic recirculation of the DMPSâ€“As complex.[130] D-Penicillamine has not demonstrated efficacy in chelating or reversing the biochemical lesions of arsenic and should not be used. Its previous advantage of oral administration is no longer relevant with the availability of succimer.

Hemodialysis

Hemodialysis removes negligible amounts of arsenic, with or without concomitant BAL therapy, and is not indicated in patients with normal renal function.[15,65] In patients with renal failure, hemodialysis clearance rates have ranged from 76â€“87.5 mL/min, with or without concomitant BAL therapy.[107,170] In 2 acutely toxic patients with renal failure, total arsenic removed during a 4-hour dialysis measured 4.68 mg in one and 3.36 mg in the other. Concomitant 24-hour urinary arsenic excretions were 3.12 mg and 2.03 mg, respectively. When renal function returned, however, the 24-hour urinary excretion of arsenic far exceeded that recovered with dialysis, with reported levels of 18.99 mg in the first patient and 75 mg in the second patient.[170] There are no published rigorous data regarding hemodialysis removal of a water-soluble complex such as DMPSâ€“As.[86]

Summary

Arsenicals produce multisystem toxicity by a variety of pathophysiologic mechanisms. A thorough understanding of inorganic arsenic metabolism and excretion as well as the different clinical manifestations of acute, subacute, and chronic toxicity are necessary to avoid misdiagnosis. Chelation therapy with BAL in the United States, or with DMPS elsewhere, if available, should be started immediately in the severely ill patient. Treatment can await laboratory results for patients with subacute or chronic toxicity, unless clinical deterioration intervenes. Environmental contamination

of water sources has become a major health problem in many countries, including the United States.

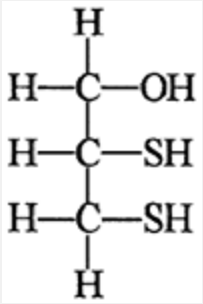
Antidotes in Depth

Dimercaprol (British Anti-Lewisite or BAL)

Mary Ann Howland

Principles of Chelation



2,3-Dimercaptopropanol (BAL)

Prior to a discussion of chelators, it is critical to understand the principles of chelation. Soft metal ions, such as Hg^{2+}, Au^{+}, Cu^{+}, and Ag^{+} have large ionic radii with a large number of electrons in their outer shell. Accordingly, they form the most stable complexes with sulfur donors and are referred to as sulfur seekers (Chap. 12).[1,5,28] The chelator or ligand, in this case, a sulfur-containing compound such as British anti-Lewisite (BAL), forms a coordinate bond with the metal by donating a pair of free electrons. Hard metals such as Na^{+}, K^{+}, Mg^{2+}, Ca^{2+}, and Al^{3+} are referred to as oxygen seekers and form the best complexes with hard ligands containing a carboxyl (COO^{-}) group, such as edetate calcium disodium ($CaNa_2EDTA$). Borderline metal ions, such as Pb^{2+}, Cd^{2+}, Cu^{2+}, As^{3+}, and Zn^{2+}, prefer nitrogen-donating ligands but will also react with both hard and soft ligands. Antidotes for metal poisoning often contain more than one type of donating group, making them effective for more than one type of metal. BAL has two adjacent sulfur groups, thus the term *dithiol;* the presence of these two sulfur groups permits the formation of a ring structure with the metal, thereby enhancing chelator stability.[1,5,28]

The most useful chelators have relatively low intrinsic toxicity, form stable complexes with the chelated metals, have tissue distribution characteristics similar to the metal to be chelated, and effect a favorable clinical outcome when administered.[1,5,28] Other desirable aspects of the metalâ€“chelator complex are elimination from the body without breaking and no redistribution to the brain or other critical organs. Unfortunately, there is no currently available chelator with all of these attributes. In addition, there are no published double-blind, randomized, placebo-controlled trials comparing outcomes with the use of metal chelators such as dimercaprol, $CaNa_2EDTA$, or succimer on lead, arsenic, or mercury poisoning in humans. The majority of efficacy data to date are derived from animal studies, several case series compared to historical controls, and several case reports. The most rigorous

human data usually describe a reduction in metal concentrations rather than improvements in clinical parameters. Redistribution characteristics of metalâ€“chelator complexes are being rigorously investigated in animal models, because redistribution to vital tissues such as the brain is of great concern. Although BAL has been in use since the late 1940s,[20] much of our current practice relies on opinion and historical precedence, and many pharmacokinetic and toxicokinetic questions remain unanswered.

History

Investigation into the use of sulfur donors as antidotes was precipitated by the World War II threat of chemical warfare with lewisite (dichloro(2-chlorovinyl)arsine) and mustard gas (dichlorodiethyl sulfide). Both are vesicant gases that cause tissue damage when combined with protein sulfhydryl (SH) groups[31] (Chap. 126). These investigations led to the discovery of the dithiol 2,3-dimercaptopropanol, called British anti-Lewisite, which combines with Lewisite to form a stable 5-membered ring.

Chemistry

BAL has a molecular weight of 124.2 Daltons and a specific gravity of 1.21.[32] BAL is an oily liquid with only 6% weight/volume water solubility, 5% weight/volume peanut oil solubility, and a disagreeable odor. Aqueous solutions are easily oxidized and therefore unstable. Peanut oil stabilizes BAL and benzyl benzoate (in the ratio of 1 part BAL to 2 parts of benzyl benzoate) renders the BAL miscible with peanut oil.[32]

Pharmacokinetics

There are no recent pharmacokinetic studies with BAL. The limited amount of information available dates back to the late 1940s. Plasma concentrations of BAL peak about 30 minutes after IM

administration and distribution occurs quickly.[32,35] Within 2 hours after IM administration to rabbits, plasma concentrations drop quickly. Urinary excretion of BAL metabolites, perhaps partially as glucuronic acid conjugates, accounted for nearly 45% of the dose within 6 hours and 81% of the dose within 24 hours.[32,34] Very little is excreted unchanged in the urine.[32] BAL is concentrated in the kidney, liver, and small intestine.[30] BAL can also be found in the feces, strongly implying that enterohepatic circulation exists. Hemodialysis may be useful in removing the BALâ€“metal chelate in cases of renal failure.[19,25,37]

Use of BAL for Arsenic Poisoning

Animal Studies

The fear that Lewisite might be sprayed over the land and its population, causing skin lesions, led researchers to investigate the potential for cutaneous application of BAL.[36] This was based on its limited water solubility and high lipid solubility. In a rodent model, low concentrations of topical BAL were very effective both in preventing lewisite-induced toxicity and in reversing toxicity when administered within 1 hour of skin exposure.[29,31] In rabbits, ocular application of BAL proved effective in preventing eye destruction

if applied within 20 minutes of exposure.[19] Additionally, urinary arsenic concentrations were significantly increased after the application of BAL.[31]

The effectiveness of both parenteral single-dose and multiple-dose BAL against lewisite and other arsenicals was studied in rabbits. When begun within 2 hours of lewisite exposure, BAL injections of 4 mg/kg every 4 hours led to a 50% survival of exposed rabbits. This dose regimen was demonstrated to be one-seventh of the maximum tolerated dose of BAL.[13]

The most recent animal studies demonstrate that although studies with BAL increase the LD_{50} (median lethal dose for 50% of test subjects) of sodium arsenite, the therapeutic index of BAL is low and arsenic redistribution to the brain occurs.[2,3,4,16,33] In these same animal models, succimer and the investigational agent 2,3-dimercaptopropane sulfonate (DMPS) also increased the LD_{50}, but with a better therapeutic index and without causing redistribution to the brain.

Human Studies

Experiments in human volunteers who were given minute amounts of arsenic demonstrated that BAL increased urinary arsenic concentration by approximately 40%, with maximum excretion occurring 2â€“4 hours after BAL administration.[38] BAL was subsequently used in the treatment of arsenical dermatitis resulting from syphilis therapy with organic arsenicals. When applied to affected skin, topical BAL produced erythema, pruritus, and dysesthesias, but had no adverse effects on unaffected skin. Intramuscular BAL produced both subjective and objective improvement, limited the duration of the arsenical dermatitis, and increased urinary arsenic elimination.[9,23,24]

In a study of 227 patients with inorganic arsenic poisoning, maximal efficacy and minimal toxicity were achieved when 3 mg/kg of BAL was administered intramuscularly every 4 hours for 48 hours and then twice daily for 7â€“10 days. This regimen resulted in complete recovery in 6 of 7 patients with severe arsenic-induced encephalopathy and demonstrated the importance of administering BAL as soon as possible after the exposure. Of 33 patients with severe arsenic-induced encephalopathy, 18 of 24 (75%) treated within 6 hours survived, versus only 4 of 9 (44%) treated after a delay of at least 72 hours.[12] Furthermore, the effectiveness of BAL was also demonstrated in 3 patients who were treated successfully after mistakenly receiving 10â€“20 times the

therapeutic dose of Mapharsen (oxophenarsine hydrochloride). A fourth patient, treated with inadequate doses of BAL, died.[12] These cases also support the effectiveness of BAL in treating arsenic-induced agranulocytosis, encephalopathy, dermatitis, and probably arsenical fever.[12]

When BAL first became more widely available, 42 children who were treated following arsenic ingestions were compared to a historical group of 111 other children who had ingested arsenic.[39] The percentage of children exhibiting symptoms on presentation were similar between groups (46%), but in the group of treated children there were fewer deaths (0 vs. 3), a shorter average hospital stay (1.6 vs. 4.2 days), and fewer cases of persistent symptoms at 12 hours (0% vs. 29.3%).

Ocular damage caused by lewisite is partly a result of the liberation of hydrochloric acid, which results in an acid injury causing localized superficial opacity of the cornea and deep penetration of lewisite into the cornea and aqueous humor with resultant rapid necrosis. In an experimental model, a 5% BAL ointment or solution applied within 2 minutes of exposure prevented the development of a significant reaction; application at 30 minutes lessened the reaction, but did not prevent permanent damage.[17]

Mercury

Because mercury also reacts with sulfhydryl groups, animal studies were performed to assess the affinity and ability of thiols to competitively chelate inorganic mercury and prevent toxicity. As in the case of arsenic, the dithiols BAL and BAL glucoside were more effective than the monothiol 1-thiosorbitol in preventing mercury-induced death and uremia.[15] The clinical efficacy of BAL in treating inorganic mercury poisoning was substantiated in patients who ingested mercuric chloride.[22,21] Thirty-eight patients ingesting more than 1 g of mercuric chloride who were treated with BAL

within 4 hours of exposure were compared to historical controls.[21] There were no deaths in the 38 patients treated with BAL as compared to 27 deaths in the 86 untreated patients. Death typically resulted from hemorrhagic gastritis and renal failure.[21] BAL is particularly useful for patients who have ingested a mercuric salt, as the associated gastrointestinal toxicity of the mercuric salt limits the potential of an orally administered antidote such as succimer.

Animal models demonstrate that when BAL is administered to chelate mercury following poisoning from elemental mercury vapor or exposure to short-chain organic mercury compounds, brain levels of mercury may increase.[6,8] However, in a rat model, the initiation of BAL therapy within 1 day of exposure to short-chain organic mercury compounds prevented neurologic toxicity.[40] When treatment was delayed for 12 days, no effect on established neurotoxicity could be demonstrated. As a result of these limited and somewhat contradictory data, BAL therapy is not recommended when patients are exposed to short-chain organic mercury compounds because it may increase brain concentrations of methyl mercury.[5,19] Other therapies may have greater usefulness (Chap. 92).

Lead

BAL may be used in combination with $CaNa_2EDTA$ to treat patients with severe lead poisoning. In all other cases, succimer has become the chelator of choice. When administering BAL in patients with lead encephalopathy, it is essential to administer the BAL first, followed 4 hours later by $CaNa_2EDTA$, concomitantly with the second dose of BAL. This regimen prevents the $CaNa_2EDTA$ from redistributing lead into the brain (the converse with regard to arsenic).[10,11] Providing two different chelators also reduces the blood lead level significantly faster than either one alone, and maintains a better molar ratio of chelator to lead.[10] Once the

mobilization of lead has begun, it is important to provide uninterrupted therapy to prevent redistribution of lead to the brain.[10]

Adverse Effects and Safety Issues

The toxicity of BAL is dose dependent and affected by urinary pH. An acidic urine allows dissociation of the BALâ€“metal chelate. Less than 1% of 700 intramuscular injections resulted in minor reactions, such as pain at the injection site, among patients

who received 2.5 mg/kg of BAL every 4â€“6 hours for 4 doses.[12] When doses of 4 mg/kg and 5 mg/kg were given, the incidence of adverse effects rose to 14% and 65%, respectively.[12] At these higher doses, the following symptoms were reported in decreasing order of frequency: nausea; vomiting; headache; burning sensation of lips, mouth, throat, and eyes; lacrimation; rhinorrhea; salivation; muscle aches; burning and tingling of extremities; tooth pain; diaphoresis; chest pain; anxiety; and agitation.[23] These effects were maximal within 10â€“30 minutes of exposure, and usually subsided within 30â€“50 minutes.[12] Elevations in systolic and diastolic blood pressure and tachycardia commonly occurred and correlated with increasing doses.[19,26] Thirty percent of children given BAL may develop a fever that can persist throughout the therapeutic period.[19] A transient reduction in the percentage of polymorphonuclear leukocytes may also occur.[19] Doses above 5 mg/kg should not be administered because of the high risk of adverse reactions. Doses above 25 mg/kg can be expected to produce a hypertensive encephalopathy with convulsions and coma.[39]

BAL is not very effective in the presence of arsenic-induced hepatotoxicity.[24] Moreover, in rats, preexistent hepatotoxicity was exacerbated when BAL was used for treatment of arsenic poisoning. Therefore, unless the hepatotoxicity is considered

arsenic-induced, hepatic dysfunction is a contraindication to BAL use.[31] BAL should not be used for patients poisoned by methylmercury because animal studies demonstrate a redistribution of mercury to the brain.[5,19]

Because dissociation of the BALâ€“metal chelate will occur in an acid urine, the urine of patients receiving BAL should be alkalinized with hypertonic $NaHCO_3$ to a pH of 7.5â€“8.0 to prevent renal liberation of the metal.[19] BAL should be used with caution in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency, as it may cause hemolysis.[18] In these cases, a risk-to-benefit analysis must be made because G6PD-deficiency syndromes are variably expressed in young cells. In addition, chelators are relatively nonspecific and may bind metals other than those desired, thus causing deficiency of an essential metal. For example, BAL given to mice increased copper elimination to 3 times normal.[7] BAL is formulated in peanut oil; therefore, the patient should be questioned regarding any known peanut allergy. Limited evidence suggests that iron supplements should not be given to patients who are receiving BAL because the BALâ€“iron complex appears to cause severe vomiting and decreases metal chelation.[10,11,14]

Unintentional IV infusion of BAL could theoretically produce fat embolism, lipoid pneumonia, chylothorax, and associated hypoxia.[34]

Dosing

Commercially available BAL is a yellow, viscous liquid with a sulfur odor. It is available in 3-mL ampules containing 100 mg/mL of BAL, 200 mg/mL of benzyl benzoate, and 700 mg/mL of peanut oil. This drug should only be administered by deep IM injection.

The dose of BAL for lead encephalopathy is 75 mg/m^2 IM every 4 hours for 5 days.[10,11] As noted earlier, the first dose of

dimercaprol should precede the first dose of $CaNa_2EDTA$ by 4 hours. Thereafter, intravenous $CaNa_2EDTA$, in a dose of 1500 $mg/m^2/d$ (up to a maximum of 2â€“3 g) as a continuous infusion, or divided into 2â€“4 doses, should be administered. These daily doses are equimolar.

The dose of BAL for severe inorganic arsenic poisoning has not been established. One regimen suggests the use of 3 mg/kg IM every 4 hours for 48 hours and then twice daily for 7â€“10 days.[12] Another regimen uses 3â€“5 mg/kg IM every 4â€“6 hours on the first day and then tapers the dose and frequency, depending on the patient's symptomatology. A third regimen reduces the number of injections by day 2 and terminates therapy within 5â€“7 days.[39]

The dose of BAL for patients exposed to inorganic mercury salts is 5 mg/kg IM initially, followed by 2.5 mg/kg every 8â€“12 hours for 1 day, followed by 2.5 mg/kg every 12â€“24 hours until the patient appears clinically improved, up to a total of 10 days.

Summary

BAL (dimercaprol) is an effective metal chelator used clinically in the treatment of inorganic mercury and arsenic toxicity, and in conjunction with edetate calcium disodium for lead encephalopathy and severe lead toxicity. [19,26]

Chapter 86
Bismuth

Rama B. Rao

Bismuth (Bi)

Atomic number = 83

Atomic weight = 208.98

Normal concentrations

Serum = 2â€“11 mg/L(9.52 nmol/L)

Urine = <4Âµg/L (< 20 nmol/L)

A 65-year-old man with a history of colon cancer requiring a colectomy with an ileostomy presented to his primary care physician for confusion and memory loss. He was admitted to the hospital for evaluation. His vital signs were blood pressure, 130/75 mm Hg; pulse, 72 beats/min; respirations, 18 breaths/min; oral temperature, 98.9Â°F (37.1Â°C); oxygen saturation, 99%. He was awake and alert, but could no longer remember his wife's name or

their telephone number. His head and neck examination were remarkable for darkened gums. His lung and heart examinations were unremarkable. The abdominal examination was notable for a functioning ileostomy, with dark stool in the ostomy bag, negative for occult blood. His neurologic examination revealed normal cranial nerve function, preserved reflexes, and mild tremor. A rapid reagent blood glucose was 110 mg/dL. His serum chemistries, liver function, magnetic resonance imaging of his brain, and spinal fluid analysis were all normal. Despite this, he became progressively more confused and developed myoclonus. He eventually became comatose and neurologically unresponsive with periodic twitching of lower extremities. He required nasogastric tube feeding and intubation. The diagnosis of Creutzfeldt-Jacob disease was entertained, and brain death protocols ensued. It was subsequently revealed that he was taking 12 oz of bismuth subgallate daily to diminish stool odor, and that this therapy was continued while hospitalized. The bismuth was stopped and the patient slowly started to awaken. Within 2 weeks he recovered his mental status completely. He was discharged to a rehabilitation center and subsequently made a complete recovery.

Bismuth is a metal that is either elemental or compounded as a salt. Elemental bismuth is nontoxic. Bismuth salts are employed for therapeutic uses and are responsible for the toxicities described in this chapter. Thus, in this chapter, *bismuth* refers to *bismuth salts*.

Bismuth is one of many xenobiotics commonly used for treatment of traveler's diarrhea, nausea, and vomiting, as well as for treatment of the flatus and odor associated with ileostomies and colostomies.[13] It is an active ingredient in both prescription and nonprescription oral preparations, as well as in bismuth-impregnated surgical packing paste.[8,56]

In the gastrointestinal tract, bismuth binds to sulfhydryl groups and decreases fecal odor through formation of bismuth sulfide.[49]

Sulfhydryl binding is also the proposed mechanism of the antimicrobial effect of bismuth, causing lysis of *Helicobacter pylori*, the causative bacteria in peptic ulcer formation. Bismuth may also inhibit bacterial enzyme function, as well as prevent adhesion of *H. pylori* to the gastric mucosa.[55]

History and Epidemiology

Nearly 300 years ago, bismuth was recognized as medicinally valuable. It was included in topical salves and oral preparations for various gastrointestinal disorders. Renal toxicity was described as early as 1802. In the early 20th century, cases of renal failure were reported in pediatric patients administered intramuscular bismuth salts for the treatment of gingivostomatitis.[6,24,47] Administration of bismuth thioglycollate and its related water-soluble compounds, triglycollamate and trithioglycollamate, was responsible for the renal failure.[7,11,28,54] Children with renal toxicity would typically present with abdominal pain, oliguria, anuria, malaise, and vomiting. Renal failure occurred with as little as one or two treatments. Alterations in consciousness usually abated with treatment or resolution of the uremia. As the use of intramuscular injections was abandoned, this form of bismuth-induced renal failure became uncommon.

Syphilis was previously treated with intramuscular bismuth. A rash known as â€œerythema of the 9th dayâ€• occasionally occurred. This consisted of a diffuse macular rash of the trunk and extremities that resolved without intervention.[15]

After administration of â€œAnalbisâ€• antipyretic rectal suppositories, patients developed hepatic failure, described histopathologically as

yellow atrophy with vacuolization.[2,21] An investigation of the suppositories suggested that diallylacetic acid, and not bismuth, was the hepatotoxin. This preparation is no longer marketed.

More recently, epidemics of bismuth-induced encephalopathy, particularly among patients with ileostomies or colostomies, were reported in France, Britain, and Australia. As a result, some countries banned or restricted bismuth preparations to prescription only. Bismuth subsalicylate, which is currently available in the United States as a nonprescription drug, is still periodically responsible for cases of encephalopathy.[14] Other reported causes of bismuth-induced encephalopathy include systemic absorption from bismuth-impregnated surgical packing paste, and transdermal absorption from chronic application of a bismuth-containing skin cream.

Toxicokinetics

Bismuth is present in nature in both the trivalent and pentavalent forms. The trivalent form of bismuth is employed for all medicinal uses ionic, as the bismuthyl (BiO) moiety, generated by hydrolysis of trivalent bismuth compounds yields a low-solubility alkaline salt. Most of orally administered bismuth remains in the gastrointestinal (GI) tract, being excreted in the feces; only 0.2% is systemically absorbed. Absorption of some bismuth preparations, such as colloidal bismuth subcitrate may increase as gastric pH increases.[35] The peak absorption ranges between 15 and 60 minutes, with high intra- and interindividual variation.[22,24] The plasma-to-blood ratio of bismuth is 1.55.[3] The distribution and elimination of orally administered bismuth follows a complex, multicompartmental model. The volume of distribution in humans is unknown.

Once in the circulation, bismuth binds to Î±$_2$-macroglobulin, IgM, Î²-lipoprotein, and haptoglobin. Bismuth rapidly enters liver, kidney, lungs, and bone. Bismuth can cross the placenta and enter the amniotic fluid and fetal circulation. It also readily crosses the bloodâ€“brain barrier. Evidence in a rat model suggests that, when administered intramuscularly, bismuth can access the central

nervous system via retrograde axonal transport.[48] In other animal models, bismuth is identified in the fenestrated membranes of synaptosomes,[37,40] localizing in the thalamus and cerebellum. This entry is similar to human reports, which also describe diffuse cortical uptake in toxic exposures.[24] Ninety percent of absorbed bismuth is eliminated through the kidneys, where it induces the production of its own metal-binding protein.

Some authors propose three different half-lives to describe the pharmacokinetics of orally administered therapeutic doses of bismuth. The first, a distribution half-life, is approximately 1â€“4 hours. The second, the plasma half-life, lasts 5â€“11 days. The third is the half-life of urinary excretion, lasting between 21 and 72 days,[3] with urinary bismuth detected as late as 5 months after the last oral dose.[22]

Pathophysiology

Similar to other metals, bismuth toxicity involves multiple organ systems. The effect of different bismuth salts can be categorized into 4 groups, based on the solubility and gastrointestinal absorption of the agent (Table 86-1).[42]

The mechanism of bismuth encephalopathy is thought to be related to neuronal sulfhydryl binding. In patients who die of bismuth encephalopathy, the gray matter concentration of bismuth is nearly twice that of the white matter.[24] In an encephalopathic patient dying from concomitant sepsis, the autopsy revealed loss of cerebellar Purkinje cells, which was not expected from sepsis alone.[25] The factors predisposing some individuals to encephalopathy from group II bismuth salts, however, are not well defined. Age, gender, and duration of therapeutic use do not predict the likelihood of developing encephalopathy.

TABLE 86-1. The Absorptive Characteristics of Bismuth Salts

Group	Chemistry	Toxicity	Examples
I	Insoluble in water Inorganic	Minimal	Bismuth subnitrate
II	Lipid soluble Organic	Neurologic	Bismuth subsalicylate Bismuth subgallate
III	Water soluble Organic	Renal	Bismuth triglycollamate
IV	Hydrolyzable Water soluble Organic	Minimal	Bicitropeptide

Clinical Manifestations

Acute

Acutely massive overdoses of bismuth ions can result in abdominal pain and oliguria or anuria. Acute renal failure can occur and is not limited to exposure to the water-soluble bismuth salts (group III). In reported cases, overdoses of colloidal bismuth subsalicylate or tripotassium dicitratobismuthate (TDC) caused acute tubular necrosis.[1,17,19,47,51] Histopathologically, bismuth causes

degeneration of the proximal tubule, similar to the effects of other heavy metals. While these xenobiotics are potentially neurotoxic, signs of encephalopathy are generally absent. In one case, a patient with bismuth-induced renal failure was described as having diminished deep-tendon reflexes, muscle weakness, and myoclonus, without an alteration in consciousness.[17]

Chronic

The most common toxicologic finding associated with repeated therapeutic doses of oral bismuth compounds is a diffuse, progressive myoclonic encephalopathy. Affected patients exhibit neurobehavioral changes, such as apathy and irritability. With continued exposure, these patients may develop difficulty concentrating, diminished short-term memory, and, occasionally, visual hallucinations.[26,27] A movement disorder characterized by muscle twitching, myoclonus, ataxia, and tremors may ensue. Weakness and, rarely, seizures may advance to immobility.[29,31] With continued bismuth administration, these patients can develop coma and die.

Rarely, patients recovering from severe encephalopathy may complain of scapular, humeral, or vertebral pain because of fractures caused by severe neuromuscular manifestations such as myoclonus.[12]

Like several other metals, bismuth can cause a generalized pigmentation of skin. Deposition of bismuth sulfide into the mucosa causes a blue-black discoloration of gums.[57] (See ILBISMUTH in the Image Library at http://www.goldfrankstoxicology.com) This can occur in the absence of toxic effects. Formation of the same compound in the gastrointestinal tract causes blackening of the stool. Liver failure is rarely reported, except in patients with multisystem organ failure from fatal neurotoxicity.

Diagnosis

The clinician must have an index of suspicion based on the acute or chronic nature of the exposure. Patients with acute massive overdoses should be observed and evaluated for possible renal failure. The earliest findings suggestive of renal compromise may be hematuria and proteinuria on urinalysis. Formation of nuclear inclusion bodies can be identified on renal biopsy or on postmortem examination of the kidney.[11,39]

The diagnosis of bismuth encephalopathy is based on a history of exposure coupled with diffuse neuropsychiatric and motor findings.[27] Other causes of encephalopathy should be entertained and excluded (Table 86-2). An abdominal radiograph will likely demonstrate radiopacities of bismuth in the intestines. Stool will be black, but will test negative for occult blood.

The presence of bismuth in the blood is confirmatory of exposure, but absolute concentrations correlate poorly with morbidity. In a review of 310 patients with bismuth encephalopathy, 288 patients (93%) had a blood concentration >100 Âµg/L, with the majority of these blood concentrations between 100 Âµg/L and 1000 Âµg/L.[26] Twenty-two patients suffered encephalopathy at blood concentrations below 100 Âµg/L.[26] In another report, 2 patients with encephalopathy had blood concentrations of 900 Âµg/L and 2500 Âµg/L, both of whom recovered when the concentration fell below 500 Âµg/L.[5] Just as blood concentrations do not reflect severity of illness, tissue concentrations may also poorly correlate with severity of illness. An example was noted in a patient who recovered from a severe encephalopathy. On discharge, he had low blood bismuth concentrations and died 3 months later of unrelated trauma. At autopsy he was found to have an elevated central nervous system (CNS) bismuth burden, but no reported symptoms at the time of the trauma.[9]

The electroencephalographic (EEG) findings of patients with bismuth encephalopathy generally demonstrate nonspecific slow wave changes.[14,17] In one study, the EEG findings were described in association with blood concentrations. At less than 50 Âµg/L, the EEG was normal or demonstrated diffuse slowing. In patients with blood concentrations of less than 1500 Âµg/L, the findings of sharp wave abnormalities were noted. At higher concentrations (>2000 Âµg/L), some patients with neurologic events, such as myoclonic jerks, did not have corresponding EEG changes. The authors proposed that an elevated body burden might have an inhibitory effect on the cerebral cortex.[9]

In encephalopathic patients with blood concentrations >2000 Âµg/L, diagnostic imaging, such as computed tomography, may demonstrate a diffuse cortical hyperdensity of the gray matter. These findings tend to resolve with recovery. Magnetic resonance imaging was normal in another encephalopathic patient.[14]

TABLE 86-2. Differential Diagnosis of Bismuth Encephalopathy

Creutzfeld-Jacob disease
Ethanol withdrawal
Lithium toxicity
Neurodegenerative leukoencephalopathies
Nonketotic hyperosmolar coma
Postanoxic and posthypoglycemic encephalopathies
Progressive multifocal ataxia
Viral encephalopathies

Treatment

Typically, supportive care results in a complete recovery. Some authors suggest GI decontamination with activated charcoal and polyethylene glycol solution.[44] Although evidence for this approach is lacking, it appears to be a reasonable initial intervention, especially in patients with severe encephalopathy.

In patients with renal toxicity, resolution is generally observed with supportive care. The use of chelating agents in acute overdose without neurotoxicity is probably not indicated. Withdrawal of the source of bismuth often results in complete reversal of symptoms within days to weeks, even in severely ill patients.

In general, the data regarding chelation are limited, and in vitro and animal models do not clearly predict in vivo human models. Chelation therapy with British anti-Lewisite (BAL) is beneficial in experimental models,[44,47] reportedly beneficial in humans,[30] and often recommended, although clear evidence of efficacy is lacking. BAL undergoes biliary elimination, offering a major advantage over other chelators in patients who may develop renal insufficiency. One study advocated the addition of dimercaptopropane sulfonate (DMPS), as BAL with hemodialysis did not affect clearance, whereas the addition of DMPS to patients needing hemodialysis was effective in enhancing elimination.[47] It is uncertain whether the clinical course of the patients was improved. In human volunteers using colloidal bismuth subcitrate, succimer and DMPS, both at a dose of 30 mg/kg, increased urinary elimination of bismuth by 50-fold.[45]

In an animal model, D-penicillamine was most efficacious in enhancing elimination of bismuth. In a human volunteer model using therapeutic doses of TDC, however, a single dose of D-penicillamine did not enhance urinary excretion.[32]

The precise timing, dosage, indications, and choice of chelator are unknown; however, chelation with succimer has few side effects and might limit the potentially fatal complications associated with

prolonged immobilization. BAL, which has more side effects, can be considered in encephalopathic patients with renal failure in whom no neurologic improvement is noted within 48 hours of bismuth withdrawal and whole-bowel irrigation.

Prevention is the most effective means of avoiding neurotoxicity. Patients and their families should be taught to recognize the subtle manifestations of bismuth-induced neurotoxicity. Blood concentrations of bismuth are not routinely performed, but a bismuth concentration >100 Âµg/L, or symptoms at lower levels, warrant withdrawal of bismuth therapy.

Bismuth Drug Interactions and Reactions

The coadministration of proton pump inhibitors (PPIs) may affect the absorption of some bismuth preparations. In a prospective evaluation of patients receiving different treatment regimens for *Helicobacter pylori*-induced dyspepsia or peptic ulcer disease, individuals taking PPIs had a statistically significant elevation in their blood bismuth concentrations. The authors suggest that the bismuth preparation usedâ€”colloidal bismuth subcitrateâ€”is more soluble and absorbable at the higher gastric pH of patients on PPIs. All of these patients received short courses of therapy (2 weeks). Although the investigators did not attempt to follow neurobehavioral

or neuropsychiatric changes, none of the patients had clinically evident bismuth toxicity.[35]

Based on this investigation, coadministration of PPIs with longer courses of colloidal bismuth subcitrate should be avoided or only offered with extreme caution. Ranitidine, which is frequently prescribed with a bismuth compound for dyspepsia or ulcer disease, does not affect the pharmacokinetics of bismuth

absorption.[22]

In the United States, where bismuth subsalicylate is the most common oral bismuth-containing compound, up to 90% of the salicylate is absorbed.[36] Salicylate toxicity has been reported and salicylate concentrations should be performed in both acute and chronic exposures. Methemoglobinemia from subnitrate salt of bismuth is uncommonly described.[20]

Summary

The most likely manifestations of bismuth toxicity are either neuropsychiatric or renal, depending on the type of compound and whether the etiology is related to chronic therapy or acute overdose. The factors predisposing some individuals to neurotoxicity from therapeutic use of oral bismuth compounds are poorly understood. Thus patients using therapeutic bismuth with new movement disorders or alterations in mental status should be assessed for possible bismuth-induced encephalopathy.

Chapter 87
Cadmium

Stephen J. Traub
Robert S. Hoffman

Cadmium (Cd)

Atomic number = 48

Atomic weight = 112.40

Normal concentrations

Whole blood = < 5Âµg/L(4 nmol/L)

Urine = <3Âµg/g creatinine(2.6 nmol/L creatinine)

A 53-year-old man who performed metalwork as a hobby became ill approximately 6 hours after welding in his shop. He developed a violent cough, and sought care from a local physician. The physician, who elicited the history of metalwork, diagnosed metal fume fever, reassured the patient that his symptoms would pass, and discharged him home.

The next morning the patient's condition worsened, and he presented to a local emergency department complaining of severe shortness of breath. His vital signs were blood pressure, 105/64 mm Hg; pulse, 117 beats/min; respiratory rate, 22 breaths/min and labored; and temperature, 101.3Â°F (38.5Â°C). Pulmonary examination revealed diffuse crackles. Pulse oxygenation was 87% on room air. Supplemental oxygen of 4 L/min via nasal cannula was administered, and the patient's oxygen saturation improved to 94%. Arterial blood gas analysis and cooximetry confirmed the patient's hypoxia and excluded methemoglobinemia and carboxyhemoglobinemia. A chest radiograph demonstrated diffuse infiltrates suggestive of bronchoalveolar fluid. Further history revealed that the patient had been welding with a cadmium-containing solder, without appropriate respiratory precautions. A working diagnosis of cadmium pneumonitis was established.

The patient's respiratory status slowly declined over the course of the next 24 hours, necessitating endotracheal intubation. He was treated with intravenous corticosteroids (dexamethasone 10 mg IV every 6 hours) and a broad-spectrum antibiotic (ceftriaxone, 1 g IV every 12 hours), but continued to deteriorate despite aggressive and appropriate supportive care and expired on hospital day 4.

History and Epidemiology

Cadmium, atomic number 48, is a transition metal in group IIB of the periodic table. In its pure atomic form, it is a bluish solid at room temperature. It is readily oxidized to a divalent ion, Cd^{2+}. Naturally occurring cadmium commonly exists as cadmium sulfide (CdS), a trace contaminant of zinc-containing ores.[37]

Cadmium sulfide, cadmium oxide, and other cadmium-containing compounds are refined to produce elemental cadmium, which is used for industrial purposes. When combined with other metals, cadmium forms alloys of relatively low melting points, which accounts for its extensive use in solders and brazing rods. Today, cadmium is

principally used as a reagent in electroplating and in the production of nickel-cadmium batteries. Other current and historical uses of cadmium include as a pigment, as part of the phosphorescent system in black-and-white televisions, and as a neutron absorber in nuclear reactors. Cadmium salts have also been used as veterinary antihelminthics.[12]

As cadmium processing has increased, so has the incidence of cadmium toxicity. Cadmium exposure with resultant toxicity usually occurs in 1 of 3 settings: environmental, occupational, or hobby work.

Environmental Exposure

Environmental exposure to cadmium generally occurs through the consumption of foods grown in cadmium-contaminated areas. Because cadmium is fairly common as an impurity in ores, areas where mining or refining of ores takes place are at highest risk for contamination. Many countries, including Sweden[44] and Belgium,[11] have reported on environmental cadmium exposure, but the most remarkable historical example of environmental cadmium pollution occurred in Japan.

In the 1950s, a mine near the Jinzu River basin discharged large amounts of cadmium into the environment, contaminating the rice that was a staple of the local food supply. An epidemic of painful osteomalacia followed, affecting hundreds of people, with postmenopausal multiparous women being most affected.[63] The afflicted were prone to develop pathologic fractures, and were reported to call out â€œitai-itaiâ€• (translated literally as â€œouch-ouchâ€•) as they walked, because of the severity of their pain.[29] These symptoms were ultimately linked to the cadmium.

Environmental exposure also occurs in smokers, who have higher blood cadmium concentrations than do nonsmokers,[84] probably as a result of cadmium contamination of the soil in which the tobacco is grown. This is noteworthy, in that cadmium and tobacco may be

synergistic causes of chronic pulmonary disease.[58]

Occupational and Hobby Exposure

Welders, solderers, and jewelry workers who use cadmium-containing alloys are at risk for developing acute cadmium toxicity through inhalation of cadmium oxide fumes. Other workers who do not work with metals per se may develop significant chronic cadmium toxicity through exposure to cadmium-containing dust.

Hobbyists who work with cadmium solders have exposures similar to occupational metalworkers. Significant cadmium toxicity in this population invariably results from metalworking in a closed space with inadequate ventilation and/or improper respiratory precautions.

Toxicokinetics

There is no known biologic role for cadmium. The bioavailability of elemental cadmium is unknown. Orally ingested cadmium salts are poorly (5â€“20%) bioavailable. However, inhaled cadmium fumes (cadmium oxide) are readily bioavailable (up to 90%).[91] Because the only data on cadmium toxicokinetics come from work with cadmium salts and oxides, â€œcadmiumâ€• in the following discussion refers to these species, unless otherwise noted.

After exposure, cadmium is taken up into the bloodstream, where it is bound to $\hat{I}\pm_2$-macroglobulin and albumin.[92] It is then quickly and preferentially redistributed to the liver and kidney. Although other organs, such as the pancreas, spleen, heart, lung, and testes, can take up part of an acute cadmium load, they do so much less avidly.[26] Cadmium enters target organs by 3 mechanisms: zinc and calcium transporters; uptake of cadmiumâ€“glutathione or cadmiumâ€“cysteine complexes by transport proteins; and endocytosis of cadmium-protein complexes.[96]

After it is incorporated in the liver and kidney, cadmium is complexed with metallothionein, an endogenous thiol-rich protein that is

produced in both organs. Metallothionein binds and sequesters cadmium. Slowly, hepatic stores of the cadmiumâ€“metallothionein complex (Cd-MT) are released. Circulating Cd-MT is then filtered by the glomerulus. A significant amount is reabsorbed and concentrated in proximal tubular cells.[79,80] This, in part, explains why the kidney is the principal target organ in cadmium toxicity.

There is no evidence that cadmium ions are oxidized, reduced, methylated, or otherwise biotransformed in vivo. The volume of distribution (Vd) of cadmium is unknown, but is presumably quite large as a consequence of significant hepatic sequestration. Cadmium distribution and elimination are complex, and an 8-compartment kinetic model is proposed.[51] The slow release of cadmium from metallothionein-complexed hepatic stores accounts for its very long biologic half-life of 10 or more years.

Pathophysiology

Cellular Pathophysiology

Cadmium is very quickly and efficiently complexed to metallothionein in vivo, which raises the question of whether free cadmium or the cadmium-metallothionein complex is the ultimate toxicant. It appears, however, that unbound cadmium mediates cellular damage.[26,36,56,61,80] The metallothionein complex is protective[23,56] and functions as a natural chelating agent with a strong affinity for cadmium.[19,52] Although metallothionein may play a role in proximal tubular concentration of cadmium, renal damage is actually attenuated by metallothionein, as metallothionein-deficient mice demonstrate more toxicity after cadmium exposure than controls.[56]

There are several mechanisms by which cadmium interferes with cellular function. Cadmium binds to sulfhydryl groups, denaturing proteins and/or inactivating enzymes. The mitochondria are severely effected by this process,[1] which may result in an increased

susceptibility to oxidative stress.[45] Cadmium also interferes with E-cadherin, N-cadherin and Î²-cateninâ€“mediated cellâ€“cell adhesion.[67,68,69] Finally, the demonstrated interference of cadmium with calcium transport mechanisms[88,89] might lead to intracellular hypercalcemia and, ultimately, apoptosis.

Specific Organ System Injury

Kidney

The renal damage caused by cadmium develops over years. Proteinuria is the most common clinical finding, and correlates with proximal tubular dysfunction, which manifests as urinary loss of low-molecular-weight proteins such as $Î²_2$-microglobulin and retinol-binding protein. Cadmium also produces hypercalcuria,[76] possibly also via damage to the proximal tubule.

Bone

Cadmium-induced osteomalacia is a result of abnormalities in calcium and phosphate homeostasis, which, in turn, result from renal proximal tubular dysfunction. In one autopsy study, the severity of osteomalacia in cadmium-exposed subjects correlated with a decline in the serum calcium-phosphate product.[83]

Lung

Acute cadmium pneumonitis is characterized by infiltrates on the chest radiograph and hypoxia. Human autopsy studies[33,66,77,93] generally show degeneration and/or loss of bronchial and bronchiolar epithelial cells.

Gastrointestinal Tract

Based on case reports,[8,94] ingested cadmium salts appear to be caustic substances with the potential to induce significant nausea,

vomiting, and abdominal pain, and result in GI hemorrhage, necrosis, and perforation. With respect to their effect on the GI mucosa, cadmium salts appear to be similar to mercuric salts (Chap. 92).

Clinical Manifestations

Acute Poisoning

Pulmonary/Cadmium Fumes

Cadmium pneumonitis results from inhalation of cadmium oxide fumes. The acute phase of cadmium pneumonitis may mimic metal fume fever (Chap. 119), but in fact, the two entities are distinctly different, both in mechanism and in clinical consequences. Whereas metal fume fever is benign and self-limited, acute cadmium pneumonitis can progress to hypoxia, respiratory insufficiency, and death.

Published case reports of patients who develop acute cadmium pneumonitis[4,5,33,66,77,85,93,95] are strikingly similar in the presentation described. Within 6â€“12 hours of soldering or brazing with cadmium alloy in a closed space, patients typically develop constitutional

symptoms, such as fever and chills, as well as a cough and respiratory distress.

On initial presentation, these patients may not appear significantly ill and instead may have a normal physical examination, oxygenation status, and chest radiograph. This relatively benign presentation may lead both to the misdiagnosis of metal fume fever and the underestimation of the severity of the patient's illness. As the pneumonitis progresses to acute lung injury (ALI) (Chap. 119), crackles and rhonchi develop, oxygenation becomes impaired, and the chest radiograph develops a pattern consistent with alveolar filling.

Despite aggressive supportive care, death may occur, usually within 3â€“5 days.[33,66,77,93]

Patients who survive an episode of acute cadmium pneumonitis may develop chronic pulmonary ailments, including restrictive lung disease,[4,5] diffusion abnormalities,[4] and pulmonary fibrosis.[85] Recovery without sequelae is also reported after exposure.[95]

Oral/Cadmium Salts

Although most acute cadmium exposures are inhalational, acute oral exposures also occur. In one case,[8] a 17-year-old woman ingested approximately 150 g of cadmium chloride and presented to the emergency department with hypotension and edema of the face, pharynx, and neck. Her condition quickly deteriorated, and she suffered a respiratory arrest. She was intubated, underwent orogastric lavage, chelation with an unspecified agent, and charcoal hemoperfusion. Multisystem organ failure ensued, and she died within 30 hours of presentation. At autopsy, the most significant finding was hemorrhagic necrosis of the upper GI tract. Her blood cadmium concentration was more than 2000 times normal.

In a second case,[94] a 23-year-old man ingested approximately 5 g of cadmium iodide in a suicide attempt and presented with acute hemorrhagic gastroenteritis. His condition deteriorated, and despite treatment with ethylenediaminetetraacetic acid (EDTA) and supportive measures, he died on hospital day 7. Autopsy did not reveal a specific cause of death.

Chronic Poisoning

Chronic cadmium poisoning generally occurs through occupational exposures, although instances of mass environmental exposure, such as occurred in Japan,[29,62] are reported. All studies of chronic cadmium poisoning in humans are retrospective, and thus neither randomized nor controlled. In addition, and especially in the industrial

setting, cadmium exposure may serve simply as a marker for other exposures, such as toxic vapors, other metals, or solvents. These other toxins may contribute to, or cause, the pathologic condition described.

Nephrotoxicity

The most common finding in chronic cadmium poisoning is proteinuria. Low-molecular-weight proteinuria is usually more significant than, and generally precedes, glomerular dysfunction, although some cadmium-exposed workers manifest predominantly glomerular proteinuria.[7] There is a doseâ€“response relationship between total-body cadmium burden and renal dysfunction,[11,43,44,63,87] although this relationship may not be as strong at low doses.[39] In most patients, proteinuria is generally considered to be irreversible even after removal from exposure,[38,49,72] but improvement is sometimes reported.[86] Less clear is the question of whether renal dysfunction progresses after removal from exposure, with studies showing both stable[38] and deteriorating[41,71,72] renal function in cadmium-exposed workers following cessation of exposure. The routes and duration of exposure, as well as blood and urine cadmium concentrations, differ markedly between these studies, limiting the importance and breadth of wider applicability of any analysis.

Occupational cadmium exposure is also associated with nephrolithiasis,[42,75] likely as a result of hypercalciuria.[76]

Pulmonary Toxicity

Large studies of workers chronically exposed to cadmium fail to demonstrate consistent effects on chronic lung disease. In one study of 57 workers with sufficient exposure to cadmium oxide to produce renal dysfunction, there was no evidence of pulmonary dysfunction, even in those with the greatest cumulative cadmium exposure.[28] In contrast, other studies demonstrate both restrictive[18] and

obstructive[22,74] changes on pulmonary function tests. Interestingly, a followup study of the group with restrictive lung disease showed improvements after cadmium exposure was reduced.[17] The discrepancies in these results may be partly a result of markedly different degrees of exposure among the various groups.

Cadmium is associated with pulmonary neoplasia; the carcinogenicity of cadmium is discussed separately (see Cancer below).

Musculoskeletal Toxicity

Osteomalacia, which was one of the most prominent features of the Itai-Itai epidemic, is a condition in which inadequate mineralization of mature bone predisposes to pathologic fractures. Although mentioned in case reports,[9,49] osteomalacia is generally not a prominent feature of most people occupationally exposed to cadmium. Victims of the original Itai-Itai epidemic were mostly women, whereas occupational cadmium exposures typically occur in men. In addition, differences in cumulative dosing and in route of exposure (oral vs. pulmonary) may account for some of the unique prominence of osteomalacia in the Itai-Itai epidemic.

Hepatotoxicity

Although the liver stores as much cadmium as any other organ, hepatotoxicity is not a prominent feature in humans with cadmium exposure, probably because hepatic cadmium is usually complexed to metallothionein.[40] The liver can potentially be a target organ, however, and hepatotoxicity is easily inducible in animals.[1,26,27,70]

Neurologic Toxicity

Cadmium exposure is linked to olfactory disturbances,[59,73,82] impaired higher cortical function,[90] and Parkinson syndrome.[64,90]

Other Organ Systems

Cadmium induces hypertension in rats,[55] but human studies have not shown a convincing link.[32,65] Although there is evidence that cadmium may cause immunosuppression affecting both humoral and cell-mediated immunity in animals,[25] a single human study showed no overt immunopathology in an occupationally exposed cohort.[48] The testes are clearly a target organ in animal exposures,[54] but the testes are not considered a major target organ in humans.

Cancer

Cadmium induces tumors in multiple animal organs, an effect that is exacerbated by zinc deficiency.[91]

In humans, cadmium exposure is associated with lung cancer. The strength of this association has been questioned because most studies have methodologic problems, such as coexposure to arsenic, a known pulmonary carcinogen.[10,50] Despite this, cadmium is designated as a human carcinogen by the International Agency for Research on Cancer.[13]

Diagnostic Testing

Other than to confirm exposure, cadmium concentrations have limited usefulness in the management of the acutely exposed patient. Diagnosis and treatment are based on the patient's history, physical examination, and symptoms. In a patient exposed to cadmium oxide fumes, ancillary tests, such as arterial blood-gas analysis and chest radiography, are more useful than actual cadmium concentrations.

In the patient chronically exposed to cadmium, both cadmium concentrations and ancillary testing may prove helpful. Urinary cadmium concentrations, which reflect the slow, steady-state turnover and release of metallothionein-bound cadmium from the liver, are a better reflection of the total-body cadmium burden than are whole blood concentrations. Workers at high risk for cadmium toxicity

should undergo a regular urinalysis for proteinuria, and the development of proteinuria should prompt immediate reassignment to exposure-free areas. For asymptomatic workers without proteinuria, 15 Âµg Cd/g urinary creatinine is considered acceptable, although renal dysfunction has occurred at concentrations as low as 5 Âµg Cd/g urinary creatinine.[21,43] This concentration is significantly higher than that of the general US population, 95% of whom have concentrations that are less than 2 Âµg Cd/g urinary creatinine.[16]

Management

Acute Exposure

Oral Exposure/Cadmium Salts

After the status of the patient's airway, breathing, and circulation are addressed, attention can be given to gastrointestinal decontamination. Although large oral exposures to soluble cadmium salts are rare, they frequently prove fatal.[8,94] The lowest reported human lethal dose is 5 g. In light of this, if a significant exposure occurs but emesis has not occurred, gastric lavage is appropriate. In this situation, a small nasogastric tube should suffice, as inorganic cadmium salts are powders, not pills. There are no specific data regarding the use of activated charcoal for acute oral cadmium toxicity; however, activated charcoal is a relatively benign intervention and is indicated in the treatment of some metal salts, such as thallium and mercury (Chaps. 92 and 96). Activated charcoal should thus be given in the absence of any contraindications (such as known perforation or pending endoscopy).

Given the relative lack of experience with acute oral cadmium poisoning, all patients with known exposures and/or abnormal findings consistent with cadmium toxicity or exposure should be admitted to the hospital for supportive care, monitoring of renal and hepatic function, and possibly evaluation of the gastrointestinal tract for

injury.

Although it seems logical to use chelation therapy in any patient with an acute life-threatening ingestion of a metal compound, the benefit of chelation in acute cadmium exposure is unproven. Multiple chelating agents have been tried, all in animal models, with inconsistent results.

The ideal chelating agent for treatment of oral cadmium toxicity would be well tolerated, decrease gastrointestinal absorption of cadmium, decrease the concentration of cadmium in organs such as the kidney and liver, and not increase cadmium concentrations in other critical organs such as the brain. Of the chelating agents studied for cadmium toxicity thus far, succimer comes closest to fulfilling these criteria. In models of acute oral cadmium toxicity, succimer decreases the gastrointestinal absorption of cadmium[3,6] and improves survival[6,47] without increasing cadmium burdens in target organs.[2,6]

In a patient thought to have ingested potentially lethal amounts of cadmium, treatment with succimer is reasonable. The succimer should be given as soon as possible after the ingestion, as the effectiveness of chelating agents decreases dramatically over time in experimental models of cadmium poisoning.[15]

It must be stressed, however, that supporting data for chelation are promising but not definitive, and are only derived from animal models. Furthermore, succimer dosing in human cadmium poisoning is unstudied. Doses that are well tolerated (10 mg/kg/dose TID) are appropriate.

Other chelating agents that may be beneficial, but for which further investigation is needed, include diethylenetriaminepentaacetic acid (DTPA)[6,14] and 2,3-dimercaptopropane sulfonate (DMPS),[14,47] both of which reduce tissue burdens and increase survival.

Most other chelating agents have been found to be either ineffective or detrimental, including 2,3-dimercaptopropanol (British anti-Lewisite, BAL),[14,19,46] penicillamine,[14,57] cyclic tetramines (such as

cyclam and tACPD),[81] detergent formula chelating agents such as sodium tripolyphosphate (STPP) and nitrilotriacetic acid (NTA),[30,31] EDTA,[60] and dithiocarbamates.[3,34]

Pulmonary/Cadmium Fumes

The patient who is ill after exposure to cadmium fumes (generally cadmium oxide) invariably presents with respiratory complaints and possibly with constitutional symptoms. The airway should be assessed and appropriate oxygenation assured, although hypoxia may not be a problem acutely. Steroids are used in most reported cases, but there are no studies to support their efficacy. Because cadmium inhalation injuries are neither benign nor self-limited, all patients with acute inhalational exposures to cadmium should be admitted to the hospital for observation and supportive care until respiratory symptoms have resolved. All such patients should have long-term followup arranged with a pulmonologist to assess the possibility of chronic lung injury, even in instances of single exposures.

Chelation should not be entertained as an option for patients with single acute exposures to cadmium fumes, as these patients do not appear to develop extrapulmonary injury.[4,5,85,95]

Chronic Exposure

Patients chronically exposed to cadmium frequently come to attention during routine screening, as those who work with cadmium are under close medical surveillance. These patients may have developed proteinuria or, less commonly, chronic pulmonary complaints.

Management is challenging. Cessation of cadmium exposure is the first intervention. However, as mentioned earlier, chronic cadmium-induced renal and pulmonary changes are largely irreversible.

Chelation for chronic cadmium toxicity is not currently recommended. There is no evidence that chelation of chronically poisoned animals improves long-term outcomes. Furthermore, in a chronically exposed

patient, the majority of cadmium is bound to intracellular metallothionein, which greatly reduces its toxicity. Any attempt to remove cadmium from these deposits risks redistributing cadmium to other organs, possibly exacerbating toxicity, as is known to occur with BAL therapy.[24]

Of all the chelating agents tested thus far in animal models of chronic cadmium toxicity, the dithiocarbamates have shown the

most success in reducing total-body cadmium burdens. Unfortunately, the most effective agents, which are highly lipophilic, also tend to cause redistribution of cadmium to the brain; their lipophilicity not only allows them to cross cell membranes into hepatocytes, but also promotes their uptake into the lipid-rich central nervous system.[35] Numerous dithiocarbamates have been synthesized and studied with regard to cadmium decorporation, however, and several species effectively reduce whole-body, renal, and hepatic cadmium concentrations without an increase in CNS cadmium.[53,78] At this time, there are no FDA-approved dithiocarbamate preparations.

Further research into the subject of chelation for chronic cadmium poisoning is ongoing, and may produce an agent that is both safe and effective without exacerbating end-organ toxicity. At present, there is insufficient evidence to justify the use of any chelating agent in the treatment of chronic cadmium toxicity.

Summary

Cadmium is a toxic element with different effects dependent on the chronicity and route of exposure. After acute oral exposure, gastrointestinal injury predominates. After acute inhalation, a severe chemical pneumonitis may ensue. With chronic environmental or occupational exposure, nephrotoxicity (usually manifested by proteinuria) is the most significant finding, although other organ systems, such as the lungs, can be affected. Treatment for all patients with suspected cadmium poisoning consists of removal from

the source, decontamination if possible, and supportive care. In the rare instance of exposure from acute cadmium salt ingestion, treatment with succimer may be warranted. At this time there is insufficient evidence to recommend chelation in the chronically cadmium poisoned patient.

Chapter 88
Chromium

Steven B. Bird

Chromium (Cr)

Atomic number	=	24
Atomic weight	=	51.99 daltons

Normal concentrations

Whole blood	=	20â€“30 Âµg/L (380â€“580 nmol/L)
Serum	=	0.05â€“2.86 Âµg/L (1â€–56 nmol/L)
Urine	=	<1 Âµg/g creatinine (<0.2 nmol/mmol creatinine)

Colleagues brought a 26-year-old chemistry graduate student to the emergency department after he admitted to drinking an

unspecified amount of a 70% potassium dichromate ($K_2Cr_2O_7$) solution. Immediately after arrival the student complained of abdominal pain and vomiting blood, followed soon after by hematochezia. His past medical history was significant only for depression, and the patient denied other ingestions or illicit drug use. His mental status was depressed to the point where the patient could offer no further history.

The patient was noted to be cyanotic, lethargic, and ill appearing. His vital signs were systolic blood pressure, 80 mm Hg; pulse, 140 beats/min; respiratory rate, 32 breaths/min; temperature, 98.6Â°F (37Â°C); and oxygen saturation, 85% on 100% oxygen via non-rebreather mask. His oropharynx contained fresh blood without obvious burns. Lungs were clear to auscultation. The abdomen was rigid without any detectable bowel sounds. Extremities were cool with cyanotic digits.

Large-volume crystalloid resuscitation was begun immediately through 2 large-bore IV lines, followed by both norepinephrine and vasopressin drips. General surgery and gastroenterology consultants were called. Several units of packed red blood cells were rapidly transfused to treat persistent hypotension accompanied by continued massive blood loss, suctioned from a nasogastric tube.

An initial arterial blood-gas concentration was pH, 7.09; PCO_2, 24 mm Hg; PO_2, 395 mm Hg; and bicarbonate, 10 mEq/L. Cooximetry demonstrated a methemoglobin concentration of 18%. A complete blood count revealed 18,000/mm^3 leukocytes; hematocrit, 34%; and platelets 210,000/mm^3. Blood chemistries were sodium, 137 mEq/L; potassium, 6.5 mEq/L; chloride, 110 mEq/L; carbon dioxide, 12 mEq/L; blood urea nitrogen, 19 mg/dL; creatinine, 1.7 mg/dL; and glucose, 96 mg/dL. The partial thromboplastin time and prothrombin time were 36 seconds and 15 seconds, respectively.

Bedside esophagogastroduodenoscopy demonstrated

circumferential burns involving the lower esophagus with apparent full-thickness burns involving the stomach and proximal duodenum. The patient was taken to the operating room where he died during attempted gastrectomy and bowel resection.

History and Epidemiology

Chromium (from the Greek word for color, *chroma*) is a naturally occurring element that may be found in oxidation states of â€“2 to +6, but primarily in the trivalent (Cr^{3+}) and hexavalent (Cr^{6+}) forms. It was first discovered in 1797 in the form of Siberian red lead (crocoite: $PbCrO_4$), and occurs only in combination with other elements, primarily as halides, oxides, or sulfides (Table 88-1). Chromium is found most abundantly in chromite ore ($FeCr_2O_4$).[8] Elemental chromium (Cr^0) does not naturally occur.

Elemental chromium is a blue-white metal that is hard and brittle. It can be polished to a fine, shiny surface, affords significant protection against corrosion, and can be added to steel to form stainless steel (which is primarily an alloy of chromium, nickel, and iron). One of the most important uses of chrome plating is to apply a hard, smooth, surface to machine parts such as crankshafts, printing rollers, ball bearings, and cutting tools. This is known as â€œhardâ€• chrome plating. Elemental chromium is also used in armor plating and safes, and as a catalyst for forming brick molds because of its high melting point and moderate thermal expansion.

The carcinogenic potential of hexavalent chromium was first recognized as a cause of nasal tumors in Scottish chrome pigment workers in the late 1800s. In the 1930s, the pulmonary carcinogenicity of chromium was described in German chromate workers.[13]

Chemical Principles

Chromium is an essential element involved in glucose metabolism. This may be through facilitation of insulin binding to insulin receptors or by amplification of the effects of insulin on carbohydrate and lipid metabolism. Chromium deficiency may play a role in the development of diabetes mellitus and arteriosclerosis.

TABLE 88-1. Common Forms of Chromium

Name	Chemical Formula	Oxidation State	Uses
Barium chromate	$BaCrO_4$	6+	Safety matches, anticorrosive, paint pigment
Calcium chromate	$CaCrO_4$	6+	Batteries, metallurgy
Chromic acid	H_2CrO_4	6+	Electroplating, oxidizer
Chromic chloride	$CrCl_3$	3+	Supplement in total parenteral nutrition
Chromic fluoride	CrF_3	3+	Mordant in dye industry, mothproofing

			agent for wool
Chromic oxide	Cr_2O_3	3+	Metal plating, wood treatment
Chromite ore	$FeCr_2O_4$	3+	Water tower treatment, held in National Defense Stockpile
Chromium picolinate	$C_{18}H_{12}CrN_3O_6$	3+	Nutritional supplement
Lead chromate	$PbCrO_4$	6+	Yellow pigment for paints and dye
Potassium dichromate	$K_2Cr_2O_7$	6+	Oxidizer of organic compounds, leather tanning, porcelain painting

The chemical properties and health risks of chromium depend mostly on its oxidative state and on the solubility of the chromium compound. Chromium is found naturally in the hexavalent (Cr^{6+}) or in the trivalent (Cr^{3+}) valence states, and these are the species

to which most human exposures occur. However, the Cr^{6+} and Cr^{3+} oxidation states have very different properties. The relationship between these oxidative states is described by the following equation:

$Cr_2O_7^{-2}$ + 14 H^+ + 6 electrons â†' 2 Cr^{3+} + 7 H_2O + 1.33 eV[15]

This difference of 1.33 eV in electric potential between the Cr^{6+} and Cr^{3+} states reflects the significant oxidizing potential of Cr^{6+} and the high energy required for the oxidation of Cr^{3+} to Cr^{6+}. Reduction of Cr^{6+} to Cr^{3+} only occurs in vivo by abstraction of electrons from cellular constituents such as proteins, lipids, DNA, and RNA, and plasma transferrin.[37]

The rapidity and completeness of the reduction of Cr^{6+} has been the subject of considerable scientific debate. Hexavalent chromium is reduced to Cr^{3+} in saliva, the gastrointestinal tract, respiratory tract epithelium and pulmonary macrophages, and in blood.[2,34] During this reduction of Cr^{6+} to Cr^{3+}, several other oxidative states transiently occur (namely, Cr^{4+} and Cr^{5+}) that contribute to the cytotoxicity, genotoxicity, and carcinogenicity of Cr^{6+} chromium compound.[47]

Although most Cr^{6+} is rapidly reduced on entering the stomach and GI tract, ingestion of Cr^{6+} in drinking water leads to measurable chromium concentrations in plasma, red blood cells, and urine. However, there is no increase in leukocyte DNAâ€“protein cross-linking, a marker of cytotoxicity and genotoxicity.[25] Hexavalent chromium can accumulate in most body tissues, raising concerns that chromium-induced toxicity and carcinogenesis may be more widespread than is currently understood.[13]

Environmental Exposure

The processing of chromium ores releases primarily Cr^{3+} into the environment. However, some quantity of hexavalent chromium is

released from chromate manufacturing and coal-based power plants.[6] The most significant environmental sources of Cr^{6+} are chromate production, ferrochrome pigment manufacturing, chrome plating, and some types of welding.[46]

The general population may be exposed to chromium via drinking water, food and food supplements (eg, chromium picolinate), joint arthroplasty, and cigarettes. Chromium has been used extensively in industrial cooling towers and air conditioning to prevent equipment and piping corrosion. Dermal exposure may occur from use of tanned leather products or wood treated with CCA (copper, chromate, and arsenate). CCA-treated lumber was voluntarily removed from the consumer market in December 2003, because of possible health concerns as a result of exposure to the arsenic and chromium. No specific adverse health effects related to CCA-treated lumber were reported by the Environmental Protection Agency prior to the voluntary withdrawal. Significant exposure from more than 160 chromate production waste sites within Hudson County, New Jersey was discovered in the late 1980s.[20] Surveillance of these residential areas continues today.

Occupational Exposure

Workers in industries that use chromium may be exposed to 100 times greater concentrations of chromium than the general population.[47] Chromium pigment production and leather tanning use significantly more trivalent chromium compounds, whereas metal finishing, wood preservation, and cooling towers use hexavalent chromium compounds (Table 88-2).

Several studies have focused on the risk of chromium exposure in welders.[41,42] Stainless steel welding liberates significantly more hexavalent chromium than do other types of welding. Other specifics,

such as the type of welding rod used and air contaminants, also

impact the occupational risk.

TABLE 88-2. Occupations At Risk for Chromium Exposure

Cement workers
Chromite ore workers
Electroplaters
Foundry workers
Galvanized steel workers
Glass polishers and glazers
Lithographers
Machinists
Painters
Photograph developers
Tanners
Textile dyers
Welders
Wood preservers

Pharmacology and Physiology

Because they possess significantly different properties, trivalent and hexavalent chromium must be evaluated separately.

Absorption

Trivalent Chromium Compounds

After oral administration, absorption of Cr^{3+} salts is limited. Approximately 98% of the compound is recovered in the feces, 0.1% is excreted in the bile, and 0.5â€“2.0% is excreted in the urine.[17,31,33] Human case reports and animal studies also

corroborate the generally poor absorption of Cr^{3+} salts by the oral, inhalational, and dermal routes, except through burns and other disrupted mucosal or epithelial surfaces.[28]

Hexavalent Chromium Compounds

Partly as a result of the structural similarity between hexavalent chromium compounds and phosphate and sulfate, Cr^{6+} is modestly absorbed after ingestion.[14] In human volunteers, approximately 10% of an orally ingested dose of sodium chromate was absorbed; duodenal administration increased absorption to roughly 50%.[17] This difference likely relates to the reduction of the hexavalent chromium to trivalent chromium in the acidic environment of the stomach. Similarly, 3 hours after a lethal ingestion of potassium dichromate (hexavalent), greater than 80% of the chromium was reduced to the trivalent state.[21] Hexavalent chromium compounds are generally not well absorbed after dermal exposure.

Inhalation of Cr^{6+} is the most consequential route of exposure. The exact rate of absorption is unknown, but is dependent on the solubility of the specific Cr^{6+} compound, the size of the particles, the phagocytic activity of the pulmonary macrophages, and general health of the lungs. Animal studies suggest that roughly 50â€“85% of small (<5 Âµm) Cr^{6+} potassium dichromate particles are absorbed.[46]

Distribution

Because most of the Cr^{6+} is rapidly reduced on absorption, Cr^{3+} accounts for virtually the entire body burden of chromium. Trivalent chromium accumulates to the greatest extent in the kidneys, bone marrow, lungs, lymph nodes, liver, spleen, and testes. The kidneys and liver account for approximately 50% of the total body burden.[14]

Elimination

Urinary excretion of trivalent chromium occurs rapidly. Roughly 80% of parenterally administered Cr^{6+} is excreted as Cr^{3+} in the urine and 2â€“20% in the feces.[33] The urinary excretion half-life of Cr^{6+} ranges from 15â€“41 hours.[23] Because Cr^{6+} undergoes reduction to Cr^{3+} following uptake by red blood cells, an apparent slow compartment is created, with the elimination half-life dependent on the life span of erythroctyes.[27] Small amounts of chromium are detectable in sweat, breast milk, nails, and hair.

Pathophysiology

Trivalent Chromium

Cr^{3+} is an essential trace metal required for the metabolism of glucose and fats.[22] Dietary chromium deficiency leads to elevated insulin concentrations, hypercholesterolemia, hyperglycemia, increased body fat, and the attendant risks of these metabolic derangements.

Chromium picolinate is a popular Cr^{3+} dietary supplement that is ingested in large daily doses.[11] There is a dearth of rigorous scientific investigation concerning the efficacy or safety of chromium picolinate. However, it appears that organ deposition of Cr^{3+} does occur.[39]

There is little or no rigorous evidence that exposure to Cr^{3+} compounds increases cancer risk. Animal work and epidemiologic studies of workers exposed to Cr^{3+} compounds have failed to demonstrate a statistically significant increased incidence of cancer.[3] There is no strong evidence of any significant end-organ toxicity as a consequence of exposure to Cr^{3+}, perhaps because Cr^{3+} is so poorly absorbed.

Hexavalent Chromium

Cr^{6+} is a powerful oxidizing agent that has corrosive and irritant effects. However, the greatest toxicity from Cr^{6+} lies in its ability to produce oxidative DNA damage. DNA strand breaks, DNAâ€“DNA and DNAâ€“protein cross-links, and nucleotide modifications all occur.[15] Modulation of the apoptosis regulatory gene p53 and activation of protein kinase C also occur.[4] Although the exact mechanisms of how Cr^{6+} effects this genotoxicity are unknown, transient toxic chromium intermediates such as Cr^{4+} and Cr^{5+}, formed during the intracellular reduction of Cr^{6+} to Cr^{3+}, are probably responsible.[40]

Inconsistent basic science data suggest that both immunostimulation and immunosuppression are mediated by chronic chromium exposure. At least one study suggests that chromium-induced immunosuppression may be responsible for implant-associated infections in patients after hip or knee arthroplasty.[49] Although human data are missing, adverse developmental effects, including cleft palate, hydrocephalus, and neural tube defects, are demonstrated in animals.[16]

Clinical Manifestations

The clinical manifestations of chromium poisoning depend on the valence of the element, the source and route of exposure, and the duration of exposure. The clinical manifestations of chromium exposure are best divided into acute and chronic (low-level exposure) effects.

Acute

Manifestations of acute, massive Cr^{6+} ingestions are similar to other corrosive metal ingestions. Gastrointestinal hemorrhage, with or without bowel perforation, may occur acutely and may lead to hepatic and pancreatic necrosis.[52] Because of the strong

oxidative properties of Cr^{6+}, intravascular hemolysis with disseminated intravascular coagulation may also develop. Renal effects include acute tubular necrosis leading to renal failure.[51] Metabolic abnormalities that occur after acute, massive, exposure include lactic acidosis, hyperkalemia, and uremia. Acute lung injury may develop acutely for up to 3 days after exposure. Although Cr^{6+} is generally not well absorbed after dermal exposure, it is a corrosive that causes inflammation and ulceration. Dermal chromic acid (H_2CrO_4) burns may lead to severe systemic toxicity with as little as 10% body surface area involvement.

Chronic

The respiratory tract is the organ most affected after chromium exposure. When inhaled, Cr^{6+} is a respiratory tract irritant that causes inflammation and, with continued exposure, ulceration (including nasal septal perforation).[24] Furthermore, the sensitizing effects of Cr^{6+} may lead to chronic cough, shortness of breath, occupational asthma, bronchospasm, and anaphylactoidlike reactions. Chronic deposition of Cr^{6+} particles may also lead to pulmonary fibrosis and pneumoconiosis.[38]

Epidemiologic studies of chromate workers in the 1980s indicated a significantly increased risk of lung cancer in those individuals exposed to Cr^{6+} compounds.[26,36] Small-cell and poorly differentiated lung carcinomas are the most common types, although nearly all pathologic types of lung cancer are associated with inhalational Cr^{6+} exposure.[1] The latency between exposure and development of lung cancer ranges from 13â€“30 years, although cases after as few as 2 years have been reported.[7]

Although conclusive evidence is missing, it appears that chronic exposure to Cr^{6+} may cause mild to moderate elevations in hepatic aminotransferases and abnormal liver architecture, as

seen on histologic specimens.[52] Unlike acute exposures, low-dose chronic chromium exposure occasionally causes only transiently elevated urinary $Î^2_2$-microglobulin levels, with no obvious lasting effects.[51]

Type IV (delayed-type) hypersensitivity reactions may occur 2 weeks after sensitization. Although uncommon in the general population, Cr^{6+} sensitivity has occurred in up to 24% of automobile part handlers and in cement workers.[29]

Because Cr^{3+} is a sensitizing agent,[19] occupational exposure to Cr^{3+} may lead to contact dermatitis (dermatitis toxicosis) in 10â€“20% of chromium workers,[12] although it is unclear to what degree exposure to Cr^{3+} itself, rather than reduced intracellular Cr^{6+}, is responsible for the dermatitis. Similarly, chromium-containing gaming table felt has led to hand dermatitis, referred to as â€œblackjack disease,â€• and painless, scarring, skin ulcerations (â€œchrome holesâ€•).

Diagnostic Testing

Chromium may be detected in blood, urine, and hair of exposed individuals. Because of the great difficulty in speciation, differentiation between Cr^{3+} and Cr^{6+} is generally not performed; instead, the total chromium concentration is generally reported. Needles used for phlebotomy and plastic containers used for sample storage may all contain significant amounts of chromium. Modern, highly sensitive assay equipment such as graphite furnace atomic absorption spectrometry, neutron activation analysis, and graphite spark atomic emission spectrometry, requires diligence in sample handling to ensure that biologic samples are not contaminated.

Because of the inherent difficulties in quantifying trace elements such as chromium, and the lack of standard chromium reference materials, the reported normal serum and urine chromium

concentrations in unexposed people have varied by more than 5000-fold over the last 50 years.[46] Consequently, older reference ranges should be interpreted with caution.[18] Similarly, there is no single reference range for either serum, blood, or urine chromium concentrations in normal subjects.

Blood or Serum

Chromium is distributed evenly between the serum and erythrocytes. Serum chromium concentrations reflect recent exposure to both Cr^{3+} and Cr^{6+}. Blood chromium concentrations, however, are indicative only of recent Cr^{6+} exposure, because of the inability of Cr^{3+} to cross the red blood cell membrane. Serum concentrations in people without occupational exposure to chromium have been reported to be from 0.05 Âµg/L (1 nmol/L)[10] to more than 2.8 Âµg/L (56 nmol/L).[46] It is not certain whether concentrations above these values should be considered potentially toxic, as no clear correlation has been found between serum or blood concentrations and physiologic effects.

Urine

Although urine chromium concentrations reflect the acute absorption of chromium over the previous 1â€“2 days, wide individual variations in metabolism and total-body burden limit the value of urinary chromium monitoring. Urine should be collected over a 24-hour period because of diurnal variation in excretion. Although not firmly established, urinary chromium concentrations in persons without occupational exposure to chromium are typically less than 1 Âµg/g creatinine.[30]

Hair and Nails

Hair and nail samples are unreliable indicators of exposure to chromium because of the difficulty distinguishing chromium

contamination of the hair sample from chromium incorporated into the hair during protein synthesis. Chromium concentrations in hair may be up to 1000 times higher than those found in serum.

Ancillary Tests

After confirmed or suspected chromium exposure, complete blood count, serum electrolytes, blood urea nitrogen, creatinine, urinalysis, and liver enzymes should be performed. If signs of systemic toxicity are evident, serial determinations of coagulation function and disseminated intravascular coagulation may be useful to guide therapy.

Management

Acute chromium ingestions are infrequent, but often severe, with significant morbidity and mortality. Consequently, after adequate airway, breathing, and circulatory support are addressed, attention should be given to decontamination.

Decontamination

As a consequence of its serious but very limited toxicity, Cr^{3+} compounds should require limited decontamination measures. However, as coingestants could be present, standard gut decontamination with activated charcoal should be considered.

Hexavalent chromium is corrosive, and profuse vomiting and hematemesis usually follow acute ingestions. Nasogastric lavage may be beneficial after Cr^{6+} ingestions if the patient presents to the emergency department within 1â€“2 hours of exposure. There are no data regarding the use of activated charcoal in acute chromium ingestions. However, as activated charcoal is a relatively benign therapy and other coingestants may be adsorbed by activated charcoal, a single dose of activated charcoal should be considered. Endoscopic visualization may be difficult after

administration of activated charcoal and the relative benefits of these two modalities need to be considered. Known or suspected perforation is an absolute contraindication to activated charcoal.

Oral *N*-acetylcysteine increases the excretion of chromium in rats,[5] but there are no human data to support use of this therapy. Years of clinical experience using *N*-acetylcysteine for other indications and the very low incidence of adverse effects, however, favor the administration of oral *N*-acetylcysteine for acute chromium toxicity.

Although ascorbic acid facilitates reduction of Cr^{6+} to Cr^{3+} in vitro, there are no data to substantiate decreased absorption.[44] There is some evidence that topical ascorbic acid may reduce dermal Cr^{6+} exposure, but this has not been demonstrated in controlled trials.[9] Thus, the routine use of ascorbic acid cannot be advocated at this time.

Chelation Therapy

The currently available chelating agents do not appear efficacious at either lowering serum or blood chromium concentrations or ameliorating chromium toxicity in experimental models. Specifically, ethylenediaminetetraacetic acid (EDTA) was found to have no effect on urinary chromium excretion in human subjects,[50] and dimercaprol (British anti-Lewisite, BAL) was not beneficial in an animal model of chromium poisoning.[32]

In a single study, DMPS (dimercaptopropane sulfonate) had no effect on urinary chromium excretion in humans.[45] D-Penicillamine also failed to increase urinary excretion of chromium.[32] There are no studies of chromium chelation with 2,3-dimercaptosuccinic acid (succimer), although there are no data to suggest that succimer would be harmful.

Extracorporeal Elimination

Hemodialysis, hemofiltration, and peritoneal dialysis are ineffective at removing chromium. Studies in animals and human case reports indicate that as little as 1% of chromium is removed by hemodialysis or hemofiltration after acute dichromate (a hexavalent compound) exposure.[21,35,43] Exchange transfusions may rapidly reduce blood chromium concentrations, but there are no data suggesting that clinical outcomes are positively affected.[48]

Summary

Chromium remains an uncommon, but serious, cause of acute metal poisoning. The acute exposure to chromium by ingestion causes gastrointestinal hemorrhage, hepatic necrosis, and renal failure. Toxicity after chronic chromium exposure includes ulcerations of the skin and nasopharynx, and more significantly, lung cancer. Definitive data regarding other types of cancer resulting from chronic Cr^{6+} exposure are unavailable. Regardless of the time course of the poisoning, treatment for chromium exposure includes removal of the patient from the source of exposure, gastrointestinal decontamination if indicated, and supportive care. There is insufficient evidence to support the use of chelating agents in either acute or chronic chromium poisoning.

Cobalt

Gar Ming Chan

Cobalt (Co)

Atomic number = 27

Atomic weight = 58.9

Normal concentrations

Serum	=	0.1â€“1.2 Âµg/L
Urine	=	0.1â€“2.2 Âµg/L

A 13-month-old, 10-kg girl was brought to the emergency department (ED) for evaluation of lethargy and vomiting of 1 week's duration and decreased oral intake and urine output for 8 hours. She had a normal birth history, no significant past medical history, and was fully immunized. On presentation to the ED, her

vital signs were blood pressure, 98/53 mm Hg; pulse, 180 beats/min; respiratory rate, 60 breaths/min; temperature, 96.5Â°F (35.8Â°C); and oxygen saturation 98% on room air. Physical examination revealed dry mucous membranes, normal reactive pupils, a clear chest with intercostal retractions, decreased bowel sounds, mottled skin, an increased capillary refill time, and a depressed mental status with minimal withdrawal to pain.

The patient was endotracheally intubated, resuscitated with 0.9% NaCl, and given ceftriaxone and ampicillin intravenously. Complete blood count revealed a white cell count of 12,000/mm^3, hemoglobin of 18.6 g/dL, an anion gap of 22 mEq/L, and a lactate concentration of 4 mmol/L. Analysis of the cerebral spinal fluid, including cell count and chemistry, was normal. The ED obtained cultures of the blood, urine, and cerebral spinal fluid (CSF) for testing. An electrocardiograph (ECG) showed a narrow complex tachycardia with low-voltage QRS complexes. Her chest radiograph revealed cardiomegaly and no infiltrates. An echocardiogram revealed a dilated cardiomyopathy with a moderate-size pericardial effusion. The patient was admitted to the pediatric intensive care unit.

Over the next 24 hours, the parents were questioned regarding genetic counseling, malnutrition, and neglect. Eventually, the patient's 4-year-old brother admitted to feeding her, about 20 refrigerator magnets 1 week prior to presentation. An abdominal radiograph revealed 20 radiopaque densities scattered throughout the gastrointestinal (GI) tract, which on reevaluation were visible on the original chest radiograph. Whole-bowel irrigation (WBI) was initiated via a nasogastric tube with polyethylene glycol electrolyte solution at 150 mL/h and titrated up to 250 mL/h. WBI was tolerated well. After 6 hours of WBI, all 20 magnets [samarium cobalt (SmCo)] were retrieved from the effluent, and a repeat abdominal radiograph revealed no further magnets in the GI tract.

The child's clinical condition did not improve. While undergoing a 24-hour urine collection for cobalt, 1000 mg/m^2/d of $CaNa_2EDTA$ (edetate calcium disodium) was administered by continuous intravenous infusion. Intravenous chelation with *N*-acetylcysteine (NAC) was also administered, using the standard 20-hour acetaminophen protocol (see Antidotes in Depth: *N*-Acetylcysteine). Intravenous thiamine (25 mg/d) was also initiated.

After 2 days of therapy, the patient's lethargy improved. Her leukocytosis, anion gap, and serum lactate concentration normalized. All of her cultures were sterile, and antibiotic therapy was discontinued. Additional laboratory results revealed hypothyroidism, evidenced by an elevated thyroid-stimulating hormone (TSH) concentration of 12 mIU/mL (normal: 1.7â€“9.1 mIU/L); a decreased total T_4 of 4.7 Âµg/dL (normal: 7.8â€“16.5 Âµg/dL); increased erythropoiesis, evidenced by an increased reticulocytosis of 8.3% (normal: â‰¤7%); and an increased erythropoietin (EPO) concentration of 30 mIU/mL (normal: 1.0â€“21.0 mIU/mL).

The patient was extubated on hospital day 3. Chelation therapy with $CaNa_2EDTA$ and NAC were stopped on day 5, and initial urine cobalt level was reported as 1237 Âµg/L. Her repeat echocardiogram prior to discharge showed substantial resolution of both the cardiomegaly and the effusion. The patient was discharged on hospital day 7 after her family received thorough counseling on poison prevention. The patient's thyroid and hematologic abnormalities had resolved completely at 2-week followup.

History and Epidemiology

The name cobalt (Co) originates from â€œkobold,â€• the German word for â€œgoblin,â€• and was given to the cobalt-containing ore, cobaltite (CoAsS), because it made exposed miners ill. Their

most likely related to arsenic toxicity from the ore, rather than from the cobalt. Georg Brandt discovered cobalt in 1753, during an attempt to prove that an element other than bismuth gave glass a blue hue.

The main industrial use of cobalt is the formation of hard, high-speed, high-temperature cutting tools. With an atomic number of 27 and a molecular weight of 58.93 daltons, Co is a light metal that has a melting point of 2723.1Â°F; (1495.1Â°C) and a boiling point of 5611.7Â°F (3099.9Â°C). These attributes make elemental cobalt a very useful industrial metal. When aluminum and nickel are blended with cobalt, an alloy (alnico) with magnetic properties is formed. Other uses for cobalt include electroplating, because of its resistance to oxidation, and as an artist's pigment because of its bright blue color.

A Co^{3+} ion is at the center of cyanocobalamin (vitamin B_{12}), which is synthesized only by microorganisms and is not found in plants. Common dietary sources include fish, eggs, chicken, pork and seafood; a diet deficient in cyanocobalamin results in pernicious anemia. Hydroxocobalamin, a Co^{3+}-containing precursor to cyanocobalamin, is a therapy for cyanide poisoning (see Antidotes in Depth: Hydroxocobalamin).

Medicinally, cobalt chloride was combined with iron salts and marketed in the 1950s as â€œRoncovite,â€• for the treatment of anemia. As recently as 1976, physicians still used cobalt in the treatment of anemias, thereby reducing transfusion requirements in spite of concomitant adverse effects.[34] The other common medical use of cobalt is as a radioactive isotope, cobalt-60 (^{60}Co), in the radiotherapy of head and neck cancers, breast cancer, and some tissue sarcomas of the extremities. This form of radiotherapy has been largely replaced by linear accelerators in the Western world.

Historically, epidemics of cardiomyopathy and goiter termed â€œbeer drinker's cardiomyopathyâ€• [10] and â€œcobalt-induced goiterâ€• [58] occurred between the 1960s and the 1970s. During this period, cobalt sulfate was added to beer as a foam stabilizer. In the 1970s, these epidemics were halted when the use of cobalt for this purely aesthetic purpose was discontinued. [91]

Sources of cobalt include chemistry kits, [63] weather indicators, [63] antiquated anemia therapies, [63] cement, [70] fly ash, [70] mineral wool, [70] asbestos, [70] molds for ceramic tiles, [40] the production of Widia-steel (used in the wood industry), [125] mining, [64] porcelain paint, [109] orthopedic implants, [62] and dental hardware. [5]

The most clinically important source, however, arises through the formation of cemented tungsten carbide, a â€œhard metal.â€• In tungsten carbide factories, powdered cobalt and tungsten are combined by an intense sintering process that exposes the metals to hydrogen, heated to 1832Â°F (1000Â°C). The first published investigation of these factories reported a 10-fold increase in workspace cobalt concentrations, compared to atmospheric concentrations. [37] These respiratory exposures have resulted in pulmonary toxicity, known as â€œhard-metal disease.â€• As a result of this report, occupational studies and preventive respiratory measures have greatly reduced the acceptable cobalt exposure level in the workplace.

Chemistry

Like other metals, cobalt is available in elemental, inorganic, and organic forms. The clinical effects of each form are less-well defined than the effects of mercury or arsenic. Elemental cobalt (Co^0) toxicity is reported by both inhalational [138] and oral exposures. [57,58] Inorganic cobalt salts most commonly occur in 1 of 2 oxidation states: cobaltous (Co^{2+}) or cobaltic (Co^{3+}). Inorganic cobalt salts, such as cobaltous chloride ($CoCl_2$) and cobaltous sulfate ($CoSO_4$), were historically used for the treatment of

anemias,[11,47,53,108,147] and were associated with the â€œbeer drinker's cardiomyopathy.â€•[1,87,93]

Organic cobalt exposure results from cyanocobalamin (vitamin B_{12}) ingestion, but because of its limited oral absorption and its rapid renal elimination, it is considered to be of low toxicity.[105] Other organic forms of cobalt (eg. stearate) are toxic, following oral exposures in rodents.[13] In comparison, the inorganic chloride, sulfate, and nitrate cobalt salts appear to have more acute toxicity in animal models, when compared to the organic forms, such as cobalt stearate.[13]

Toxicokinetics

Based on animal studies, oral absorption of cobalt oxides, salts, and metals via the gastrointestinal tract is highly variable, with a reported bioavailability of 5â€“45%.[71,81] In human studies, both iron deficiency and iron overload (hemochromatosis) enhance radiolabeled $^{57}CoCl_2$ absorption in the small bowel.[99] Inhaled cobalt oxide is approximately 30% bioavailable,[81] but the volume of distribution and elimination half-life are not defined.

Most (50â€“88%) absorbed cobalt (organic and inorganic) is eliminated renally, and the remainder is eliminated in the feces.[123] Acutely, an increase in the inorganic cobalt burden will result in increased renal elimination.[68] However, this initial increased elimination rapidly diminishes to a steady state, despite a large body burden.[2,99] Thus, a significant percentage of elimination of a large cobalt exposure will be delayed.

The characteristic elimination of cobalt correlates with the patterns of occupational exposure.[138] For example, a worker with a standard workweek will have much higher urine cobalt levels on Friday morning when compared to Monday morning.[138] However, Monday afternoon urine cobalt levels may be higher than Friday morning levels because of the rapid elimination that occurs

following an initial exposure.[2,138] Based on these findings, the exposure over time must be considered when interpreting urinary cobalt concentrations.[7]

Pathophysiology

Like most other metals, cobalt is a multiorgan toxin. $CoSO_4$ inhibits several key enzyme systems and interferes with initiation of protein synthesis.[8] Polynucleotide phosphorylase, an essential enzyme in RNA synthesis, requires Mg^{2+} to function normally. The enzyme functions at 50% that of normal in the presence of $CoSO_4$.[8] It is hypothesized that Co^{2+} is capable of displacing Mg^{2+}, the normally required cofactor, from the enzyme cofactor site.[8]

$CoCl_2$ increases the rate of glycolysis and at the same time decreases oxygen consumption,[20] suggesting that cobalt may inhibit aerobic metabolism. In vitro studies demonstrate that divalent cations, Zn^{2+}, Cd^{2+}, Cu^{2+}, and Ni^{2+}, inhibit Î±-ketoglutarate dehydrogenase, a mitochondrial Krebs cycle enzyme (Chap. 13).[143] When compared to these divalent cations, Co^{2+}, is not as potent an inhibitor of this same enzyme.[143] However, when NADH (the reduced form of nicotinamide adenine dinucleotide) is added to this in vitro model, Co^{2+} is capable of inhibiting up to 95â€“100% of the reaction.[143] This model suggests that NADH abundance, such as in chronic ethanol use, may potentiate the inhibition of

Î±-ketoglutarate dehydrogenase.[144] Cobalt may also complex with the reduced form of Î±-lipoic acid, thereby interfering with the Krebs cycle.[145] Moreover, cobalt salts are capable of inhibiting dihydrolipoic acid by complexing with its sulfhydryl groups.[23,143] These reactions result in the inability to convert both pyruvate into acetylcoenzyme A (acetyl-CoA) and Î±-ketoglutarate into succinylcoenzyme A (succinyl-CoA). These two enzymes are

integral in the efficient transition from anaerobic glycolysis to the Krebs cycle and for the Krebs cycle to produce reducing equivalents (Chap. 13 and Antidotes in Depth: Thiamine Hydrochloride). These toxic effects may help explain why the combination of chronic ethanol use and cobalt exposure results in cardiomyopathy (see â€œBeer Drinker's Cardiomyopathy below).[143]

In addition to enzyme inhibition, oxidant-mediated toxicity is supported by in vivo and in vitro studies of $CoCl_2$-induced pulmonary toxicity (see Chronic Exposure, Pulmonary below).[97] Xenobiotics implicated in free radical-mediated pulmonary injury are capable of accepting an electron from a reductant and subsequently transferring the electron to oxygen, forming a superoxide free radical (Chap. 12). Cobalt is then capable of accepting another electron, which starts the cycle over again, a process known as redox cycling. This will result in an accumulation of free radicals in the lung as a result of the abundance of oxygen ready to receive electrons and result in injury (Chap. 12).

Cobalt chloride inhibits tyrosine iodinase (Chap. 49).[74] This enzyme is responsible for combining iodine (I_2) with tyrosine to form monoiodotyrosine and serves as the first step in the synthesis of thyroid hormone. Inhibition of tyrosine iodinase results in a decrease in T_3 and T_4, which may result in clinical hypothyroidism and goiter (see Clinical Effects, Endocrine below).

Multiple animal models demonstrate that $CoCl_2$ administration results in reticulocytosis, polycythemia, and erythropoesis.[43,72,90,100,101,147] These events occur in both the bone marrow and extramedullary locations.[11,45] Although the pathogenesis of these events remains largely unknown,[23] one theory is that cobalt binds to iron-binding sites such as transferrin,[65] resulting in impaired oxygen transport to renal cells, which, in turn, induces erythropoietin production. In an animal model of anemia, a greater degree of gastrointestinal iron uptake

occurs in cobalt-treated rats compared to rats with either hypoxia or nephrectomy.[45] A similar study in mice suggested that the rise in iron uptake exceeded that following exogenous erythropoietin.[3]

Cobalt chloride inhibits neuromuscular transmission by competing with Ca^{2+}, another divalent ion. Cobalt ion is 20 times more potent than magnesium with regard to its ability to compete with calcium for a site on the motor nerve terminal.[142] This may be the manner by which some of the neurological symptoms occur.

Clinical Effects and Toxicity

The single, acute, minimal toxic dose of cobalt compounds is not well defined. In fact, varying effects have occurred at variable doses in different patients. Patients with â€œbeer drinker's cardiomyopathyâ€• received an average daily dose of 6â€“8 mg of $CoSO_4$ (over weeks to months) and developed life-threatening illness,[69,93] whereas infants being treated for anemia who received much higher daily cobalt doses of an iron-cobalt preparation (40 mg of $CoCl_2$ and 75 mg of $FeSO_4$) for 3 months did not develop similar toxic effects of acidemia, cardiomyopathy, or shock.[114] The inconsistency of these findings suggests that multiple factors are responsible for the development of the clinical manifestations; in this case, the role of ethanol metabolism may be an important variable. Death also has been reported after acute cobalt exposure.[63]

Organ systems affected by acute cobalt poisoning are endocrine,[57] gastrointestinal,[34,47] hematologic,[43,72,90,147] cardiovascular,[58] metabolic,[58] and the central[47,122] and peripheral nervous systems.[122] Chronic inhalational exposures affect the pulmonary[16,21,37,76,77,111,130] and dermatologic systems.[41,117,146] Radioactive ^{60}Co used for radiation therapy is associated with radiation burns (Chap. 128). Unlike acute toxicity, chronic cobalt exposure is not associated with an increased mortality rate; a cohort study evaluating more than 1100 persons with pulmonary

exposures to cobalt salts and oxides over a 30-year period was unable to show an increased mortality rate.[95]

Clinical Manifestations

Acute Exposure

Cardiovascular

â€œBeer Drinker's Cardiomyopathy.â€•

In 1966, a Veterans Affairs (VA) Hospital in Nebraska cared for 28 males with a history of beer drinking who presented with tachycardia, dyspnea, and lactic acidosis but without any finding of congestive heart failure.[87] The mortality rate for these cases was 38% and occurred rapidly, within 72 hours of presentation, as a consequence of severe acute metabolic acidosis and cardiac failure.[87] The survivors were successfully treated with supportive care and thiamine therapy.[87] Of the survivors, most responded immediately to therapy and a lack of response was found to be secondary to complications; most commonly, symptomatic pericardial effusions or embolic events.[87] Epidemiologic evaluation revealed that these men commonly drank large quantities of beer.

Ultimately, 64 cases and 30 fatalities were reported from Nebraska.[137] Autopsies were performed in 26 of the decedents. Common postmortem cardiac findings were dilated cardiomyopathy and cellular degeneration with vacuolization and edema and a lack of inflammation and fibrosis.[87] When cobalt was later implicated in the pathogenesis of these deaths, preserved cardiac tissue of 8 decedents revealed cobalt concentrations 10 times greater than that of controls.[137]

Within a year of the Nebraska cases, similar reports began to emerge from Quebec.[93] Forty-eight beer drinkers (only 2 of whom

were women) developed unexplained cardiomyopathy with a mortality rate of 46%.[93] The only common association among all of these patients was the consumption of brand â€œXXXâ€• beer.[93] The producers of this beer had factories in Quebec City and Montreal. The only difference between the two breweries was that the one in Quebec added 10 times the amount of $CoSO_4$ to the beer as a foam stabilizer.[91] Clinical findings in these cases included tachycardia, tachypnea, polycythemia, and low-voltage ECGs.[92] Reports began to appear 1 month after the Quebec City produced beer with the excessive cobalt was released on the market and no new patients were reported in Quebec after its beer with the excessive cobalt concentration was removed from the market.[91]

In 1972, 20 additional cases occurred in Minneapolis with similar findings of tachycardia, dyspnea, pericardial effusion, polycythemia, and lactic acidosis, and a mortality rate of 18% acutely, and 43% over a 3-year period.[1] Thus, several outbreaks have been recorded in beer drinkers with cardiomyopathy, metabolic acidosis, and a high mortality, all of which have been associated with the addition of $CoSO_4$ to the beer.

Because the clinical findings resemble the cardiomyopathy associated with chronic alcoholism[39] and infantile malnutrition,[106] a debate persists as to whether cobalt is the sole cause of this syndrome. The chronic alcoholism and infantile malnutrition cardiomyopathies are caused by poor protein intake and vitamin deficiency and both have histologic findings similar to those of cobalt cardiomyopathy. For example, myocardial biopsy of dogs with cobalt-induced cardiac failure revealed diffuse cytosolic vacuolization, loss of cross-striations, and interstitial edema,[120] all of which are similar to findings of malnutrition.[39,106] However, some other findings may be specific to cobalt-associated cardiomyopathy. For example, a small retrospective analysis revealed myocyte atrophy and myofibril loss to be present in

people with cobalt-associated cardiomyopathy significantly more often than in those with idiopathic dilated cardiomyopathy.[14]

Some animal models of cobalt cardiomyopathy were only able to reproduce pathologic and ECG findings if cobalt was combined with ethanol,[139] while others required protein deficiency.[115] Contrary to these studies, several rodent and canine models of cobalt poisoning and nutritional supplementation have demonstrated cardiac lesions,[51,119,120] cardiac failure,[54,119,120] and ECG abnormalities.[52,119]

Despite the implication that cobalt-induced cardiomyopathy requires malnutrition or alcoholism, a case of cardiac toxicity following acute cobalt poisoning has been reported.[57,58] However, it is difficult to identify other cases reported outside of the aforementioned small epidemics in beer drinkers. In a controlled study of occupationally exposed subjects evaluated with echocardiograms, significantly more cobalt-exposed workers had diastolic dysfunction when compared to controls.[79] However, none of these subjects under study developed congestive heart failure.[79] There are rare reports of cardiomyopathy in chronically exposed workers,[9,19,67] which suggests that the cardiomyopathy reported in the â€œbeer drinkersâ€• cohort is multifactorial and not solely caused by cobalt.

Another source of doubt regarding of the role of cobalt in the development of cardiomyopathy is the relatively low dose of cobalt needed to induce heart failure in these patients.[69] In patients receiving 20â€“75 mg/d of $CoCl_2$ for various red cell dysplasias, there were no reports of heart failure,[69] whereas the â€œbeer drinker's cardiomyopathyâ€• group reportedly consumed only 6â€“8 mg of $CoSO_4$ from drinking 24 pints of cobalt-containing beer.[69,91] All patients who developed cardiomyopathies were malnourished, which supports the theory that a multifactorial nutritional deficiency in the presence of excessive cobalt may be necessary for the development of cardiomyopathy.[69]

Endocrine

Both acute and chronic cobalt exposures are associated with thyroid hyperplasia and goiter. A series of patients with severe sickle cell anemia treated with cobalt therapy also developed goiter with varying degrees of thyroid dysfunction,[53,73] including clinical hypothyroidism.[74] In one patient, the goiter was so severe that airway obstruction developed.[73]

More recent occupational data suggest that inhalational exposure to cobalt metals, salts, and oxides may result in abnormalities in thyroid function studies.[138] When 82 workers in a cobalt refinery were compared to sex- and age-matched controls, exposed workers had significantly lower T_3 levels.[138]

Within the previously mentioned beer drinker's cardiomyopathy cohort, 11 of 14 decedents had abnormal thyroid histology.[116] Among them, the most common findings were follicular cell abnormalities and colloid depletion, which were not present on thyroid analysis from 11 randomly selected autopsies that served as controls.[116]

Hematologic

Anemias of the newborn,[17,66,108] erythrocyte hypoplasia,[124] red cell aplasia,[141] renal failure,[47] and chronic infection[113] have all been successfully treated with cobalt salts. Patients undergoing $CoCl_2$ therapy for these diseases had increased hemoglobin,[47,108] hematocrit,[47,108] and red cells,[47] but the benefits did not persist after cessation of therapy.[47,108]

In a published series, Peruvian cobalt miners working in an open pit at 4300 m (2.7 miles) elevation developed clinical effects, including headache, dizziness, weakness, mental fatigue, dyspnea, insomnia, tinnitus, anorexia, cyanosis, polycythemia, and conjunctival hyperemia, consistent with acute mountain sickness.[64] When the study group was compared to age-, height-,

and weight-matched high-altitude controls, the study group was noted to have higher chronic mountain sickness scores.[64] The only difference detected was elevated serum cobalt levels in the study group.[64]

In addition to effects on red cells, recent work demonstrates transient hemolysis, methemoglobinemia, and methemoglobinuria from subcutaneous $CoCl_2$ exposure in mice.[59] These findings may explain reports of dark urine following cobalt exposure in other animal models.[49,132] Human cases have not been reported.

Other

Gastrointestinal distress following the ingestion of â€œtherapeuticâ€• doses of cobalt salts,[122] as well as of elemental cobalt, has been reported.[63] Decreased proprioception, impaired cranial nerve VIII function, and nonspecific peripheral nerve findings are reported with acute oral $CoCl_2$ exposures.[122]

Chronic Exposure

Pulmonary

Two pulmonary diseases are associated with cobalt exposure: asthma and â€œhard-metal disease.â€• Occupational asthma is reported in hard-metal workers with a prevalence of 2â€“5%[16,76,77] at exposure levels as low as 50 Âµg/m^3.[77] As is the case with most causes of occupational asthma, cobalt-hypersensitivity-induced asthma is most likely immune-mediated rather than toxicologic.[18,76,130] Most hard-metal workers are exposed to other metals, such as tungsten (W) and nickel (Ni), in addition to Co, and these other metals may account for some cases of occupational asthma that are attributed to cobalt.[128,129] However, in a small but well-performed study of patients with cobalt-associated asthma, intradermal $CoCl_2$ resulted in a positive

wheal response in all subjects, and 50% of patients had a positive radioallergosorbent test (RAST) score, which correlated to the wheal size.[127]

Cobalt-associated pulmonary toxicity was first noted in tungsten-carbide workers,[37,55] and was subsequently referred to as â€œhard-metal disease.â€• Exposures result from the process by which tungsten-carbide is sintered with cobalt. Signs and symptoms of hard-metal disease include upper respiratory tract irritation, exertional dyspnea, severe dry cough, wheezing, and interstitial lung disease ranging from alveolitis to progressive fibrosis. The prevalence of hard-metal disease is largely unknown. In one study, 11 of 290 (3.8%) exposed workers were diagnosed with interstitial infiltrates on chest radiographs, but only 2 (0.7%) had a decreased predicted total lung capacity.[133]

Certain individuals who are exposed to large doses of hard-metal for prolonged periods never develop disease, which suggests that a susceptible population exists. A glutamate substitution for lysine in position 69 of the Î² unit HLA-DP has a strong association with hard-metal disease, similar to the situation with chronic beryllium disease.[107] Clinically, hard-metal disease is difficult to distinguish from berylliosis, although an occupational history should be helpful.

Common findings of hard-metal disease on histopathology are multinucleated giant cells and interstitial pneumonitis with bronchiolitis.[6] Elevated levels of cobalt in lung tissue can be detected,[112,131] even as long as 4 years after exposure.[112] Bronchoalveolar lavage commonly reveals multinucleated giant cells, type II alveolar cells, and alveolar macrophages in patients with interstitial lung disease.[21] The finding of multinucleated giant cells from bronchoalveolar lavage washing is characteristic of hard-metal disease.[18,24,25,88,140]

A cross-sectional study of more than 1000 tungsten-

carbideâ€“exposed workers found an increased odds ratio [OR] of 2:1 for having a work-related wheeze when exposed to greater than 50 Âµg/m^3 of Co.[134] In the same study, workers with exposures recorded at greater than 100 Âµg/m^3 had higher OR (5.0) of having a chest radiograph profusion score of â‰¥1/0.[134] This profusion score, established by The International Labor Organization (ILO) and most recently updated in 2000, is a grading system for pneumoconioses. When used to grade radiographs of asbestosis, this score correlates strongly with mortality risk,[86] reduced diffusing capacity, and decreased ventilatory capacity.[56,96] A score of 0/1 is suggestive but not diagnostic (â€œnegativeâ€•), and a score of 1/0 is presumptively diagnostic but not unequivocal (â€œpositiveâ€•).[26] Additional studies have similarly concluded that pulmonary disease occurs when individuals are exposed to doses of cobalt that approach 100 Âµg/m^3.[75] Thus, the current threshold limit value (TLV) is <50 Âµg/m^3.

Until 1984, all reported cases of hard-metal disease were associated with the combination of cobalt and other metals, such as nickel, cadmium, and tungsten.[6,55,77,134] Diamond polishers started using high-speed grinding disks coated with abrasive microdiamonds embedded in a matrix of cobalt powder.[78] Several case reports illustrate that cobalt-exposed diamond polishers develop clinical[48] and pathologic findings similar to hard-metal disease, strengthening the link to cobalt.[18,24,98] Some authors still contend that the presence of other metals[6,55,77,134] and diamond dust[24,48,98] are confounding factors.[138] As in cases of hard-metal disease, most reported cases show resolution of symptoms on removal from the exposure,[24] although this is not always sufficient.[98]

There are very few reports of isolated cobalt exposures. In an age- and sex-matched study of 82 workers with respiratory exposures to cobalt oxides, cobalt salts, cobalt metal, and no other metal, researchers were unable to detect a difference between exposed

(mean: 8 years; time-weighted average [TWA]: 125 Âµg/m^3, 25% >500Âµg/m^3) and unexposed workers with any objectively measured pulmonary tests.[138] Neither group had any abnormality in chest radiography that would suggest pulmonary fibrosis.[138] The only significant pulmonary differences detected were a higher reported rate of dyspnea, both on exertion and at rest, and the presence of wheezing in the exposed group.[138] These authors concluded that cobalt contributes to the development of pulmonary disease but is not independently responsible for the development of pulmonary fibrosis.[138]

Despite the progressive and debilitating nature of hard-metal disease, most signs and symptoms improve with cessation of exposure.[85,89,148] Moreover, the length and dose of exposure do not appear to correlate with the presence or severity of illness, suggesting that individual susceptibility is the most important risk factor for illness.[85,118]

Renal

A single report associates reversible renal tubular necrosis with the chronic administration of $CoCl_2$ as treatment for anemia.[122] Some animal models of cobalt cardiomyopathy demonstrate cellular changes in renal tissue.[50] However, when 26 cobalt-exposed hard-metal workers were evaluated for urinary albumin, retinol-binding protein (RBP), Î²$_2$-microglobulin, and tubular brush border antigens, no detectable difference could be found between the study group and controls.[44] Based on these few reports, it appears that acute and chronic exposure to cobalt has little effect on the kidneys.

Dermatologic

In a study of 1782 construction workers, 23.6% developed dermatitis and 11.2% developed oil acne while using cobalt-containing cement, fly ash, or asbestos.[70] As in hard-metal

disease, it is difficult to isolate cobalt as the sole contributor to the development of dermatitis. Nickel, the classic toxicant causing dermatitis, is commonly found in some of these preparations and may be implicated in the development of cutaneous sensitivity.[41,117]

Reproductive

A pregnant woman with hard-metal disease was able to bring her fetus to term and deliver without complication.[110] In pregnant rats, $CoCl_2$ exposure results neither in teratogenicity nor fetotoxicity.[103] Only doses that are toxic to the mother result in fetal toxicity.[33]

In mice, chronic exposure to cobalt results in impaired spermatogenesis and decreased fertility, without affecting follicular-stimulating hormone (FSH) or leuteinizing hormone (LH), whereas acute exposures did not demonstrate similar reproductive effects.[104] Additional murine studies discuss the possible interactions between cobalt with iron and zinc, which are both essential elements for spermatogenesis.[4] Despite these findings, there are no reported human cases that associate cobalt exposure with teratogenicity or impaired fertility.

Carcinogenesis

Based solely on animal experiments leading to the development of soft-tissue sarcomas following the injection of $CoCl_2$ into soft tissue, the International Agency for Research on Cancer (IARC) considers cobalt and cobalt-containing compounds possibly carcinogenic to humans.[12,22,35,135] There are case reports and cohort studies that suggest that pulmonary exposure to Co^{2+} increases the risk for lung cancer. However, these studies were unable to control for other known carcinogens such as arsenic.[22] The largest cohort study to date followed more than 1100 workers for more than 38 years and found no increase in the prevalence of

lung cancer.[94]

Diagnostic Testing

Body fluid cobalt concentrations are not readily available and therefore cannot be used to direct emergent clinical care. Some adjunctive testing that might support a clinical diagnosis of cobalt toxicity includes complete blood count (CBC), reticulocyte count, EPO concentration, and TSH concentration. The results of these tests might reflect the level of exposure or potential toxicity discussed above.

Cardiac Studies

Electrocardiogram, echocardiogram, and radionuclide angiocardiography with ^{99}Tc are useful screening tests for detecting abnormalities associated with cobalt cardiomyopathy and/or pulmonary hypertension caused by hard-metal disease.[19] It is important to remember that these cardiac tests are neither specific for, nor diagnostic of, cobalt-induced cardiomyopathy. Biopsy of myocardial

tissue may show multinucleated giant cells, but testing of this nature may be impractical.

Pulmonary Testing

Patients with hard-metal lung disease may demonstrate bilateral upper lobe interstitial lung disease on chest radiograph. However, patients may have signs and symptoms of disease without specific radiographic findings.[110] Pulmonary function testing in occupationally exposed workers may show decreased vital capacity[110] and a decrease in transfer factor for carbon monoxide (TLCO), both of which might be useful in identifying patients at risk for developing pulmonary fibrosis.[136] Some authors suggest

an inversion of the CD4/CD8 ratio in bronchoalveolar lavage washings as a useful tool for diagnosis and evaluation of progression of illness and that normalization is a marker for improvement.[111] Despite these available tests, a definitive diagnosis of hard-metal disease requires a tissue sample with findings of multinucleated giant cells in the setting of interstitial pulmonary fibrosis.

Cobalt Testing

Cobalt is primarily eliminated in the urine, and to a lesser extent in the feces, making urine cobalt evaluation most appropriate.[81] The difficulty lies in the interpretation of the result. Cobalt is detectable in the urine after inhalational exposure and reflects elimination kinetics that are rapid during an initial exposure, but which slow after prolonged exposure.[81,121] Because of this variable elimination pattern, it is difficult to interpret both urine and blood concentrations unless the dose and length of exposure are precisely known. Furthermore, the defined patterns may be applicable only to shift workers using soluble forms of cobalt.[81]

Further complicating the interpretation of urinary cobalt levels is the abundance of organic cobalt in the form of vitamin B_{12}. A detailed vitamin supplementation history is required prior to the interpretation of a urine or blood cobalt level, as a diet regimen high in vitamin B_{12} might increase urine cobalt concentrations. For this reason, speciation of cobalt has been investigated. The ratio of inorganic to organic cobalt is higher in occupationally exposed workers (2.3) when compared to controls (1.01), independent of the wide variations of urinary cobalt concentrations.[46] This is a promising area of study for the evaluation of a cobalt-exposed worker.

Toxic concentrations of cobalt in serum and urine are poorly defined. Published literature on â€œnormal concentrationsâ€• is fraught with variability that may reflect differences in the

population under study and the techniques used for measurement. Normal serum concentrations of cobalt are frequently reported as 0.1â€“1.2 Âµg/L.[2,10,57,58,61,126] In comparison, a single, acutely poisoned patient had a reported serum concentration of 41 Âµg/L.[57] Normal reference urine cobalt concentrations are between 0.1 and 2.2 Âµg/L.[2,10,57,58,61,102,126] In contrast, patient with an acute elemental cobalt ingestion had a concentration of 1700 Âµg/L on a spot urinalysis several days after the exposure.[58]

Patients with chronic exposures should be evaluated differently as discussed above (see Toxicokinetics). Exposed workers, without clinical disease, have reported spot urine concentrations that range from 10 Âµg/L to several hundred Âµg/L.[60]

Treatment

Acute Management

Patients with acute cobalt poisoning require aggressive therapy. It is reasonable to conclude that the same decontamination principles used for other metals apply to cobalt. There have been no studies to date examining the benefit of gastric emptying, activated charcoal, or whole-bowel irrigation (WBI). An attempt at WBI for radiopaque solid forms of cobalt should be made prior to endoscopic or surgical removal. Regardless of the decontamination procedure used, chelation therapy should not be initiated until the gastrointestinal cobalt source has been removed. If there is a large stomach burden in a solid form, endoscopic or surgical removal may be beneficial,[58] keeping in mind that the administration of activated charcoal, prior to surgical removal, can obscure visualization of the surgical field (Chap. 8). After decontamination, the next crucial steps are reduction of tissue burden and prevention of end-organ toxicity.

The data on chelation therapy are, unfortunately, limited to animal

models[27,28,29,30,31,32,33,82,83,84] and a single human case report.[58] The basis of chelation therapy originates from the mid-20th century when oral protein intake was found to result in a reduction of cobalt toxicity in calves[36] and rats.[51] Certain sulfur-containing proteins serve as good chelators for some metals.

In a series of animal models of acute cobalt toxicity, several agentsâ€”*N*-acetylcysteine (NAC), succimer, ethylenediaminetetraacetic acid (EDTA), glutathione, and diethylenetriaminepentaacetic acid (DTPA)â€”were evaluated for their ability to enhance urinary and fecal elimination of cobalt.[84] Succimer and EDTA enhanced fecal elimination;[84] glutathione and DTPA enhanced urinary elimination; and NAC enhanced elimination by both elimination routes.[84]

In two separate animal studies, NAC reduced tissue burden and injury caused by cobalt in the liver and spleen.[32,84] Glutathione, another sulfur-containing protein, also reduced tissue concentrations of cobalt, but only in the spleen.[84]

The sulfur-containing amino acids NAC,[28,32] L-cysteine,[27,28] L-methionine,[28] and L-histidine[31] were studied for their ability to reduce mortality in rats that were given an LD_{50} (median lethal dose for 50% of test subjects) of $CoCl_2$ orally and intraperitoneally. NAC, L-cysteine,[28] and L-histidine[31] therapy were more effective than L-methionine in protecting against mortality. In a similar fashion, Na_2EDTA was effective in reducing mortality.[30] In all of these therapies, the successful reduction in mortality from these therapies is predicated on early administration.[27,28,30,31,32]

In a murine model, L-cysteine, NAC, glutathione, L-histidine, sodium salicylate, D,L-penicillamine, succimer, *N*-acetylpenicillamine (NAPA), diethyldithiocarbamate (DDC), BAL, 4,5-dihydroxy-1,3-benzene disulfonic acid, DTPA, $CaNa_2EDTA$, and deferoxamine mesylate were each evaluated for exposures to an LD_{50} and an LD_{99} of $CoCl_2$.[83] Agents that were ineffective at

improving survival following an LD_{50} were sodium salicylate, NAPA, BAL, 4,5-dihydroxy-1,3-benzene disulfonic acid, and deferoxamine mesylate.[83] Chelators that were seemingly effective at LD_{50}, but not at LD_{99}, were L-histidine and D,L-penicillamine.[82] NAC, L-cysteine, and succimer were able to improve survival by 40â€“50%.[83] The most effective chelators at LD_{99} were EDTA and DTPA.[82,83] An expanded analysis of this data revealed that EDTA and DTPA had a better therapeutic index when compared to succimer.[83] In this study, BAL was ineffective,[83] as is suggested in an in vitro study where BAL was unable to chelate Co^{2+} that was already bound to Î±-ketoglutarate.[143]

Human chelation data are available from a single pediatric case report of the ingestion of multiple elemental cobalt-containing magnets, yielding a serum cobalt level of 4.1 Âµg/dL.[58] $CaNa_2EDTA$ 50 mg/kg/d IV for 5 days enhanced renal elimination of cobalt, and the metabolic acidosis and the cardiac dysfunction also resolved simultaneously.[58]

In conclusion, based on a single case report, several animal studies, and safety profiles, $CaNa_2EDTA$ and NAC can be considered as antidotal therapy. Indications for treatment include patients who demonstrate end-organ manifestations of toxicity, which includes acidemia, cardiac failure, pericardial effusion, clinically significant goiter, and hyperviscosity syndrome. Based on years of experience with lead, $CaNa_2EDTA$ should be administered in doses of 1000 mg/m^2/d by continuous infusion for 5 days. If the diagnosis is confirmed and signs of cardiac failure and metabolic acidosis persist after 5 days, an alternate chelator (succimer) can be started. Similarly, NAC dosing should be based on the acetaminophen experience. The 20-hour intravenous NAC protocol should be initiated, and continued as in the case of fulminant hepatic failure (see Antidotes in Depth: *N*-Acetylcysteine), for as long as the patient can tolerate therapy, or continued if cardiac failure or acidemia persist. If there are contraindications to

intravenous NAC, oral NAC can be administered using one of the acetaminophen treatment regimens. Thiamine hydrochloride should be administered to all patients presenting with or without overt cardiomyopathy, regardless of whether or not the patient is an alcoholic or malnourished. The dose of thiamine is not well defined but should be based on its safety and clinical experience with its use in the treatment of Wernicke encephalopathy. The daily administration of 100 mg of parenteral thiamine can be increased to 100 mg every hour for life-threatening manifestations (cardiac failure and metabolic acidosis) (see Antidotes in Depth: Thiamine Hydrochloride).

Occupational and Chronic Exposure

As is the case for occupational poisonings, prevention is of paramount importance. The use of skin protection and improvement of personal hygiene has reduced exposure and the amount of urinary cobalt in occupationally exposed workers.[80] Barrier and emollient creams cannot prevent the dermatitis associated with cobalt metal exposures.[42]

Large, statistically significant reductions in urinary cobalt were demonstrated after the implementation of aspirator systems over machines in the production of Widia steel.[15] These aspirators reduced ambient cobalt levels by as much as a factor of 6.[38]

Summary

Acute cobalt exposure results in multiorgan system toxicity, including the cardiac, endocrine, hematopoietic, gastrointestinal, and neurologic systems. In contrast, chronic toxicity, dependent primarily on the route of exposure, mainly involves the pulmonary and dermal areas. The evaluation of the patient is determined by the cobalt source and type (elemental, inorganic, or organic), route of poisoning, and time and duration of exposure. Cobalt

measurements in blood and urine are possible, but toxic concentrations are poorly defined. Treatment of a chronic-exposure patient is mainly symptomatic and is often dependent on improved industrial hygiene. Acute poisoning with end-organ manifestations may require aggressive GI decontamination and chelation therapy using $CaNa_2EDTA$ and NAC, and sometimes succimer.

A 16-year-old boy presented to the hospital 3 days after reportedly ingesting 1 tablespoon of K77 Root Killer crystals in an attempt to gain attention from his aunt. The patient denied suicidality and stated that he did not know that the granules, used to halt the growth of tree roots into the home septic system, were toxic. Immediately after ingesting the product, the boy was given milk by his aunt. According to the patient, this prompted 4 episodes of blue-colored emesis containing the ingested substance. Although he had abdominal pain for the next 72 hours, the patient did not seek medical care because he assumed that these symptoms would be transient. There was no suggestion that this was, indeed, a serious suicide attempt.

Ultimately, the patient presented to the hospital because he developed dark-brown discoloration of his urine, yellowing of his eyes, and worsening abdominal pain. He denied throat discomfort, hematemesis, or melena. His presenting vital signs were blood pressure, 102/52 mm Hg; pulse, 86 beats/min; and respirations, 18 breaths/min. Additionally, he was afebrile. His physical examination was significant for the presence of scleral and sublingual icterus, although dermal jaundice was not appreciated. His oropharynx was normal and his chest was clear. On abdominal examination there was moderate tenderness over the left upper quadrant and left costovertebral angle. There was no rebound or involuntary guarding. Stool obtained by rectal examination was negative for occult blood. The patient's neurologic examination was normal.

A chest radiograph was normal. His initial laboratory assessment was remarkable for a hematocrit of 20%, normal chemistries

(anion gap, 5) and renal function (BUN, 15 mg/dL; creatinine, 0.8 mg/dL). Hepatic studies revealed an aspartate aminotransferase (AST) of 54 IU/L, alkaline phosphatase of 77 IU/L, and a total bilirubin of 5.2 mg/dL with a direct bilirubin of 0.2 mg/dL.

The patient was started on oral D-penicillamine, 500 mg every 6 hours, all these findings were consistent with copper sulfate poisoning, and was hydrated aggressively with intravenous 0.9% sodium chloride at 500 mL/h. His clinical status improved over the next 72 hours, and no blood transfusion was required; his hematocrit fell to 15%.

Copper is among the more frequently reported metals to which patients are exposed. It routinely ranks third, behind lead and arsenic, in nonmedicinal metal exposures (medicinals include as iron or lithium), reported to US Poison Control Centers (Chap. 130). Still, acute symptomatic poisoning remains relatively rare in this country. In India, copper sulfate ingestion is a leading cause of suicide.[102] In that country, copper sulfate poisoning is reportedly responsible for nearly a third of all poisonings requiring hemodialysis and is the most common nephrotoxic indication for dialysis.[6 , 28 , 30] The dramatic clinical presentations and potential for poor outcome without appropriate treatment highlight the toxicologic significance of copper.

Copper, in its various forms, is still used extensively in our society. As the metal, it is used in both wiring and plumbing. Its use in coinage, at least in the United States, fell dramatically when it was replaced by zinc in the penny. Copper salts are widely used in fungicides, algicides, and plant growth regulators.[19] They are also important as catalysts, particularly in the petroleum industry. Among the most widespread uses of copper was in chromated-copper arsenate (CCA) in pressure-treated wood products. CCA, added to the wood to prevent rot, gained notoriety because of concerns about the leaching of arsenic into the environment, particularly around children's playgrounds (Table 90-1).[68]

History and Epidemiology

Copper is available naturally, either as native copper (elemental copper) or as one of its sulfide or oxide ores. Important ores include malachite ($CuCO_3$ Â·$(OH)_2$), chalcocite (Cu_2 S), cuprite (Cu_2 O), and chalcopyrite ($CuFeS_2$ or Cu_2 SÂ·Fe_2 S_3). Chalcopyrite, a yellow sulfide ore, is the source of 80% of the world's copper production. The smelting, or separation, of copper ores began about 7000 years ago; copper gradually assumed its current level of importance at the start of the Bronze Age, around 3000 B.C. Smelting begins with roasting to dry the ore concentrate, which, in more modern times, is further purified by electrolysis to a 99.5% level of purity. The sulfide ores have a naturally high arsenic content, which is released during the extraction process, posing a risk for those who perform copper smelting.

TABLE 90-1. Important Copper Products

Although, as noted, acute copper poisoning is uncommon in the United States, the historical role of copper as a therapeutic agent remains noteworthy. Copper sulfate was used in burn wound debridement until cases of systemic copper poisoning were reported.[53] Interestingly, in one report, each wound debridement procedure was associated with a fall of 8â€“10% in the child's hematocrit. In the 1960s, copper sulfate (250-mg dose, containing 100 mg copper ion) ironically was a recommended emetic agent, typically for use in children following potentially toxic exposures.[60] It was recognized for its rapid onset and effectiveness, and it compared favorably with syrup of ipecac. However, copper-induced emesis was rapidly identified to be a highly dangerous practice, and use was generally discontinued,[53,70,106] although fatal cases still occur.[70] Copper salts are administered in religious rituals as a green-colored â€œspiritual water,â€• containing 100â€“150 g/L of copper sulfate as an emetic to â€œexpel one's sins.â€•[7,105]

There is a growing body of knowledge linking copper to the

promotion of both physiologic and malignant angiogenesis.[50] In this latter case, copper may enable tumor expansion, invasion, and metastasis. Additionally, copper binding to amyloid fibers in the brain of patients with Alzheimer disease may lead to local oxidative damage and cause the characteristic neurodegeneration.[24, 35] Copper is also similarly implicated in the pathogenesis of both Parkinson disease and autism.[27, 120]

Acute or chronic copper poisoning occurs when the metal is leached from copper pipes or copper containers. This occurs frequently when carbon dioxide gas, used for postmix soft drink carbonation, backflows into the tubing transporting water to the soda dispensers. This creates an acidic solution of carbonic acid that leaches copper from the equipment pipes.[116] Similarly, storage of acidic potable substances, such as orange or lemon juice, in copper vessels may cause copper poisoning. A particularly dangerous situation occurs when acidic water is inadvertently used for hemodialysis.[36, 73] In this circumstance, the leached copper avoids the normal gastrointestinal barrier and is delivered parenterally to the patient's circulation. In one reported series, the copper concentration in the dialysis water was 650 Âµg/L, causing several poisonings and the death of a patient with a whole-blood copper concentration of 2095 Âµg/L.[36] Similarly, stagnant water or hot water,[94] even if not highly acidic,[98] can accumulate copper ions from pipes and cause poisoning.[9, 37]

Although most natural water contains a small quantity of copper (4â€“10 Âµg/L), it is tightly bound to organic matter and therefore not orally bioavailable. Copper pipes typically add about 1 mg of copper to the daily intake of an adult. The Environmental Protection Agency guidelines permit up to 1.3 mg/L of copper in drinking water, although in some areas concentrations intermittently may be as high as 60 mg/L. Copper in water may be tasted at concentrations of 1â€“5 mg/L, and a blue-green discoloration is imparted when the levels are greater than 5

mg/L.[34] Acute gastrointestinal symptoms occurs when water contains more than 25 mg/L,[55] although levels as low as 3 mg/L are often considered toxic. In one blinded, randomized study comparing copper-adulterated water to pure water, women appeared more sensitive than men to copper, but both groups were symptomatic when the copper concentration was 6 mg/L.[8]

Metallic copper is ideal for electrical wiring because it is highly malleable and can be drawn into fine wire. Its electrical conductivity is only exceeded by silver. Similarly, its excellent heat conductivity accounts for its widespread use in cookware. Although the metal is reactive with air, it forms a resistant layer of insoluble copper carbonate on its surface. It is this water- and air-resistant compound that accounts for the green coloration of ornamental roofing and statues. Because copper is a soft metal, it must be strengthened prior to use in structural applications or as a coinage metal. This is most commonly done by the creation of copper alloys. Brass is an alloy of copper compounded with as much as 35% zinc. Similarly, bronze contains copper combined with up to 14% zinc. Gun metal is an alloy that contains 88% copper, 10% tin, and 2% zinc. Sterling silver and white gold also contain copper.

Chemical Principles

Metallic copper (Cu^0) has an oxidation state of zero and, although not in itself poisonous, may react in acidic environments to release copper ions. The metallic copper contraceptive intrauterine device (IUD) derives its efficacy from the local release of copper ions.[14] Metallic copper bracelets, worn by patients with rheumatoid arthritis and other ailments, purportedly derive their far-reaching antiinflammatory effect through dermal copper ion absorption and distribution to affected tissues.[114] Local copper ion release is responsible for the occasional case of dermatitis that occurs following skin exposure to copper metal.[54] Ingestion of large

amounts of metallic copper, for example as coins, may rarely produce acute copper poisoning.[119] Poisoning in this situation is a result of the release of large amounts of copper ion from copper alloy by the acidic gastric content. Also, finely divided metallic copper dust or bronze powder used in industry and for gilding, when inhaled, although not systemically bioavailable, may produce life-threatening bronchopulmonary irritation, presumably as a consequence of the local release of ions.[47]

The majority of patients suffering from acute copper poisoning are exposed to ionic copper. In copper sulfate, also known as cupric sulfate, the copper atom is in the +2 oxidation state. Copper sulfate is used as a fungicide and algicide, and to eradicate tree roots that invade septic, sewage, and drinking-water systems.[89] Copper sulfate is the most readily available form and is the form involved in the majority of nonindustrial copper salt exposures. Copper sulfate was a favorite ingredient in many home chemistry sets because of its brilliant blue color when dissolved in water. Although serious poisoning, particularly in children,[115] led regulatory agencies in the United States to restrict its use, it still accounts for the most consequential chemistry set-related toxic exposures reported in other countries.[79] Similarly, homegrown copper sulfate crystals from kits are occasionally responsible for fatal poisonings.[46]

Cuprous salts, containing copper in the +1 oxidation state, are unstable in water and readily oxidize to the cupric form. Regardless of oxidation state, there are numerous copper salts used in industry and agriculture (Table 90-1), many of which are not poisonous. Because those salts that are water soluble are more likely to be toxic, it is important to determine the nature of the copper product implicated in an exposure. Analogously, when examining the medical literature, it is critical to discern which form of copper is involved in the scientific experiment or case report before applying the results to clinical practice.

Pharmacology and Physiology

Copper is 1 of 8 essential metals that our body stores in milligram amounts (100â€“150 mg). Daily requirements of copper are approximately 50 Âµg/kg in infants and 30 Âµg/kg in adults. The average daily intake of copper in the United States is about 1 mg.[111]

The daily requirement is satisfied by nuts, fish, and green vegetables such as legumes, although our largest source is generally from drinking water. Copper deficiency is exceedingly rare even in the poorest communities, and is most frequently caused by excessive zinc intake[64] or by a genetic aberration such as Menkes â€œkinky-hairâ€• syndrome, in which intestinal copper uptake is impaired. Menkes syndrome is characterized by mental retardation, thermoregulatory dysfunction, hypopigmentation, connective tissue abnormalities, and pili torti (kinky hair). Interestingly, with the increased focus on the role of copper in neurodegenerative disorders and cancer, some authors suggest intentionally depleting patients of their copper stores with tetrathiomolybdate, an experimental copper chelator.[43]

Copper is absorbed by an active process involving a Cu-ATPase (adenosine triphosphatase) in the small intestinal mucosal cell membrane, also known as the Menkes ATPase (see below). The gastrointestinal absorption varies with the copper intake and the food source[51] and is as low as 12% in patients with high copper intake. In the presence of damaged mucosa, such as following acute overdose, the fractional absorption is likely to be significantly higher.[71] Once absorbed, copper is rapidly bound to carriers such as albumin, ceruloplasmin, and amino acids, such as histidine, for transport to the liver and other tissues. Its half-life in the plasma is approximately 15 minutes. After being released locally in the reduced form from its carrier, copper uptake by the hepatic cells occurs via a specific uptake pump.[91] This process, which is facilitated by the reducing agent ascorbic acid, provides a

potential window, however brief, for detoxification of the ion by chelating agents.

In the hepatocyte, complex trafficking systems exist (involving ceruloplasmin, metallothionein, and other metallochaperones within the cytoplasm) to prevent copper toxicity and to aid delivery to the appropriate enzymes.[40 , 90] A distinct Cu-ATPase, located on certain subcellular organelles such as the *trans* -Golgi network or pericanalicular lysosomes, assists in the appropriate localization and elimination, respectively, of the metal.[25] By this mechanism, copper is either incorporated into enzymes or released, as a metallothioneinâ€“copper complex, directly into the biliary system for fecal elimination.

Some copper is released from the liver, bound primarily to ceruloplasmin, an $\hat{I}\pm_2$ -sialoglycoprotein with a molecular weight of 132,000 daltons. Ceruloplasmin-bound copper accounts for approximately 90â€“95% of serum copper. Ceruloplasmin is a multifunctional protein that binds 6 atoms of copper per molecule. Copper bound to this carrier has a plasma half-life of approximately 24 hours. Ceruloplasmin is also involved in the mobilization of iron from its storage sites, and it serves an analogous role as a ferroxidase during the ferrousâ€“ferric conversion. Copper (I) is oxidized directly by ceruloplasmin, thereby avoiding the generation of reactive oxygen species. Approximately 5â€“10% of serum copper is bound to albumin under normal conditions, but following acute poisoning, the majority of the excess copper binds to albumin. The albumin-copper complex represents the â€œfreeâ€• or toxicologically active copper. The amount of unbound copper in the blood under normal circumstances is well below 1%.

Alcohol dehydrogenase

Melanin production

Enzyme Function

TABLE 90-2. Important Copper-Containing Enzymes and Proteins and Their Functions

There are several important copper-containing enzymes in humans (Table 90-2). The common link among these enzymes is their participation in redox (reduction-oxidation) reactions in which a molecule, typically oxygen, donates or shares its electrons with another compound. In this respect, the physiology, chemistry, and toxicology of copper are most similar to that of iron. In fact, â€œblue-bloodedâ€• animals, such as octopi and spiders, use copper in hemocyanin, a blue pigment, in an analogous manner that â€œred-bloodedâ€• animals use iron in hemoglobin.

The volume of distribution of copper is 2.0 L/kg and the $t_{1/2}$ of erythrocyte copper is 26 days. The elimination of copper occurs

predominantly through biliary excretion following complexation with ceruloplasmin. Biliary excretion approximates gastrointestinal absorption, and averages 2000 Âµg/24 h.[5 , 90 , 112] Renal elimination under normal conditions is trivial, accounting for approximately 5â€“25 Âµg/24 h.[5]

Toxicology and Pathophysiology

Redox Chemistry

In acute overdose, a high fraction of the serum copper remains bound to low-affinity proteins, such as albumin, and thus is biologically active. Because copper, as a transition metal, is capable of assuming one of several different oxidation, or valence, states, it is an active participant in redox reactions. In particular, participation in the Fenton reaction and Haber-Weiss cycle explains the toxicologic effects of copper as a generator of oxidative stress and inhibitor of several key metabolic enzymes (see Fig. 12-2).[38] In particular, the mitochondrial electron transport chain and lipid membranes serve as ready sources of electrons for copper reduction, establishing a chain of events that ultimately leads to mitochondrial or membrane dysfunction, respectively.[81]

Erythrocytes

Cupric ion inhibits sulfhydryl groups on enzymes in important antioxidant systems, including glucose-6-phosphate dehydrogenase and glutathione reductase.[95] However, while support for these effects is only indirect, intraerythrocyte concentrations of reduced glutathione fall demonstrably following copper exposure.[77] This effect is presumably part of the protective role that glutathione, a nucleophile or reducing agent, normally has on oxidants, such as either cupric ions or the reactive oxygen species they generate.[75 , 76] Thus in the setting of copper poisoning, in which excessive quantities of oxidants are produced,

the depletion of glutathione presumably augments peroxidative membrane damage.

In the presence of sulfhydryl-rich cell membranes, such as those on erythrocytes, cupric ions are reduced to cuprous ions, which are capable of generating superoxide radicals in the presence of oxygen.[65] This one-electron reduction of oxygen regenerates the cupric ion, allowing redox cycling and continuous generation of reactive oxygen species (Fig. 90-1). The importance of hemoglobin-derived reactive oxygen species is demonstrated by the lack of hemolysis in the presence of anaerobic conditions or in an environment saturated with carbon monoxide.[12] The in vitro hemolytic activity of copper sulfate is reduced by albumin and several sulfhydryl-containing compounds, including D-penicillamine and succimer.[3] Interestingly, dimercaptopropane sulfonate (DMPS), another sulfhydryl-containing compound often used as a chelator, exacerbates copper-induced hemolysis. This paradoxical effect is variably ascribed to concomitant inhibition of superoxide dismutase, an important antioxidant enzyme, or to the ability of DMPS to efficiently reduce either membrane dithiols or cupric ions, in either case increasing the generation of superoxide.[2]

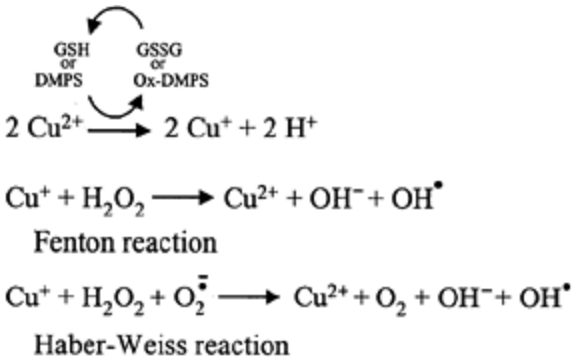

Figure 90-1. In the cupric or Cu^{2+} state, copper is reduced by sulfhydryl-containing compounds such as glutathione (GSH) or dimercaptopropane sulfonate (DMPS) to its cuprous form (Cu^{+}), forming disulfide links in the process. Oxidized glutathione (GSSG) is subsequently enzymatically reduced by glutathione reductase to

regenerate GSH. Superoxide anions (O_2^-), formed when molecular oxygen (O_2) acquires an additional electron, are continually generated by mitochondria. Both the Fenton and the Haber-Weiss reaction use the cuprous form of copper as a catalyst to convert hydrogen peroxide or superoxide radical into the more biologically consequential hydroxyl radical ($OH^{Â·}$).[14, 73]

Hemolysis frequently occurs within the first 24 hours in patients with acute copper poisoning.[30, 105, 118] This time of onset differs markedly from hemolysis that follows most other oxidant stressors and is likely a result of the differing nature of the erythrocyte insult; that is, the hemolysis following most oxidant exposures is caused by precipitation of hemoglobin as Heinz bodies and subsequent erythrocyte destruction by the reticuloendothelial system. This may also occur in the setting of acute copper poisoning, particularly following less substantial exposure. Additionally, and accounting for the early hemolysis, copper also directly oxidizes the erythrocyte membrane, thereby initiating red cell lysis independently of the reticuloendothelial system.[4, 93] Oxidant-induced disulfide cross-links in the erythrocyte membrane reduce its stability and flexibility, thereby predisposing to early cell rupture.[4]

Copper-induced oxidation of the heme iron within the erythrocyte produces methemoglobinemia.[80] Given the high incidence of hemolysis, the methemoglobin is commonly released within the plasma. In this situation, methylene blue should not be expected to reliably reduce the ferric iron because this reaction generally requires an intact erythrocyte.

Liver

Although most of the accumulated copper in hepatocytes is rapidly complexed with metallothionein or otherwise used, failure to

completely sequester copper ions allows their participation in redox reactions. Hepatic cells are protected from copper toxicity in vitro by prior induction of metallothionein with zinc or cadmium salts or by the infusion of metallothionein. These hepatic protective effects support the toxicologic significance of free intracellular copper. These findings also explain the therapeutic use of zinc acetate in patients suffering from Wilson disease,[21] because copper itself is not a good inducer of metallothionein in humans.

Copper ions also generate hydroxyl radicals, which are potent inducers of both lipid peroxidation, and other reactive oxygen species. Lipid peroxidation is confirmed in hepatocytes by the measurement of increased production of oxidation products. The peroxidative effect on biologic membranes is worse in animals deficient in vitamin E and is prevented by vitamin E replacement, presumably because of the role of vitamin E as a free radical scavenger.[59 , 103] These effects are most pronounced in mitochondria, perhaps as a consequence of the reduction of cupric to cuprous ion in these organelles.[45 , 104] Copper also accumulates in the cellular nuclei, where localized production of hydroxyl radicals may form DNA adducts and cause apoptosis.[92] Histologically, liver damage follows a centrilobular pattern of necrosis.

The sequelae of the potent hepatotoxic effects of copper are not isolated to the liver. Once liver necrosis occurs, typically at liver concentrations greater than 50 mg/g dry weight, massive release of copper into the blood occurs, which may be of sufficient magnitude to cause hemolysis. This sequence of events is common during the crises of Wilson disease, and may allow for an understanding of the delayed secondary episode of hemolysis that occurs in some copper-poisoned patients.

Kidney

The kidneys bioaccumulate copper. Although primarily bound to metallothionein when available, copper is otherwise free to participate in oxidant-generating reactions in a manner analogous to that of iron. Thus, reactive oxygen species are probably also responsible for the nephrotoxic effects of copper. Pathologic analyses of the kidneys of oliguric or anuric patients typically reveal acute tubular necrosis, and some analyses demonstrate hemoglobin casts. These findings suggests that renal failure may result indirectly from the hemoglobinuria induced by the massive release of free extracellular hemoglobin. The urinary hemoglobin, like myoglobin, may undergo conversion to ferriheme or release its iron, either of which results in oxidative stress on the renal tubular epithelial cell. Additionally, free intravascular hemoglobin may cause renal vasoconstriction through the local scavenging of nitric oxide within the renal arterioles.

Central Nervous System

Although charged entities such as copper ions do not readily cross the bloodâ€“brain barrier, elevated cerebrospinal fluid copper concentrations are characteristic of chronic copper overload conditions such as Wilson disease.[107] This accumulation is accomplished through carrier-mediated transport of albumin-bound, not ceruloplasmin-bound, copper into the central nervous system.

Clinical Manifestations

Acute Copper Salt Poisoning

Gastrointestinal irritation is the most common initial manifestation of copper salt poisoning. This syndrome includes the rapid onset of emesis and abdominal pain, possibly followed by gastroduodenal hemorrhage, ulceration, or perforation.[8 , 31] Blue coloration of the vomitus may occur following the ingestion of certain copper salts,

particularly copper sulfate.[46, 99, 115] Blue vomitus is not, however, pathognomonic for copper poisoning and also occurs in patients who ingest boric acid, methylene blue, or food dyes. Other common symptoms include retrosternal chest pain and a metallic taste. The lethal dose of ingested copper sulfate is suggested to be 0.15â€“0.3 g/kg, but this is unverified.

Given its location within the gastrointestinal tract, the liver receives the initial and most substantial exposure to any ingested copper. Consequently, hepatotoxicity is a frequent, although rarely an isolated,[56] manifestation of acute copper sulfate poisoning, typically occurring in the patients with more severe poisoning. Jaundice, while among the most common clinical and biochemical findings following overdose, can be hepatocellular or hemolytic.[10]

Hemolysis is more common than hepatotoxicity, and is invariably in those with liver damage.[77, 101] As noted, copper-induced hemolysis often occurs rapidly following exposure and may be severe (see Pathophysiology above and Chap. 24). In most reported cases, the discovery of significant methemoglobinemia occurs early in the patient's clinical course and is rapidly followed by hemolysis.[29] Because free methemoglobin is filterable, methemoglobinuria may occur, although it cannot be differentiated from other heme forms in the urine without specialized testing.

Renal and pulmonary toxicity occur occasionally and represent extraerythrocytic manifestations of the oxidative effects of the copper ions. In spite of massive intravascular hemolysis, hemoglobinuric renal failure is uncommon in patients who receive adequate volume-replacement therapy.[30]

Hypotension and cardiovascular collapse occur in patients with the most severe poisoning and is likely multifactorial in origin.[99] Undoubtedly, intravascular volume depletion from vomiting and

diarrhea is involved. However, the severity and poor patient outcome despite appropriate volume loading suggests that the

direct effects of copper on vascular and cardiac cells are also involved. Sepsis, as a result of transmucosal invasion, may also be partially responsible.[71]

Depressed mental status, ranging from lethargy to coma, or seizures following acute poisoning are likely epiphenomena related to damage to other organ systems. These findings are particularly common in patients with hepatic failure, and are comparable to those of hepatic encephalopathy from other causes. In patients with chronic copper poisoning, such as Wilson disease, neurologic manifestations are prominent (see Chronic Copper Poisoning below), and typically involve movement disorders.

Intravenous injection of copper sulfate reportedly produces a clinical syndrome identical to that which occurs following ingestion.[17 , 84] Inadvertent subcutaneous administration of a veterinary copper glycinate solution produced skin necrosis in the area of the injection.[11]

Although not strictly a form of copper poisoning, inhalation of copper oxide fumes, generated during welding or other industrial processes, may produce metal fume fever, a syndrome historically called â€œbrass chillsâ€• or â€œfoundry workers' ague.â€• Patients with this syndrome present with cough, chills, chest pain or fever that are most likely immunologic, and not toxicologic, in origin (Chap. 119). However, copper oxide formation, unlike zinc oxide, only occurs at extremely high temperatures, accounting for the relative infrequency of the copper-induced metal fume fever.

Chronic Copper Poisoning

Although hepatolenticular degeneration, known as Wilson disease, is a condition of chronic copper overload, there are qualitative similarities to acute copper poisoning. Wilson disease is an inherited, autosomal recessive disorder of copper metabolism affecting approximately 1 in 40,000 persons. The gene implicated

in this disease (ATP7B) codes for a hepatocyte membrane-bound copper-binding protein that is required for the maturation of ceruloplasmin and the biliary excretion of copper. Transgenic replacement models, in which human ATP7B is expressed in deficient animals, demonstrate normalization of copper excretion.[74] The resultant increase in hepatic copper concentrations produces continuing oxidative stress on the hepatocyte and cellular necrosis with the inevitable development of cirrhosis. Patients undergo periodic fluctuations in the extent of their copper-induced hepatotoxicity, and episodes of severe hepatotoxicity are frequently associated with hemolysis as stored copper is released from dying hepatocytes. The adverse effects of copper on the lenticular nucleus in the basal ganglia cause movement disorders such as ataxia, tremor, parkinsonism, dysphagia, and dystonia.[82] None of the other forms of copper poisoning are associated with substantial or direct neurotoxicity. Psychiatric manifestations, such as behavioral changes or mood disorders, may also occur.[21] Accumulation of copper within the cornea accounts for the characteristic green-brown Kayser-Fleischer rings. Although the patient's serum copper levels are decreased, they typically have a reduced ceruloplasmin concentration, caused by the failure of copper incorporation into ceruloplasmin and release from the liver, and an elevated urinary copper concentration. Treatment involves lifelong therapy with D-penicillamine, trientine (triethylene tetramine), or molybdenum salts if the patient is D-penicillamine sensitive. Zinc acetate, FDA approved as a maintenance therapy, induces the formation of intestinal metallothionein and thereby blocks copper absorption by enhancing intestinal mucosal cell sequestration.[22] Orthotopic liver transplantation results in improvement in nearly all aspects of the disease, including the central nervous system and ocular manifestations.[41]

Chronic exogenous copper poisoning is uncommon in adults, but is reported following the use of copper-containing dietary

supplements.[83] However, subacute or chronic exposure is common in children in some parts of the world. This condition, commonly called childhood cirrhosis in India or idiopathic copper toxicosis elsewhere, generally occurs in the setting of excessive dietary intake of copper because of copper-contaminated water from brass vessels used to store milk. These children may have a genetic predisposition to copper accumulation, as signs of chronic liver disease develop by several months of age and progress rapidly.[97, 100] Both serum copper and ceruloplasmin levels are markedly elevated, which differentiates this disease from Wilson disease. The incidence of the disease has fallen dramatically, probably as a result of improved nutrition and replacement of copper utensils and storage containers with those made of steel.

â€œVineyard sprayer's lung,â€• first described in 1969, refers to the occupational pulmonary disease that occurred among Portuguese vineyard workers applying Bordeaux solution, a 1â€“2% copper sulfate solution neutralized with hydrated lime ($Ca(OH)_2$).[86] The patients developed interstitial pulmonary fibrosis and histiocytic granulomas containing copper. Many of these workers also developed lung adenocarcinoma, hepatic angiosarcoma, and micronodular cirrhosis, raising the possibility of a carcinogenic effect of chronic copper exposure.[87] There is also a suggestion of an increased incidence of pulmonary adenocarcinoma among smelters, who are, however, exposed to many other xenobiotics, including arsenic, a known carcinogen.[72] Copper is not on the list of suspected carcinogens compiled by the International Agency of Research on Cancer (IARC).

Ophthalmic effects of copper salts, primarily following occupational exposure, include irritation of the corneal, conjunctival, or adnexal structures. Chronic ophthalmic exposure to particulate elemental copper or one of its alloys may result in chalcosis lentis, from the Greek word *chalkos*, or copper. This chronic exposure manifests as a green-brown discoloration of the lens or cornea, similar to Kayser-Fleischer rings.

Diagnostic Testing

Real-time testing for copper is impractical and almost all management decisions must be based on clinical criteria. Copper levels are often obtained for confirmatory or investigative purposes. Although never adequately studied, whole-blood copper concentrations may correlate better with clinical findings than do serum copper concentrations.[31] The rapid movement of copper from serum into the erythrocyte presumably explains this finding. However, although there is a statistical relationship between the whole-blood copper levels and the severity of poisoning,[31 , 113] there is little correlation between clinical findings at any given copper concentration, regardless of which biologic tissue is measured. Similarly, other than at extremely high or low values, there is no defined value at which the prognosis may be established with certainty. Reported serum copper concentrations in patients with hemolysis range from 96â€“747 Âµg/dL, and those following severe poisoning have values of 6600 Âµg/dL[46] and 8267 Âµg/dL.[29] Serum copper concentrations in 11 patients with copper-induced acute renal failure

ranged from 115â€“390 Âµg/dL.[28] The normal urinary copper excretion per 24 hours is approximately 25 Âµg, and is reportedly as high as 628 Âµg/24 h in patients with copper poisoning.[39]

Occasionally serum copper concentrations reveal a secondary rise, likely as a consequence of release during hepatocellular necrosis. This secondary rise typically occurs only in patients with life-threatening poisoning, and clinical evaluation is far more important and relevant than serial copper levels.[101]

Elevated copper levels are also noted in patients with inflammatory conditions, biliary cirrhosis, and pregnancy. These conditions are associated with an elevated ceruloplasmin, and the fraction of bound copper in the serum remains normal. Patients

with Wilson disease have elevated hepatocyte copper content, but their serum copper levels are generally below normal unless hepatic necrosis is occurring.

Although serum ceruloplasmin levels rise in patients with acute copper poisoning,[113] presumably reflecting increased hepatic synthesis, the ceruloplasmin concentration cannot be used to define the patient's prognosis. Tissue metallothionein levels may also rise after copper poisoning, but the implication of this finding, which is limited by the inability to rapidly obtain tissue samples, is unknown.[67]

Routine laboratory testing following acute copper salt poisoning should include an assessment for both hemolysis and hepatotoxicity. Differentiation of these etiologies as a cause for jaundice is made by standard methodology, such as comparison of the bilirubin fractions and an assessment of the hepatic enzymes and hemoglobin; that is, indirect bilirubin is proportionally elevated in patients with hemolysis, whereas the direct fraction rises in patients with hepatocellular necrosis. An assessment of the patient's electrolyte and hydration status is warranted. The prothrombin time may be prolonged in the absence of liver injury or disseminated intravascular coagulopathy and may be the result of a direct effect of free copper ions on the coagulation cascade.[80] In addition, many reports document an abnormal glucose 6-phosphate dehydrogenase (G6PD) activity, suggesting causation for hemolysis. However, interpretation of this test result is difficult, as copper poisoning interferes with the measurement of G6PD.

Although copper metal embedded in the skin is clearly visible, topically applied copper salts are not visualized.[15] The clinical usefulness of radiographs to identify ingested copper solutions is unstudied. Still, obtaining an abdominal radiograph, while probably of low clinical yield, may be justified, if it occasionally alters management.

Management

Optimal and aggressive supportive care is the cornerstone to the effective management of patients with acute copper poisoning. Attention to antiemetic therapy, fluid and electrolyte correction, and normalization of vital signs are the critical steps before consideration of chelation therapy. Gastrointestinal decontamination is of limited concern because the onset of emesis generally occurs within minutes of ingestion and is often protracted. Although oral activated charcoal is unlikely to be harmful, it is of unproved benefit, and it may hinder the ability to perform gastrointestinal endoscopy to evaluate the corrosive effects of a copper salt on the mucosal surface.[18] For this reason, even though activated charcoal may be able to adsorb the remaining copper in the proximal gastrointestinal tract, it is relatively contraindicated in most situations. Advanced therapy for patients with renal failure may include hemodialysis, and liver transplantation may be needed for patients with life-threatening hepatic failure.

Chelation Therapy

Chelation therapy should be initiated when hepatic or hematologic complications are present or the patient is severely poisoned. Studies on the efficacy of chelation therapy following acute copper salt poisoning are limited. Even when administered early and appropriately, organ damage and death still occur. Application of the data from the existing literature is complex because of the lack of controlled therapeutic studies of human copper poisoning. Although experimental animal models and uncontrolled human data exist, the results are frequently contradictory. Three drugs are clinically available, and most dosing and efficacy data derive either from their use in the treatment of patients with Wilson disease or from their effects on copper elimination during chelation of patients manifesting toxicity from other metals.

Most patients with copper poisoning are initially treated with intramuscular British anti-Lewisite (BAL).[108 , 115] Although BAL may be less effective, its use is appropriate in patients in whom vomiting or gastrointestinal injury prevents oral D-penicillamine administration. Furthermore, because the BALâ€“copper complex primarily undergoes biliary elimination, whereas D-penicillamine undergoes renal elimination, BAL proves useful in patients with renal failure. When tolerated, D-penicillamine therapy should be started simultaneously or shortly after the initiation of therapy with BAL.

Calcium disodium ethylenediaminetetraacetate ($CaNa_2$ EDTA) reduces the oxidative damage induced by copper ions in experimental models.[117] However, it does not greatly enhance the elimination of copper when used for the chelation of other metals.[96 , 109] In addition, short-term use of $CaNa_2$ EDTA inactivates dopamine Î²-hydroxylase in humans, presumably by chelating its copper moiety.[33] However, because the in vivo activity of this enzyme is restored on the addition of exogenous copper, the potential for inhibition of the formation of neuronal norepinephrine during the treatment of acute poisoning is unknown. Interestingly, CuCaEDTA is used as a copper supplement in animals, and overdose of this formulation results in copper poisoning.[42]

D-Penicillamine (Cuprimine), a structurally distinct metabolite of penicillin, is an orally bioavailable monothiol chelator. It is used in the treatment of lead, mercury, and copper toxicity, as well as in the management of rheumatoid arthritis and scleroderma. D-Penicillamine is effective in preventing copper-induced hemolysis in patients with Wilson disease. Its protective mechanism is primarily mediated through chelation of unbound copper ions, rendering them unable to participate in redox reactions.[62] The D-penicillamineâ€“copper complex undergoes rapid renal clearance in patients with competent kidneys. The use of D-penicillamine is not

formally studied in the patients with acute copper salt poisoning, but case studies and animal models suggest that copper elimination is enhanced.[20, 44, 53] The recommended dose is 1â€“1.5 g/d given orally in 4 divided doses. D-Penicillamine is also indicated for the treatment of chronic exogenous copper poisoning, such as Indian childhood cirrhosis. Initiation early in the course of disease, along with discontinuation of the exposure, is associated with hepatic recovery and dramatically improved survival rates.[13]

Although D-penicillamine appears effective, it is associated with several significant complications. For example, D-penicillamine is associated with a worsening of neurologic findings in nearly 50%

of patients treated for Wilson disease.[23] Subacute toxicities of D-penicillamine include aplastic anemia, agranulocytosis, and renal and pulmonary disease. Long-term use of D-penicillamine is also associated with the development of cutaneous lesions and immune system dysfunction. However, in the brief treatment necessary for acutely poisoned patients, the major risk is the potential for hypersensitivity reactions that occur in 25% of patients who are penicillin allergic. This hypersensitivity reaction is likely related to contamination of the pharmaceutical preparation with penicillin, rather than immunologic cross-reactivity.[52, 58] The use of D-penicillamine during pregnancy is associated with congenital abnormalities, although all of the data are derived from women with Wilson disease who had long-term therapy.[88]

Succimer is sometimes described as an ineffective copper chelator, although it is able to triple the baseline copper elimination in a murine model.[26] Given its ease of use, relative safety, and benefit in experimental models,[1] succimer may be used in lieu of D-penicillamine in patients with mild or moderate poisoning. Under these circumstances, the use of standard lead poisoning dosing regimens is warranted (Chap. 91 and Antidote in Depth: Succimer [2,3-Dimercaptosuccinic Acid]) DMPS, an experimental chelating agent which is gaining popularity for the treatment of arsenic

poisoning, prevents acute tubular necrosis in copper-poisoned mice.[78] DMPS also proved to be the most effective of a panel of chelators in a murine model of copper sulfate poisoning,[57] and it substantially increased urinary copper elimination in nonpoisoned individuals.[110] However, DMPS, unlike D-penicillamine, forms intramolecular disulfide bridges, which, in so doing, liberates an electron. This property, which accounts for its potency as a reducing agent, also probably explains its propensity to worsen copper-induced hemolysis in vitro.[2,3] Because an adequate analysis of risk versus benefit is unavailable, DMPS should not be used to chelate copper-poisoned patients at this time.

Trientine, an orally bioavailable agent, is the second-line agent for patients with Wilson disease, but its use in patients with acute copper poisoning is unreported. This, too, is the case with zinc therapy, which is also of proven efficacy in Wilson disease, but has no known role in the treatment of acute copper poisoning. The need for several weeks of zinc therapy prior to realizing full efficacy makes its therapeutic use in acutely poisoned patients questionable. Although large oral doses of zinc salts may limit the absorption of copper ion, the concomitant gastrointestinal irritant effects of zinc ion make this therapy impractical.[49]

Tetrathiomolybdate is an FDA-recognized chelating agent with orphan drug status that, although not marketed, may be available through compounding pharmacies, typically as ammonium tetrathiomolybdate. Tetrathiomolybdate is suggested to benefit copper-poisoned animals in uncontrolled studies,[85] but its use in acute copper poisoning in humans is unstudied. Tetrathiomolybdate depleted the copper stores in a patient with cancer who purchased the compound over the Internet as an â€œalternativeâ€• antiangiogenesis therapy.[69]

Extracorporeal Elimination

Limited data exist regarding the extent to which copper ion is

eliminated by various extracorporeal means. Exchange transfusion is of undefined, but probably limited, benefit in acute copper sulfate poisoning.[32] Hemodialysis membranes undoubtedly allow copper ions to cross, based on the epidemics in which hemodialysis actually resulted in copper poisoning.[36] Although copper should be similarly cleared by hemodialysis, its relatively large volume of distribution limits the potential clinical usefulness of this technique. Furthermore, copper ions are highly protein bound, and the dialyzable concentration is typically less than 1 pmol/L, suggesting that hemodialysis would have little clinical usefulness. This fact is supported by case reports in which serum or dialysate concentrations of copper are assessed.[84] Furthermore, given the propensity of hemodialysis to lyse erythrocytes, which may release stored copper and worsen toxicity, hemodialysis is not recommended.[48] Peritoneal dialysis is not useful in patients with fulminant Wilson disease.[66] Peritoneal dialysis removed less than 700 Âµg in a copper sulfate-poisoned child whose copper concentration was 207 Âµg/dL.[48] However, in the same patient, the addition of albumin to the dialysate removed 9 mg of copper at a time when the child's serum copper concentration had fallen to a lower level. One patient was treated with albumin dialysis using a 44 g/L albumin-containing dialysate and a slow dialysate flow rate (1â€“2 L/h) in a manner similar to routine continuous venovenous hemodiafiltration.[16 , 63] The patient's clinical condition improved, the serum copper concentrations normalized, and 105 mg of copper was removed. Plasma exchange enhanced the elimination of copper in patients with fulminant Wilson disease.[61 , 63] Copper removal ranged from 3â€“12 mg per treatment, but it is unclear if either of these removal techniques would be beneficial following an ingestion of gram quantities of copper sulfate.

Management of the hepatic toxicity requires little more than standard supportive care. The potential benefit of *N* -acetylcysteine is unstudied, although it is useful in many forms of fulminant hepatic failure. Liver transplantation should be

considered, but specific criteria for transfer to a specialized liver unit or for transplant, other than those that are applicable for Wilson disease or other more common, noncopper etiologies, are undefined.

There are no controlled data on the treatment of acute copper poisoning in pregnancy. The available data on pregnant women with Wilson disease document that D-penicillamine is teratogenic and that zinc may be the preferred therapeutic agent.

Summary

Acute copper poisoning is rare in the United States but is associated with dramatic toxicologic effects, primarily hemolysis and hepatotoxicity. The toxicologic effects of copper are primarily mediated by oxidative stress on the erythrocyte and hepatocyte, and this similarity to iron salt poisoning adds a framework for the conceptual understanding of the disease. The infrequency of acute copper poisoning severely limits our ability to perform controlled studies on its management. Chelation is most commonly performed with BAL and D-penicillamine, but succimer is likely to be beneficial. Succimer is more familiar to most clinicians and has fewer associated adverse effects, so it may be acceptable. Extracorporeal elimination is unlikely to be of benefit. Fortunately, exhaustive research into diseases of copper metabolism, particularly Wilson disease, which has periodic exacerbations similar to acute copper poisoning, provides insight into managing patients with acute copper salt poisoning.

Chapter 91
Lead

Fred M. Henretig

Lead (Pb)

Atomic number = 82

Atomic weight = 207

Normal concentrations

Whole blood = < 10 Âµg/dL (<0.48 mmol/L)

A 3-year-old boy was rushed to the emergency department (ED) by the rescue squad after having a 20-minute seizure at home. He initially appeared postictal, with flaccid muscle tone and minimal response to painful stimulation. Soon after arrival, he had another seizure, was treated with intravenous diazepam, which, in turn, was complicated by respiratory failure necessitating endotracheal intubation. The electrocardiogram (ECG) monitor revealed a normal sinus rhythm. A rapid bedside test for blood glucose was 194 mg/dL. Arterial blood-gas determination after intubation revealed normal

ventilation and oxygenation, with metabolic acidosis. Another generalized seizure occurred 5 minutes later, but it resolved immediately with a second dose of diazepam 0.2 mg/kg.

Further history revealed that this child was in his usual state of health until 3 days prior to admission, when he developed symptoms of an upper respiratory infection. Two days later he developed tactile fever, vomited once, and appeared less active. On the day of admission, he seemed drowsy, vomited several times, and in the evening developed twitching and abnormal eye movements, prompting a call to the rescue squad.

His past medical history was notable for developmental delay, primarily in the speech and personal-social spheres. He spoke only single words, was not toilet trained, and was unable to dress himself. His mother denied any history of head trauma or recent ingestion, but did comment that 3 weeks previously she had to remove paint chips from the child's mouth.

Physical examination revealed an intubated child with a blood pressure of 84/50 mm Hg, a heart rate of 120 beats/min, a manually ventilated respiratory rate of 25 breaths/min, and a temperature of 100.9Â°F (38.3Â°C). There were no signs of external trauma. Cardiac, pulmonary, and abdominal examinations were normal. The neurologic examination revealed an obtunded child with intermittent withdrawal to pain. At times, tonic extensor posturing was noted. Pupils were 3 mm and sluggishly reactive, with normal fundi. Deep tendon reflexes were 3+ to 4+ on the left leg and 2+ to 3+ on the right leg. There was bilateral sustained ankle clonus. Plantar extension was present on the left, and the response was equivocal on the right.

The patient went immediately to CT scan, which revealed diffuse cerebral edema and loss of gray-white matter differentiation (Fig. 91-1). Recurrent seizure activity necessitated additional therapy with phenobarbital and was followed by midazolam infusion. The child was also treated with hyperventilation and dexamethasone for increased

intracranial pressure, and empirically with ceftriaxone and acyclovir for possible viral and/or bacterial central nervous system (CNS) infection. A lumbar puncture was performed, revealing opening pressure of 46 cm H_2O (Nl = 10â€“28 cm H_2O) clear, colorless fluid, and closing pressure of 15 cm H_2O. The cell count was 3 white blood cells (WBC)/mm^3 and 0 red blood cells (RBC)/mm^3, with cerebrospinal fluid (CSF) protein of 96 mg/dL and glucose of 108 mg/dL. One dose of mannitol was given after the lumbar puncture confirmed elevated intracranial pressure. Additional pertinent positive laboratory tests included hemoglobin, 6.6 g/dL; mean corpuscular volume (MCV), 50 Âµm^3; and peripheral blood smear positive for RBC basophilic stippling. Urinalysis showed 4+ glucose, 5â€“10 WBCs, 0â€“5 RBCs, and 1+ protein. Radiographic studies were negative for radiopaque foreign bodies of the abdomen, but positive for dense metaphyseal bands at the wrist (Fig. 91-2). Blood lead concentration was 220 Âµg/dL, and erythrocyte protoporphyrin was 649 Âµg/dL.

Despite anticonvulsant therapy with phenytoin, phenobarbital, and midazolam infusion, a continuous reading electroencephalogram demonstrated periodic epileptiform activity. Pentobarbital was added to the therapeutic regimen, resulting in intermittent burst suppression of up to 40 seconds' duration. The child underwent a

5-day course of parenteral chelation therapy with dimercaprol (British anti-Lewisite, BAL) and edetate calcium disodium ($CaNa_2$ EDTA). After a 2-day interval, the child received a second 5-day course of chelation, resulting in a blood lead concentration of 33 Âµg/dL.

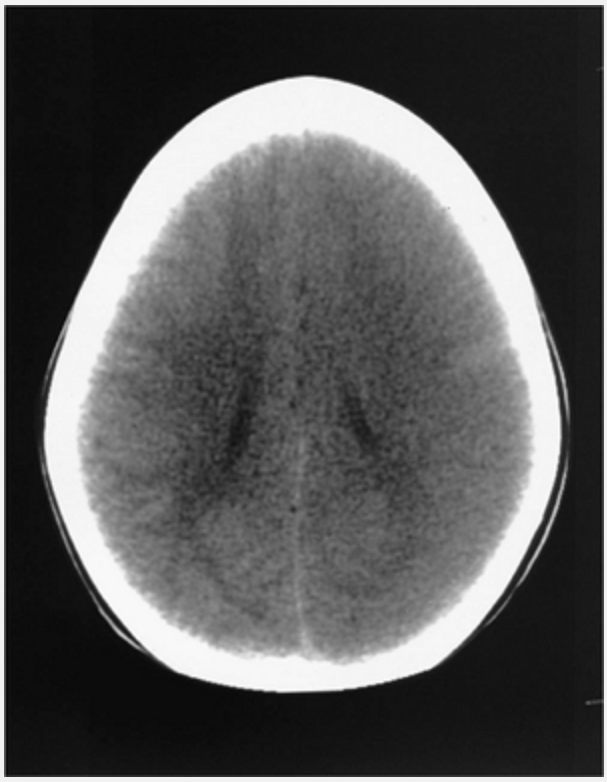

Figure 91-1. Computerized tomography scan of the brain reveals diffuse cerebral edema and loss of gray-white matter differentiation. *(Courtesy of Department of Radiology, St. Christopher's Hospital for Children, Philadelphia, PA.)*

The patient required high-dose pentobarbital for 6 days and continuous midazolam infusion for 14 days to suppress seizure activity. He was hospitalized for 23 days prior to transfer to a chronic care rehabilitative facility. His neurologic examination prior to transfer was notable for choreoathetoid movements and generalized hypotonia, inability to localize visual or auditory stimuli, and nonpurposeful movements of the extremities. An MRI on day 22 revealed cerebral and cerebellar cortical atrophy with multiple areas of infarction involving the frontal and parietal lobes (Fig. 91-3).

Physical Properties

Lead is a silvery-gray, soft metal, with an atomic weight of 207.21 and an atomic number of 82. It has a low melting point, 621.3Â°F (327.4Â°C), and boils at 2948Â°F (1620Â°C) at atmospheric pressure.[122] It is widely distributed geologically, and occurs principally as two isotopes, ^{206}Pb and ^{208}Pb. Metallic lead is relatively insoluble in water and dilute acids, but will dissolve in nitric, acetic, and hot, concentrated sulfuric acids. In compounds, lead assumes valence

states of +2 and +4. Inorganic lead compounds may be brightly colored and vary widely in water solubility; several are used extensively as pigments in paints such as lead chromate (yellow) and lead oxide (red). Lead also forms organic compounds, of which two, tetramethyl and tetraethyl lead, were used commercially as gasoline additives.[56] These are essentially insoluble in water, but readily soluble in organic solvents.[104] Lead complexes with ligands containing sulfur, oxygen, or nitrogen as electron donors. It thus forms stable complexes with several ligands common to biologic molecules, including â€“OH, â€“SH, and â€“NH_2. Complexes with sulfhydryl (â€“SH) groups are thought to be of most toxicologic importance. There is no known physiologic role for lead, and any lead found in human body fluids represents environmental contamination.[86]

History and Epidemiology

Industrial Applications

Lead's low melting point and malleability made it one of the first metals smelted and used by human society. Lead-based ocher paints are believed to date to approximately 40,000 B.C. Ancient Egyptians

and Hebrews used lead, and the Phoenicians established lead mines in Spain circa 2000 B.C. The Greeks and Romans produced lead during the process of extracting silver intended for coinage. Roman society found many uses for lead, including pipes, cooking utensils, and ceramic glazes, and a common practice was to use sapa, a grape syrup simmered down in lead vessels, as a sweetener and preservative.[83] Postindustrial lead use increased dramatically, and today, lead is the most widely used nonferrous metal, with global production on the order of 9 million tons annually.[56] Lead is used widely in industry for its waterproofing and electrical- and radiation-shielding properties. Use of both lead-based paint for house paint and leaded gasoline has been essentially eliminated by regulation in the United States since the 1980s, but persistence of lead paint in older homes still constitutes an enormous environmental challenge.[4]

History of Lead-Related Health Effects

The problem of human poisoning from lead, known as plumbism, dates back to antiquity. Dioscorides, a Greek physician in the 2nd century B.C., observed that lead makes the mind â€œgive way.â€•[167] Pliny cautioned the Romans of the danger of inhaled fumes from lead smelting.[79] Modern authors have suggested that extensive use of sapa in Roman aristocratic society contributed to the downfall of Roman dominance.[83] Lead poisoning was also recognized in Colonial times. Benjamin Franklin observed, in 1763, the â€œdry gripesâ€• (abdominal colic) and â€œdanglesâ€• (wristdrop) that afflicted tinkers, painters, and typesetters, as well as the â€œgripesâ€• caused by rum distillation in leaden condensing coils.[74] Lead salts, particularly lead acetate (sugar of lead), were used medicinally in the early 19th century for control of bleeding and diarrhea. With the 19th-century Industrial Revolution, lead poisoning became a common occupational disease. The reproductive effects of lead poisoning were also noted by the turn of the 20th century, including the high rate of stillbirths, infertility, and abortions among women in the pottery industry, or who were married to pottery

workers.

The modern history of childhood plumbism can be traced to the recognition of lead-paint poisoning in Brisbane, Australia, in 1897.[79] Lead poisoning was reported in US children in 1917, and by 1943 it was established that children who recovered from clinical plumbism were frequently left with neurologic sequelae and intellectual impairment. Symptomatic childhood lead poisoning was a frequent occurrence in US pediatric medical centers throughout the 1950s and 1960s, a period during which research established effective chelation therapy protocols with British anti-Lewisite (BAL) and edetate calcium disodium ($CaNa_2EDTA$).[26] From the 1970s to present, the research thrust in childhood lead poisoning has centered on the recognition and quantification of more subtle neurocognitive impairment caused by subclinical lead poisoning.[12,80] Over this time period, the Centers for Disease Control and Prevention (CDC) have steadily revised downward the definitions of a normal blood lead concentration (BLL) in children. The CDC definition of lead poisoning was 60 Âµg/dL in the early 1960s, whereas the current action level is 10 Âµg/dL.[20]

Sources of Human Exposure

Numerous sources of lead exposure exist, and can be generally classified as environmental, occupational or â€œexotic.â€• *Environmental* exposures affect the entire population, particularly young children. These exposures occur primarily by ingestion or inhalation, though handâ€“mouth exposure to some form of lead paint derivative predominates in most cases of childhood lead poisoning in the United States (Table 91-1). Because of its continuing, major impact in the United States today, lead paint exposure is further detailed here.

Lead pigments (typically lead carbonate) account for 50% by weight of many white house paints from the pre-World War II era. Since 1978, paint intended for interior or exterior residential surfaces,

toys, or furniture in the United States may contain, by law, no more than 0.06% lead.[4] However, an estimated 3 million tons of lead remain in 57 million US homes built prior to 1980 and painted with lead-based paint. This aging housing stock has created an enormous environmental hazard of lead exposure to these children, and to adult homeowners, house painters, and construction workers who become involved in sanding, scraping, and restoration of painted surfaces in these homes. Furthermore, lead-based paint is still allowed for industrial, military, marine, and some outdoor uses, such as structural components of bridges and highways; occasionally, some of this paint is inadvertently used in homes.[20] Attempts to abate lead-painted outdoor structures can pollute entire communities.[59]

TABLE 91-1. Environmental Lead Sources

Source	Comment
Leaded paint	Especially pre-1978 homes
Dust	House dust from deteriorated lead paint
Soil	From yards contaminated by deteriorated lead paint, lead industry emissions, roadways with high leaded gasoline usage
Water	Leached from leaded plumbing (pipes, solder), cooking utensils, water coolers

Air	Leaded gasoline (pre-1976 United States, still prevalent worldwide), industrial emissions
Food	Lead solder in cans (pre-1991 United States, still prevalent in imported canned foods); â€œnaturalâ€• calcium supplements; â€œmoonshineâ€• whiskey; lead-foilâ€“covered wines; contaminated flour, paprika

Although paint-derived lead exposure may result from pica in some children, most lead paint exposure in childhood relates to the crumbling, peeling, flaking, or chalking of aging paint.[20] These fine paint particles are incorporated into household dust and yard soil, where ordinary childhood handâ€“mouth activity results in ingestion.[21] Seasonal variations in house dust lead content occur, with higher levels in the summer months. This correlates well with predictable increases in BLLs in preschool children. This may reflect, in part, increased exposure to leaded street dust and soil while playing outdoors, and/or increased contamination of windowsills and floors by outdoor dust gaining entrance through open windows. Adults, as well as children, may develop paint-related lead poisoning when homeowners renovate Victorian-era homes in rural areas or urban neighborhoods undergoing regentrifying.[5,20]

Adults with *occupational* exposures and persons of all ages with *recreational* or *exotic* exposures to lead constitute another large group of persons at risk. It is estimated that more than 1 million workers in the United States, employed in more than 100 occupations, are exposed to lead.[100] The most important route of absorption in occupational settings is inhalation of lead dust and fumes. In addition, workers may eat, drink, or smoke in lead-dustâ€“contaminated areas, resulting in some ingestion as well

(contaminated cigarettes may provide a source of oral exposure). However, presence of lead in the workplace, per se, does not imply a significant risk of poisoning. The risk is correlated with several factors that contribute to the occurrence of respirable lead fumes or dust particles in the worksite atmosphere.[104] There are three general categories of such factors. The first relates to the degree of hazard inherent in the work process itself, including high temperatures (eg, >1832Â°F [1000Â°C]); significant aerosol, dust, or fume production; and less-mechanized technology. Second, the adequacy of dust elimination, such as local and general ventilation, is critical. The third category is that of worksite and personal hygiene, including proper use of protective clothes and equipment, and thorough housekeeping. In general, small shops employing few workers are more hazardous than large factories with hundreds or thousands of employees. The small, sometimes â€œbackyardâ€• operations are less likely to adhere to industry safety regulations. They are less automated and have less environmental control, and the relatively few workers are less educated about potential risks and protective equipment usage.[32] Despite the risk factors that may be specific to each worksite, there are some types of lead-related work that are more hazardous than others, based on actual surveys of BLLs and reported incidence of clinical poisoning (Table 91-2).[100,104]

For convenience, environmental and occupational/recreational lead exposures have been discussed separately, although there is considerable overlap. For example, workers who fail to change lead-dustâ€“covered work clothes or shoes may bring this occupational lead hazard home and secondarily contaminate their children's environment.[100]

Finally, numerous additional *exotic sources* are also reported sporadically, such as exposures to contaminated folk medications or cosmetics, ingested lead foreign bodies (Fig. 91-4), or retained bullets.[20] These, too, are highlighted separately in Table 91-2.

Prevalence

Several recent national and regional surveys have evaluated current US population-based trends in BLLs and sociodemographic correlates. The CDC recently estimated that BLLs are >9 Âµg/dL in 434,000 children ages 1â€“5 years, and that approximately 10,000 adult workers are reported each year with BLLs >24 Âµg/dL.[16] Although such numbers are impressive, they represent a considerable decrease from prevalence rates done in decades prior, and it is certainly the observed clinical experience that symptomatic pediatric plumbism, in particular, is far less common than it was a generation ago. Nevertheless, for young minority children and the poor who reside in our nation's deteriorating central cities, the battle is far from won.[18] For example, the CDC reported in 2000 that children enrolled in Medicaid had a prevalence of elevated BLLs three times greater than those not enrolled.[14] Refugee, immigrant, and foreign-born adopted children remain at particularly high risk,[13] and remarkable cases of extremely elevated BLLs (>100 Âµg/dL) may still be detected on routine screening.[31]

TABLE 91-2. Occupational and Recreational Lead Sources

High-risk occupations
Automobile radiator repairers
Crystal glass makers
Firing range instructors, bullet salvagers
Lead smelters, refiners
Metal welders, cutters (includes bridge and highway reconstruction workers)
Painters, construction workers (sanding, scraping, or spraying of lead paint; demolition of lead-painted sites)
Polyvinyl chloride plastic manufacturers
Shipbreaking

Storage battery manufacturers, repairers, recyclers

Moderate-risk occupations

Automobile factory workers and mechanics

Enamelers

Glass blowers

Lead miners

Plumbers

Pottery glazers

Ship repairers

Shot makers

Solderers

Type founders

Varnish makers

Wire and cable workers

Low-risk occupations

Electronics manufacturers

Jewelers

Pipefitters

Printers

Rubber product manufacturers

Traffic police officers, taxi drivers, garage workers, turnpike tollbooth operators, gas station attendants (exposed to leaded gasoline exhaust fumes)

Recreational and hobby sources

Crafters of ceramics

Furniture refinishing, restoring

Home remodeling, refinishing

Painting (fine artist's pigments)

Repair of automobiles, boats

Stained glass making

Target shooting, recasting lead for bullets

Exotic sources

Complementary remedies, cosmetics; ingested lead foreign bodies, retained lead bullets; illicit substance abuse (heroin,

methamphetamine, leaded gasoline â€œhuffingâ€•); burning batteries, leaded paper, or wood for fuel; use of lead-glazed ceramics; handâ€“mouth contact with pool cue chalk, glazes, leaded ink; vinyl miniblinds

Toxicology

Pharmacokinetics

Inorganic Lead

Absorption

Gastrointestinal (GI) absorption is less efficient than pulmonary absorption. Adults absorb an estimated 10â€“15% of ingested lead in food, and children have a higher GI absorption rate, averaging 40â€“50%.[1,41] However, it should be noted that fasting and diets deficient in iron, calcium, and zinc enhance GI absorption of lead, factors that are frequent among groups of young children.[41,66] A study of adults under fasting conditions found a lead absorption rate from beverage consumption of almost 60%.[49] The role of essential trace elements in decreasing lead absorption is assumed to be a consequence of competitive absorption processes; an iron-binding protein, mobilferrin, initially identified in rat duodenum, is also found in human duodenal mucosa and competitively binds lead.[27]

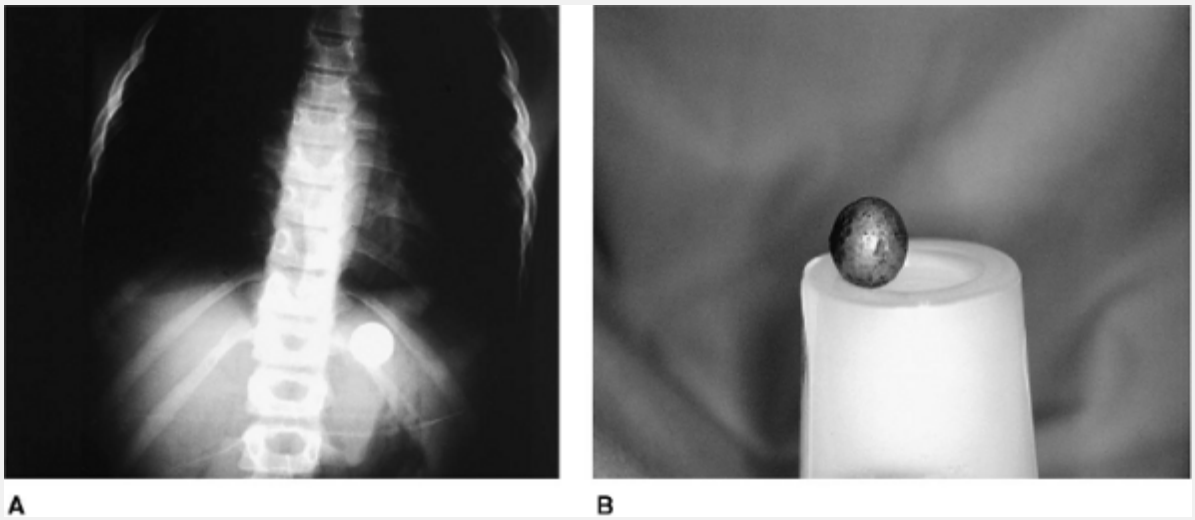

Figure 91-4. An unusual source of lead poisoning. A. Radiograph of the abdomen reveals ingested metallic foreign body. B. The ingested foreign body was a Civil War era musketball from the collection of the patient's father. *(Courtesy of Evaline Alessandrini, MD, Division of Emergency Medicine, Children's Hospital of Philadelphia, Philadelphia, PA.)*

The overall absorption of inhaled lead averages 30â€“40%. Of note, both minute ventilation and the concentration of lead in air determine airborne lead exposure, and thus a worker engaged in vigorous physical activity will absorb considerably more lead than a person in the same atmosphere at rest. Likewise, children, with relatively greater volume of inhaled air per unit of body size because of higher metabolic rates, are proportionally at greater risk in a given degree of atmospheric lead pollution. It is estimated that children have a 2.7-fold higher lung deposition rate of lead than do adults.[1]

Cutaneous absorption of inorganic lead is low; one study found an average absorption of 0.06% through intact skin.[75] Alkyl leads may have appreciable cutaneous absorption that is capable of causing

toxicity.[104]

Transplacental lead transfer is critical in fetal and neonatal lead exposure, which has been under increasing scrutiny in recent years. Lead readily crosses the placental barrier throughout gestation, and lead uptake cumulative until birth. Breast milk from heavily exposed mothers may likewise be a potential source of lead exposure, and may require lead concentration analysis before breast feeding can be safely recommended.[9]

Distribution

Absorbed lead enters the bloodstream where at least 99% is bound to erythrocytes.[40] From blood, lead is distributed into both a relatively labile soft-tissue pool and into a more stable bone compartment. This classic three-compartment model may be somewhat of an oversimplification. Currently, at least two bone compartments are recognized: a more labile pool in trabecular bone and a more stable pool in cortical bone. In adults, approximately 95% of the body lead burden is stored in bone, versus only 70% for children. The remainder is distributed to the major soft-tissue lead-storage sites, including liver, kidney, bone marrow, and brain. Most of the toxicity associated with lead is a result of soft-tissue uptake, so that the relative decrease in bone storage is another comparative disadvantage for lead-poisoned children.

Lead uptake into soft tissues occurs in a complex fashion that depends on numerous factors, including blood lead concentrations, external exposure factors, and specific tissue kinetics.[1] In general, tissue lead content in populations without very excessive exposure averages 200â€“500 parts per billion (ppb) but rises above this with excessive exposure, rapidly producing overt toxicity. For example, brain lead content in humans with overt encephalopathy is on the order of 1â€“2 parts per million (ppm) or less (eg, only twice the above-noted range). BLLs of <100 ppb (10 Âµg/dL) are associated with subtle toxic effects in critical target organs.[12]

Lead in the central nervous system (CNS) is of particular toxicologic importance, and studies have addressed specific storage sites. Lead preferentially concentrates in gray matter and certain nuclei.[40] Fetal brain uptake is relatively higher than with postnatal exposure in animal models. The highest brain concentrations are found in the hippocampus, cerebellum, cerebral cortex, and medulla.

Unlike soft-tissue storage, bone lead accumulates throughout life. Bone storage begins in utero, and occurs across all ranges of exposure, so that there is no threshold for bone lead uptake.[1] Total body accumulation of lead may range from 200â€“500 mg in workers with heavy occupational exposure.[40] Bone lead is thought to be relatively metabolically inert, but it can be mobilized from the more labile compartment, and contributes as much as 50% of the blood lead content. This may be of particular importance during pregnancy and lactation, in elder persons with osteoporosis,[111]

and in children with immobilization because of fracture or neurologic disease.[72] Lead also accumulates in teeth, particularly the dentine of children's teeth, a phenomenon that has been used to quantify cumulative lead exposure in young children.[80]

Excretion

Absorbed lead that is not retained is primarily excreted in urine (approximately 65%) and bile (approximately 35%).[1] A miniscule amount is lost via sweat, hair, and nails. Children excrete less of their daily uptake than adults, with an average retention of 33% versus 1â€“4%, respectively.[132] Biologic half-lives for lead are estimated as follows:[1,68,93] blood (adults, short-term experiments), 25 days; blood (children, natural exposure), 10 months; soft tissues (adults, short-term exposure), 40 days; bone (labile, trabecular pool), 90 days; and bone (cortical, stable pool), 10â€“20 years.

Organic Lead

Alkyl lead compounds have unique pharmacokinetics that are less-well characterized.[10] Tetraethyl lead is lipid soluble, easily absorbed through intact skin, and distributed widely to lipophilic tissues, including the brain. Tetraethyl lead is metabolized to triethyl lead, which is believed to be the major toxic compound. Alkyl leads may slowly release lead as the inorganic form, with subsequent kinetics as noted above.

Pathophysiology

General Effects

Similar to many metals, lead is a complex toxin exerting numerous pathophysiologic effects in many organ systems.[40] Furthermore, genetic polymorphism may impact on individual susceptibility to lead.[84] At the biomolecular level, lead functions in three general ways. First, its affinity for biologic electron-donor ligands, especially sulfhydryl groups, allows it to bind and impact numerous enzymatic, receptor, and structural proteins. Second, lead is chemically similar to calcium and interferes with numerous metabolic pathways, particularly in mitochondria and in second-messenger systems regulating cellular energy metabolism. Lead-induced mitochondrial injury can result in apoptosis, a phenomenon particularly well studied in animal models of retinal cells.[60] Lead may function as an inhibitor or agonist of calcium-dependent processes. For example, lead inhibits neuronal voltage-sensitive calcium channels[8] and membrane-bound Na^{+}â€“K^{+}â€“ATPase (adenosine triphosphatase),[113] but activates calcium-dependent protein kinase C.[70] Third, lead exhibits mutagenic and mitogenic effects in mammalian cells in vitro and is carcinogenic in rats and mice.[189] Evidence for human carcinogenicity, however, is lacking.[34]

Neurotoxicity

Lead's neurotoxicity involves several mechanisms, including

apoptosis, excitotoxicity, adverse influence on neurotransmitter and second-messenger function, mitochondrial injury, cerebrovascular endothelial damage, and impaired development and function of both oligodendroglia and astroglia, although particularly the former, with resultant abnormal myelin formation. In severe cases, pathologic changes may result in cerebral edema and increased intracranial pressure. Lead-induced dysfunction is reported for several neurotransmitter systems, including the classic acetylcholine-, dopamine-, norepinephrine-, Î³-aminobutyrate (GABA)-, glutamate-, and *N*-methyl-D-aspartateâ€“dependent systems.[28,40,60] Many of these phenomena can be linked to lead's ability to substitute for calcium, as noted above.

Peripheral neuropathy is a classic effect of occupational lead poisoning. The neuropathology in humans is poorly characterized, but there is primarily Wallerian degeneration. In animal models, it is associated with Schwann cell destruction, segmental demyelination, and axonal degeneration.[40] Sensory nerves are less affected than motor nerves.

Hematologic

Lead is hematotoxic in several ways, including via potent inhibition of several enzymes in the heme biosynthetic pathway (Chap. 24 and Fig. 24-3). It also induces a defect in erythropoietin function secondary to associated renal damage.[46,99] Shortened erythrocyte life span is believed to be caused by increased membrane fragility. Inhibition of Na^{+}â€“K^{+}â€“ATPase and pyrimidine-5â€²-nucleotidase may impair erythrocyte membrane stability by altering energy metabolism. The inhibition of pyrimidine-5â€²-nucleotidase is also thought to underlie the appearance of basophilic stippling in erythrocytes, representing clumping of degraded RNA, which is normally eliminated by this enzyme.[85]

Renal

Functional changes associated with acute lead nephropathy include decreased energy-dependent transport, resulting in a Fanconilike syndrome of aminoaciduria, glycosuria, and phosphaturia. These changes are believed to be related to disturbed mitochondrial respiration and phosphorylation, and are reversible with discontinuation of exposure and/or treatment.[43] A pathologic finding is characteristic nuclear inclusion bodies in renal tubular cells, composed of leadâ€“protein complex. Lead is a renal carcinogen in rodent models, but its status in humans is uncertain.[34,40]

The association of plumbism with gout (â€œsaturnine goutâ€•) was noted more than 100 years ago. Lead decreases renal uric acid excretion, with resulting elevated blood urate concentrations and urate crystal deposition in joints. Renal function is virtually always impaired in patients with gout. (See ILBASOPHILICSTIPPLING in the Image Library at http://www.goldfrankstoxicology.com)

Cardiovascular

The most important manifestation of lead toxicity on the cardiovascular system is hypertension. This is likely caused by altered calcium-activated changes in contractility of vascular smooth muscle cells, secondary to decreased Na^{+}â€“K^{+}â€“ATPase activity and stimulation of the Na^{+}-Ca^{2+} exchange pump. Lead may also affect vessels by altering neuroendocrine input or sensitivity to such stimuli, or by increasing reactive oxygen species which enhance nitric oxide inactivation.[64] Elevated plasma renin activity is found after periods of modest exposure, although activity may drop to normal or lower in chronic severe exposure.[126] Rarely, cardiotoxicity is reported.[79,95,112] Animal models demonstrate increased sensitivity to norepinephrine-induced dysrhythmias and decreased myocardial contractility, protein phosphorylation, and high-energy phosphate generation.[57] Lead-induced impairment of intracellular calcium metabolism may impact on cardiac electrophysiology.

Reproductive System

Impairment of both male and female reproductive function is associated with overt plumbism. Gametotoxic effects in animals of both sexes and chromosomal abnormalities in workers with BLLs >60 Âµg/dL are reported.[40] Testicular endocrine hypofunction occurs in smelter workers with BLLs in the 60-Âµg/dL range.[97]

Endocrine

Reduced thyroid and adrenopituitary function are found in adult lead workers.[102,103] Children with elevated lead levels have depressed secretion of human growth hormone and insulinlike growth factor.[52]

Skeletal System

In addition to the skeletal system's importance as the largest repository of lead body burden, studies suggest that bone metabolism also is adversely affected by lead.[40] Hormonal response is altered by reduced 1,25-dihydroxyvitamin D_3 levels and by inhibition of osteocalcin. Both new bone formation and coupling of normal osteoblast and osteoclast function may thus be impaired.[39,115] Bands of increased metaphyseal density on radiographs of long bones in young children with heavy lead exposure demonstrate increased calcium deposition in the zones of provisional calcification (Fig. 91-2). Impaired bone growth and shortened stature are associated with childhood lead poisoning. Impaired calcium or cyclic adenosine monophosphate (cAMP) messenger systems may underlie these cellular effects.

Gastrointestinal

Gastrointestinal effects are partly explained by spasmodic contraction of intestinal wall smooth muscle, analogous to that

believed to occur in vascular walls.[104]

Clinical Presentation

Inorganic Lead

The numerous observed lead-induced pathophysiologic effects accurately predict that the clinical manifestations of lead poisoning are diverse. These manifestations of lead toxicity are often characterized as falling into distinct syndromes of acute and chronic symptomatology. In most cases, these distinctions really describe a continuum of severity, with more severely exposed persons manifesting the classic â€œacuteâ€• lead toxicity syndrome. Rarely, patients with massive acute inhalational exposure, intentional overdose of soluble lead compounds, or intravenous administration of lead-contaminated substances of abuse present with clinical findings that are somewhat unique, but overlap considerably with the more severe cases of chronic lead exposure. By far, the most important contexts of lead toxicity in the United States today are related to chronic environmental exposure in children, and chronic occupational exposure in adult workers. These are sufficiently distinct in epidemiology, clinical manifestations, and current recommended management approaches that they are described separately (Tables 91-3 and 91-4). Severe symptomatic poisoning is rare in recent years among persons of all ages, although it is still reported.[19,73,130] In 2000, a Sudanese refugee child died of lead toxicity in New Hampshire.[15] It should be first reemphasized that the occurrence of overt clinical symptoms in lead-exposed persons is in most cases the culmination of a long history of lead exposure. As total dose increases, these symptoms are almost always preceded first by measurable biochemical and physiologic impairment, followed, in turn, by subtle prodromal clinical effects that may only become apparent in hindsight. In general, children are considered to be more susceptible than adults to toxicity for a given dose (eg, measured

blood lead concentration); however, the data for this primarily concern effects on the CNS.

TABLE 91-3. Clinical Manifestations of Lead Poisoning in Children

Clinical Severity	Typical Blood Lead Concentrations (Âµg/dL)
Severe	
CNS: Encephalopathy (coma, altered sensorium, seizures, bizarre behavior, ataxia, apathy, incoordination, loss of developmental skills; papilledema, cranial nerve palsies, signs of increased ICP) GI: Persistent vomiting Heme: Pallor (anemia)	>70â€“100
Mild/moderate	
CNS: Hyperirritable behavior, intermittent lethargy, decreased interest in play, â€œdifficultâ€• child GI: Intermittent vomiting, abdominal pain, anorexia	50â€“70
Asymptomatic	

CNS: Impaired cognition, behavior PNS: Impaired fine-motor coordination Misc: Impaired hearing, growth	0â€“49

CNS = central nervous system; GI = gastrointestinal; Heme = hematologic; ICP = intracranial pressure; Misc = miscellaneous; PNS = peripheral nervous system.

Symptomatic Children

Acute lead encephalopathy is the most severe presentation of pediatric plumbism (Table 91-3). It may be

associated with cerebral edema and increased intracranial pressure. Encephalopathy is characterized by pernicious vomiting and apathy, bizarre behavior, loss of recently acquired developmental skills, ataxia, incoordination, seizures, altered sensorium, or coma. Physical examination may reveal papilledema, oculomotor or facial nerve palsy, diminished deep-tendon reflexes, or other evidence of increased intracranial pressure.[19,130] There may be pallor if there is coexisting anemia in patients with more chronic exposure. Encephalopathy usually occurs in children ages 15â€“30 months, is associated with BLLs >100 Âµg/dL, although it is reported with BLLs as low as 70 Âµg/dL, and tends to occur more commonly in summer months, when BLLs peak.[89] Milder but ominous symptoms that may portend incipient encephalopathy include sporadic vomiting, hyperirritable or aggressive behavior, periods of lethargy interspersed with lucid intervals, and decreased interest in play activities. Many patients seek medical advice for vomiting and lethargy during the 2â€“7 days prior to onset of frank encephalopathy. Additional symptoms include anorexia, constipation, and intermittent abdominal pain.[26,89] Physical examination of such children usually reveals no specific abnormalities.

TABLE 91-4. Clinical Manifestations of Lead Poisoning in Adults

Clinical Severity	Typical Blood Lead Concentrations (Âµg/dL)
Severe	
CNS: Encephalopathy (coma, seizures, obtundation, delirium, focal motor disturbances, headaches, papilledema, optic neuritis, signs of increased ICP) PNS: Footdrop, wristdrop GI: Abdominal colic Heme: Pallor (anemia) Renal: Nephropathy	>100
Moderate	
CNS: Headache, memory loss, decreased libido, insomnia	70â€“100
GI: Metallic taste, abdominal pain, anorexia, constipation	70â€“100
Renal: Nephropathy with chronic exposure Misc: Mild anemia, myalgias, muscle weakness, arthralgias	

Mild	
CNS: Tiredness, somnolence, moodiness, lessened interest in leisure activities Misc: Impaired psychometrics, reproduction; hypertension	40â€“69
CNS = central nervous system; GI = gastrointestinal; Heme = hematologic; ICP = intracranial pressure; Misc = miscellaneous; PNS = peripheral nervous system.	

Death and serious neurologic sequelae occurred frequently when encephalopathy was common. Mortality was 65% in the prechelation era, dropping to <5% with the advent of effective chelation. The incidence of permanent neurologic sequelae, including mental retardation, seizure disorder, blindness, and hemiparesis, is 25â€“30% in patients who develop encephalopathic symptoms prior to onset of chelation.[26]

Subencephalopathic symptomatic plumbism usually occurs in children 1â€“5 years old and is associated with BLLs >70 Âµg/dL, but may occur with concentrations as low as 50 Âµg/dL. Unfortunately, common complaints in well children of this age (â€œterrible twos,â€• with functional constipation and who don't eat as much as parents expect) often overlap with the milder range of reported symptoms of lead poisoning. Not infrequently parents of children diagnosed by routine blood screening recognize milder symptoms only in hindsight, after chelation treatment (â€œit seemed as if the child was going through a phaseâ€•).[37] This is especially true currently, when symptomatic plumbism is rarely reported.[19,20] Other uncommon clinical presentations are described,[26] including isolated

seizures without encephalopathy (indistinguishable from idiopathic epilepsy), chronic hyperactive behavior disorder, isolated developmental delay, progressive loss of cortical function simulating degenerative cerebral disease, peripheral neuropathy (reported particularly in children with sickle-cell hemoglobinopathy),[35] and a syndrome of colicky abdominal pain, vomiting, constipation, and myalgias of trunk and proximal girdle muscles.

Asymptomatic Children

Children with *elevated body lead burdens, but without overt symptoms*, represent the largest group of persons believed to be at risk of chronic lead toxicity. The subclinical toxicity of lead in this population centers around subtle effects on growth, hearing, and neurocognitive development. This last effect, in particular, is the subject of intense research interest and scrutiny. An effort to rigorously evaluate several modern (since 1979), carefully done studies of the low lead and intelligence association (cross-sectional studies with blood or tooth lead, and prospective studies), and combine their results with a statistical meta-analysis technique has been reported.[91] The overall finding was that even though the majority of individual studies failed to achieve statistical significance when taken together, there was a significant inverse association between lead exposure and IQ, on the order of 1â€“2 IQ points for BLL increases from 10â€“20 Âµg/dL. Since that publication, another study evaluated IQ in patients from 6 months to 5 years old and found that BLLs were inversely correlated with IQ at 3 and 5 years of age, and that the magnitude of effect was a 4.6-point decrement in IQ for each 10 Âµg/dL increase in BLL. Of particular concern, this effect was even greater for children in the 1â€“10 Âµg/dL BLL range.[12]

Adults

Adults with occupational lead exposure may manifest numerous signs

and symptoms representing disorders of several organ systems. Severity of symptoms correlates roughly with BLLs (Table 91-4). True acute poisoning occurs rarely, after very high respiratory,[56] large oral,[81] or intravenous exposures.[82] Such patients may present with colic, hepatitis, pancreatitis, hemolytic anemia, and encephalopathy over days or weeks. Most adult plumbism is related to chronic respiratory exposure, although some authors have used the term *acute poisoning* to include patients with such exposure whose symptoms are severe and of relatively recent onset (within 6 weeks of presentation) and whose exposure is relatively brief (average 1 year or less).[30]

The hallmark of severe toxicity is *acute encephalopathy*, which has been rarely reported in adults since the 1920s.[30] The majority of modern cases are actually not associated with occupational exposures, but rather with ingestion of illicit â€œmoonshineâ€• whiskey. Of fatal adult cases in the United States between 1979 and 1988, moonshine was the lead source in 22 of 25 patients for which the lead source was identified.[116] Encephalopathy in adults is usually associated with very high BLLs (typically >150 Âµg/dL) and is manifested by seizures (75% of cases), obtundation, confusion, focal motor disturbances, papilledema, headaches, and optic neuritis.[73,129] Adult patients with severe plumbism often manifest attacks of abdominal colic, are virtually always anemic, and are at significant risk for severe peripheral nerve palsy (eg, wristdrop, footdrop) and nephropathy. Rarely are cardiac dysfunction and electrocardiographic abnormalities reported.[95]

Moderate plumbism in adults typically involves CNS, peripheral nerve, hematologic, renal, gastrointestinal, rheumatologic, endocrine/reproductive, and cardiovascular findings.[56,100,104] At BLLs >80 Âµg/dL such symptoms may include headache, memory loss, decreased libido, and insomnia. Gastrointestinal symptoms may include metallic taste, abdominal pain, decreased appetite, weight loss, and constipation. Musculoskeletal and rheumatologic complaints at this stage include muscle pain and joint tenderness. Peripheral

neuropathy may occur, primarily motor, manifesting as muscle weakness, numbness of the legs, occasional paresthesias, tremor, and hyperreflexia. Many patients at this stage have mild anemia, and those with chronic exposure are at risk for nephropathy.

Mild plumbism may manifest minor CNS findings such as changes in mood and cognition. Subtle neurocognitive abnormalities demonstrable by neuropsychiatric testing are being found in both adults and children with modest elevations in blood lead concentration. Studies have documented abnormal psychometrics and nerve conduction in workers recently exposed to lead as BLLs rose to >30 Âµg/dL.[67] Early symptoms, manifesting at BLLs of 40â€“70 Âµg/dL, may be subtle, and include increased tiredness at the end of the day, disinterest in leisure-time pursuits, falling asleep easily, moodiness, and irritability. Effects on reproductive function and blood pressure may also be apparent in this range of exposure. Historically, infertility and stillbirths were common among heavily exposed women lead workers. More recent studies found reduced

sperm counts, impaired sperm motility, and abnormal morphology in battery workers with BLLs >40 Âµg/dL,[7] and increased incidence of menstrual irregularity and spontaneous abortion in lead-exposed female workers in China.[53] Prematurity is more common in children of pregnancies associated with elevated maternal lead levels.[78] Increased blood pressure is probably the most prevalent adverse health effect observed from lead exposure in adults. Epidemiologic studies document significant associations between hypertension and body lead burdens. The association is particularly strong for adult men ages 40â€“59 years, with an approximate 1.5â€“3.0 mm Hg rise in systolic pressure for every doubling of BLL beginning at 7 Âµg/dL.[90,121] Additional studies have correlated body lead burden with several other disorders of aging, including decline in cognitive ability,[105] electrocardiographic abnormalities,[22] chronic renal dysfunction,[64] and cataract prevalence.[108]

Physical examination findings will vary with degree of severity. Mild

and moderate symptoms usually occur in patients with normal examination findings.[32] In encephalopathic patients, typical changes of stupor, coma, posturing, and papilledema are noted. Milder abnormal neurologic findings include dominant wrist or hand weakness, paresthesia, and tremor. One author described grayish stippling of the retina circumferential to the optic disk,[115] but other authors dispute this finding.[87] A bluish-purple gingival lead line (Burton line), representing lead sulfide precipitation, is described rarely in adult patients with poor oral hygiene. Abdominal guarding and tenderness are occasionally observed. Patients with gout may have typical joint findings of acute arthritis. Severely anemic patients may exhibit pallor. Careful neuropsychologic testing may reveal abnormalities of memory span, rapid motor tapping, visual motor coordination, and grip strength.[30]

Organic Lead

Clinical symptoms of tetraethyl lead (TEL) toxicity are usually nonspecific initially, and include insomnia and emotional instability.[10,104] Nausea, vomiting, and anorexia may occur. The patient may exhibit tremor and increased deep-tendon reflexes. In more severe cases, these symptoms progress to an encephalopathy with delusions, hallucinations, and hyperactivity, which may resolve or deteriorate to coma and, occasionally, death. Severe cases may also develop hepatic and renal injury. Because many reported patients are exposed via intentional abuse of leaded gasoline, much of the literature reporting this syndrome may be confounded by accompanying volatile hydrocarbon toxicity.[118] Of note, in contrast to inorganic lead poisoning, patients with significant TEL toxicity do not consistently manifest hematologic abnormalities or elevations of heme synthesis pathway biomarkers. In addition, there is no close correlation of neurotoxicity severity with measured BLL.[48]

Assessment

Clinical Diagnosis in Symptomatic Patients

For all patients in whom plumbism is considered, based on clinical manifestations, the medical evaluation should first include a comprehensive past medical history, noting only foreign-body ingestions or gunshot wounds with retained bullets. Further inquiry should elicit environmental, occupational or recreational sources of exposure as detailed earlier (Tables 91-1 and 91-2). A child between the ages of 1 and 5 may be at further risk if there is persistent vomiting, lethargy, irritability, clumsiness, or loss of recently acquired developmental skills; afebrile seizures; a strong history of pica, including acute unintentional ingestions,[47] or aural, nasal, or esophageal foreign bodies;[131] residence in a pre-1960sâ€“built home, especially with deteriorated paint, or one that has undergone recent remodeling; a family history of lead poisoning; iron-deficiency anemia; evidence of child abuse or neglect;[36,106] or is foreign-born.[13]

The differential diagnosis of plumbism is broad. Adult patients may be misdiagnosed as having carpal tunnel syndrome, Guillain-BarrÃ© syndrome, sickle-cell crisis, acute appendicitis, renal colic, and infectious encephalitis. Children are often initially considered to have viral gastroenteritis, or even to have insidious symptoms passed off as a difficult developmental phase.

The patient who presents to the ED with acute encephalopathy that may represent lead poisoning presents the physician with a dilemma: severe lead toxicity requires urgent diagnosis, but confirmatory blood lead assays are usually unavailable on an immediate basis.[50] For adults, a history of occupational exposure is often available from past medical records or family members, and lead encephalopathy can be strongly considered with positive supportive laboratory findings (usually available on urgent basis) such as anemia, basophilic stippling, elevated erythrocyte protoporphyrin (especially

>250 Âµg/dL), and abnormal urinalysis. In this context, it might be appropriate to institute presumptive chelation therapy while awaiting lead concentrations. In children, a similar indication for presumptive treatment would be suggested by a constellation of clinical features and ancillary studies, such as age 1â€“5 years, a prodromal illness of several days' to weeks' duration (suggestive of milder lead-related symptoms), occurrence in summer, history of pica and source of lead exposure, the laboratory features noted above, which are equally helpful in young children, radiologic findings of dense metaphyseal â€œlead linesâ€• at wrists or knees (Fig. 91-2), and/or evidence of recent pica for lead paint particles on abdominal radiographs (Fig. 91-5). In both adults and children, the decision to institute empiric chelation treatment should not deter additional emergent diagnostic efforts to exclude or to confirm other important entities while blood lead concentrations are pending. An important consideration in this context may be the suspicion of an acute, potentially treatable CNS infection (eg, bacterial meningitis or herpetic encephalitis). Lumbar puncture may be dangerous in patients with lead encephalopathy because of the risk of cerebral herniation. If immediate lumbar puncture is thought to be highly desirable, a computed tomography scan would allow determination of severe cerebral edema, midline shift, or other evidence of especially high risk for herniation. If performed, the minimal amount of fluid necessary for diagnosis (<1 mL) should be removed using a small-gauge needle. Alternatively, empiric treatment for infectious processes can be initiated while the lead concentration is pending, and delayed lumbar puncture can be performed if the blood lead concentration is normal.

Laboratory Evaluation

In patients suspected of having plumbism, laboratory testing is used to augment the evaluation of both lead exposure and lead toxicity. The *whole BLL* is the principal measure of lead exposure available in clinical practice. In any patient suspected of symptomatic plumbism, whole blood should be collected by venipuncture into special lead-

free evacuated tubes. The BLL is typically determined by atomic absorption spectrophotometry. For asymptomatic children, BLL screening is often performed by capillary blood testing for convenience; however, venous confirmation of elevated capillary lead concentrations, unless extremely high (eg, >69 Âµg/dL) or the patient

is clearly symptomatic, is still considered mandatory prior to chelation or other significant interventions. The *erythrocyte protoporphyrin concentration* test reflects lead's inhibition of the heme synthesis pathway (Chap. 24) and had been used as a screening tool in the past, but is no longer considered sufficiently sensitive. The erythrocyte protoporphyrin concentration test may still be useful for tracking response to therapy and in distinguishing acute from chronic lead exposure, as an adjunct to the emergency diagnosis of symptomatic plumbism, if emergent BLL determination is not available, and, rarely, in the evaluation of suspected factitious plumbism. Routine *serum chemistries, renal function tests, urinalysis*, and *complete blood count* are indicated in patients who are symptomatic or about to undergo chelation therapy. *Radiographic studies* may suggest recent lead ingestion and/or toxicity. Abdominal films may reveal lead paint chips or other ingested lead foreign material (Figs. 91-4 and 91-5). The finding of â€œlead lines,â€• metaphyseal densities at the ends of long bones in young children, may substantiate a clinical diagnosis of plumbism before BLLs are available (Fig. 91-2). Finally, *X-ray fluorescence* technology estimates bone lead,[51] and thus indirectly is a cumulative measure of body lead exposure. The X-ray fluorescence technique has been used in research studies of issues concerning past chronic heavy lead exposure and a variety of current health outcomes.[128]

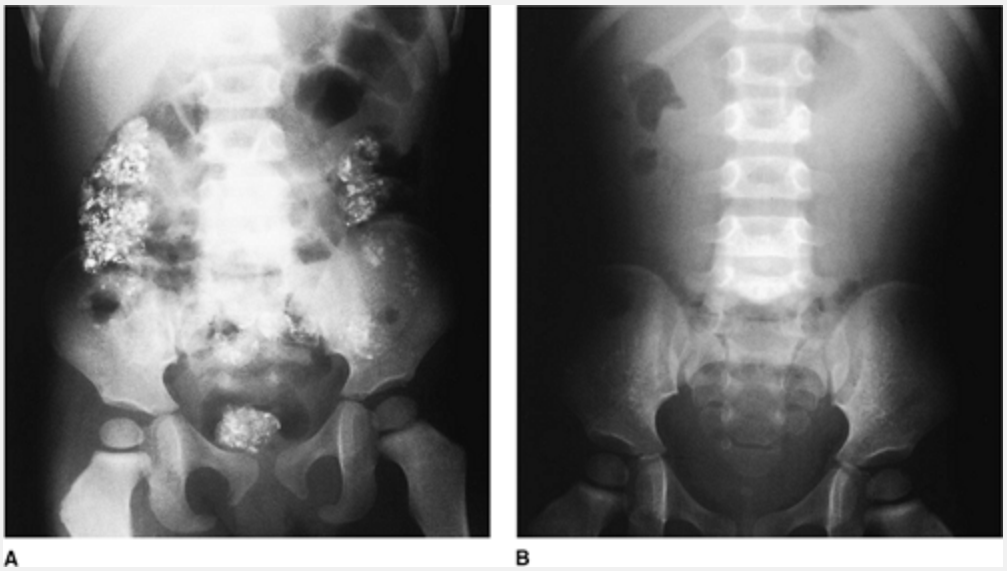

Figure 91-5. A. Abdominal radiograph of a child who had massive paint chip ingestion. B. Followup radiograph after whole-bowel irrigation. *(Courtesy of Department of Radiology, St. Christopher's Hospital for Children, Philadelphia, PA.)*

Screening

Although outside the scope of this discussion, screening is an essential public health practice for the prevention of severe plumbism in both children and adults from high-risk settings. Table 91-5 outlines the current CDC[17] pediatric recommendations, which also are endorsed by the American Academy of Pediatrics.[2] Likewise, the Occupational Safety and Health Administration (OSHA) maintains a lead standard for US workers formulated to reduce workplace exposure to lead, to decrease symptomatic lead poisoning, and to provide quality medical care to workers with elevated blood lead levels.[123,124,125] Table 91-6 summarizes the action BLL values for worker notification, removal, and reinstatement.

Management

There are several caveats about the management of lead poisoning. First, the most important aspect of treatment is removal from further exposure to lead. Unfortunately, effective implementation of this therapy is often beyond the control of the clinician, but rather depends on a complex interplay of public health, social, and political actions. Currently, the ability to control exposure is generally more applicable to adults with occupational exposures than to children exposed to residential hazards. Second, in children for whom some residual lead exposure continues, optimization of nutritional status is vital in order to minimize absorption. Finally, pharmacologic therapy with chelation agents, although a mainstay of therapy for symptomatic patients, is an inexact science, with numerous unanswered questions despite almost 50 years of clinical use.[3,6,58] The rationale for chelation therapy of lead-poisoned patients is that chelating drugs complex with lead, forming a chelate that is excreted in urine, feces, or both. Chelation therapy does increase lead excretion, reduce blood levels, and reverse hematologic markers of toxicity during therapy. Reports from the 1950s found symptomatic improvement in adults chelated for lead colic.[127] The institution of effective combination chelation treatment of childhood lead encephalopathy in the 1960s certainly contributed to the dramatic decline in mortality and morbidity of that devastating degree of plumbism.[26] However, the same era saw major advances in pediatric critical care, in general, and medical management of increased intracranial pressure, in particular. The situation of chelation therapy for asymptomatic patients with mildly to moderately

increased body burdens of lead is even less clear, and many questions regarding efficacy and safety remain.[25,42,58] To date, long-term reduction of target tissue lead content or reversal of toxicity is not demonstrated in human trials.[71,98]

TABLE 91-5. Pediatric Screening and Followup Guidelines

Screening
Screen 1. All high-risk children at ages 1 and 2 y (3â€“6 y if not previously screened) 2. Selected low-risk children (any affirmative answer to risk questions) (high-risk community = 12% of young children with elevated BPb, 27% of homes built before 1950; all children enrolled in Medicaid)
Personal Risk Questionnaire 1. Does your child live in or regularly visit a home built before 1950? 2. Does your child live in or regularly visit a home built before 1978 undergoing remodeling or renovation (or renovated within 6 mo)? 3. Specific exposure questions: Personal, family, or playmate history of lead poisoning Occupational, industrial, hobby exposures Proximity to major roadway Hot tap water for consumption Cultural exposures (complementary remedies, cosmetics, ceramic food containers, trips, residence outside United States, international adoptees) Migrant farm workers, receipt of poverty assistance History of pica for paint chips, dirt History of iron deficiency

Followup	
BPb (Âµg/dL)	*Recommended Action*
â‰¤9	Retest in 1 y
10â€“14	Retest in 3 mo; education
15â€“19	Retest in 2 mo; education; if 15â€“19 twice, refer for case management
20â€“44	Clinical evaluation; education; environmental investigation and control
45â€“69	Clinical evaluation and case management within 48 h; education; environmental investigation and control; chelation therapy
â‰¥ 70	Hospitalize child; immediate chelation therapy; education; environmental investigation and control

BPb = venous blood lead.
Educational interventions as per Table 91-7.
Chelation therapy as per Table 91-8.
Adapted from Centers for Disease Control and Prevention: Screening Young Children for Lead Poisoning: Guidance for State and Local Public Health Officials. US Dept of Health and Human Services, Atlanta, CDC, 1997.

Decreasing Exposure

All patients with significantly elevated lead concentrations warrant identification of the lead exposure source and specific environmental interventions (Table 91-7). In adults, this usually involves changes in their worksite.[32,104] Remedial actions might include improvements in ventilation, modification of personal hygiene habits, and optimal use of respiratory apparatus. It is vital to prohibit smoking, eating, and drinking in a lead-exposed work area. Work clothes should be changed after each shift and should not be lockered together with street clothes.

TABLE 91-6. OSHA General industry[a] Standard for Various Lead Concentrations in Blood (BLLs)

Number of tests	BLL (Âµg/dL)	Action Required
1	â‰¥40	Notification of worker in writing; medical examination of worker and consultation
3 (average)	â‰¥50	Removal of worker from job with potential lead exposure
1	â‰¥60	Removal of worker from job with potential lead exposure

2	<40	Reinstatement of worker in job with potential lead exposure

[a] The construction industry standard is similar for worker notification (at 40 Âµg/dL) and reinstatement (<40 Âµg/dL Ã— 2) but requires worker removal for a single value â‰¥50 Âµg/dL.

Table 91-7 also summarizes several specific educational guidelines that may be offered to parents of lead-exposed children.[4,11,20] Overarching principles include home lead paint abatement (done preferably by professionals, with the family out of the home), home dust reduction techniques, decreasing soil lead exposure, and nutritional evaluation and counseling. Clinicians who have primary responsibility for children with elevated lead levels should refer to the CDC's exhaustive monograph, which details such pediatric case mananagement.[20]

Chelation Therapy

The indications for and specifics of chelation therapy are determined by patient age, blood lead concentration, and clinical

symptomatology (Table 91-8). Three chelation agents are currently recommended as drugs of choice for the treatment of lead poisoning: BAL and $CaNa_2EDTA$ are used parenterally for more severe cases, and succimer is available for oral therapy. Pharmacologic profiles of these three agents are detailed in the corresponding Antidotes in Depth. A fourth drug, D-penicillamine, has been used orally for patients with mild to moderate excess lead burdens. Unfortunately, D-penicillamine has a toxicity profile that includes serious, life-threatening hematologic disorders and reversible, but serious, dermatologic and renal effects; consequently, since 1991, its role in lead poisoning treatment has been largely replaced by succimer. Currently, the American Academy of Pediatrics recommends D-penicillamine use only when unacceptable adverse reactions to both succimer and $CaNa_2EDTA$ occur, and it remains important to continue chelation.[3]

TABLE 91-7. Reducing Lead Exposure

Adults
(Evaluate possible sources beyond occupational setting: Tables 91-1 and 91-2)
- Implement OSHA lead standard
- Improve ventilation
- Use respiratory apparatus
- Wear protective clothing; change from work clothes before leaving worksite
- Modify personal hygiene habits
- Prohibit eating, drinking, smoking in worksite

Children
(Consider possible sources beyond lead paint exposure: Tables 91-1 and 91-2)
- Notify local health department

Home lead paint abatement (professional contractors if possible; use plastic sheeting, low dust-generating paint removal; replacement of lead-painted windows, floor treatment; final cleanup with high-efficiency particle air vacuum, wet-mopping)

Avoid most hazardous areas of home, yard

Dust control: wet-mopping, sponging with high-phosphate detergent; frequent hand, toy, pacifier washing

Soil lead exposure reduction by planting grass, shrubs around house

Use only cold, flushed tap water for consumption

Optimize nutrition: avoid fasting; iron, calcium sufficient diet; iron and/or calcium supplementation as necessary

Avoid food storage in open cans

Avoid imported ceramic containers for food, beverage use

Evaluate parental occupations, hobbies

TABLE 91-8. Chelation Therapy Guidelines[a]

Condition, BPb (Âµg/dL)	Dose	Regimen/Comments
Adults		
Encephalopathy	BAL 450 $mg/m^2/d$[a]	75 mg/m^2 IM every 4 h for 5 d
	$CaNa_2EDTA$ 1500 $mg/m^2/d$[a]	Continuous infusion or 2â€“4 divided IV doses for 5 d (start 4 h after BAL)

Symptoms suggestive of encephalopathy or >100	BAL 300â€“450 $mg/m^2/d^a$ $CaNa_2EDTA$ 1000â€“1500 $mg/m^2/d^a$	50â€“75 mg/m^2 every 4 h for 3â€“5 d Continuous infusion or 2â€“4 divided IV doses for 5 d (start 4 h after BAL) Base dose, duration on BPb, severity of symptoms (see text)
Mild symptoms or 70â€“100	Succimer 700â€“1050 $mg/m^2/d$	350 mg/m^2 tid for 5 d, then bid for 14 d
Asymptomatic and <70	Usually not indicated	Remove from exposure (Table 91-7)
Children		
Encephalopathy	BAL 450 $mg/m^2/d^a$ $CaNa_2EDTA$ 1500 $mg/m^2/d^a$	75 mg/m^2 IM every 4 h for 5 d Continuous infusion or 2â€“4 divided IV doses for 5 d (start 4 h after BAL)
Symptomatic or > 69	BAL 300â€“450 $mg/m^2/d^a$ $CaNa_2EDTA$ 1000â€“1500	50â€“75 mg/m^2 every 4 h for 3â€“5 d Continuous infusion or 2â€“4 divided IV doses for 5 d (start 4

	mg/m^2/d[a]	h after BAL) Base dose, duration on BPb, severity of symptoms (see text)
Asymptomatic: 45â€“69	Succimer 700â€“1050 mg/m^2/d or $CaNa_2EDTA$, 1000 mg/m^2/d[a] (*or rarely*, D-penicillamine)	350 mg/m^2 tid for 5 d, then bid for 14 d Continuous infusion or 2â€“4 divided IV for 5 d (see text)
20â€“44	Routine chelation not indicated (see text)	If succimer used, same regimen as per above group
	Attempt exposure reduction	(Table 91-7)
<20	Chelation not indicated	
	Attempt exposure reduction	(Table 91-7)

BPb = blood lead (Âµg/dL); EP = erythrocyte protoporphyrin; IM = intramuscular; IV = intravenous; d = day.

[a] Doses expressed mg/kg: BAL 450 mg/m^2 (24 mg/kg); 300 mg/m^2 (18 mg/kg).
$CaNa_2EDTA$ 1000 mg/m^2 (25â€“50 mg/kg); 1500 mg/m^2 (50â€“75 mg/kg) adult maximum 2â€“3 g/d). Succimer 350 mg/m^2 (10 mg/kg).
Subsequent treatment regimens based on postchelation BPb and clinical symptoms (see text).
Adapted from references 3, 20, 56, 89, and 92

Chelation is not a panacea for lead poisoning. It is a relatively inefficient process, with a typical course of therapy decreasing body content of heavy metal by 1â€“2%.[58,77] Furthermore, there is little evidence that chelating agents have significant access to critical sites in target organs, particularly in the brain.[29] Assumptions that reducing blood lead level will improve subtle neurocognitive dysfunction or other subclinical organ toxicity are appealing theoretically, but unproven.[98,120]

Pediatric Therapy

Lead encephalopathy is an acute life-threatening emergency and should be treated under the guidance of a multidisciplinary team in the intensive care unit of a hospital experienced in the management of critically ill children. Encephalopathy requires treatment by combination parenteral chelation therapy with maximum-dose BAL and $CaNa_2EDTA$, and meticulous supportive care.[3,20,26] Such combination therapy has a dramatic effect on decreasing BLLâ€”to 50% or less of baseline within 15 hours, and to 75â€“80% of baseline by 48â€“72 hours. It is far superior to monotherapy with $CaNa_2EDTA$ in this regard.[26]

Chelation is instituted with intramuscular (IM) BAL 75 mg/m^2/d (or 25 mg/kg/d) in 6 divided doses.[3,20] The second dose of BAL is given 4 hours later, followed immediately by intravenous (IV) $CaNa_2EDTA$, in maximum concentration of 0.5% solution, at 1500 mg/m^2/d (or 50 mg/kg/d) as a continuous infusion over several hours or in divided-dose infusions.[3,20,89] The delay in initiating $CaNa_2EDTA$ infusion is based on past observations of clinical deterioration in encephalopathic patients treated with $CaNa_2EDTA$ alone.[3,26] Therapy is typically continued with both agents for 5 days, although in milder cases with prompt resolution of encephalopathy and decrease of BLL to <50 Âµg/dL, BAL may be discontinued after 3 days, with continuation of $CaNa_2EDTA$ alone for 2 more days.

The presence of radiopaque material in the gastrointestinal tract on radiography has raised concern that parenteral chelation might enhance absorption of residual gut lead. This issue is not settled fully,[25,54] but most experts advocate initiation of chelation without delay in seriously symptomatic patients. It seems reasonable to simultaneously attempt bowel decontamination,[3] as with a whole-bowel irrigation solution. One case report described the successful use of chelation therapy begun with parenteral BAL and $CaNa_2EDTA$ and then enteral succimer (initiated after 3 days of whole-bowel irrigation) for a child with lead encephalopathy and an extraordinarily high BLL of 550 Âµg/dL.[39] Generally, oral fluids, feedings, and medications are withheld for at least the first several days. Careful provision of adequate intravenous fluids optimizes renal function while avoiding overhydration and the risk of exacerbating

cerebral edema. The occurrence of the syndrome of inappropriate secretion of antidiuretic hormone (SIADH) may be associated with lead encephalopathy,[26,117] so urine volume, specific gravity, and serum electrolytes should be closely monitored, especially as fluids are gradually liberalized with clinical improvement. In the context of lead encephalopathy, this approach would need to be tempered by the requirement for maintaining good urine output to optimize

chelation efficacy.

Seizure control is usually accomplished with benzodiazepines. Rarely, continuous infusions of midazolam or high-dose pentobarbital therapy may be necessary.[130] Ongoing anticonvulsant therapy is typically continued with phenytoin or phenobarbital.

Recent advances in *management of cerebral edema and increased intracranial pressure* have not as yet been critically evaluated in the currently rare context of lead encephalopathy. Lumbar puncture should be avoided if lead encephalopathy is highly suspected and acute infectious processes are not. It seems reasonable that noninvasive measures such as hyperventilation and steroids might have a salutary effect at minimal risk of increased iatrogenic morbidity.[3,130] Mannitol administration has been suggested as a possible adjunct in the therapy of such patients when cerebral edema is complicated by SIADH and/or impaired renal function.[26] Whether more aggressive measures, such as intracranial pressure monitoring, induced hypothermia, or barbiturate coma, would decrease mortality or morbidity further is unknown.

Children with *milder symptoms, or* who are *asymptomatic with BLL*. >70 Âµ*g/dL*, should be chelated with a regimen similar to that recommended for encephalopathy. It is likely that this group of patients will require only 2â€“3 days of BAL in addition to 5 days of $CaNa_2EDTA$. The asymptomatic patients in this group might also be adequately treated with 2,3-dimercaptosuccinic acid (succimer) plus $CaNa_2EDTA$, or even succimer alone, but these regimens have not been studied in such children. Intensive care monitoring may be prudent for such patients as well, at least during the initiation of chelation therapy.[77]

Chelation therapy is widely recommended for *asymptomatic children with BLLs between* 45 and 70 Âµ*g/dL*.[3,6,20,77] Children without overt symptoms may be treated with succimer alone, which has documented efficacy in lowering BLLs and short-term safety since its FDA approval in 1991.[45,62] Succimer is initiated at 30 mg/kg/d (or

1050 mg/m^2/d) orally in 3 divided doses; this is continued for 5 days, then decreased to 20 mg/kg/d (or 700 mg/m^2/d) in 2 divided doses for 14 additional days.[3,44] The original data establishing this empiric dosing regimen were based on surface area rather than body weight.[44] For younger children, the alternative dosing by body weight results in suboptimal dosing.[96] Although the ability to chelate children orally with succimer makes it tempting to prescribe routinely for outpatient therapy, and some animal evidence suggests succimer does not enhance enteral lead absorption,[55] clinical reports suggest that children must be protected from continued lead exposure during succimer chelation.[23,24] Home abatement and reinspection should be accomplished before initiation of ambulatory succimer therapy; if this is not feasible, hospitalization is still warranted. Alternative regimens (for rare patients with succimer intolerance or allergy, or parental noncompliance) include inpatient parenteral chelation with $CaNa_2EDTA$ at 25 mg/kg/d for 5 days,[3] or an outpatient oral course of D-penicillamine.

After initial chelation therapy, *decisions to repeat treatment* are based on clinical symptoms and followup BLLs. Patients with encephalopathy or any severe symptoms, or initial BLL >100 Âµg/dL, will often require repeated courses of treatment. It is suggested that at least 2 days elapse before restarting chelation. The precise regimen and dosing of chelating agents are determined by ongoing symptomatology and the repeat BLLs (Table 91-8). A third course of chelation should rarely be necessary sooner than 5â€“7 days after the second course ends.[89] For patients with milder degrees of plumbism (eg, asymptomatic, initial BLL <70 Âµg/dL), it is reasonable to allow 10â€“14 days of reequilibration before restarting treatment.[3]

The management of *asymptomatic children with BLLs of* 20â€“44 Âµ*g/dL* is controversial.[23,69,76,120] The National Institutes of Health-sponsored Treatment of Lead-exposed Children (TLC) trial found only modest efficacy of succimer in reducing BLL. Furthermore, at 3 years postenrollment no benefit was noted in treated patients on measures

of cognition, neuropsychiatric function, or behavior.[98] Of note, small, but statistically significant, decrements in growth velocity were noted in the treatment group, which might reflect trace mineral depletion. This study has been criticised, particularly for using a single chelating agent and having failed to lower BLL significantly over time between treated and control groups.[109] Since its initial publication, the primary findings of the TLC trial on lack of cognitive improvement were confirmed in a 7-year followup study.[33] In addition, a reanalysis of the original data found that falling blood concentrations did correlate with improved cognitive scores over the initial 36-month trial period (~ IQ points for each 10 Âµg/dL drop in BLL), but only in the placebo group.[65] Currently, the CDC[20] and the American Academy of Pediatrics[3] recommend aggressive environmental and nutritional interventions with close monitoring of blood lead concentrations, *without routine chelation therapy*, for such children. Nevertheless, there may still be potential indications for occasional chelation treatment in this group, including BLLs at the higher end of the range (eg, 35â€“44 Âµg/dL), especially if BLLs remain the same or rise over several months after rigorous environmental controls are instituted, in younger children (eg, younger than 2 years old), with evidence of biochemical toxicity (an elevated erythrocyte protoporphyrin concentration, after iron supplementation, if necessary), or any hint of subtle symptoms.

BLLs of 10â€“19 Âµg/dL are defined by the CDC as representing excessive exposure to lead, but do not require chelation therapy. Close monitoring (for the 10â€“14 Âµg/dL range) and careful environmental investigation and interventions as necessary (particularly for the 15â€“19 Âµg/dL range) are appropriate and sufficient.[3,20] The educational approaches outlined earlier should be included in the case management of all children with even modestly elevated lead levels (Table 91-7).

Adult Therapy

General Considerations

The first principle in the treatment of adults with lead poisoning is that chelation therapy may not substitute for adherence to OSHA lead standards at the worksite and should never be given prophylactically.[33,56] In addition to the guidelines for decreasing lead exposure noted earlier, chelation therapy is indicated for adults with significant symptoms (encephalopathy, abdominal colic, severe arthralgias, or myalgias) and evidence of target organ damage (neuropathy or nephropathy), and possibly in asymptomatic workers with markedly elevated BLLs and/or evidence of biochemical toxicity or increased chelatable lead.[99,104,107] Table 91-8 outlines chelation therapy regimens for adults. Recent reports support the use of succimer in adult

patients with mild to moderate plumbism after environmental and occupational remedies have been instituted.[63,92] Treatment of patients with tetraethyl lead toxicity is largely supportive, with sedation as necessary. If blood lead concentrations are significantly elevated, chelation as described above may be considered, but it has not been found clinically efficacious.[104,118]

Pregnancy, Neonatal, and Lactation Issues

An area of particular concern in the management of adult plumbism involves decisions regarding therapy during pregnancy. As noted previously, lead freely passes the placental barrier and accumulates in the fetus throughout gestation. Chelation therapy during early pregnancy poses theoretical problems of teratogenicity, particularly that caused by enhanced fetal excretion of potentially vital trace elements, or translocation of lead from mother to fetus (see also the relevant Antidotes in Depth). Symptomatic pregnant women with elevated BLLs certainly warrant chelation therapy, regardless of these concerns. Additionally, of some reassurance regarding fetal health, a recent case series and 25-year literature review of lead

poisoning during pregnancy found no reports of chelation-associated birth defects in the handful of such published cases.[110] It should be noted that despite falls in maternal BLL with chelation therapy, newborn BLLs may be considerably higher and, in some cases, approximated the pretreatment maternal BLL, implying limited efficacy for in utero fetal chelation. However, the newborn's hemoglobin level was generally much higher than the mother's, and thus some of the maternalâ€“neonatal difference in lead concentrations may simply reflect this difference in hemoglobin concentration and hence total blood lead content. In general, there currently seems little support for routine chelation therapy in pregnant women who would not otherwise warrant treatment based on their own symptoms or degree of elevated BLL.

Postnatally, infant BLLs may decline over time without chelation, but this occurs very slowly.[101] In 2 reported neonates exposed to prenatal maternal chelation, who were then monitored for 2 weeks postpartum, the BLL remained stable or rose until chelation therapy was instituted.[88,119] In 2 additional cases of neonates whose mothers were not treated prepartum, BLLs also remained stable or rose for 17 days to 3 weeks.[38,114] Thus, postpartum chelation therapy is warranted for neonates, depending on BLLs, as per the guidelines described above for older children. Lastly, the issue of allowing mothers with elevated BLLs to breast-feed their infants may arise. One small case series found that breast milk from 2 women with BLLs of 34 and 29 Âµg/dL, respectively, had clinically insignificant lead content (<0.01 Âµg/mL).[9] Breast milk analysis may be warranted in such cases, particularly with BLLs of 35 Âµg/dL or greater, before safely advising continued nursing.

Summary

Lead is a ubiquitous element in the earth's crust that has long been used by humans for a variety of purposes. Metallic lead finds many uses for its waterproofing and electrical and radiation shielding

properties. Lead compounds are used as paint pigments and find many applications in the manufacture of plastics, ceramics, glass, and explosives.

Lead poisoning or plumbism has an equally long history, dating back to antiquity. Today, lead poisoning is primarily an important environmental health problem for young children exposed to deteriorated lead paint, and as an occupational exposure for adult workers, although numerous other exotic exposures are continually reported.

Lead has toxic effects on multiple organs, involving especially the hematologic and neurologic systems in patients of all ages, and renal injury with hypertension in adults. This can result in a broad spectrum of clinical effects, ranging from vague constitutional symptoms without overt physical signs to an acute encephalopathy with potentially fatal cerebral edema and increased intracranial pressure. Several techniques have been used to estimate increases in body lead burden, but currently the measurement of whole-blood lead concentration is favored.

The mainstays of treatment are removal from exposure and chelation therapy for those patients with symptoms or significantly elevated body lead burdens. Defining a group of asymptomatic patients that will benefit from chelation therapy has been difficult and controversial. Parenteral chelation with $CaNa_2EDTA$ and BAL is efficacious in lowering BLLs and reducing mortality and morbidity from severe lead poisoning. Succimer, an oral chelator, also has efficacy in reducing BLLs in asymptomatic children.

Antidotes in Depth

Succimer (2,3-Dimercaptosuccinic Acid)

Mary Ann Howland

History

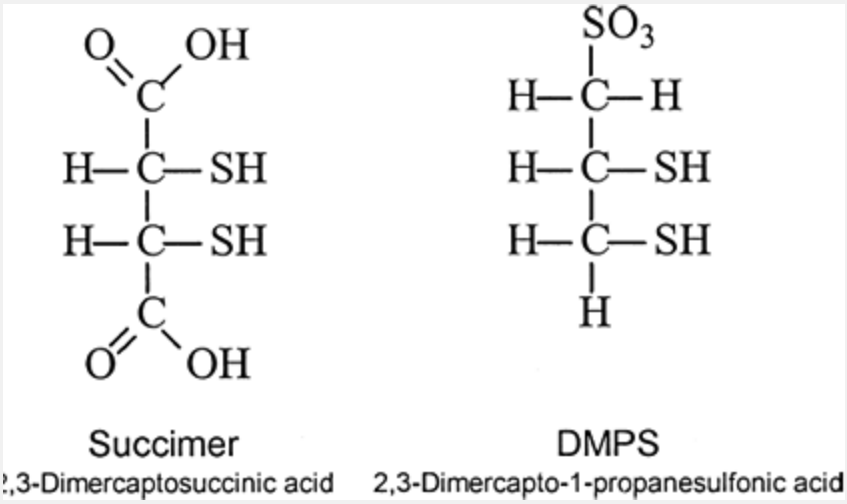

Figure. No Caption Available.

Succimer was initially synthesized in 1949 in England.[66] In 1954, antimony-a,aâ€²-dimercaptopotassium succinate (TWSb) was developed to treat schistosomiasis.[38] TWSb is antimony bound to the potassium salt of succimer in a 2:3 ratio, forming a water-soluble drug with 50 times less toxicity than the previously used antimony compound, tartar emetic. Several years later, a group from Shanghai demonstrated the ability of the sodium salt of succimer to increase the LD_{50} (median lethal dose for 50% of test subjects) of tartar emetic 16-fold in mice.[97] An early review of the Chinese experience with IV succimer in the treatment of occupational lead and mercury poisoning suggested efficacy similar to IV edetate calcium disodium ($CaNa_2EDTA$) in increasing urinary lead and to IM DMPS (racemic-2,3-dimercapto-1-propanesulfonic acid, unithiol) for mercury, with little observed toxicity.[95] This experience, subsequent widespread use in Asia[70,73,83,95,96,99] and Europe,[16,30,36,39,58,91] and the realization that succimer could be used orally,[3,45] led to US-based animal experiments, human trials, and FDA approval in 1991 for the treatment of lead-poisoned children.

Pharmacology

Succimer is a white crystalline powder with a molecular weight of 182 daltons and a characteristic sulfur odor and taste. Succimer is the meso form of 2,3-dimercaptosuccinic acid; the racemic form is being investigated.[33] Because it contains four ionizable hydrogen ions, succimer has four different pK_asâ€”2.31, 3.69, 9.68, and 11.14â€”with the dissociation of the two lower values representing the carboxyl groups and the two higher values the sulfur groups.[4] Lead and cadmium bind to the adjoining sulfur and oxygen atoms, whereas arsenic and mercury bind to the two sulfur moieties,

forming pH-dependent water-soluble complexes[79] (see Fig. A24-1). Succimer is highly protein-bound to albumin through a disulfide bond. Subhuman primate studies of IV and oral ^{20}C succimer indicate that following an IV dose, radiolabel is eliminated almost exclusively via the kidney, with only trace amounts (<1%) excreted via feces or expired air.[66] Following the administration of a single oral dose of 10 mg/kg, succimer is rapidly and extensively metabolized.[61] Approximately 20% of the administered dose is recovered in the urine, presumably reflecting the low bioavailability of the drug. Of the total drug eliminated in the urine, 89% is altered and in the form of disulfides of L-cysteine. The majority of the altered succimer is in the form of a mixed disulfide. The remaining 11% is excreted as unaltered free succimer.[61] Maximal excretion of succimer occurs in urine specimens collected between 2 and 4 hours after administration. Surprisingly, the blood only contains albumin-bound succimer and no evidence of the altered disulfide moieties, which suggests that the kidney may be involved in the biotransformation of succimer.

Lead

In addition to precise analysis of metal elimination kinetics, measures of clinical outcome are essential for an understanding of the utility of this agent. The Treatment of Lead-exposed Children (TLC) trial is a step in that direction.[93] The TLC trial is a randomized, multicenter, double-blind, placebo-controlled, ongoing study to examine the effects of succimer on cognitive development, behavior, stature, and blood pressure in children 1â€“3 years old with blood lead concentrations between 20 and 44 Âµg/dL.

Several groups are studying the efficacy of succimer in reducing blood, brain, and tissue lead by using rat and nonhuman primate models of childhood and adult lead poisoning.[84,85,87] Although monkeys most closely resemble humans in their lead-associated

toxicity, their use is costly;[72] the rat model is economical but of limited use because of the species differences with regard to lead and succimer metabolism and efficacy. The primate experiments are exciting, but one substantial criticism is the lack of comparison groups with regard to dimercaprol and $CaNa_2EDTA$ treatment. Notably that the animal evidence suggests that isolated blood lead concentrations do not accurately reflect brain lead concentrations. If this finding is also true in humans, the importance and ability to interpret blood lead concentrations will be significantly altered.

The validity of using blood lead concentrations as a marker of brain lead was studied in the adult rhesus monkey. Lead was administered orally for 5 weeks to achieve a target blood lead concentration of 35â€“40 Âµg/dL.[28] Five days after lead exposure ceased, succimer chelation was initiated in the currently approved dosage regimen. Two IV doses of radioactive lead tracer were administered prior to succimer chelation to study the kinetics of recent versus chronic lead uptake and distribution. Four areas of the brain, as well as blood and bone, were assayed for lead. Merely stopping further lead exposure significantly reduced blood lead concentrations by 63% and brain lead concentrations by 34% compared to pretreatment concentrations, and was not statistically different than succimer administration after halting exposure. However, when an integrated area under the blood drug concentration versus time curve (AUC) blood analysis was used over the 19-day succimer treatment course, instead of a single blood lead concentration, the differences between succimer and control were statistically significant.

How clinically significant these differences are is unclear. Succimer-treated animals showed the biggest drop in blood lead concentrations over the first 5 days, while a similar end point was gradually achieved in the control. The lead from both the recent exposure (radioactive tracer lead) and chronic exposure declined to the same extent, independent of treatment with succimer. A

better correlation was found between brain prefrontal cortex lead concentrations and an integrated blood lead analysis than with a single blood lead measurement.

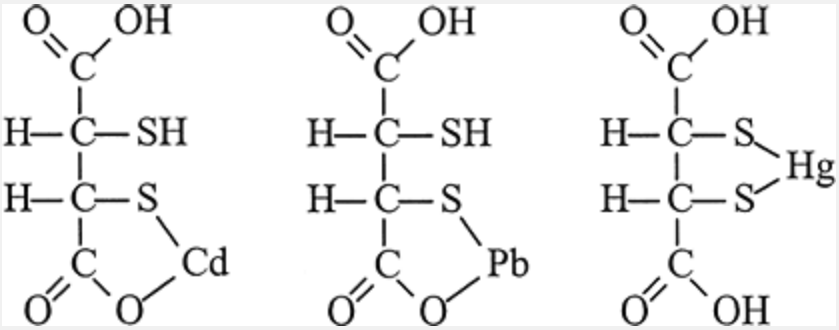

Figure A24-1. The chelation of cadmium, lead, and mercury with succimer.

Similarly, a study in neonatal rats demonstrated that increasing the duration of succimer chelation from 7â€“21 days decreased brain lead concentrations without a corresponding decrease in blood lead concentrations.[84] The authors proposed that a slow rate of egress of brain lead to the blood was responsible for the demonstrable benefit of prolonging therapy to 21 days. In this study, succimer decreased blood lead concentration by approximately 50% when compared to the vehicle as control, and this difference persisted for the 21 days of treatment. With succimer treatment, brain lead concentration decreased by 38% at 7 days and by 68% at 21 days. Previous animal studies demonstrated the ability of succimer to enhance urinary lead elimination [37,45,87] and to reduce blood,[14,26,34,35,50,76,85,87,88,90] brain,[14,26,76,89,90] liver,[87] and kidney lead concentrations,[14,26,35,50,76,90] while reducing[14,50,76,90] or showing

no effect on bone lead concentrations.[26,87] These studies differ in the amounts and duration of lead administration prior to chelation, as well as in route, dose, and duration of chelation. It is noteworthy that several months after a course of succimer chelation, tissue lead concentrations were similar to pretreatment values, indicating that the short-term effects did not persist.[26] Given the limited absolute amount of lead that is actually eliminated by chelation in comparison to the total body burden, particularly bone, these transient effects are not surprising.

Under a variety of experimental conditions in animals, succimer prevents the deleterious effect of lead on heme synthesis,[14,45,76] blood pressure,[54] and behavior.[88]

Published studies of the use of succimer in both children and adults with chronic lead poisoning demonstrate consistent findings.[17,24,46,47,48,59,71] During the first 5 days of succimer chelation (1050 mg/m^2/d in children, 30 mg/kg/d in adults in 3 divided doses), the blood lead concentration dropped precipitously by approximately 60â€“70%. This blood lead concentration remained unchanged during the next 14â€“23 days of continued therapy. Increases in urinary lead excretion coincide with the drop in blood lead concentration, with maximal excretion occurring on day 1.[24,47] Calculations indicate that urinary lead excretion exceeds estimated blood content. This suggests that some lead is being removed from soft tissues as a concentration gradient is established from tissue to blood to urine.[24,48] Typically, 2 weeks after the completion of succimer, blood lead concentration rebounds to values 20â€“40% lower than pretreatment values. In the one randomized, double-blind, placebo-controlled trial of succimer use in children with pretreatment blood lead concentrations of 30â€“45 Âµg/dL, followup at 1 month and at 6 months showed no differences between succimer-treated children and controls.[71] Succimer restores red blood cell D-aminolevulinic acid dehydratase (ALA-D) activity, decreases erythrocyte protoporphyrin, and decreases urinary excretion of D-

aminolevulinic acid and coproporphyrin.[17,24,47,48,71]

There is a large body of evidence reporting on the usage and safety profile of succimer in adults with chronic lead poisoning.[11,16,36,39,43,92,94] The published experience outside the United States with the use of oral succimer for metal poisoning includes nearly 100 adult cases and contributes considerably to the supporting evidence. At least 74 additional individuals have been successfully treated parenterally (IM or IV) with the sodium salt of succimer.[11,16,36,39]

Lead Encephalopathy

The experience with the use of succimer in severely lead-poisoned subjects, including those with encephalopathy, is very limited.[36,39,47] Three children with mean blood lead concentrations of >70 Âµg/dL who were treated with 5 days of succimer achieved comparable declines in blood lead concentration to two similar children who had been treated previously with a combination of British anti-Lewisite (BAL) for 3 days and $CaNa_2EDTA$ for 5 days.[47] Three adult patients with encephalopathy achieved significant improvement following succimer chelation.[36] A 3-year-old child with a massive lead exposure superimposed on chronic lead poisoning and a blood lead concentration of 550 Âµg/dL was given BAL and $CaNa_2EDTA$ for 5 days, with whole-bowel irrigation (WBI) performed on the first 3 days and succimer following WBI beginning on day 3 and continuing for 19 days. The blood lead concentration dropped from 550 Âµg/dL to 70 Âµg/dL on day 5, but rebounded to 99 Âµg/dL 2 days after BAL and $CaNa_2EDTA$, but not the succimer, were discontinued.[42]

Arsenic

Succimer has been used for arsenic toxicity in China and the Soviet Union since 1965.[3,11] Animal studies with sodium arsenite

and lewisite demonstrate the ability of succimer to improve the LD_{50} with a good therapeutic index, lack of redistribution of arsenic to the brain as compared to BAL or control, and reduced kidney and liver arsenic concentrations.[3,11,57,80] A few case reports attest to the ability of succimer to enhance the urinary excretion of arsenic.[27,81] A randomized, placebo-controlled trial of succimer in treating 21 patients with chronic arsenic poisoning in India, demonstrated improved clinical results and enhanced urinary excretion in both the treatment and placebo groups, but no statistical differences could be demonstrated.[65] A comparison of BAL, succimer, and DMPS as arsenic antidotes, demonstrated higher therapeutic indices for succimer and DMPS over BAL in chronic arsenic poisoning.[69] The authors speculated that the lipophilic nature of BAL might make it preferable for use in acute toxicity, especially with lipophilic organoarsenicals. This issue needs further investigation.

Mercury

Succimer enhances the elimination of mercury and has been used to treat patients poisoned with inorganic, elemental, and methyl

mercury. It improves survival, decreases renal damage, and enhances elimination of mercury following inorganic mercury[4,20,50,53,62,78,98] and methylmercury exposure in animals.[1,2,7,63] However, one study in mice subjected to intraperitoneal mercuric chloride demonstrated an enhanced deposition of mercury in motor neurons following chelation with succimer or DMPS.[32] Of 53 construction workers who were exposed to mercury vapor, 11 received succimer and *N*-acetyl-*d,l*-penicillamine in a crossover study.[19] Mercury elimination was increased during the period of succimer administration compared to the period of *N*-acetyl-*d,l*-penicillamine administration. Because the chelators were administered for only 2 weeks late in the clinical course, therapeutic benefit could not be evaluated. When

succimer was given to victims of an extensive Iraqi methylmercury exposure, blood methylmercury half-life decreased from 63 days to 10 days.[3]

Pharmacokinetics

The pharmacokinetics of a single oral dose of succimer were determined in 3 children and 3 adults with lead poisoning, and in 5 healthy adult volunteers.[29] Children received 350 mg/m^2 of succimer, and adults received 10 mg/kg of succimer. The peak concentration and the time to peak blood concentration of total succimer (parent vs. altered oxidized metabolites) were similar for all three groups. The half-life of total succimer was 1.5 times longer in the children than in either adult group. The renal clearance of total succimer was greater in healthy adults than in lead-poisoned patients. Distribution of succimer (parent and/or oxidized metabolites) into erythrocytes appeared greater in poisoned patients than in the healthy adults.[29]

The metabolism of succimer was studied in lead-poisoned children and in normal adults.[13] The results indicate that succimer undergoes an enterohepatic circulation facilitated by gastrointestinal (GI) microflora. Similar to the previous pharmacokinetic study, moderate lead exposure impaired the renal elimination of succimer.

Adverse Effects and Safety Issues

Succimer is generally well tolerated with few serious adverse events reported.[24,25] Common adverse effects are gastrointestinal in nature, including nausea, vomiting, flatus, diarrhea, and a metallic taste in 10â€“20% of patients. Mild elevations in aspartate aminotransferase (AST) and alanine aminotransferase (ALT) are reported.[23,25,48,59,74] A single patient developed severe hyperthermia and hypotension reportedly related to succimer

administration.[74] Rarely, chills, fever, urticaria, rash, reversible neutropenia, and eosinophilia are reported.[17,24,25,43] During the latest open-labeled prospective study in children, apparently unrelated adverse events included an elevation in bone-derived alkaline phosphatase, eosinophils, and elevated serum aminotransferases.[24]

The Chinese have reported a high incidence of more serious adverse effects (including dizziness and weakness) in response to IV or IM succimer.[96,99] This discrepancy is undoubtedly related to the relatively low (approximately 20%)[66] oral bioavailability of succimer as a result of first-pass metabolism. Therefore, parenteral administration delivers a substantially greater dose.

Incidental chelation of essential elements is always a concern with the use of chelating agents. A number of studies using succimer demonstrate no rise in urinary zinc, copper, iron, or calcium.[24,36,39,46,47,48] Urinary excretion of essential elements was the focus of a study in a primate model of childhood lead exposure.[85] Infant rhesus monkeys were exposed to lead for the first year of life to achieve blood lead concentrations of 40â€“50 Âµg/dL. Succimer was administered in the standard dosage regimen and complete urine collections over the first 5 days were analyzed for calcium, cobalt, copper, iron, magnesium, manganese, nickel, and zinc. Only when the data were analyzed collectively for all 8 elements for all 5 days was there a statistically significant increased urinary elimination. These results raise concern that children with repeated succimer chelation may be at risk for enhanced elimination of essential elements.[24,85,87] An obvious concern regarding the safety of succimer is that there is still relatively limited clinical experience with the drug, particularly with regard to long-term administration.

One concern with administering succimer orally is that outpatient management might permit continued unintentional lead exposure and the possibility for succimer-facilitated lead absorption. Studies

with D-penicillamine, dimercaprol,[51] and $CaNa_2EDTA$ demonstrate enhanced lead absorption and elevated blood lead concentrations.

Most blood lead concentrations are measured by graphite furnace atomic absorption spectrophotometry, in which case succimer does not interfere with the measurement. However, if blood lead concentrations were to be measured by anodic stripping voltammetry, succimer would affect the results by chelating the mercury in the electrode.[24]

Animal studies suggest that succimer does not promote lead retention in the face of continued exposure unless lead exposure is overwhelming.[45,52,76] A radiolabeled lead tracer administered to adult volunteers suggested that succimer increased the net absorption of lead from the gastrointestinal tract and may have distributed it to other tissues, as well as having enhanced urinary elimination.[86] Absorption is bimodal and consistent with an initial phase, followed by a delayed increase attributable to an enterohepatic effect. It may be that succimer-enhanced urinary lead elimination often exceeds enhanced lead absorption. One study reported 2 children with environmental exposure and dramatic rises in blood lead concentration while receiving succimer.[24] In the event of unintentional exposure to a new lead source, decontamination of the gastrointestinal tract should complement oral succimer.[67]

Although iron supplementation cannot be given concomitantly with BAL, because the BALâ€“iron complex may be a potent emetic, iron has been given concomitantly to patients receiving oral succimer without any adverse effects.[49] The prevalence of both iron deficiency and elevated blood lead concentrations is highest among poor, inner-city children.[60] Because heme is a constituent of all cells, including those of the brain, it appears clinically prudent to provide iron supplementation during chelation therapy, when the heme pathway is freed of the inhibitory effects of lead. The timing of administration of the iron should be separate from

administration of the succimer.[24]

A case report describes a 3-year-old child who reportedly ingested 185 mg/kg of succimer and was asymptomatic.[82] There was a dose-dependent effect of succimer on early and late fetal resorption and on fetal body weight and length when succimer was administered to pregnant mice during organogenesis. No observed teratogenic effects were noted when 410 mg/kg, or approximately 5% of the acute LD_{50}, of succimer was administered subcutaneously.[31] Succimer 30â€“60 mg/kg/d was administered by gavage to lead-poisoned rats from day 6 to day 21 of gestation.[22] These doses

of succimer decreased embryonic and fetal blood lead concentrations and normalized offspring body weight at 13 weeks. Although succimer was able to reverse some lead-induced immunotoxic effects, succimer itself caused problems with the immune system that persisted into adulthood.[22] The use of succimer in pregnancy is restricted to women who warrant therapy based on their symptoms.[24]

Combined Chelation Therapy

Succimer could be combined with $CaNa_2EDTA$ to take advantage of the ability of succimer to remove lead from soft tissues, including the brain, while capitalizing on the ability of $CaNa_2EDTA$ to mobilize lead from bone.[26] A number of rodent models have examined this combination and found it to be superior in enhancing the elimination of lead, in reducing tissue concentrations of lead, and in restoring some lead-induced biochemical abnormalities.[34,35,89] Although the addition of succimer to $CaNa_2EDTA$ prevented the redistribution of lead to the brain caused by $CaNa_2EDTA$ alone, the combination also increased urinary excretion of zinc, calcium, and iron.[89,90] A retrospective review comparing dimercaprol plus CaEDTA to succimer plus

$CaNa_2EDTA$ in children with blood lead concentrations >45 Âµg/mL, demonstrated a similar reduction in blood lead concentrations at the end of treatment and at 14 and 33 days following the termination of treatment.[18] Blood lead concentration reductions were approximately 75%, 40%, and 37% at the end of therapy, and at 14 and 33 days posttreatment, respectively. The succimer plus $CaNa_2EDTA$ combination was better tolerated.[18]

DMPS

DMPS (racemic-2,3-dimercapto-1-propanesulfonic acid, Na salt) is an investigational metal chelator that, like succimer, is a water-soluble analog of BAL.[3,7,21] A dose of 15 mg/kg of DMPS is equimolar to 12 mg/kg of succimer. DMPS was used in the former Soviet Union since the late 1950s and continues to be used in Russia and other former Soviet countries. DMPS also is marketed in both oral and parenteral forms in Germany as Dimaval. DMPS seems promising in mercury and arsenic poisoning.[3,7,9,12,21,41] DMPS is associated with an increase in the urinary excretion of copper and the development of Stevens-Johnson syndrome.[23] Like succimer, DMPS does not appear to redistribute mercury or lead to the brain. More research needs to be done to determine whether DMPS is more advantageous than succimer, given its lower LD_{50} in rodents (5.22 mmol/kg vs. 16.5 mmol/kg for succimer).

Dosing

Succimer (Chemet) is available as 100-mg bead-filled capsules. For patients who cannot swallow the capsule whole, it can be separated immediately prior to use and the contents sprinkled into a small amount of juice or on apple sauce, ice cream, or soft food, or placed on a spoon and followed by a fruit drink. The dosage is 350 mg/m^2 in children, 3 times a day for 5 days, followed by 350 mg/m^2 twice a day for 14 days. In adults, the dosage is 10 mg/kg in the same regimen as above. However, using 10 mg/kg in

children rather than dosing based on body surface area, as was done during the premarketing trials, might result in patient underdosing.[68]

Unanswered Questions

In spite of the epidemic of lead poisoning, there is a paucity of rigorous data defining the role of succimer. There are many unanswered questions regarding clinical efficacy, pharmacokinetics, and dosage regimens, for example:[56,68] How exactly does succimer bind lead in the blood? Is it succimer, its active disulfide cysteine metabolites, or both that bind lead? What happens to the cysteine conjugates? How do the kidneys handle the lead chelate? What exactly is reabsorbed in the enterohepatic circulation, succimer, the cysteine metabolites, and the lead chelated form? Should a longer succimer-dosing regimen be used? And, the most important question of all, does succimer chelation improve clinical outcome?

Summary

Succimer (meso-2,3-dimercaptosuccinic acid) is an orally active metal chelator that is FDA approved for the treatment of lead poisoning in children with blood lead concentrations >45 Âµg/dL. Succimer is also being used to treat lead-poisoned adults, children with blood lead concentrations <45 Âµg/dL, and patients poisoned with arsenic and organic and inorganic mercury. Succimer has many advantages over dimercaprol and $CaNa_2EDTA$, the two other agents used for the same clinical problems. The advantages of succimer use include oral administration, limited effects on trace metals such as zinc, enhanced patient tolerance, limited toxicity, the ability to coadminister iron, if needed, and no contraindication in glucose-6-phosphate dehydrogenase-deficient individuals.[24] In contrast to $CaNa_2EDTA$, succimer does not redistribute lead to the brain of poisoned animals.[9,26] The role of succimer alone and in

conjunction with other chelators to treat lead encephalopathy continues to be defined.[56,68]

Edetate Calcium Disodium ($CaNa_2EDTA$)

Mary Ann Howland

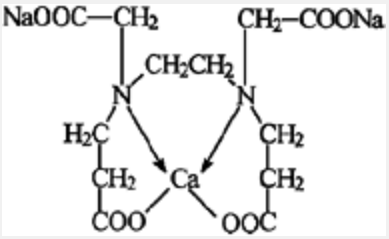

Figure. No Caption Available.

Edetate calcium disodium ($CaNa_2EDTA$) is a chelating agent that is primarily used for the management of lead poisoning. $CaNa_2EDTA$

has been replaced by succimer (2,3-dimercaptosuccinic acid) for the treatment of patients with lead levels between 45 and 70 Âµg/dL Although, in conjunction with dimercaprol, $CaNa_2EDTA$ retains a role in the management of serious lead poisoning and lead encephalopathy, even this role is being challenged by succimer.

Chemistry

Edetate calcium disodium belongs to the family of polyaminocarboxylic acids. Although it is capable of chelating many metals, its current use is almost exclusively in the management of lead poisoning. The term *chelate* has its origin in the Greek word *chele*, which means â€œclaw,â€• implying an ability to tightly grasp the metal.[38] Implicit in chelation is the formation of a ring-structured complex. When $CaNa_2EDTA$ chelates lead, the calcium is displaced and the lead takes its place, forming a stable ring compound.[23]

Pharmacokinetics

$CaNa_2EDTA$ is an ionic, water-soluble compound with a molecular weight of 374 daltons. The volume of distribution is small (0.05â€“0.23 L/kg) because of its polar nature and approximates that of the extracellular fluid compartment in normal individuals,[19,23] but is smaller in patients with renal dysfunction.[29] $CaNa_2EDTA$ appears to penetrate cells such as erythrocytes poorly,[2,19] and <5% of $CaNa_2EDTA$ gains access to the spinal fluid.[19,23] Oral administration of $CaNa_2EDTA$ is not practical because of an oral bioavailability of <5%. The half-life is about 20â€“60 minutes.[3,19,23] Renal elimination approximates the glomerular filtration rate,[28] which correlates with creatinine clearance,[29] and results in the excretion of 50% of $CaNa_2EDTA$ in the urine within 1 hour, and more than 95% within 24 hours.[19,23] When $CaNa_2EDTA$ combines with lead, it forms a stable, soluble,

nonionized compound that is subsequently excreted in the urine. Following $CaNa_2EDTA$ administration, urinary lead excretion is increased 20â€“50-fold.

Lead

Animals

Animal studies demonstrate a decrease in tissue lead stores, including brain concentrations, when measurements are performed following $CaNa_2EDTA$ therapy.[21] One study concluded that $CaNa_2EDTA$ failed to reduce lead levels in the rat model.[13] Furthermore, another rat study that examined the effect of $CaNa_2EDTA$ on brain lead concentrations following a single dose demonstrated a significant increase in brain lead concentrations,[14] suggesting that $CaNa_2EDTA$ may initially mobilize lead and facilitate redistribution to the brain. Additional doses enhance lead elimination, reduce blood lead concentrations, and subsequently reduce brain lead concentrations. This phenomenon may explain why some human case reports demonstrate worsening lead encephalopathy when $CaNa_2EDTA$ is used without concomitant dimercaprol (British anti-Lewisite [BAL]) therapy.

Humans

$CaNa_2EDTA$ is capable of reducing blood lead concentrations, enhancing renal excretion of lead, and reversing the effects of lead on hemoglobin synthesis.[11] With chronic exposure blood lead concentrations rebound considerably, days to weeks following the cessation of $CaNa_2EDTA$, as is the case after terminating other chelators.[1,2,20] Although $CaNa_2EDTA$ has been used clinically since the 1970s, no rigorous clinical studies have ever been performed to evaluate whether $CaNa_2EDTA$ is capable of reversing the neurobehavioral effects of lead.[12] Chelators, including $CaNa_2EDTA$, are incapable of dramatically decreasing the body burden of lead,

because only several milligrams of lead are eliminated during chelation.[8,9,31] A study of children with blood lead concentrations of 25â€“50 Âµg/dL who were given 5 days of $CaNa_2EDTA$ revealed very little difference in blood lead, bone lead, or erythrocyte protoporphyrin concentrations, when compared to pretreatment values.[25] Another study in children demonstrated no additional benefits of $CaNa_2EDTA$ on cognitive performance beyond that which was achieved by limiting further lead exposure and correcting an iron deficiency anemia.[30] A followup study in children with initial blood lead concentrations of approximately 30 Âµg/dL suggested an improvement in perceptual motor performance over a 6-month period beyond that which was achieved by the treatment of the iron-deficiency anemia.[33]

$CaNa_2EDTA$ Mobilization Test

The $CaNa_2EDTA$ mobilization test was once widely recommended as a diagnostic aid for assessing the potential benefits of chelation therapy.[24,26] When scrutinized,[7] it can only be considered obsolete and is therefore no longer recommended.[11,14] Criticisms include difficulties with administration, unreliability as a predictor of total-body lead burden, expense, and the risk of worsening toxicity through redistribution of lead to either the kidney or brain.[11]

Adverse Effects and Safety Issues

The principal toxicity of $CaNa_2EDTA$ is related to the metal chelate. In mice, the intraperitoneal (IP) LD_{50} (median lethal dose for 50% of test subjects) values of various $CaNa_2EDTA$ metal chelates are $CaNa_2EDTA$, 14.3 mmol/kg; lead EDTA, 3.1 mmol/kg; and mercury EDTA, 0.01 mmol/kg.

When $CaNa_2EDTA$ is given to patients with lead poisoning, the

sites of major renal toxicity are the proximal convoluted tubule, the distal convoluted tubule, and the glomeruli.[23] This toxicity may be caused by the release of lead in the kidneys during excretion.[23] Of 210 children who received dimercaprol and $CaNa_2EDTA$, 21% had biochemical evidence of nephrotoxicity, and 3% developed acute oliguric renal failure, which resolved over time without the need for hemodialysis.[24] Other studies failed to demonstrate any cases of renal failure in more than 1000 patient courses of therapy, when $CaNa_2EDTA$ was given in divided daily doses of 1000 mg/m^2 IV over 1 hour, every 6 hours.[26] Because lead toxicity causes renal damage independent of chelation, it is important to monitor renal function closely during $CaNa_2EDTA$ administration and to adjust the dose and schedule appropriately.[28,29] Nephrotoxicity may be minimized by limiting the total daily dose of $CaNa_2EDTA$ to 1 g in children or to 2 g in adults, although higher doses may be needed to treat lead encephalopathy. Continuous infusion while maintaining good hydration seems to increase efficacy and decrease toxicity.[28] Because the administration of disodium EDTA can lead to life-threatening hypocalcemia $CaNa_2EDTA$ has become the preparation of choice and hypocalcemia is no longer a clinical concern. Other adverse effects of $CaNa_2EDTA$, most of which are uncommon, include malaise, fatigue, thirst, chills, fever, myalgias, dermatitis, headache, anorexia, urinary frequency and urgency, sneezing, nasal congestion, lacrimation, glycosuria, anemia, transient hypotension, increased prothrombin times, and inverted T waves.[23] Mild increases in alanine aminotransferase (ALT) and aspartate aminotransferase (AST) (usually reversible), and decreases in alkaline phosphatase, are frequently reported. Extravasation may result in the development of painful calcinosis at the injection site.[34] Depletion of endogenous metals, particularly zinc, iron, and manganese, can result from chronic therapy.[5,37] A decrease in serum dopamine Î²-hydroxylase, a copper-dependent enzyme, without any demonstrable decrease in

serum copper occurred after a single injection of $CaNa_2EDTA$ in 3 adult lead welders.[15] Although the clinical relevance of this is unknown, it merits further investigation.[15]

An animal study suggests that gastrointestinal lead absorption may be enhanced by either intraperitoneal or oral administration of $CaNa_2EDTA$;[20] consequently, removal of lead from the environment should always remain the first strategy in the management of lead toxicity. In the event of unintentional exposure to a new lead source, decontamination of the gastrointestinal tract must complement chelation.[27]

The safety of $CaNa_2EDTA$ has not been established in pregnancy, and a risk-to-benefit analysis must be made if its use is considered. In a model of lead poisoning in pregnant rats, fetal resorption decreased and the number of live fetuses increased when $CaNa_2EDTA$ was used, although the placental levels of lead were increased.[17] Zinc levels were not affected. Another study, however, found that when $CaNa_2EDTA$ was given to pregnant rats not poisoned with lead, increases in submucous clefts, cleft palate, adactyly/syndactyly, curly tail, and abnormal ribs and vertebrae resulted.[4] These teratogenic effects occurred with doses of $CaNa_2EDTA$ comparable to human doses and without causing noticeable changes in the mother except for weight gain. Use of zinc calcium EDTA and zinc EDTA preparations in pregnant rats caused no teratogenic effects at low dose but resulted in the development of submucous cleft palates in 30% of the offspring receiving the higher dose of zinc calcium EDTA.[4]

Dosing and Administration

The dose of $CaNa_2EDTA$ is determined by the patient's body surface area or weight (up to a maximum dose) and the severity of the poisoning and renal function (Chap. 91 and Table 91-8).[11,25,30] For patients with lead encephalopathy, the dose of $CaNa_2EDTA$ is 1500 $mg/m^2/d$ by continuous IV infusion, starting 4

hours after the first dose of dimercaprol and after an adequate urine flow is established.[10] Simultaneous dimercaprol and $CaNa_2EDTA$ therapy is administered for 5 days, followed by a rest period of at least 2â€“4 days, which permits lead redistribution. Dosage adjustments limiting the daily dose to 50 mg/kg are necessary when $CaNa_2EDTA$ is used in patients with renal dysfunction.[19,28,29] There is limited evidence to suggest that folic acid, pyridoxine, and thiamine increase the antidotal properties of $CaNa_2EDTA$.[35] A blood lead concentration should be measured 1 hour after the $CaNa_2EDTA$ infusion is discontinued, to avoid falsely elevated blood lead concentration determinations.

In symptomatic children without manifestations of lead encephalopathy, the dose of $CaNa_2EDTA$ is 1000 $mg/m^2/d$, in addition to dimercaprol at 50 mg/m^2 every 4 hours. However, with FDA approval, and the demonstrated ability to reduce brain lead concentrations in animals, succimer is increasingly replacing $CaNa_2EDTA$ as the chelator of choice in lead-poisoned children without encephalopathy.[9]

Because of the pain associated with IM administration, most clinicians recommend that $CaNa_2EDTA$ be administered at concentrations of approximately 0.5% by continuous IV infusion over 24 hours in 5% dextrose or 0.9% NaCl. Concentrations greater than 0.5% may lead to thrombophlebitis and should be avoided. $CaNa_2EDTA$ is incompatible with other solutions. Careful attention to total fluid requirements in children and patients who have or who are at risk for, lead encephalopathy is paramount.[23,30] Rapid intravenous infusions in patients with lead encephalopathy may increase intracranial pressure and cerebral edema. In children with acute lead encephalopathy, starting BAL 4 hours prior to $CaNa_2EDTA$ appears to be more effective than starting $CaNa_2EDTA$ prior to and simultaneously with BAL.[6,12] In addition, treating with two chelators also reduces the blood lead concentration significantly faster than does $CaNa_2EDTA$ alone, while maintaining a better molar ratio of chelator to lead.[6]

If $CaNa_2EDTA$ is to be administered IM to avoid the use of an IV and fluid overload, then procaine is added to the $CaNa_2EDTA$ in a dose sufficient to produce a final concentration of 0.5%. This can be accomplished by mixing 1 mL of a 1% procaine solution with each mL of chelator.[23] The procaine minimizes pain at the injection site.

Combination Therapy with Succimer or DMPS

The possible benefit of combining $CaNa_2EDTA$ with succimer or 2,3-dimercapto-1-propane-sulfonic acid (DMPS) is under investigation in animals.[16,18,36] The combination of $CaNa_2EDTA$ with succimer appears more potent than either individual agent in promoting urine and fecal lead excretion, and decreasing blood and

liver lead concentrations. However, this approach might increase nephrotoxicity and zinc depletion.

Availability

Calcium disodium EDTA is available as calcium disodium versenate in 5-mL ampules containing 200 mg of $CaNa_2EDTA$ per milliliter (1 g per ampule).[23] Disodium edetate (sodium EDTA) should not be considered an alternative to $CaNa_2EDTA$ because of the risk of life-threatening hypocalcemia associated with sodium EDTA use.

Summary

$CaNa_2EDTA$ reduces blood lead concentrations, enhances urinary lead excretion, and reverses lead-induced hematologic effects. Studies evaluating long-term effects in reversing lead-induced neurotoxicity have not been performed. $CaNa_2EDTA$ remains the

standard of care for patients with lead encephalopathy when used in conjunction with dimercaprol. A $CaNa_2EDTA$ challenge test is no longer recommended as a diagnostic gesture.[11,14] Recommended doses and dosage schedules should not be exceeded and should be reduced when the creatinine clearance is reduced. Patients should be well hydrated to achieve an adequate urine flow prior to and during $CaNa_2EDTA$ therapy.

A 16-year-old boy presented to the emergency department approximately 40 minutes after having intentionally ingested

â€œseveral teaspoonsâ€• of mercuric oxide (HgO) from his chemistry set. On arrival, he was alert and oriented, but diaphoretic and vomiting. He complained of midepigastric pain and a metallic taste in his mouth. Initial vital signs were: blood pressure, 130/80 mm Hg; pulse, 110 beats/min; respiratory rate, 18 breaths/min; and rectal temperature, 99.7Â°F (37.6Â°C). Physical examination revealed an anxious, somewhat pale young man who was repeatedly vomiting blood-tinged, nonbilious material. He had no respiratory distress or drooling. Other than a grayish discoloration of the buccal mucosa, examination of the oropharynx was unremarkable. The lungs were clear. The cardiac examination was normal, except for a sinus tachycardia. The abdominal examination revealed a nondistended, soft abdomen, moderately tender to deep palpation in the epigastric region; no masses or organomegaly were appreciated. Rectal examination was negative for blood. Examination of the skin was unremarkable. The neurologic examination was normal, except for mild tremulousness. The patient was attached to a cardiac monitor, and he was given 1 L of 0.9% sodium chloride solution (IV) over the subsequent 15 minutes. Results of a complete blood count (CBC), electrolytes, blood urea nitrogen (BUN), creatinine, glucose, prothrombin time, partial thromboplastin time (PTT), and liver enzymes were within normal limits. Blood was obtained for whole-blood mercury concentrations, and the bladder was catheterized to collect urine for 24-hour urine mercury quantification. Initial spot urinalysis revealed 2+ proteinuria.

The electrocardiogram (ECG) was normal, except for sinus tachycardia. Upright chest and abdominal radiographs revealed the presence of a radiopaque substance scattered throughout the GI tract, but no extraluminal air. Figures 92-1A and B are abdominal radiographs of a patient with a similar exposure.

Endoscopic examination of the upper gastrointestinal (GI) tract was considered but rejected based on the patient's clinical presentation. Instead, the patient underwent gastric lavage and

received 1 g/kg of activated charcoal. Whole-bowel irrigation with polyethylene glycol electrolyte lavage solution was begun. The rectal effluent contained flecks of blood. A subsequent abdominal radiograph after whole-bowel irrigation revealed no radiopaque densities.

History and Epidemiology

The toxicologic manifestations of mercury are well known as a result of thousands of years of medicinal applications, industrial use, and environmental disasters.[54 , 85] Mercury occurs naturally in small amounts as the elemental silver-colored liquid (quicksilver); as inorganic salts such as mercuric sulfide (cinnabar), mercurous chloride (calomel), mercuric chloride (corrosive sublimate), and mercuric oxide; and as organic compounds (methylmercury and dimethylmercury). In recent centuries, mercury preparations were widely used to treat both syphilis and constipation. The musician Paganini was one of several famous persons whose gingivitis, dental decay, ptyalism (excessive salivation), and erethism (pathologic shyness) were attributed to mercury therapy.[62] In the 1800s, the United States witnessed an epidemic of â€œhatters' shakesâ€• or â€œDanbury shakesâ€• and â€œmercurial salivationâ€• in hat industry workers.[95] Danbury, CT, was a US center of felt hat manufacturing in which mercuric nitrate was used to mat animal furs to make felt.[85 , 95]

In the early 1900s, acrodynia, or â€œpink disease,â€• was described in children who received calomel for ascariasis or teething discomfort.[10] Vividly described in a series of 41 children, the development of acrodynia was more common in younger children, did not seem to correlate with mercury dose, and was not necessarily related to urine concentrations of mercury.[94]

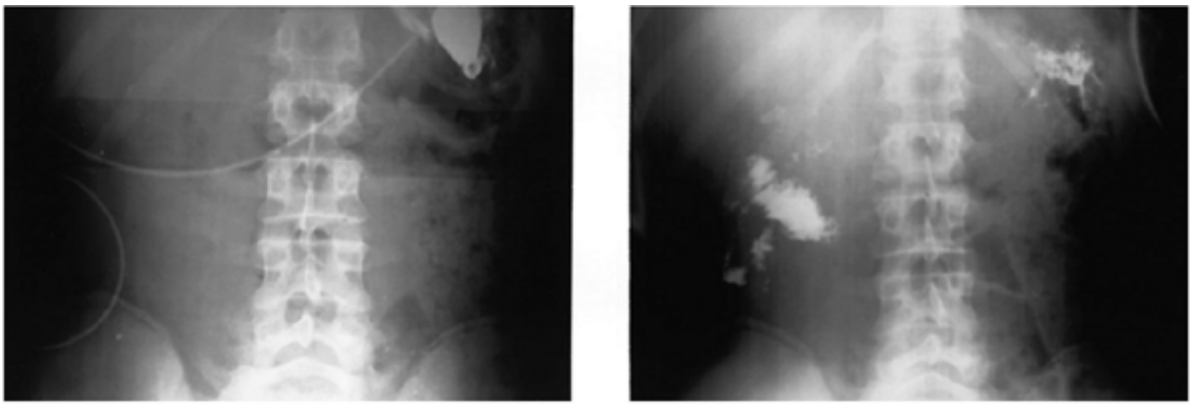

Figure 92-1. A chemist ingested mercuric oxide in a suicide attempt. A. Initial plain abdominal radiograph reveals the radiopaque liquid in the stomach. B. A second radiograph shows progression of the toxin through the bowel. The patient was followed radiographically as the mercuric oxide was expelled into the feces.

One of the most devastating epidemics of mercury poisoning occurred as the result of a decade of contamination of Minamata Bay in Japan by a nearby vinyl chloride plant during the 1940s. Methylmercury accumulated in the bay's marine life and poisoned the inhabitants of the local fishing community. Although officially only 121 victims were initially counted, thousands more are believed to have been affected by what has subsequently been named Minamata disease.[67, 87] The largest outbreak of methylmercury poisoning to date occurred in Iraq in late 1971. Approximately 95,000 tons of seed grain intended for planting and treated with methylmercury as a fungicide were baked into bread for direct consumption, resulting in widespread neurologic symptoms, 6530 hospital admissions, and more than 400 deaths.[4, 16, 72]

In 1990, the EPA banned mercury-containing compounds from interior paints.[2] However, mercury-containing paints manufactured prior to that ruling may still be on the interior walls and mercury

containing paint can still be sold for outdoor use. In 1997, a scientist succumbed to delayed, progressive neurologic deterioration following dermal exposure to a minute quantity of dimethylmercury.[59]

TABLE 92-1. Potential Occupational Exposures to Mercury

Contemporary exposures occur in the form of mercury-tainted seafood and mercury-based preservatives (thimerosal). However, a once widely feared source of potential poisoning, mercury-containing dental amalgam, does not appear to result in clinically important poisoning. Occasionally, exposure to mercury from thermometers leads to poisoning in the home. Tables 92-1 and 92-2 show the potential occupational and nonoccupational risks for mercury exposure.

Forms of Mercury and Kinetics

The three important classes of mercury compounds (elemental, inorganic, and organic) differ with respect to toxicodynamics and toxicokinetics (Table 92-3). Each of the three classes of mercurials produces distinct clinical patterns of poisoning stemming in part from their unique kinetic features (Table 92-4). Within each class, the specific poisoning, manifestations are determined by route of exposure, rate of exposure, distribution, and biotransformation of mercury within the body, and relative accumulation or elimination of mercury by the target organ systems.

Absorption

Elemental Mercury

Elemental mercury (Hg^0) is absorbed primarily via inhalation of vapor, although slow absorption following aspiration, subcutaneous deposition, and direct intravenous embolization is reported.[45, 56, 92, 98] Although elemental mercury is moderately volatile at room temperature, volatilization increases significantly when it is heated. Vaporization may also be hastened by aerosolization. Both occur when elemental mercury is vacuumed.[77] When inhaled by human volunteers, 75â€“80% of a stable, radioactive mercury vapor mixture is absorbed.[33] However, as elemental mercury is negligibly absorbed from a normally functioning gut, it is usually considered nontoxic when ingested. Abnormal gastrointestinal (GI) motility prolongs mucosal exposure to elemental mercury and increases subsequent ionization to more readily absorbed forms. Similarly, anatomic GI abnormalities such as fistulae or perforation may be associated with extravasation of mercury into the peritoneal space where elemental mercury is oxidized to more readily absorbed inorganic forms.

Inorganic Mercury Salts

The principal route of absorption for inorganic mercury salts is the

GI tract. Approximately 10% of inorganic mercury salts are absorbed after dissociation of ingested soluble divalent mercuric salts such as mercuric chloride ($HgCl_2$).[51] Absorption of a relatively insoluble monovalent mercurous compound, such as calomel (HgCl), is thought to depend on its oxidation to the divalent form.[60] Inorganic mercury salts are also absorbed across skin and mucous membranes, as evidenced by urinary excretion of mercury following the dermal application of mercurial ointments and powders containing HgCl.[94] The degree of dermal absorption varies by concentration of mercury, skin integrity, and the lipid solubility of the vehicle. With substantial dermal exposures to inorganic mercury salts, skin absorption may be difficult to distinguish from concomitant absorption via other routes, such as ingestion.

Elemental Inorganic (Salt) Organic (Alkyl)

TABLE 92-4. Differential Characteristics of Mercury Exposure

Organic Mercury Compounds

As in the case of inorganic mercury salts, organic mercury compounds are primarily absorbed from the GI tract. Methylmercury, considered the prototype of the short-chain alkyl compounds, is approximately 90% absorbed from the gut.[51] Aryl and long-chain alkyl compounds have greater than 50% gastrointestinal absorption.[60] Although both dermal and inhalational absorption of organic mercury compounds are reported, precise quantitation and exclusion of concomitant

absorption by ingestion are difficult to determine.[20, 24, 96, 97]

Distribution and Biotransformation

After it is absorbed, mercury distributes widely to all tissues, predominantly the kidneys, liver, spleen, and central nervous system (CNS). The initial distributive pattern into nervous tissue of elemental and organic mercury differs from that of the inorganic salts because of their greater lipid solubility.

Elemental Mercury

Although peak levels of elemental mercury are delayed in the CNS as compared to other organs (2â€“3 days vs. 1 day),[31] significant accumulation in the CNS may occur following an acute, intense exposure to elemental mercury vapor. Conversion of elemental mercury to the charged mercuric cation within the CNS favors retention and local accumulation of the metal. As elemental mercury does not covalently bind to other compounds, its toxicity depends on its oxidation initially to the mercurous ion (Hg^{+}) and then to the mercuric ion (Hg^{2+}) by the enzyme catalase.[51] Because this oxidation-reduction reaction favors the mercuric cation at steady state, the distribution and late manifestations of metallic mercury toxicity eventually resemble those of inorganic mercury salt poisoning. Conversely, and to a lesser extent, inorganic mercuric ions are reduced to the elemental state, although the site and mechanism of this reaction are not well understood.[60]

Inorganic Mercury Salts

The greatest concentration of mercuric ions is found in the kidneys, particularly within the renal tubules. Very little mercury is found as free mercuric ions. At least in animal studies, administration of mercury induces the renal synthesis of

metallothionein, a compound that binds to and detoxifies mercuric ions.[7] In blood, mercuric ions are found within the red blood cells and are bound to plasma proteins in approximately equal proportions. Blood concentrations are greatest immediately following inorganic mercury exposure, with rapid waning as distribution to other tissues occurs. Although penetration of the bloodâ€“brain barrier is poor because of low lipid solubility, slow elimination and prolonged exposure contribute to consequential CNS accumulation of mercuric ions. Within the CNS, mercuric ions are concentrated in the cerebral and cerebellar cortices. Although inorganic mercurials undergo organification in marine life, as in the Minamata

Bay disaster, the importance of this conversion in humans is unknown.[20] Animal studies demonstrate that the placenta functions as an effective barrier to mercuric ions.[60]

Organic Mercury Compounds

Once absorbed, aryl and long-chain alkyl mercury compounds differ from the short-chain organic mercury compounds (ie, methylmercury) in an important way. The former possess a labile carbon-mercury bond, which is subsequently cleaved, releasing the inorganic mercuric ion. Thus, the distribution pattern and toxicologic manifestations produced by the aryl and long-chain alkyl compounds beyond the immediate postabsorptive phase are comparable to those of the inorganic mercury salts, but the organification has facilitated absorption and reduced the caustic effects.[61] In contrast, short-chain alkyl mercury compounds possess relatively stable carbon-mercury bonds that survive the absorptive phase, although conversion to the inorganic mercuric cation at a rate of less than 1% per day may occur following absorption.[96] Because it is lipophilic, methylmercury readily distributes across all tissues, including the bloodâ€“brain barrier and placenta.[33] An important consequence of this property is the

devastating neurologic degeneration that develops in prenatally exposed infants with Minamata disease.

After methylmercury is distributed to brain tissue, its fate is uncertain. Animal evidence indicates that methylmercury is converted to inorganic mercury in brain tissue.[48] Primates fed oral methylmercury daily for periods exceeding 1 year and then killed within a few days of the last exposure, demonstrated an average brain inorganic mercury fraction of only 19%. When the postexposure period was extended to between 150 and 650 days, the inorganic mercury fraction increased to 88%. Similarly, long-term survivors of methylmercury poisoning had a higher ratio of inorganic mercury to total mercury in their brains.[22] In one patient who survived 22 years following methylmercury ingestion, autopsy revealed that the brain mercury was nearly completely in the inorganic form.

Methylmercury concentrates in red blood cells (RBCs) to a much greater degree than do mercuric ions, with an RBC-to-plasma ratio of about 10:1 (contrast with 1:1 RBC-to-plasma ratio for inorganic mercury).[42, 60, 96] However, despite this apparent affinity for nervous tissue and red blood cells, the greatest methylmercury concentrations are found in the kidneys and liver. Also, because of the extensive sulfhydryl bonds in hair, methylmercury deposits in hair at concentrations approximately 250 times that found in whole blood.[41, 86]

Elimination

Elemental Mercury/Inorganic Mercury Salts

Mercuric ions are excreted through the kidney by both glomerular filtration and tubular secretion, and in the GI tract by transfer across gut mesenteric vessels into feces. Small amounts are

reduced to elemental mercury vapor and volatilized from skin and lungs. The total-body half-life of elemental mercury and inorganic mercury salts is estimated at approximately 30â€“60 days.[15 , 51]

Organic Mercury Compounds

In contrast to elemental mercury and inorganic mercury salts, the elimination of short-chain alkyl mercury compounds is predominantly fecal. Enterohepatic recirculation contributes to its somewhat longer half-life of about 70 days. Less than 10% of methylmercury is excreted in urine and feces as the mercuric cation.[96]

Pathophysiology

The pervasive disruption of normal cell physiology by mercury is believed to arise from its avid covalent binding to sulfur, replacing the hydrogen ion in the body's ubiquitous sulfhydryl groups. Mercury also reacts with phosphoryl, carboxyl, and amide groups, resulting in widespread dysfunction of enzymes, transport mechanisms, membranes, and structural proteins. The role of mercury is being investigated in a variety of cellular alterations including oxidant stress, microtubule disruption, protein and DNA synthesis, and cell membrane integrity.

Mercury deposits in all tissues. Not surprisingly, the clinical manifestations of mercury toxicity involve multiple organ systems with variable features and intensity. Necrosis of the gastrointestinal mucosa and proximal renal tubules, which occurs shortly after mercury salt poisoning, is thought to result from direct oxidative effect of mercuric ions. An immune mechanism is attributed to the membranous glomerulonephritis and acrodynia associated with the use of mercurial ointments.[8] Postmortem examination of the kidneys from two women who died following chronic abuse of mercurous chloride-containing laxatives, revealed severe proximal tubular atrophy and mercury deposition within the

cortical interstitium and renal macrophages.[93]

Neurologic manifestations of methylmercury poisoning correlated with pathologic findings in the brains of both adults and children believed to have been prenatally exposed.[53, 87] Grossly, atrophy of the brain is more severe in children who had prenatally or postnatally acquired methylmercury, when compared with the brains of those exposed as adults. In the adult brain, neuronal necrosis and glial proliferation are most prominent in the calcarine cortex of the cerebrum and in the cerebellar cortex. In fetal Minamata disease, similar lesions are present, but in a more diffuse and severe form. Atrophy of the cerebellar hemispheres, postcentral gyri, and calcarine area of the brain on magnetic resonance images in organic mercury-poisoned patients, correlate with clinical findings of ataxia, sensory neuropathy, and visual field constriction, respectively.[44] Neuropathologic examination of the brain of a woman who died after dermal exposure to dimethylmercury revealed lesions in the cerebellum, temporal lobe, and visual cortex.[80]

In rats neuronal cytotoxicity of methylmercury may result in part from muscarinic receptor mediated calcium release from smooth endoplasmic reticulum of cerebellar granule cells.[47] There is animal evidence that methylmercury may trigger reactive oxygen species production. In addition, methylmercury inhibits astrocyte uptake of cysteine, the rate-limiting step in the production of glutathione, a major antioxidant in mammalian cell systems.[79]

Clinical Syndromes

Elemental Mercury

Symptoms of *acute elemental mercury inhalation* occur within hours of exposure and consist of cough, chills, fever, and shortness of breath. Gastrointestinal complaints include nausea,

vomiting, and diarrhea, accompanied by a metallic taste, dysphagia, salivation, weakness, headaches, and visual disturbances. Chest radiography during the acute phase may reveal interstitial pneumonitis and both patchy atelectasis and emphysema. Symptoms may resolve or progress to acute lung injury, respiratory failure, and death. Survivors of severe pulmonary manifestations may develop

interstitial fibrosis and residual restrictive pulmonary disease. The acute respiratory symptoms may occur concomitantly with or lead to the development of, subacute inorganic mercury poisoning, manifested by tremor, renal dysfunction, and gingivostomatitis.[11, 40, 70] Thrombocytopenia may also occur during the acute phase.[27]

While acute exposure to elemental mercury vapor occurs most commonly in the occupational setting, poisonings caused by mishandling of the metal in the home are well reported.[13, 36, 55, 82] In fact, attempts at home metallurgy employing metallic mercury have resulted in fatalities with ambient air concentrations of mercury as high as 0.9 mg/m^3 (National Institute for Occupational Safety and Health [NIOSH] recommended exposure level [REL] 8-hour time-weighted average [TWA] 0.05 mg/m^3 for mercury vapor).[14] The lethal dose of inhaled elemental mercury has not been determined. As with other inhaled toxins, younger individuals may be more sensitive to the pulmonary toxicity of mercury vapor.[55] Although pulmonary toxicity from elemental mercury usually results from inhalation of vapor, massive endobronchial hemorrhage followed by death has occurred secondary to direct *aspiration of metallic mercury* into the tracheobronchial tree.[100]

Gradual volatilization of elemental mercury results in chronic toxicity, both in the occupational setting and in the home, from improper handling, such as vacuuming spilled mercury.[77]

The clinical importance of volatilized metallic mercury from dental

amalgams for both the dentist and patient has been a point of contention for years. The preponderance of evidence currently refutes the idea that dental amalgam causes mercury poisoning. Several comprehensive reviews of the subject conclude that (a) occupational exposure to mercury from dental amalgam is acceptably low, provided that recommended preventive measures such as adequate ventilation are adhered to; (b) the quantity of mercury vaporized from dental amalgam by mechanical forces, such as chewing is clinically insignificant; and (c) only in very rare cases will immunologic hypersensitivity to mercury amalgam (manifested as cutaneous signs and symptoms and confirmed by patch testing) necessitate removal of the amalgam.[23 , 25 , 26 , 46 , 81]

Unusual cases of chronic toxicity have resulted from intentional *subcutaneous or intravenous injection of elemental mercury* (Figs. 6-6 and 92-2).[35 , 56] Aside from management of local and systemic mercury toxicity, local wound care and excision of deposits of mercury were additional therapeutic challenges presented by these cases. Serial or repeat radiographs are useful in guiding the removal of the radiopaque deposits.

Inorganic Mercury Salts

Acute *ingestion of mercuric salts* produces a characteristic spectrum from severe irritant to caustic gastroenteritis. Immediately following the ingestion, a grayish discoloration of mucous membranes and metallic taste may accompany local oropharyngeal pain, nausea, vomiting, and diarrhea, followed by abdominal pain, hematemesis, and hematochezia. The lethal dose of mercuric chloride is estimated to be 30â€“50 mg/kg.[88] The hallmarks of severe acute mercuric salt ingestion are hemorrhagic gastroenteritis, massive fluid loss resulting in shock, and acute tubular necrosis.[75]

Oropharyngeal injury, nausea, hematemesis, hematochezia, and

abdominal pain were the most prominent symptoms in a series of 54 patients who presented after ingesting up to 4 g of mercuric chloride.[88] In this series, a fatal outcome was associated with the early development of oliguria (within 3 days). The development of anuria appeared to be related to the dose of mercuric chloride ingested. The histopathologic finding of proximal tubular necrosis following mercuric salt poisoning results from both direct toxicity to renal tubules by mercuric ions and renal hypoperfusion caused by shock. Consequently, aggressive fluid therapy is useful.[76]

Figure 92-2. Anteroposterior (A) and lateral (B) view of the elbow after an unsuccessful suicidal gesture involving an attempted intravenous injection of mercury in the antecubital fossa. Note extensive mercury deposition, which was partially removed by surgical intervention. *(Courtesy of Diane Sauter, MD.)*

Acute ingestion of mercuric salts is usually intentional, but

unintentional ingestion occurs sporadically in both children and adults.[37] Although ingestion of button batteries containing mercuric oxide is associated with a greater incidence of fragmentation than with other batteries, clinically significant systemic mercury toxicity by this route has not been reported.[49, 52]

Mercuric chloride-containing stool preservatives are another potential source of unintentional inorganic mercury poisoning. Ingestion of 10â€“20 mL of a polyvinyl alcohol preservative that contained 4.5% mercuric chloride resulted in bloody gastroenteritis and proteinuria.[78] Ethnic medicines are also associated with unintentional inorganic mercury poisoning.[39] Not subject to FDA regulation and available without prescription, these xenobiotics are often inadequately labeled and of variable composition (Chap. 43).

Subacute or chronic mercury poisoning occurs after (a) inhalation, aspiration, or injection of elemental mercury; (b) ingestion or application of inorganic mercury salts; or (c) ingestion of aryl or long-chain alkyl mercury compounds. Slow in vivo oxidation of elemental mercury and dissociation of the carbonâ€“mercury bond of aryl or long-chain alkyl mercury compounds result in the production of the inorganic mercurous and mercuric ions.

The predominant manifestations of subacute or chronic mercury toxicity include gastrointestinal symptoms, neurologic abnormalities, and renal dysfunction. Gastrointestinal symptoms consist of a metallic taste and burning sensation in the mouth, loose teeth and gingivostomatitis, hypersalivation (ptyalism), and nausea.[94] The neurologic manifestations of chronic inorganic mercurialism

include tremor, as well as the syndromes of neurasthenia and erethism. Neurasthenia is a symptom complex that includes fatigue, depression, headaches, hypersensitivity to stimuli,

psychosomatic complaints, weakness, and loss of concentrating ability. Erethism, derived from the Greek word *red* , describes the easy blushing and extreme shyness of the afflicted. Other symptoms of erethism include anxiety, emotional lability, irritability, insomnia, anorexia, weight loss, and delirium. The mercurial tremor is well described in numerous case reports as a central intention tremor (Chap. 19) that is abolished during sleep. In the most severe forms of mercury-associated tremor, choreoathetosis and spasmodic ballismus may be present. Other neurologic manifestations of inorganic mercurialism include a mixed sensorimotor neuropathy, ataxia, concentric constriction of visual fields (â€œtunnel visionâ€•), and anosmia.

Chronic poisoning with mercuric ions is associated with renal dysfunction, which ranges from asymptomatic, reversible proteinuria, to nephrotic syndrome with edema and hypoproteinemia. An idiosyncratic hypersensitivity to mercury ions is thought to be responsible for acrodynia, or â€œpink disease,â€• which is an erythematous, edematous, and hyperkeratotic induration of the palms, soles, and face, and a pink papular rash that was first described in a subset of children exposed to mercurous powders.[94] The rash is described as morbilliform, urticarial, vesicular, and hemorrhagic. This symptom complex also includes excessive sweating, tachycardia, irritability, anorexia, photophobia, insomnia, tremors, paresthesias, decreased deep-tendon reflexes, and weakness. The acral rash may progress to desquamation and ulceration. The prognosis is favorable, after withdrawal from mercury exposure. Childhood acrodynia has become uncommon since the abandonment of mercurial teething powders and diaper rinses. Occasional case reports are still noted, however, with fluorescent light bulbs and phenylmercuric-acetateâ€“containing paint implicated.[2 , 89]

Thimerosal is an example of an aryl or long-chain alkyl mercury compound that results in chronic inorganic mercury toxicity. It is a compound that is widely used as a preservative in the

pharmaceutical industry (Chap. 53). Although initial kinetics suggest a stable ethylâ€“mercury bond, the later elimination phase more closely resembles that of the inorganic mercury compounds. Thimerosal is approximately 50% mercury by weight. Generally considered safe, toxicity and death can nevertheless occur following both intentional overdose and excessive therapeutic application of merthiolate (0.1% thimerosal or 600 Âµg/mL mercury).[66 , 71]

Recent concern that the cumulative dose of thimerosal in childhood immunizations may exceed federally recommended maximum mercury doses (Environmental Protection Agency, 0.1 Âµg/kg/d; Agency for Toxic Substances and Disease Registry, 0.3 Âµg/kg/d; Food and Drug Administration, 0.4 Âµg/kg/d) led to a call by the American Academy of Pediatrics to reduce or eliminate thimerosal from vaccines.[3] In particular, controversy exists whether thimerosal causes autism. Although sensitization following use in vaccinations has been reported in atopic children,[65] clinical mercury toxicity has not been reported in appropriately immunized children. Moreover, a number of studies suggest that the incidence of autism is unrelated to use of thimerosal-containing vaccines.[50 , 64 , 83] At the present time, there is clearly more evidence for risk to child health from the diseases targeted for prevention by the vaccines, than from thimerosal. Nevertheless, since 2001, routinely administered childhood vaccines in the United States, with the exception of injectable influenza vaccine, contain only trace amounts of thimerosal.[34]

Organic Mercury Compounds

In contrast to the inorganic mercurials, methylmercury produces an almost purely neurologic disease that is usually permanent, except in the mildest of cases. Although the predominant, syndrome associated with methylmercury is that of a delayed neurotoxicity, acute gastrointestinal symptoms, tremor,

respiratory distress, and dermatitis may occur.[20, 96] In addition, electrocardiographic abnormalities (ST segment changes) and renal tubular dysfunction are associated with this poisoning.[24, 32]

The lipophilic property and slower elimination of methylmercury may contribute to its profound neurologic effects.[24] Characteristically, clinical manifestations follow the initial poisoning by a latent period of weeks to months. Consequently, the lethal dose of methylmercury is difficult to determine. As noted previously, infants exposed prenatally to methylmercury were the most severely affected individuals in Minamata. Often born to mothers with little or no manifestation of methylmercury toxicity themselves, exposed infants exhibited decreased birth weight and muscle tone, profound developmental delay, seizure disorders, deafness, blindness, and severe spasticity. The development of neurologic symptoms in infants exclusively breast-fed by women exposed to methylmercury after delivery, and the detection of mercury in the milk of lactating women, implies a risk for mercury poisoning via breast milk.[43] In one series of lactating women, mercury concentrations in milk were approximately 30% of concentrations found in blood.[63] The rapid decline of blood mercury concentrations in both suckling rats and breast-feeding human infants is attributed to rapid growth of body volume combined with limited transport of mercury by milk.[58, 73, 74]

Several weeks after methylmercury-contaminated grain was ingested in Iraq, patients began to appear with paresthesias involving the lips, nose, and distal extremities. Symptomatic patients also noted headaches, fatigue, and tremor. More serious cases progressed to ataxia, dysarthria, visual field constriction, and blindness. Other neurologic deficits included hyperreflexia, hearing disturbances, movement disorders, salivation, and dementia. The most severely affected patients lay in a mute rigid posture punctuated only by spontaneous crying, primitive reflexive movements, or feeding efforts.[72]

While the outlook for methylmercury neurotoxicity is generally considered dismal, observations over the subsequent two years, in 49 Iraqi children poisoned during the 1971 outbreak, revealed complete resolution or partial improvement in all but the most severely affected.[4] Of 40 symptomatic children, 33 mildly to severely affected children showed partial to complete resolution of symptoms, but the seven children classified as â€œvery severely poisonedâ€• remained physically and mentally incapacitated.

The extreme toxicity of dimethylmercury was tragically demonstrated by the delayed fatal neurotoxicity that developed in a chemist who inadvertently spilled dimethylmercury on a break in the gloves on her hands. Over a period of several days, she developed progressive difficulty with speech, vision, and gait. Despite chelation and exchange transfusion, she died within several months of the exposure.[59]

An important route of organic mercury exposure is through seafood consumption. The safe level of methylmercury in seafood remains controversial. The FDA's action level of 1 ppm for methylmercury in fish was set to limit consumption of methylmercury to less than one-tenth of levels found in cases of symptomatic poisoning. The Environmental Protection Agency (EPA) established a reference dose for methylmercury of 0.1 Âµg/kg/d.[68 , 90]

Although elevated blood concentrations (19â€“53 Âµg/L) of mercury were found in one group of self-reported high consumers of seafood, increased incidence of cognitive and gastrointestinal complaints were not.[38] Even so, concentrations at which fetuses suffer adverse effects are unknown. Longitudinal studies of fish-eating populations are conflicting. No effect of a high prenatal fish diet was found on developmental markers in children followed to nine years of age in the Seychelles Islands. In the Faroe Island and New Zealand studies, however, a subtle but significant effect on neuropsychological development was seen.[19 , 29 , 84] One

reason for the discrepancy seen between the populations may be the different concentrations of methylmercury in the seafood consumed by each. The mean concentration of methylmercury in the whale meat consumed in the Faroe Islands was 1.6 Âµg/g, and mean mercury concentration of mercury found in New Zealand shark was 2.2 Âµg/g. In contrast, mean methylmercury content of Seychellois fish was 0.3 Âµg/g.[57] The threshold concentration for neuropsychological effects may lie between these levels. The FDA recommends that at-risk populations (ie, pregnant women and women who may become pregnant, nursing mothers, and young children) avoid the large predator fish (eg, shark, swordfish, tilefish, and king mackerel) that contain levels of methylmercury approaching 1 ppm.[91] The FDA has ruled that consumption advice is not indicated for the top 10 seafood species, which make up 80% of all seafood consumed: canned (nonalbacore) tuna, shrimp, pollack, salmon, cod, catfish, clams, flatfish, crabs, and scallops. These species contain levels of mercury less than 0.2 ppm and are rarely consumed in quantities in excess of the recommended weekly limit of 2.2 pounds. The recommendations are not as clear for albacore tuna, which may have levels of mercury as high as 0.34 ppm. The FDA-recommended limit of albacore tuna consumption by at-risk populations is less than 6 ounces per week, but some consumer advocacy groups feel that the limit should be lower.[18]

Laboratory

The dual findings of unexplained neuropsychiatric and renal abnormalities in an individual should alert the clinician to the possibility of mercurialism, as should an at-risk occupation or access by the patient to a mercurial product (Tables 92-1 and 92-2).

Occupational or environmental exposure and a consistent clinical scenario may be suggestive of mercury poisoning, but

demonstration of mercury in blood, urine, or tissues is necessary for confirmation of exposure. Of the many methods available to measure mercury, cold atomic absorption spectrometry is rapid, sensitive, and accurate, but cannot distinguish the various forms of mercury. Thin-layer and gas chromatographic techniques can be used to distinguish organic from inorganic mercury.[20] Blood should be collected into a trace element collection tube obtained from the laboratory performing the assay. Urine should be collected for 24 hours into an acid-washed container obtained from the laboratory. Spot collections must be adjusted for creatinine concentration. Attempts to measure or otherwise handle the specimen should be avoided to prevent contamination.

There is considerable overlap among concentrations of mercury found in the normal population, asymptomatic exposed individuals, and patients with clinical evidence of poisoning. There is no definitive correlation between either blood or urine mercury levels and mercury toxicity. However, mercury serves no useful role in human physiology, and concentrations less than 10 Âµg/L and 20 Âµg/L for whole blood and urine, respectively, are generally considered to reflect background exposure in nonpoisoned individuals. Following long-term exposure to elemental mercury vapor, levels as low as 35 Âµg/L for blood and 150 Âµg/L for urine may be associated with nonspecific symptoms of mercury poisoning.[28]

For inorganic mercury poisoning, urine mercury levels may correlate roughly with exposure severity and neuropsychiatric symptoms,[69] but the relationship to total-body burden is probably poor. Urine mercury values have their greatest usefulness in confirming exposure and monitoring the efficacy of chelation therapy. Whole-blood mercury concentrations may reflect intense, acute inorganic mercury exposure, but become less reliable as redistribution to tissues takes place.

Because organic mercury is eliminated via the fecal route, urine

mercury levels are not useful in methylmercury poisoning. Because methylmercury concentrates in red blood cells, the total-body methylmercury burden is best reflected acutely by whole-blood levels.[20, 42] As methylmercury distributes to and accumulates in brain, the severity of clinical manifestations probably more closely reflects the degree of the irreversible neuronal destruction that has taken place, rather than the current body burden of mercury. Correlation of increasing blood mercury concentrations with prevalence of paresthesias was suggested in a population of Iraqis studied early in the course of methylmercury poisoning.[17] However, in another group of patients, blood concentrations did not correlate with severity of methylmercury poisoning.[72] This apparent discrepancy may have resulted from the finding that paresthesias are among the earliest reported symptoms of methylmercury poisoning.

Because mercury accumulates in hair, hair analysis has been employed as a tool for measuring mercury burden. However, because metal incorporation reflects past exposure and hair avidly binds mercury from the environment, the reliability of this method is questionable and is not recommended. In addition to mercury assays, neuropsychiatric testing, nerve conduction studies, and urine assays for *N* -acetyl-Î²-D-glucosaminidase and $Î²_2$ -microglobulin are advocated for early detection of subclinical inorganic and organic mercury toxicity.[25, 32, 69]

Initial Management

After initial assessment and stabilization, the early toxicologic management of mercury poisoning includes termination of exposure by removal from vapors; washing exposed skin; gastrointestinal decontamination; supportive measures, such as hydration and humidified oxygen; baseline diagnostic studies, such as complete blood count, serum chemistries, arterial blood gas, radiographs, and electrocardiogram; specific analysis of blood and

urine for mercury; consideration of possible cointoxicants; and meticulous monitoring.

Elemental Mercury

Inhalation of mercury vapors or aspiration of metallic mercury can result in life-threatening respiratory failure; in this situation, stabilization of cardiorespiratory function is the initial priority. Postural drainage and endotracheal suction may be effective in removing aspirated metallic mercury. Parenteral deposition of subcutaneous or intramuscular mercury may be amenable to surgical excision, if well localized (Fig. 92-2).

An adjunct to the initial management of patients with mercury poisoning is consideration for environmental decontamination. Elemental mercury that spills onto solid surfaces should be adsorbed to sand and the resulting mixture then swept into tightly sealed containers. Ideally, a mercury decontamination kit should be used. The kit consists of calcium polysulfide, which contains excess sulfur to convert mercury to water-insoluble mercuric sulfide (cinnabar). Absorbent surfaces, such as carpets, should be removed. Spilled mercury compounds should not be vacuumed because vacuuming could volatilize the substances.[12] Guidance for decontamination of major spills and disposal of materials can be provided by local and federal hazardous materials agencies.

Inorganic Mercury Salts

Ingestion of inorganic mercuric salts may lead to cardiovascular collapse caused by severe gastroenteritis and third-space fluid loss. Fluid resuscitation is a priority. Gastrointestinal decontamination of ingested inorganic salts of mercury is particularly problematic because of their causticity and risk for perforating injury. Nevertheless, one series of mercuric chloride

ingestion of up to 4 g reported recovery without long-term gastrointestinal sequelae in patients who did not succumb to renal failure.[88] Therefore, unless there is high suspicion for penetrating gastrointestinal mucosal injury, removal of mercury from absorptive surfaces should take priority over endoscopic evaluation. The prominence of vomiting makes gastric lavage unnecessary for most patients with inorganic mercury poisoning.

Metals are among the substances that are often considered to be poorly adsorbed to activated charcoal. Nevertheless, the serious nature of late sequelae following mercury absorption, the typically small quantities of mercury ingested, and evidence that inorganic mercuric salts in fact have substantial adsorption to activated charcoal (800 mg mercuric chloride to 1 g activated charcoal in one in vitro study) justify administration of activated charcoal.[5] Whole-bowel irrigation with polyethylene glycol solution may also be useful in removing residual mercury and should be considered, following its progress with serial radiographs.

Organic Mercury Compounds

Organic mercury exposures do not typically present as single, acute ingestions but rather as chronic or subacute ingestion of contaminated food. Therefore, gastrointestinal decontamination is generally moot with respect to organic mercury poisoning. Nevertheless, its irreversible toxicity coupled with unsatisfactory treatments calls for aggressive decontamination when acute ingestions do occur.

Treatment: Chelation

After initial stabilization and decontamination, early institution of chelating agents may minimize or prevent the widespread effects of poisoning. A high degree of protein binding and distribution to the brain are responsible for the lack of efficacy of other measures

to increase mercury clearance, such as peritoneal dialysis and hemodialysis.[75] In one report of the use of continuous venovenous hemodiafiltration (CVVHDF) in combination with a chelating agent, in a patient with severe inorganic mercury poisoning, 12.7% of the ingested dose was recovered in the ultrafiltrate.[21] Hemodialysis may nevertheless ultimately be necessary, because of the acute renal failure that often follows mercuric chloride poisoning.

Chelating agents have thiol groups that are believed to compete with endogenous sulfhydryl groups for the binding of mercury, thereby preventing inactivation of sulfhydryl-containing enzymes and other essential proteins (see Antidotes in Depth: Dimercaprol [British Anti-Lewisite or BAL] and Antidotes in Depth: Succimer [2,3-Dimercaptosuccinic Acid] for further discussion). A history of significant mercury exposure, combined with the presence of typical symptoms of mercury poisoning, is an appropriate indication for the institution of chelation therapy. Elevated blood and urine mercury concentrations can help support the decision to begin chelation therapy in unclear cases, and may also be used to guide duration of therapy. Provocative chelation, in which urinary mercury excretion before and after a chelating dose is compared to determine degree of mercury poisoning, is of dubious value.[38] Chelation tends to increase urinary elimination of mercury, regardless of exposure history and baseline excretion.

Elemental Mercury and Inorganic Mercury Salts

For clinically significant acute inorganic mercury poisoning, dimercaprol (BAL) should be administered for 10 days in decreasing dosages of 5 mg/kg/dose every 4 hours IM for 48 hours, then 2.5 mg/kg every 6 hours for 48 hours, followed by 2.5 mg/kg every 12 hours for 7 days. This dosing regimen of BAL, derived from the use of BAL in lead poisoning, may be adjusted according to clinical response and the occurrence of adverse

reactions.

When a patient is able to take oral medications, BAL therapy can be replaced with 2,3-dimercaptosuccinic acid (succimer) at 10 mg/kg orally 3 times a day for 5 days, then twice a day for 14 days if the GI tract is clear. As headache, nausea, vomiting, abdominal pain, and diaphoresis may result from BAL chelation therapy, oral succimer is recommended in patients who are not acutely ill or who have been chronically poisoned.

Either BAL or succimer are considered the treatments of choice for inorganic mercury poisoning in the United States, but a few other chelating agents deserve mention. DMPS (2,3-dimercapto-1-propanesulphonate) is a water-soluble dimercaprol derivative that is used in Europe. It can be administered both IV and orally. D-Penicillamine is an orally administered monothiol. Its adverse effectsâ€”gastrointestinal distress, rashes, leukopenia, thrombocytopenia, and proteinuriaâ€”although uncommon in therapeutic doses, seriously limit the usefulness of the drug. *N*-acetyl-D,L-penicillamine (NAP), an investigational analog of D-penicillamine, is thought to be a more effective chelator of mercury than is D-penicillamine, perhaps because of its greater stability.[6 , 30]

Organic Mercury Compounds

The neurotoxicity of methylmercury and other organic mercury compounds is resistant to treatment, and therapeutic options are less than satisfactory. In rats, both BAL and D-penicillamine effectively reduced tissue mercury and prevented neurologic toxicity if administered within the first day of a methylmercury injection.[99] Neither agent reversed neurologic toxicity when administered 12 days after methylmercury injection. DMPS, D-penicillamine, NAP, and a thiolated resin all led to a marked reduction of blood half-life of mercury (ie, 10, 24, 23, and 19 days, respectively, vs. 60 days) during the outbreak of

methylmercury poisoning in Iraq in 1971.[17] Clinical improvement was not observed in any treatment group, but it is reasonable to postulate that reducing the total-body burden of methylmercury may prevent or limit progression of

disease. When studied in mice poisoned with methylmercury,[1] succimer was superior to NAP, DMPS, and a thiolated resin in decreasing brain mercury and increasing urinary excretion. Brain mercury was decreased to 35% of control, and total-body burden fell to 19%. Some animal evidence suggests that BAL may increase mercury mobilization into the brain.[9] For this reason and the lack of serious GI symptoms necessitating parenteral chelation, BAL should not be used for the treatment of organic mercury poisoning.

As the neurologic impairment associated with methylmercury is both profound and essentially irreversible, early recognition of poisoning and prevention of neurotoxicity are essential to a successful outcome. Although further investigation is necessary, succimer may prove to be the treatment of choice for methylmercury poisoning because of its apparently low toxicity and reported efficacy in animal trials.

Summary

Mercury poisoning by any of the three major formsâ€”elemental, inorganic, and organicâ€”presents a complex toxicologic problem associated with a large variety of clinical presentations. An ever-present awareness of the problems, coupled with the knowledge of the differing clinical forms is essential for both early recognition and effective treatment. Although some chelating agents do show promise in the treatment of mercury poisoning, neurologic sequelae, particularly those resulting from organic mercury exposures, remain largely irreversible. Promotion of public education regarding the dangers of mercury, its avoidance, and

proper disposal may aid in the prevention of mercury poisoning.

Chapter 93
Nickel

John Curtis
Michael I. Greenberg

Nickel (Ni)

Atomic number = 28

Atomic weight = 58.7

Normal concentrations

Serum = < 1 Âµg/dL (<17 nmol/L)

Urine = < 6 Âµg/L (<100 nmol/L)

A 16-year-old woman presented to her physician complaining of a pruritic rash that began around her umbilicus. She had first noticed small papules several months earlier and over the past 2 weeks the rash had worsened and spread to involve the skin on the anterior neck and flexural areas of the arms. Her physical examination was notable for small areas of erythema and

lichenification on the earlobes, which she stated had begun a year earlier, after she had pierced her ears. There was no fever and no involvement of mucous membranes, joints, palms, or soles. She reported no prescription or nonprescription medications or recreational drug use. Dimethylgloxime spot tests of her belt buckle and earrings were positive for free nickel. A diagnosis of nickel allergy was made, and the patient was treated with topical corticosteroids and antihistamines. She was instructed to avoid exposure to nickel in clothing and jewelry and given a dimethylgloxime test to detect free nickel on metal surfaces. At a followup 1 month later she reported complete resolution of her symptoms.

History and Epidemiology

Nickel is a white, lustrous metal whose name is derived from the German word â€œkupfernickelâ€• or â€œdevil's copper.â€• It was first identified in 1751 in a mineral known as niccolite. Nickel comprises 0.008% of the earth's crust and is found in diverse locations, ranging from meteorites and soil to bodies of fresh- and saltwater.

First produced by the Chinese, nickel has been used as a component in a variety of metal alloys for more than 1700 years. The first malleable nickel was produced by Joseph Wharton following the American Civil War. Wharton went on to sell bulk quantities of nickel to the US government for the minting of 3-cent coins, and later donated the equivalent of 3.3 million of these coins to help fund what is today known as the Wharton School of Business.[65] The modern United States 5-cent piece, the â€œnickel,â€• is actually only approximately 25% nickel by weight.[73]

Nickel ores typically consist of accumulations of nickel sulfide minerals of relatively low nickel content. Although a variety of technical methods for extracting nickel from ore have been

developed, one method of special note was developed in 1890 by Ludwig Mond. He is credited with the discovery of nickel carbonyl. The Mond process for the extraction of nickel involves passing carbon monoxide over smelted ore. This creates nickel carbonyl, which then decomposes at high temperatures to produce purified nickel and carbon monoxide.[65] Nickel has not been mined in the United States since 1993,[14] and despite an increasing worldwide demand, as of 2002 there were still no active domestic nickel mines.[34] Nickel is imported into the United States from other nickel-rich countries such as Canada, Russia, and Australia, while production of nickel in the United States is essentially limited to the recycling of nickel-containing metals.

Nickel is a siderophoric material that forms naturally occurring alloys with iron, a property that has made it useful for many centuries in the production of coins, tools, and weapons. Today, most nickel is used in the production of stainless steel, a highly corrosion-resistant alloy containing 8â€“15% nickel by weight.[79]

Occupational exposure to nickel and nickel-containing compounds occurs in a variety of industries, including nickel mining, refining, reclaiming, and smelting. Chemists, magnet makers, jewelry makers, oil hydrogenator workers, battery manufacturers, petroleum refinery workers, electroplaters, stainless steel and alloy workers, and welders are at increased risk for exposure to nickel and nickel-containing compounds.[41] The vast majority of nonindustrial

human exposures to nickel are usually from dietary and environmental sources. Cigarette smoke also contains nickel and may contribute to human exposure.[26] In the occupational setting, nickel carbonyl is responsible for the great majority of acute nickel toxicity, while in clinical practice, the most common health issue related to nickel is the development of allergic dermatitis from jewelry and clothing. Nickel ranks behind poison ivy and poison oak as the second most common cause of allergic contact

dermatitis;[24] in a recent patch testing study, more than 30% of adolescents demonstrated an allergy to nickel.[20]

Toxicology and Pharmacokinetics

Exposure

Nickel occurs naturally in soil, volcanic dust, fresh- and saltwater, but also enters the environment from the combustion of fuel oil, municipal incineration, nickel refining processes, and the production of steel and other nickel alloys that may allow aerosolized nickel to be disseminated into the environment.

The specific form of nickel emitted to the atmosphere depends on the source. Complex nickel oxides, nickel sulfate, and metallic nickel are associated with combustion and incineration, as well as smelting and refining processes. Consequently, ambient air levels of these forms of nickel tend to be higher in urban areas, and concentrations of nickel in urban household dust may be elevated under certain circumstances and thus may pose some variable exposure risk for young children who crawl or sit on floors.

Nickel carbonyl, $Ni(CO)_4$, deserves special mention. This highly volatile, highly useful, and very deadly liquid nickel compound is commonly used in nickel refining and petroleum processing, and as a chemical reagent. Its high vapor pressure and high lipid solubility lead to rapid systemic absorption through the lungs. In the air and in the body, it decomposes into metallic nickel and carbon monoxide and its toxicity has been compared to that of hydrogen cyanide.[35] Employees are commonly screened for low-level exposure to nickel carbonyl, but disasters such as the Gulf Oil Company refinery incident in 1953, and the Toa Gosei Chemical company incident in 1969, resulted in hundreds of inhalational exposures.[65]

Levels of metallic nickel in drinking water in the United States are

generally below 20 Âµg/L.[42] Elevated levels of nickel in household and other potable and nonpotable water sources may result from corrosion and leaching of nickel alloys present in various plumbing fixtures, including valves and faucets.[2] Although many water suppliers in the United States monitor nickel levels in their water, there is currently no US Environmental Protection Agency (EPA) regulation regarding how much nickel is permissible in drinking water.

Dietary intake is a recognized source of nickel exposure for humans. Foods high in nickel include nuts, legumes, cereals, and chocolate. Although evidence exists for uptake and accumulation of nickel in certain plants, nickel does not seem to bioaccumulate along the food chain.[79] Nickel is not considered an essential element for human health and dietary recommendations for nickel have not been established. Although estimates vary widely, one author estimated that a 70-kg reference human contains 0.5 mg of nickel, giving an average body concentration of 7 ppb.[7] No clear biologic function has been determined for nickel in humans. However, it may serve as a cofactor for various enzymes, or it may facilitate iron absorption or metabolism in microorganisms, as in certain nickel-dependent blue-green algae.[75]

Absorption

Nickel enters the body through the skin, lungs, and gastrointestinal tract. The amount of absorption depends strongly on the solubility of the nickel compound in water. Once in the body nickel exists primarily as the divalent cation. Thus, regardless of the particular nickel compound, it is elemental nickel that is measured in the serum or urine.

Following inhalational exposure, nickel tends to accumulate in the lungs, and only 20â€“35% of nickel deposited in the human lung is systemically absorbed into the bloodstream.[7,25] The remainder of the inhaled material is swallowed, expectorated, or deposited in

the upper respiratory tract. Subsequent systemic absorption from the respiratory tract is dependent on the solubility of the specific nickel compound in question. Soluble nickel salts (nickel sulfate and nickel chloride) are more easily absorbed, whereas the less-soluble oxides and sulfides of nickel have much lower levels of absorption.

A man who died of adult respiratory distress syndrome 13 days after being exposed to fumes containing high concentrations of metallic nickel (approximately 380 mg/m^3) had very high levels of nickel in his urine (700 Âµg/L).[52] This case report demonstrates that metallic nickel can be systemically absorbed from the lungs; however, many authorities believe that pulmonary levels must be high enough to result in local lung tissue injury before systemic absorption occurs following inhalational exposure.

Because soluble nickel compounds tend to be more readily absorbed from the respiratory tract when compared with nonsoluble or poorly soluble nickel,[72] exposure to the soluble nickel chloride or nickel sulfate results in higher urinary nickel concentrations than does exposure to less-soluble nickel oxide or nickel subsulfide. The half-life of nickel in the lungs of rats exposed by inhalation is reported to be 32 hours for nickel sulfate,[28] 4.6 days for nickel subsulfide, and 120 days for green nickel oxide,[8] a fact that probably reflects slow dissolution and absorption from the lungs.

Following ingestion, approximately 27% of the total nickel in nickel sulfate given to humans in drinking water is absorbed, whereas only approximately 1% is absorbed when given in food.[66] Serum nickel concentrations peak between 1.5 and 3 hours following ingestion of nickel.[15,49,66] The bioavailability of nickel increased when nickel was administered in a soft drink, but decreased when nickel was given with whole milk, coffee, tea, or orange juice.[59] The presence of food appears to reduce the absorption of nickel, and most ingested nickel remains in the gut and is excreted in the

feces.

Human studies show that several nickel compounds are capable of penetrating the skin.[23,46] In one study, radioactive nickel sulfate was applied to occluded skin.[46] It was determined that 55â€“77% of the applied nickel was absorbed within 24 hours, with most of the nickel being absorbed in the first few hours. It could not be determined, however, if the nickel had been absorbed into the deep layers of the skin or into the bloodstream. In a study using excised human skin, only 0.23% of an applied dose of nickel chloride permeated skin after 144 hours when the skin was not occluded, whereas 3.5% permeated occluded skin.[23]

Distribution

In human serum, the exchangeable pool of primarily divalent nickel is bound to albumin, L-histidine, and Î±$_2$-macroglobulin.[45] A

nonexchangeable pool of nickel that is tightly bound to a transport protein known as nickeloplasmin also exists in the serum. Nickel crosses the placenta,[56] and may accumulate in breast milk, resulting in the potential for nickel exposure to offspring.[19]

Nickel also appears to be concentrated in various solid organs rather than in serum. An autopsy study of individuals not occupationally exposed to nickel reports the highest concentrations of nickel in the lungs, followed by the thyroid, adrenals, kidneys, heart, liver, brain, spleen, and pancreas.[53] Nickel concentrations in the nasal mucosa are higher in workers exposed to less-soluble nickel compounds relative to soluble nickel compounds,[72] indicating that, following inhalation exposure, less-soluble nickel compounds remain deposited on the nasal mucosa.

Elimination

In humans, most ingested nickel is excreted in the feces; however,

because more than 90% of ingested nickel does not leave the gut,[63] most of the nickel found in feces represents this unabsorbed fraction rather than the elimination of body nickel.[49,66]

Regardless of the route of exposure, absorbed nickel is excreted in the urine and workers occupationally exposed to nickel have increased urinary concentrations of nickel.[4,22,25,29,72] Following inhalational exposure to green nickel oxide, nickel was only excreted in the feces, implying that the removal of nickel oxide from the lungs is macrophage mediated rather than through mechanisms dependant on dissolution and absorption.[8] Following exposure to nickel subsulfide, nickel was excreted in both the urine and the feces, with greater amounts in the urine on days 6â€“14 postexposure. These results indicate that dissolutionâ€“absorption plays an important role in the removal of nickel subsulfide from the lungs; thus, in the lungs, nickel subsulfide behaves essentially like a soluble compound.[8]

The elimination half-life of nickel depends on the source of exposure. It is important to note that prolonged elevation of serum and urine nickel concentrations from inhalational exposure to insoluble nickel represents continued slow absorption.

In nickel workers, urinary excretion increased from the beginning to the end of the shift, indicating that a fraction is rapidly eliminated.[25,72] Similarly, urinary excretion increased as the workweek progressed, indicating a fraction that was excreted more slowly.[25]

Studies with radioactive nickel chloride injected into rats show that 68% of administered nickel is eliminated in the urine during the first day,[48] and urine nickel concentration is commonly assumed to measure exposure over the past 2â€“3 days.[15]

In workers who unintentionally ingested water contaminated with nickel sulfate and nickel chloride, the mean serum half-life of nickel was 60 hours.[64] This half-life reportedly decreased

substantially (to 27 hours) when the workers were treated with intravenous fluids.

There are no data regarding excretion of nickel in humans or animals after dermal exposure.

Clinical Manifestations

Acute

The most important source of acute, nondermatologic nickel toxicity is nickel carbonyl. Exposure to this compound is associated with pulmonary, neurologic, and hepatic dysfunction.[65]

The specific clinical manifestations associated with acute exposure to other forms of nickel depend on the specific compound and route of exposure. Inhalation of nickel-containing aerosolized particles tends to affect the lungs and upper airways directly whereas ingestion and intravenous administration may result in systemic toxicity, usually involving the neurologic system. By far the most common disorder associated with acute exposure to nickel is an allergic dermatitis.

Nickel Dermatitis

Nickel dermatitis was first reported in the late 1800s in nickel-plating workers and was recognized as an allergic reaction in 1925. Since then, nickel has been recognized as a common cause of allergic contact dermatitis. One population survey reported that 3% of males and 15% of females demonstrated evidence of allergy to nickel.[39] The 5-fold greater prevalence of nickel allergy in females is presumably a consequence of their higher rates of body piercing and more frequent wearing of jewelry, both of which are risk factors for nickel sensitization.[37,54]

Nickel dermatitis is classified into two types: primary and

secondary. The more common primary dermatitis presents as a typical eczematous reaction in the area of skin that is in contact with nickel. It is characterized initially by erythematous papules that may proceed to lichenification. Areas typically involved are the wrists, as a result of wearing watches and bracelets, pierced ears, and periumbilical eruptions at the site of contact with nickel-containing buttons on jeans or nickel-containing belt buckles. (See ILNICKEL in the Image Library at http://www.goldfrankstoxicology.com) Approximately 50% of all belt buckles and 10% of buttons on blue jeans contain nickel.[13]

The secondary form involves a more widespread dermatitis as a result of other exposures, such as ingestion, transfusion, inhalation, and implantation of metal medical devices, and may be regarded as a systemic contact dermatitis elicited by nickel. Secondary eruptions are typically symmetrically distributed and may localize in the elbow flexure, on the eyelids, on the sides of the neck and face, and can become widespread. Nickel in foods, excessive skin contact, and certain orthodontic appliances with high nickel content are all linked to this eczematous eruption. Nonetheless, more recent research indicates that standard stainless steel orthodontic appliances do not increase the rate of nickel sensitivity.[50,51]

The most common cause for nickel dermatitis in women is direct contact from jewelry, garments, wristwatches, and occupational contact in the metal, hairdressing, tailoring, hotel, and restaurant industries. In men, nickel dermatitis is often occupational but may also, in some individuals, be related to jewelry, body piercing, and garments.

It is reported that the bimetallic core structure of the 1 euro and 2 euro coins creates an electrical potential that results in the release of nickel when in contact with sweat.[44] Although studies report no increase in the prevalence of nickel sensitivity before and after the switch to the euro in the general population,[37] positive patch tests

to euro coins[47] and cases of dermatitis in certain high-risk patients have been reported.[55]

One study[36] showed that following skin application, nickel salts are retained in the skin for an extended period of time, which could lead to prolonged antigen processing and consequent immune responses in dermal tissue. Additionally, when in contact with the skin, nickel is oxidized to form soluble, stratum corneum-diffusible compounds that may penetrate the intact stratum and have the potential to elicit allergic reactions.[30,31]

The allergic reaction caused by contact with nickel is a type IV delayed hypersensitivity immune response that typically occurs in two phases. In the first phase, sensitization occurs when nickel enters the body. The second phase occurs when the body is reexposed to nickel, at which time allergy manifests. The diagnosis of nickel allergy is suggested by specific historical findings listed in Table 93-1.

TABLE 93-1. Findings Suggestive of Nickel Dermatitis

Previous history of allergic response to jewelry
Multiple piercings
Eruptions at the site of metal contact, or flexural areas if generalized
Eruptions following placement of orthodontic appliances containing high concentrations of nickel (unusual)
Seasonal dermatitis in warm months (increased metalâ€“skin contact and increased sweating)

Nickel Carbonyl

Perhaps the most important cause of acute toxicity from nickel exposure is nickel carbonyl. Nickel carbonyl is a volatile liquid compound that dissociates into carbon monoxide and metallic nickel. It is the most potentially harmful form of nickel and the majority of acute occupational nickel exposures involve nickel carbonyl. Once dissociated, nickel carbonyl can be oxidized in tissues to Ni^{2+}. Nickel carbonyl is described as having a â€œmustyâ€• or â€œsootyâ€• odor, although thresholds for detection vary considerably and potentially harmful exposures cannot be excluded simply by a reported lack of odor. Exposure to concentrations <100 mg/m^3 is fatal in rats after 20 minutes.[61,67]

Nickel carbonyl exposure may cause symptoms rapidly or symptoms may be delayed. In a series of 179 exposures, approximately 40% of patients reported symptoms within 1 hour of exposure. It is important to note however that symptoms were delayed for approximately 1 week in 20% of patients, and even patients with mild initial symptoms could develop severe delayed symptoms, although usually, within the next 2 days.[58] In patients who developed symptoms shortly following exposure, the initial manifestations involved nonspecific complaints, including respiratory tract irritation, chest pain, cough, dyspnea, frontal headache, dizziness, weakness, and nausea. Cases manifesting only these initial signs are categorized as mild intoxication.[58]

Symptoms of severe acute nickel carbonyl poisoning generally develop over the course of several hours to days and may be associated with acute lung injury and interstitial pneumonitis. Myocarditis, marked by prolonged ECG changes, including ST- and T-wave changes, as well as QTc interval prolongation, are reported.[58] Neurologic symptoms associated with severe poisoning include altered mental status, seizures, and extreme weakness that sometimes necessitates mechanical ventilation. A moderate leukocytosis (10,000â€“15,000 white blood cells/mm^3), nonspecific opacities on chest radiography, and elevation of transaminases may occur, but these tend to resolve over the

course of several weeks. Deaths from nickel carbonyl exposures are typically caused by interstitial pneumonitis and cerebral edema occurring within 2 weeks of initial exposure.[67] Survivors usually recover completely, although the development of a prolonged neurasthenic syndrome can occur and may last in some cases for up to 6 months.[58]

Parenteral Administration

Acute parenteral toxicity from nickel-containing compounds was associated with water used in hemodialysis which was heated in a nickel-plated tank.[77] The concentration of nickel in the delivered water was 0.25 mg/L, and serum concentrations reportedly reached over 3 mg/L. Through back-extrapolation, serum concentrations were estimated to have been as high as 9 mg/L. These patients developed nonspecific symptoms, including headache, nausea, and vomiting, similar to nickel carbonyl poisoning, although no respiratory complaints were reported. The effects resolved after several hours, and the patients recovered without sequelae.[77]

Acute ingestions of contaminated water containing 1.63 g Ni^{2+}/L as nickel salts caused nausea, vomiting, diarrhea, weakness, and headache, as well as pulmonary symptoms, including cough and dyspnea, lasting up to 48 hours.[64] Estimated ingested doses of nickel (as Ni^{2+}) were 0.5â€“2.5 g and serum concentrations as high as 13.4 Âµg/L were reported. The death of a 2-year-old female followed ingestion of 2.2â€“3.3 g Ni in the form of nickel sulfate crystals. Following ingestion, this child reportedly developed depressed mentation, nuchal rigidity, mydriasis, erythema, tachycardia, and acute lung injury.[21]

Although transdermal absorption is typically of minor clinical significance, disruption of the normal integument may allow for more efficient systemic absorption. A metal refinery worker suffered a 40% body surface area partial-thickness chemical injury

resulting from exposure to a chemical mixture that included nickel carbonate and nickel sulfate. Preincident, this individual's measured serum nickel concentration was 0.023 Âµmol/L (1.33 Âµg/L). On postinjury day 6 the serum concentration was 0.490 Âµmol/L (28 Âµg/L). Chelation with $CaNa_2EDTA$ was begun for concomitant cobalt poisoning, and the patient recovered without manifesting signs of nickel toxicity.[43]

Chronic Nickel Exposure

Chronic inhalational exposure to nickel is associated with injury as well as specific histologic changes in the nasopharynx and upper respiratory tract, including atrophy of the olfactory epithelium,[27] rhinitis, sinusitis, nasal polyps, and septal damage.[11] More distal pulmonary effects may include asthma[38] and pulmonary fibrosis.[9,27]

Although evidence of the effects of chronic nickel exposure on reproduction remains limited, a study of Indian welders occupationally exposed to nickel and cadmium showed reduced sperm count and quality, with a positive correlation between sperm tail defects and serum nickel concentrations.[18]

The International Agency for Research on Cancer (IARC) classifies nickel compounds as a group 1 carcinogen.[32] The potential for and mechanisms of carcinogenesis of nickel depend heavily on the specific compounds studied. Animal studies show a threshold doseâ€“response curve for inflammation with soluble compounds (nickel sulfate), and similar curves describing the risks of pulmonary cancers with the less-soluble nickel oxides and nickel subsulfide.[57] Although earlier studies of occupationally exposed workers, primarily electroplaters and refinery workers, also showed increased rates of nasal and pulmonary tumors, more recent studies of refinery workers in more modern environments with lower levels of nickel exposure do not show increased risks of cancer or any cause of mortality.[60]

Soluble compounds such as nickel sulfate cause a threshold-dependent inflammatory response, and may act as promoters of malignancies without a directly genotoxic effect. Insoluble nickel oxides and nickel sulfide bind to chromatin and nucleic acids[16] and also affect expression of various mRNAs.[76] Thus under some conditions, these compounds may be carcinogenic through genetic

and/or epigenetic mechanisms. The more potent carcinogenic effects of insoluble nickel compounds may be a consequence of their increased cellular uptake.[17]

Diagnostic Testing

Although nickel is widely distributed to many body fluids and tissues, urine and blood are the most commonly analyzed samples. Urine collection should ideally use acid-washed, metal-free containers. Some authors recommend correcting urinary nickel concentration per gram of urine creatinine, but it is not clear that this offers any particular advantage in clinical decision making. The average nickel concentration in serum is 0.3 Âµg/L, whereas the value in urine ranges from 1â€“3 Âµg/L.[70] Concentrations among workers occupationally exposed to nickel may be substantially higher and serum concentrations of more than 8 Âµg/L are indicative of excessive exposure.[40]

Nickel concentrations rise in urine, serum, and whole blood following oral administration. In these studies, serum concentrations were slightly higher than, but correlated well with whole blood. Urine and blood concentrations primarily reflect exposure in the past 2 days.[15]

Urine nickel concentrations are used more commonly than blood for monitoring of workplace exposures and for prognostic and therapeutic decision making in nickel carbonyl exposures. An 8-hour collection is typically performed, and the average urinary excretion of nickel (in these nickel workers) is 2 Âµg/L, with an

upper limit of normal of 5 Âµg/L. In cases of nickel carbonyl poisoning, concentrations of <100 Âµg/L in the initial 8-hour specimen may imply mild toxicity. Concentrations of 100â€“500 Âµg/L are classified as moderate, while concentrations >500 Âµg/L are categorized as severe poisonings.[67] These guidelines are often used in guiding treatment decisions. Urine nickel concentrations rise prior to the onset of symptoms in nickel carbonyl poisoning, making this a potentially useful screening tool for both workforce surveillance and acute exposures.

Testing metal surfaces for free nickel is possible and sometimes necessary in the evaluation and treatment of nickel dermatitis. Patients with clinically important sensitivity or suspect medical histories can order an inexpensive, commercially packaged dimethylgloxime spot test, allowing them to test metal objects for the presence of free nickel.[13]

Treatment

The first step in treatment of nickel-related medical problems is eliminating the exposure, which includes detection and removal of the source. In the case of acute exposures to nickel carbonyl, removal of clothing to prevent continued exposure and thorough skin decontamination may be necessary.

Symptomatic treatment for pulmonary symptoms associated with hypoxia includes the administration of supplemental oxygen. The use of bronchodilators and corticosteroids may also be necessary for the treatment of concomitant bronchospasm. Mechanical ventilation will be required in the most severe cases.

The administration of intravenous fluids to promote diuresis reduces the half-life of orally ingested nickel chloride by approximately 50%.[64] It is important to note, however, that hemodialysis does not effectively remove nickel from the serum.[77]

Chelation

Because there are no controlled human trials, specific recommendations for the use of chelation to treat nickel toxicity are not currently supported by the literature. As a result, extrapolation from animal studies and case reports are the bases for most treatment regimens. Most studies and reports involving treatment have focused on workers exposed to nickel carbonyl.

Several drugs are proposed as potential treatments for nickel carbonyl exposures. Studies in rats with various chelating agents show some protection by administration of British anti-Lewisite (BAL) and D-penicillamine,[78] whereas calcium EDTA had no protective effect.[62] Although BAL was been used in the past,[67] the most recent literature has focused on the use of diethyldithiocarbamate (DDC) (Chaps. 77 and 96).

DDC is a chelating chemical formerly used as the color reagent for urine nickel measurements. Rats exposed to several times the LD_{50} (median lethal dose for 50% of test subjects) for nickel carbonyl had dramatically reduced mortality when pretreated with DDC; the antidotal efficacy, however, decreased with increasing delay to treatment.[6] A proposed treatment regimen for exposed workers focused on analysis both of the exposure and of the initial 8-hour urine collection.[67] Patients with suspected severe poisonings are typically given the first gram of DDC in divided oral doses. When less-severe exposures are suspected, treatment decisions are based on the urinary nickel concentration. At concentrations <10 Âµg/dL, no initial therapy is given as delayed symptoms are unlikely to develop. At concentrations between 10 and 50 Âµg/dL, an oral regimen consisting of 1 g DDC initially, 0.8 g at 4 hours, 0.6 g at 8 hours, and 0.4 g at 16 hours is used. DDC is continued at a dose of 0.4 g every 8 hours until there is symptomatic improvement and urine nickel concentration is normal. Severe exposures with urinary nickel concentrations >50 Âµg/dL can be treated using the same regimen, although these

patients frequently require closer monitoring. Critically ill patients are given parenteral DDC starting at a dose of 12.5 mg/kg. However, given the animal data that the route and timing of administration are important to survival, some authors recommend that parenteral DDC be given as soon as possible following nickel carbonyl poisoning.[12] Although typically well-tolerated, DDC is capable of inducing a disulfiram reaction (Chap. 77) if taken with alcohol, and there are concerns about using DDC when there is concurrent cadmium exposure.[3]

Disulfiram is metabolized into two molecules of DDC. Given that DDC is not pharmaceutically available in the United States, there is some interest in the use of disulfiram as an antidote for nickel carbonyl. Although case reports describe successful treatment of nickel carbonyl toxicity with disulfiram,[35] concern exists because of animal studies showing that disulfiram increased nickel concentration in brain tissue.[5] One treatment regimen was 750 mg PO every 8 hours for 24 hours, followed by 250 mg every 8 hours.[35]

Considering that the majority of the literature and almost all human case reports of nickel carbonyl refer to the use of DDC, it is considered the treatment of choice for nickel toxicity. Although commonly available as a reagent, pharmaceutical-grade DDC is not produced commercially. It is recommended that the regional poison control center be contacted if necessary to assist with treatment decisions.

Treatments evaluated for divalent nickel exposure are D-penicillamine and *N*-benzyl-D-glucamine dithiocarbamate (NBG-DTC), which, while not commonly available, more effectively lowers brain nickel concentrations than does DDC, perhaps because of its lower lipid solubility.[68]

Contact dermatitis from nickel is treated using standard measures, including avoidance, topical steroids, and oral antihistamines.

Some patients have benefited from dietary alteration to reduce nickel intake. Although sometimes advised, there does not appear to be a role for avoiding stainless steel cookware to reduce the nickel content of food.[1]

Summary

Nickel is an important metal that is ubiquitous in the human environment and vital to the functioning of an industrialized society. This constant exposure to nickel is reflected by high rates of nickel sensitivity and dermatitis in the public. Although systemic toxicity from nickel is rare, it is a potentially important cause of occupational illness. Acute toxicity from nickel carbonyl and the potential cancer risk posed by chronic inhalation of nickel-containing dusts and fumes remain important concerns in many industries.

Chapter 94
Selenium

Diane P. Calello

Selenium (Se)

Atomic number = 34

Atomic weight = 78.96

Normal concentrations

Whole Blood = 0.1â€“0.34 mg/L

Serum = 0.04â€“0.6 mg/L

Urine = <0.03 mg/L

Hair = 0.36 ng/g

A 30-year-old corrections officer was brought to the emergency department by his girlfriend 2 hours after a suicidal ingestion of gun bluing solution. The label on the empty bottle revealed that it

contained 2% selenious acid and copper nitrate. On physical examination, his vital signs were: blood pressure, 80/30 mm Hg; pulse, 120 beats/min; respiratory rate, 18 breaths/min; temperature 98.6Â°F (37Â°C), and pulse oximetry revealed 100% oxygen saturation on room air. He was somnolent but arousable, and complained of abdominal pain followed by several episodes of bloody emesis. Further evaluation revealed an ECG with diffuse T-wave flattening and ST changes, creatinine of 1.5 mg/dL, and the following arterial blood gas values: pH, 7.1; PCO_2, 28 mm Hg; PO_2, 100 mm Hg. His urinalysis was positive for blood but negative for erythrocytes; the creatine phosphokinase was 1430 IU. His hepatic aminotransferases were also elevated.

Because of the delay in presentation and the suspicion of caustic esophageal injury, he did not receive gastrointestinal decontamination. Two large-bore IV lines were inserted and 3 L of 0.9% sodium chloride was administered. Despite aggressive volume resuscitation, his blood pressure fell to 70/26 mm Hg, prompting the administration of IV dopamine (15 Âµg/kg/min) and subsequently epinephrine via a central venous line. He developed ectopy with multiple premature ventricular complexes, and his mental status deteriorated further. Cardiac arrest followed soon thereafter, with ventricular fibrillation progressing quickly to asystole. Further resuscitation attempts were unsuccessful, and he expired 12 hours after ingestion. A serum selenium concentration was later reported as 46 mg/L. Postmortem pathologic examination revealed severe corrosive gastritis and red pigmentation of all viscera.

Selenium was discovered by JÃ¶ns Berzelius in 1817 as a contaminant of sulfuric acid vats that was causing illness in Swedish factory workers. He originally believed it to be the element tellurium (from the Latin *tellus*, â€œearthâ€•), but on finding it to be an entirely new, yet similar, element, he named it for the Earth's satellite (from the Greek *selene*, â€œmoonâ€•). Selenium has unusual light-sensitive electrical conductive

properties, leading to its widespread use in industry. It is both an essential component of the human diet, as well as a potentially deadly poison.

History and Epidemiology

Much of what is known about selenium centers around its role as an essential trace element required in the diet of living things, not around its toxic properties. In the 1970s, it was discovered to be an essential cofactor of the enzyme glutathione peroxidase. Keshan disease, an endemic cardiomyopathy associated with multifocal myonecrosis, periacinar pancreatic fibrosis, and mitochondrial disruption, was described in 1979 in Chinese women and children who consumed a selenium-poor diet over several years.[11] Kashin-Beck disease, a disease causing shortened stature as a result of chondrocyte necrosis, is described in young children in Russia, China, and Korea; although other factors are also likely involved, people with this disease show some improvement with selenium supplementation.[1]

These observations prompted the establishment, in 1980, of the United States' recommended daily allowance (RDA) of selenium. Taking into account the level of supplementation required to

achieve optimal glutathione peroxidase activity in selenium-deficient study populations, as well as the amounts required to cause toxicity, the recommendation calls for 55 Âµg/d. Deficiency occurs below 20 Âµg/d.[11]

Chronic selenium toxicity, or selenosis, has occurred throughout history. Described first in animals, the acute syndrome of â€œblind staggersâ€• and the more chronic â€œalkali diseaseâ€• affected livestock eating highly seleniferous plants, causing blindness, walking in circles, anorexia, weight loss, blindness, ataxia, and dystrophic hooves. Humans in seleniferous areas of China and Venezuela develop similar integumentary symptoms

(dermatitis, hair loss, and nail changes) at an intake >100 times the RDA, approximately 6000 Âµg/d.[5,37]

Selenium is found in abundance and widely distributed throughout the earth's crust, usually as a metal selenide in sulfide ores such as marcasite, arsenopyrite, and chalcopyrite. It is found in the soil where it has leached from bedrock, in groundwater, and in volcanic gas. The highest soil levels of selenium in the United States are in the midwest and west. Dietary selenium is easily obtained through meats, grains, and cereals. Brazil nuts, grown in the foothills of the highly seleniferous Andes Mountains, contain the highest concentration measured in food, but chronic selenium toxicity from Brazil nuts has not been reported and would only be expected after massive ingestion.[1]

In industry, selenium is generated primarily as a byproduct of electrolytic copper refining, and in the combustion of rubber, paper, municipal waste, and fossil fuels. In general, selenium compounds are used in glass manufacture and coloring, photography and xerography, rubber vulcanization, and as insecticides and fungicides. Selenium sulfide is the active ingredient in many antidandruff shampoos. Gun bluing solution, used by law enforcement for cleaning of the exterior surface of firearms, is composed of selenious acid, as well as other compounds, such as cupric sulfate in hydrochloric acid, nitric acid, copper nitrate, and methanol. Table 94-1 lists industrial uses of selenium compounds. Table 94-2 lists common acceptable selenium exposure concentrations.

Chemical Principles

Selenium is a nonmetal element of group VIA of the periodic table, which also contains oxygen, sulfur, and tellurium. Selenium exists in elemental, organic and inorganic forms, with important oxidation states of 0 (elemental), â€“2 (selenide, Se^{2+}), +2 (selenite, SeO_3^{2+}) and +4 (selenate, SeO_4^{2+}). Solubility in water

generally increases with oxidation state, so elemental selenium and metal selenides are insoluble, whereas alkali selenites and selenates are highly water soluble. Selenium behaves similarly to sulfur both in its tendency to form compounds and in biologic systems.[1] Selenium is both photovoltaic (able to convert light to electricity) and photoconductive (conducts electricity faster in bright light), which has led to its use in photography, xerography, and solar cells.

TABLE 94-1. Selenium Compounds and Their Uses

Chemical Formula	Name	Uses
Se	Selenium, elemental	Photography, catalyst, xerography
SeS_2	Selenium sulfide	Antidandruff shampoo
SeO_2	Selenium dioxide	Catalyst, photography, xerography, glass decolorizer, vulcanization of rubber
$SeOCl_2$	Selenium oxychloride	Solvent, plasticizer
SeF_6	Selenium hexafluoride	Gaseous electrical insulator

H_2SeO_3	Selenious acid	Gun bluing solution
H_2Se	Hydrogen selenide, selenium hydride	â€”
Na_2SeO_3	Sodium selenite	Glass and porcelain manufacture
Na_2SeO_4	Sodium selenate	Insecticide

TABLE 94-2. Selenium Regulations and Advisories

Oralâ€”recommended intake and exposure limits		
RDA (2000)	55 Âµg/d[a]	(0.8 Âµg/kg/d)
NAS-TUL ATSDR-chronic oral MRL[b]	400 Âµg/d 5 Âµg/kg/d	(5.7 Âµg/kg/d)
Waterâ€”limits		

WHO	Drinking water	0.01 mg/L
FDA	Bottled water	0.01 mg/L
EPA	MCL, Drinking	0.05 mg/L
Airâ€”limits[c]		
NIOSH		
REL (TWA)		0.2 mg/m^3
IDLH		1.0 mg/m^3
OSHA		
PEL (TWA)		0.2 mg/m^3

ATSDR = American Toxic Surveillance and Disease Registry; EPA = Environmental Protection Agency; FDA = Food and Drug Administration; MCL= maximum contaminant level; MRL = minimal risk level; NAS = National Academy of Sciences; NIOSH = National Institute for Occupational Safety and Health; OSHA = Occupational Safety and Health Administration; PEL = permissible exposure limit; RDA = recommended daily allowance; REL = recommended exposure limit; TUL = tolerable upper limit; TWA = time-weighted average; WHO = World Health Organization.

[a]Values differ for pregnant and lactating women, children,

and neonates.
[b]No acute or intermediate MRL has been established. Chronic = >365 days.
[c]Ambient background air concentrations are usually in the ng/m^3 range.

At least three allotropes of elemental selenium are described: a gray substance, which predominates at room temperature, red crystals, and a red amorphous powder.[1] In general, toxicity from elemental selenium is rare and only occurs from long-term exposure. Hydrogen selenide (H_2Se) is formed from the reaction of water or acids with metal selenides, or from the reaction of hydrogen with soluble selenium compounds; at room temperature it exists in gaseous form and results in industrial inhalation exposures. The organic alkyl compounds (dimethylselenide, trimethylselenide) are the least toxic and are byproducts of endogenous selenium detoxification (methylation). Selenious acid (H_2SeO_3) is the most toxic form of selenium, generated from the reaction of selenium dioxide with water; ingestion of selenious acid is usually fatal.

Pharmacology and Pathophysiology

There are 3 categories of selenium normally found in the body. First, selenium-specific proteins, or selenoproteins, contain selenocysteine residues and play specific roles primarily in redox (reduction-oxidation) physiology. Second, there are a number of nonspecific proteins containing selenium, for example as selenomethionine in place of methionine, in which selenium appears to have no specific role but which may represent a storage form of selenium; other examples include nonspecific proteins containing selenocysteine, and ubiquitous plasma proteins, such as albumin, which bind selenium. Third, selenium has several

inorganic forms throughout the body, such as selenate, alkyl selenides, and elemental selenium (Se^0).

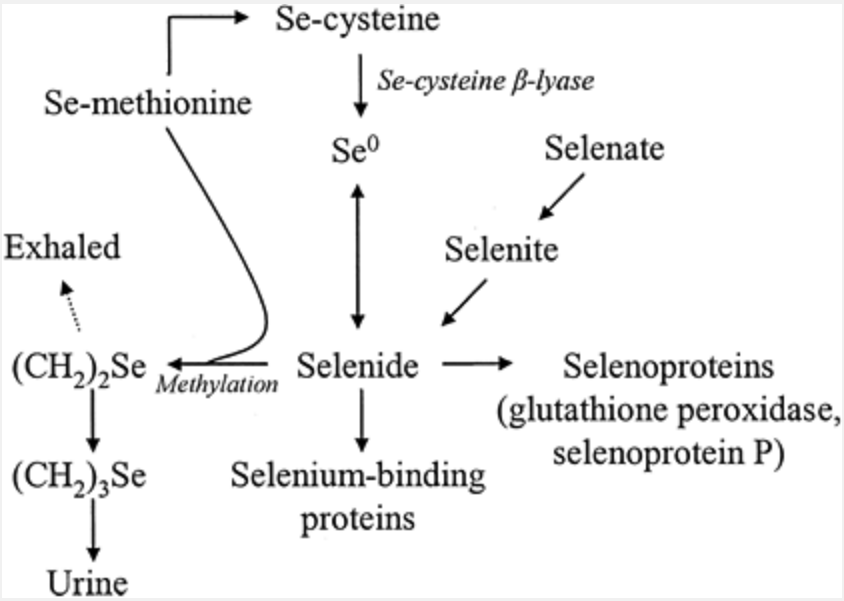

Figure 94-1. Metabolism of selenium. The selenide anion is central in selenium metabolism. Organic selenocysteine is converted via the Î²-lyase enzyme to elemental selenium, then to selenide. Selenomethionine may either undergo transsulfuration to selenocysteine or methylation to excretable metabolites. The selenate and selenite salts are reduced to selenide. Selenide then undergoes one of three processes: methylation, incorporation into selenoproteins, or binding by nonspecific plasma proteins.[1,13]

The known specific selenoproteinsâ€”glutathione peroxidase, iodothyronine 5-deiodinases, and thioredoxin reductaseâ€”each contain a selenocysteine residue at the active site. The most well-studied selenoprotein is glutathione peroxidase, responsible for detoxification of reactive oxygen species. Using reduced

glutathione (GSH) as a substrate, glutathione peroxidase catalyses the reduction of hydrogen peroxide to water and oxidized glutathione (GSSG, or glutathione disulfide) (Fig. 94-1); the reaction is made possible by oxidation of the selenocysteine unit on the enzyme.[4,30] Other selenocysteine-containing proteins also appear to have antioxidant properties, such as thioredoxin reductase. The thyroid hormone deiodinases are responsible for the conversion of thyroxine (T_4) to the active triiodothyronine (T_3) form.

In selenium deficiency, glutathione peroxidase activity is decreased, and GSH and glutathione-S transferases are increased.[30] Consequently, selenium-deficient rats are much less vulnerable to substances detoxified by glutathione-S transferase, such as acetaminophen and aflatoxin B.[6] However, selenium deficiency potentiates toxicity to prooxidants such as nitrofurantoin, diquat, and paraquat.[6] In animal studies of metal toxicity, selenium also appears to either increase or decrease (depending on the individual metal) the effects of silver, cadmium, arsenic, copper, zinc, mercury, and fluoride; conversely, vanadium, tellurium, and arsenic modify the effects of selenium deficiency or excess.[14,20,27,32] Although it is proposed that this is accomplished through the formation of insoluble seleniumâ€“metal complexes, these relationships are not entirely understood.[13]

Less is known about the biochemical mechanism of selenium toxicity, and what is known is not from overdose data, but from in vitro studies. Paradoxically, excess selenium causes oxidative stress, presumably as a result of prooxidant tendencies of selenide (RSe^-) anions. In addition, the replacement of selenium for sulfur in enzymes of cellular respiration may cause mitochondrial disruption, and the substitution of selenomethionine in place of methionine may interfere with protein synthesis. Selenium's integumentary effects are also most likely a result of interpolation of selenium into disulfide bridges of structural proteins such as keratin.[35]

Pharmacokinetics and Toxicokinetics

Gastrointestinal absorption varies with the species of selenium, and human data are limited. Elemental selenium is the least bioavailable (up to 50%), followed by inorganic selenite and selenate salts (75%);[23] selenious acid is quite well absorbed in the lungs and gastrointestinal tractâ€”approximately 85% in animal studies.[10] Organic selenium compounds are the most absorbed at approximately 90% as determined by isotope tracers in human volunteer studies.[2,23]

Inhalational absorption was documented in a group of workers exposed to selenium dioxide and hydrogen selenide gas,[2,17] but quantitative inhalation studies in humans are not available. Dermal absorption appears to be limited. Selenium disulfide shampoos are not systemically absorbed as measured by urinary selenium levels,[10] except in cases of repeated use on excoriated skin.[29]

The toxic dose of selenium varies widely between selenium compounds, as demonstrated by LD_{50} (median lethal dose for 50% of test subjects) animal studies,[32] and parallels gastrointestinal bioavailability. Elemental selenium has no reported adverse effects in acute overdose, although long-term exposure can be harmful. The selenium salts, particularly selenite, are more acutely toxic, as is selenium oxide (SeO_2) through its conversion to selenious acid in the presence of water. Selenious acid may be lethal with as little as a tablespoon of 4% solution in children.

The metabolic fate of selenium centers on the selenide anion (Fig. 94-1), which has 1 of 3 final processes: (a) incorporation into selenoproteins such as glutathione peroxidase and triiodothyronine; (b) binding by nonspecific plasma proteins such as albumin or globulins; or (c) hepatic methylation into nontoxic, excretable metabolites. Trimethylselenide is the primary metabolite and is excreted by the kidneys, the major elimination

pathway for selenium. Fecal elimination also occurs. Dimethylselenide production is usually minor, but increases with dose or exposure; this compound is volatilized through exhalation and sweat, and is responsible for the garlic odor of patients exposed to excess selenium. The remaining selenium in the body is >95% protein-bound within 24 hours.[1,32] Toxicokinetic data are limited and vary by compound.

Clinical Manifestations

Acute Overdose

Dermal and Ophthalmic Exposure

Dermal exposure to selenium dioxide, which is converted to selenious acid, and to selenium oxychloride, a vesicant that is hydrolyzed to hydrochloric acid, causes significantly painful caustic burns, although the tissue destruction is not usually severe.[12] Excruciating pain may result from accumulation under fingernails. Unsurprisingly, selenious acid can also produce a pustular and ulcerative caustic burn.

Corneal burns with severe pain, lacrimation, and conjunctival edema are reported after exposure to selenium dioxide sprayed unintentionally into the face.[24] In chronic exposures, â€œrose eye,â€• a red discoloration of eyelids with palpebral conjunctivitis, is also described.

Inhalational Exposure

When inhaled, all selenium compounds have the potential to be respiratory irritants. In general, inhaled elemental selenium dusts are less systemically toxic than those compounds that are converted to selenious acid. Hydrogen selenide inhalation toxicity

is reported repeatedly throughout the industrial literature.[8] Hydrogen selenide is oxidized to elemental selenium, so acutely toxic exposures are limited to confined spaces where the hazardous gas may accumulate; however, like hydrogen sulfide (H_2S), its ability to cause â€œolfactory fatigue,â€• which renders the exposed persons anosmic to the toxic fumes, can be very hazardous (Chap. 21).[8] Acute exposure to high concentrations of hydrogen selenide gas produces throat and eye pain, rhinorrhea, wheezing, and pneumomediastinum, with residual restrictive and obstructive disease that can remain on pulmonary function testing years later.[31]

In contrast, selenium dioxide and selenium oxide fumes form selenious acid in the presence of water in the respiratory tract. Twenty-eight workers in a selenium rectifier plant were inadvertently exposed to smoke and high concentrations of selenium oxide in an enclosed area. Initial symptoms included bronchospasm with upper respiratory irritation and burning. Some acutely developed hypotension, tachycardia, and tachypnea, which resolved over 2 hours. Patients went on to develop chemical pneumonitis, fever, chills, headache, vomiting, and diarrhea. Five patients required hospitalization for respiratory support, with fever, leukocytosis, and bilateral infiltrates. All patients recovered without sequelae.[36]

Selenium hexafluoride is a caustic gas used in industrial settings as an electrical insulator. Its caustic properties are derived from its conversion, in the presence of water, to elemental selenium and hydrofluoric acid. Severe pain and burning of the eyes, skin, and respiratory tract similar to that seen with hydrofluoric acid exposure can occur following inhalation of selenium hexafluoride (Chap. 101).

Oral Exposure

There are no reported cases of acute overdose with elemental

selenium. All reported cases of acute oral selenium poisoning have occurred with selenium salts, their corresponding acids, and selenium oxides, and the mechanism remains unclear. Gastrointestinal symptoms predominate at low doses, with attendant minor abnormalities in hepatic aminotransferases serum bilirubin and alkaline phosphatase. More severely poisoned patients develop weakness, elevation in creatine phosphokinase (CPK) concentrations, and renal insufficiency as a result of direct tissue injury, myoglobinuria, and hemolysis. Caustic esophageal and gastric burns, myocardial and mesenteric infarction, and metabolic acidosis all contribute to poor outcome in these patients.[25,28] The unifying feature in all serious cases of selenium poisoning is refractory hypotension, a combined product of decreased contractility from acute toxic cardiomyopathy and decreased peripheral vascular resistance. Multisystem organ failure often results, with the acute respiratory distress syndrome, cerebral edema, and death.[9,19,34] The underlying mechanism for this clinical syndrome is not well understood. Postmortem red pigmentation of viscera is also consistently reported and is likely caused by the accumulation of selenium compounds, some of which have a red or rust color (see Chemical Principles above).

Ingestion of the selenium salts is associated with the above symptoms, but usually with good outcome.[9,34] A 15-year-old female survived a suicidal ingestion of approximately 22 mg/kg selenium as sodium selenate, possibly because of near-immediate induction of emesis. She presented with strong garlic odor, diarrhea, and diffuse T-wave flattening on ECG, which progressed to T-wave inversions and a prolonged QTc interval that resolved over 2 weeks. Her serum selenium concentration was 3.1 mg/L on admission (normal: 0.04â€“0.6 mg/L), with a 24-hour urine concentration of 0.8 mg/L (normal: <0.03 mg/L). She underwent treatment with vitamin C and British anti-Lewisite (BAL) and recovered.[9]

Ingestion of even small quantities of selenious acid, however, is

almost invariably fatal. As little as 15 mL of a 4% selenious acid gun bluing solution can be fatal in a child. Selenium oxide and dioxide are also highly toxic via the oral route, presumably because of their conversion to selenious acid. A 17-year-old boy who ingested, in a suicide attempt, an estimated 10 g of selenium dioxide used as a chemistry reagent was found apneic and pulseless, and failed resuscitation; pathology revealed orange-brown discoloration of all viscera.[19] In a similar scenario, 2 g of selenium dioxide produced a severe but nonfatal caustic (grade III) gastric ulceration.[18]

Chronic

Elemental selenium is implicated in a number of long-term exposure cases. Many descriptions of chronic selenium toxicity, or selenosis, come from inhabitants of the Hubei province of China from 1961â€“1964, the majority of whom developed clinical signs after an estimated average consumption of 5 mg of selenium per day (but as little as 910 Âµg/d) derived from local crops and vegetation. Inhabitants of a seleniferous area of Venezuela, consuming approximately 300â€“400 Âµg/d, also develop symptoms of selenium excess; however, the low socioeconomic and poor dietary status of the subjects may also contribute to their symptoms. In contrast, US residents in a seleniferous area with a high selenium intake (724 Âµg/d) over 2 years who were compared to a control population and monitored for symptoms and laboratory abnormalities, remained asymptomatic, with only a clinically insignificant elevation of hepatic aminotransferases in the high-selenium group.[22] Average selenium levels were serum, 0.215 mg/L; whole blood, 0.322 mg/L; and urine 0.17 mg/L.

Selenosis is similar to arsenic toxicity, with its most consistent manifestations being nail and hair abnormalities. The hair becomes very brittle, breaking off easily at the scalp, with regrowth of discolored hair, and the development of an intensely pruritic scalp

rash. The nails are also brittle, with white or red ridges that can be either transverse or longitudinal; the thumb is usually involved first, and paronychia can develop. The skin becomes erythematous, swollen, and blistered, slow to heal, and with a persistent red discoloration. Increased dental caries may occur.[15] Neurologic manifestations include hyperreflexia, peripheral paresthesia, anesthesia, and hemiplegia. Although cardiotoxicity is described with both selenium deficiency and acute poisoning, no such cases are reported with human selenosis. Aside from one case described in the Chinese series, in which there is insufficient postmortem data, there are no reported deaths from intermediate or chronic exposure. Selenium concentrations in these populations averaged 3.2 mg/L (range: 1.3â€“7.5) in whole blood, 2.68 mg/L (0.88â€“6.63) in urine, and 32.2 ng/g in hair.[37]

Selenosis may also occur as a result of overzealous dietary supplement use. In 1983, a 57-year-old woman taking a selenium supplement labeled as 150-Âµg tablets developed progressive symptoms of alopecia, nail streaking, paronychia, and fingernail loss. Three months into her course the manufacturer recalled the lot for superpotency; analysis revealed the tablets contained instead 31 mg of selenium, a dose 200 times higher than labeled. Subsequently, 12 other individuals on the same supplement developed symptoms. All patients recovered after discontinuation of the supplement.[7,16]

Selenosis also is reported in the industrial setting. Copper refinery workers demonstrate garlic odor and gastrointestinal and respiratory symptoms coincident with exposure to selenium dust and fumes.[17] Long before regulatory workplace standards were in place, intense garlic odor of the breath and secretions was recognized as a reason to remove a worker from selenium until the odor subsided. Neuropsychiatric findings such as fatigue, irritability, and depression are reported throughout the industrial literature and are difficult to quantify. Early reports exist such as

the factory worker being â€œunable to tolerate his children about himâ€• at the end of the day when working with selenium.

Although carcinogenicity is suggested by a number of animal studies, in humans the data available suggest, if anything, an inverse correlation between selenium intake and cancer risk. The International Agency for Research on Cancer (IARC) does not list selenium as a suspected carcinogen.[2] Animal studies also suggest that selenium has embryotoxic and teratogenic properties.[13]

Diagnostic Testing

Over time, selenium is incorporated into blood and erythrocyte proteins. As a result, whole-blood and erythrocyte selenium concentrations are more useful for quantifying chronic exposure than plasma and serum concentrations, which change rapidly in relation to selenium intake and are better measures following acute exposure. In general, a serum concentration >1 mg/L is associated with mild toxicity, and a concentration >2 mg/L is associated with serious toxicity.[2] However, concentrations do not demonstrate a predictable relationship with exposure, toxicity, or time course.

Urine concentrations reflect very recent exposure, as urinary excretion of selenium is maximum within the first 4 hours. In addition, urine concentrations are an imperfect measure as they can be affected by the most recent meal and hydration status. However, in general a normal urinary concentration is <0.03 mg/L.

Hair concentrations of selenium were measured in the Chinese populations of interest, and may be a useful measure of exposure.[33,37] However, the usefulness of hair selenium is limited in countries such as the United States where the use of selenium sulfide shampoos is widespread.

Freezing of liquid biologic specimens following collection is recommended to retard the enzymatic formation of difficult-to-

detect volatile metabolites. Other ancillary tests to assess selenium toxicity include ECG, thyroid function, platelet counts, hepatic transaminases, creatinine, and serum creatine phosphokinase. These are abnormal in some patients, for example, in patients with selenious acid poisoning, and are not indicated in cases not expected to cause systemic toxicity.

Management

Pain Management

Treating painful skin, nail bed burns, or ocular pain with 10% sodium thiosulfate solution or ointment may provide relief of symptoms as the result of a reduction of selenium dioxide to elemental selenium.[12] In one series, workers exposed to selenium dioxide fumes reported similar relief from inhalation of fumes from ammonium hydroxide soaked sponges; the mechanism of this is unclear, and further study is required before this practice can be recommended.[36]

Workers exposed to selenium hexafluoride gas can be treated with calcium gluconate gel to affected areas. This is the same treatment as in hydrofluoric acid exposures, which is discussed in Chap. 101.

Decontamination

As with any toxic exposure, prompt removal from the source is required if possible. Patients with dermal exposure should be irrigated immediately. There are limited data to support the use of aggressive gastrointestinal decontamination following the ingestion of most selenium substances as there is little expected acute toxicity. However, in compounds with the potential for producing systemic toxicity, such as the selenite salts, decontamination with orogastric lavage or activated charcoal may be warranted.

Although there are no charcoal adsorption data to guide this therapy, it should be given in light of potential benefit until further information is available.

Special consideration should be given to the ingestion of selenious acid, which is both a caustic agent with attendant decontamination difficulties and a serious systemic poison. The judicious use of orogastric lavage may be indicated based on time since ingestion, amount ingested, presence or absence of spontaneous emesis, and the clinical condition of the patient.

Chelation and Antidotal Therapy

There are no proven antidotes for selenium toxicity. Animal studies and scant human data suggest that chelation with dimercaprol (BAL),[21] $CaNa_2EDTA$ (edetate calcium disodium), or succimer form nephrotoxic complexes with selenium, do not speed clinical recovery and may, in fact, worsen toxicity.[20,21,28] Arsenical compounds appear to ameliorate selenium toxicity through enhanced biliary excretion,[8,13,17,20] but there are no studies to guide this potentially toxic therapy. Vitamin C is hypothesized to limit oxidative damage, but has not been studied. Bromobenzene may accelerate urinary excretion of selenium,[8] but its inherent toxicity would limit its use, regardless of efficacy.

Extracorporeal removal techniques such as hemodialysis or hemofiltration decrease selenium concentrations in patients undergoing the procedure regularly for renal failure, so theoretically this could be of use in lowering toxic serum selenium concentrations. However, because of extensive protein binding, this benefit may be only minor and only relevant to patients undergoing frequent dialysis. Although there are reports of using hemodialysis in patients with acute selenium poisoning, further study must occur before this can be recommended.[18,19]

Supportive Care

This is the mainstay of therapy in selenium poisoning. In particular, patients with selenious acid toxicity require intensive monitoring and multisystem support to survive.

Summary

Selenium is an essential trace element and is required in the diet of both animals and humans. However, in overdose or with excessive exposure, toxicity can result. In particular, ingestion of selenious acid is often fatal. Other selenium compounds cause variable toxicity, usually in the setting of occupational exposure. Elemental selenium can cause symptoms with excess long-term exposure. Although it is

possible to obtain blood, urine, and hair selenium concentrations to confirm exposure, there is no clear relationship between levels and clinical outcome. Supportive therapy remains the standard of care.

A 46-year-old woman who was status post breast biopsy was wheeled fro
(OR) to a recovery bay where she was attached to cardiac and pulse oxi
was extubated without complication in the OR and still remained lightly s

vital signs from the OR recorded as: blood pressure, 116/72 mm Hg; puls respiratory rate, 16 breaths/min; temperature, 99Â°F (37.2Â°C); and O_2 2 L nasal canula. Minutes after her arrival, a staff member became conce dusky-cyanotic appearance and called for assistance and a cardiac arrest caused the patient to open her eyes and then sit upright. Her oxygen sat oximetry remained at 99% on room air despite what appeared to be her the patient's resident arrived she confirmed to the recovery room staff th standing history of argyria, which she developed as a teenager after usin nasal spray to treat allergies.

Silver is a so-called precious metal that has been used for thousands of y impressive array of applications including coinage, an abstract financial and tool material, chemical catalyst, electrical conductor, and medicinal naturally occurs throughout the earth's crust at an average concentration and at 0.1 ppb in seawater. Consequential toxicity of silver is uncommon can lead to permanent disability.

Second only to gold in weakness of interaction with oxygen, silver has c malleability, and both thermal and electrical conductivity. These propertie widespread use throughout the health, science, and engineering industries key component in batteries, mechanical bearings, catalysts, coins, electr coatings, photography, medical bactericidal agents, and water purificatio

The prevalence of silver notwithstanding, silver poisoning is rare and is o occupational exposure or self-administration of silver-containing products medicinal purposes. Since the mid-20th century, the use of silver for me infrequently resulted in iatrogenic overuse and subsequent argyria, which bluish-gray discoloration of skin that is the primary manifestation of chro overexposure.[6]

History and Background

Although the symbol of silver, Ag, is derived from the Latin and Greek wo silverâ€”*argentum* and *argyros* â€”the word we use in English is derived Germanic *Silubr* and *Sirebro* .[52] Even the alchemist symbol of silver (a cr dalton symbol (a coinlike circumscribed letter S) etch the impression of si

precious element.

In Asia Minor and on islands in the Aegean Sea, dumps of slag (scum for surface oxidation) demonstrate that silver was being separated from lead B.C.[26] The use of silver as a precious metal with trade value appears to 600 B.C., when weighed pieces of silver were exchanged for goods. Silve circa 550 B.C. in the Mediterranean, and was adopted by various empires nation-states thereafter. Today, only Mexico uses silver in circulating coir States incorporates silver purely in commemorative and proof coins.

A traded commodity on the world's markets, silver has been used as an standard for various economies throughout modern banking history until

Beyond the economic role of silver, the electrical and thermal conductive element make it an invaluable material for scientific instrument manufac It is ubiquitous and is found in commonly used electronic devices and ap silver contacts neither corrode nor overheat. Silver propelled the dawn of telecommunicationsâ€”it was the choice

for Morse's first telegraph contacts in 1844â€”and made the jet age possi plated bearings have the adequate dry lubricity necessary for safe engine volatile oil lubricants. Today, washing machines, cars, personal digital as electronics all use small amounts of silver in their functional parts. Silver clouds to cause precipitation.

Epidemiology

Humans are exposed to varying minute amounts of silver on a daily basis most closely related to occupation. Silver is released into the environmen manufacture for use in photography, mirrors, plating, inks and dyes, and for germicides, antiseptics, caustics, and analytical reagents. Silver-salt c oxidation-reduction and polymerization reactions, provide a source of silve silver powder pigments and paints.[31] Workplace exposure is often via tra transmucosal (eg, oral and nasal mucosa), or inhalational routes from si during various mining, refining, and manufacturing processes. Both the N Occupational Safety and Health (NIOSH) and the Occupational and Safety

Administration (OSHA) have established the safe occupational exposure li and soluble compounds as 10 Âµg/m^3 air per 8-hour work shift. The estir silver from average environmental exposure for humans not working in industries ranges from 10â€“88 Âµg/d.[15]

Medical Use of Silver Salts

Silver has a 1^+ (Ag^+) valence when bonding with other elements and co complex ions and salts. Because of the microcidal effects of silver cations concentrations,[47] silver has been used as a simple medicinal and bacteric Phoenicians and early Greeks knew to store water, wine, and vinegar in during long sea voyages, just as later American pioneers added silver coi and jugs of milk to keep them fresh.[42] The phrase â€œborn with a silver mouthâ€• referred originally to health and not wealth, as silver pacifiers were used to help ward off childhood illnesses. Today silver is used in w cartridges and supermarket products for washing vegetables, and is even sterilize recycled drinking water on the MIR space station and NASA spac

TABLE 95-1. Medicinal Silver-Containing Products[14,24,50]

The antibacterial activity of silver is related to both direct binding to bioti disruption of hydrogen ions and thus, pH balance. Silver ions bind to elec proteins (sulfhydryl, amine, carboxyl, phosphate, and imidazole) to inhib and provoke protein denaturation and precipitation.[19] Silver also intercala destroying the double helix, thereby inhibiting fungal DNAse.[16] Silver ions leakage through a bacterial (*Vibrio cholerae*) membrane, leading to loss force in oxidative phosphorylation, with subsequent energy loss and cell resistance to silver was not reported until the mid-1970s, followed shortly identification of the genes for silver resistance in bacteria.[47]

Although banned from routine administration by intravenous, intramuscula the United States, silver salts are approved for use in topical medications, styptic or as a key component of burn care. Approved medicinal uses for States apply only to silver salts and compounds (Table 95-1).

Silver sulfadiazine added to burn dressings kills bacteria and increases the reepithelialization across partial-thickness wounds.[9] Concerns of long-terr use of these products by some clinicians.[8] Central venous catheters impre sulfadiazine and silver-impregnated Foley catheters are used to lower the

Colloidal Silver Controversy

The medicinal triumphs of silver are greatly exaggerated, with the elemer some as a â€œcure-all.â€• Claims have been made that oral administra treat, among other things, acne, allergies, appendicitis, arthritis, bubonic cholera, diabetes, gonorrhea, herpes, HIV, leprosy, systemic lupus erythe disease, malaria, meningitis, pneumonia, rheumatism, trench foot, and c Colloidal silver proteins (CSPs) (gelatinous suspensions of finely divided

used as oral medications in the late 19th and early 20th century to treat including syphilis, epilepsy, and nasal allergies.[16] However, in 1960, the Dispensary declared that â€œthere is no justification for

this internal use, either theoretically or practically,â€• and silver was ba nonprescription drugs.[16] In 1999, the US Food and Drug Administration i declaring that all nonprescription drug products containing colloidal silver â€œnot recognized as safe and effective and are misbranded.â€•[18] Howe reintroduced for use as health and dietary supplements.[19] After the anth 2001, the mayor of Tampa, Florida, called for CSPs to be mixed into the as a protective â€œelixirâ€• without any scientific justification.[2]

Route of Administration $t_{1/2}$ in Days

TABLE 95-2. Initial (Phase One) Elimination Half-Life of Silver

Pharmacology

Silver that is absorbed into the body is transported by globulins in blood skin and liver, with average daily intake excreted in the bile and eliminate 30â€“80 Âµg/d) and urine (up to 10 Âµg/d).[16] Silver elimination through two phases: phase one has a relatively short $t_{1/2}$ ranging from 1â€“2.4 d route of administration (Table 95-2), and phase two elimination has a t_1 thought to represent liver deposition and clearance.[34 , 41]

Although one study on a single human subject showed 18% of a single do administered silver acetate salt was retained after 30 weeks, animal stud absorption along the GI tract, with 90% of ingested silver excreted within

ingestion.[15]

Humans retain 0â€“10% of their daily silver exposure of 10â€“88 Âµg/d.[5] silver can accumulate in humans throughout life, with a possible estimate accumulation of 230â€“480 mg by 50 years of age.[15]

Pathophysiology

When used as intended in electronic devices or as coinage (ie, when not and under average exposure conditions, silver is not considered to be tox quantities, however, silver manifests cardiovascular, hepatic, and hemat Acutely, administration of 50 mg or more of metallic silver intravenously pulmonary edema, hemorrhage, and necrosis of bone marrow, liver, and mechanism for this acute toxicity was studied only in the water flea (*Dapl* silver blocks Na^+ -K^+ -adenosine triphosphate (ATPase) activity.[4] Toxicity by system, in Table 95-3 .

Cardiovascular

Rats given 0.1% silver nitrate in drinking water for 218 days developed hypertrophy that was not attributable to silver deposition in the heart de pigmentation in other body organs.[38]

Hepatic

Vitamin E and selenium-deficient rats developed hepatic necrosis with u after being given silver salts.[7 , 11 , 53] Silver can induce selenium deficie inhibits synthesis of seleno-enzyme glutathione peroxidase.

Hematologic

Topical application of silver correlated with bone marrow depression with leukopenia or aplastic anemia.[8]

Renal

Tubular lesions are demonstrated in animals, and acute tubular necrosis (identified in humans.[32]

Neurologic

Silver deposits in peripheral nerves, basal membranes, macrophages, and found in one reported case of a 55-year-old female with progressive vert hypoesthesia, and weakness after self-administration of silver salts to trea

years.[55]

Seizures were reported in a schizophrenic patient who ingested >20 mg s years. Serum silver concentrations were elevated (12 Âµg/L). Seizures r with discontinuation of silver ingestion and a subsequent decrease in silv concentration to nondetectable levels 3 months later.[37]

Dermatologic

Generalized argyria, localized argyria, and argyrosis (silver deposition in after chronic administration of silver.

TABLE 95-3. Silver Toxicity: Systemic Manifestations

Argyria

The most significant effect of silver overexposure or ingestion in humans permanent bluish-gray discoloration of skin resulting from silver throughc (See ILARGYRIA1 and ILARGYRIA2 in the Image Library at http://www.goldfrankstoxicology.com).

Cases of argyria have been reported in the medical literature since at leas century. One of the most famous cases of argyria is that of the Barnum a â€œBlue Manâ€• who died at New York's Bellevue hospital in 1923 and v autopsy as follows: â€œThe color of the skin was of an unusually deep blu distance appeared almost black. This deep color was almost uniform thro body, although it was more intense over the exposed skin areas.â€•[23] Si Jacobs, an American woman who developed argyria as a teenager during of a nasal CSP for allergies, has shared her story on the World Wide Web others of the effects of prolonged contact with, or ingestion of, silver salt also featured as an Image in Clinical Medicine in the *New England Journal* 2000, a Montana legislator running for reelection made headlines as the lawmaker who promoted the use of colloidal silver health supplements.[3]

Pathophysiology of Argyria

Generalized argyria can result from either simple mechanical impregnation

particles or inhalational and oral absorption of particulate silver. Local ro absorption may be through the conjunctiva or oral mucous membranes a treatment with silver salts. As recently as 2002, a 42-year-old European argyria after weekly application for 4 years of a topical nasal vasoconstr manufactured by Siegfried, Sweden) available in Austria. The patient usec treat his drug-induced rhinopathy; each drop of medication contained 0.8 protein.[49] More directly,

colloidal silver protein ingestion for â€œhealth supplementationâ€• leads silver that can produce argyria. In 1933, argyria was reported in a 33-ye had ingested 48 mg/d of elemental silver (from silver nitrate capsules) d week periods over 1 year to treat chronic gastrointestinal symptoms.[5] He concentrations remained at 500 Âµg/L for 3 months after discontinuation indicating significant silver deposition in tissues.

Mechanical impregnation of silver produces localized argyria or argyrosis eyes) following repeated contact with metallic silver or silver salts.[29] Loca reported from both implanted acupuncture needles and short-contact acu particle deposition may occur from silver needles used repeatedly during sessions.[30] Silver sulfadiazine use produces localized argyria in and arour Localized argyria of the tongue and gingiva is described in patients with amalgams.[28 , 43] These patients may also have elevated tissue concentra there are no known cases of significant absorption resulting in generalize long-standing wearing of silver earrings has resulted in local contact arg Corneal argyrosis was frequently reported from prolonged use of colloida eyedrops, but as these drops are no longer used, the condition has beco disease caused by both inadequate eye protection and workers rubbing ey contaminated by silver particles.[44 , 46 , 59] Additionally, industrial exposur involved in silver mining and manufacturing increases the workplace risk argyria, although development of signs of argyria from uninterrupted oc takes a minimum of 24 years.[12] Employees are susceptible to localized ar argyrosis from working with smaller amounts of silver in specific applicatio of metallic films on glass and china, manufacture of electroplating solutio processing, preparation of artificial pearls, and simple cutting and polishir

Histopathology of Argyria

Surprisingly, there are no pathologic changes or inflammatory reactions v level from silver deposition or impregnation. Rather, the skin discoloration from the silver itself and from the induction of increased melanin produc are initially found within fibroblasts and macrophages, then extracellularly membrane of blood vessels, sweat glands, dermoepidermal junction, and muscles (Chap. 29). Patients with argyria commonly manifest increased sun-exposed skin. The proposed mechanism for this process is that silver are reduced to their elemental form via photoactivation, similar to photo development. Silver plus light then further stimulates melanogenesis, inc light-exposed areas.

Argyria develops in stages, beginning with an initial gray-brown staining progressing to hyperpigmentation and bluish-gray discoloration in sun-ex sclerae, nail beds and mucous membranes become hyperpigmented; on a noted to be blue. Confirmation of the diagnosis of argyria is through skin hematoxylin and eosin staining, showing brown-black clusters of silver g

Argyria occurs at exposure levels much lower than those associated with of silver; the degree of discoloration is directly proportional to the amour or ingested.[22] The threshold dose for silver accumulation and retention r generalized argyria varies considerably. Discoloration has been reported i as little as a cumulative 1 g of metallic silver administered intravenously (arsphenamine used to treat syphilis over a 2-year period in the early 19 tolerated infusions containing up to 5 g of elemental silver over 9 months change was noted.[22]

Diagnostic Testing

Urine and serum concentrations of silver can be measured as indices of s also tested for silver, but airborne silver particles may bind to hair and

In individuals without a history of medicinal silver ingestion or occupation normal serum silver concentration is â‰¤1 Âµg/L and normal urinary sil â‰¤2 Âµg/L (24-hour urine collection).[54] Workers who smelt and refine prepare silver salts for use in the photographic industry have mean serur

11 Âµg/L and urine silver concentrations of 2.6 Âµg/L (in single â€œspot

Treatment of Argyria

Chelators such as British anti-Lewisite and D-penicillamine are ineffective silver toxicity and argyria.[16] Topical hydroquinone 5% may reduce the nu granules in the upper dermis and around sweat glands, as well as diminis melanocytes.[39] Sunscreens and opaque cosmetics are used to prevent fu darkening from sun exposure.

As oxidant deficiencies may enhance silver toxicity, antioxidants, such as vitamin E, may play a role in reversing effects of silver exposure. Seleni glutathione peroxidase synthesis is diminished when silver binds to, and intracellular selenium.[7 , 53] Supplemental vitamin E and selenium increas in rats and chickens.[7] Selenium and sulfur are being considered as possib argyria. Selenium may act to precipitate or chelate silver: silver selenide and should reduce the availability of monovalent silver to interfere with activities.[1 , 36 , 45] Hence, increased selenium intake is theorized to bind rather than skin deposition. Silverâ€“sulfur complexes may be investigate although the silverâ€“sulfur complex is not as stable.[45]

Carcinogenicity of Silver

Silver is not classified as a human carcinogen and no data link therapeutic human cancer, nor has silver been found to be mutagenic.[15] Although ani that silver implanted subcutaneously can lead to local sarcoma formation, been deemed uninterpretable in regard to carcinogenicity as implantation solids, such as, plastic and smooth ivory, produce similar results.[15] Colloi into rats induces growths at injection sites, but intramuscular injections c not induced cancer.[21] Local inflammatory responses notwithstanding, silve inert substance and not a human carcinogen.

Emergency Management

Although systemic toxicity of silver is predominantly a result of chronic rarely encounter a patient who has

ingested a CSP, a silver-containing medicinal product, or a silver salt. Bu cautery should be managed as burns. Silver ingestion should be manage salt ingestion should be treated as a caustic ingestion (Chap. 100).

Summary

Silver toxicityâ€”primarily argyria and burnsâ€”is still occasionally encou the workplace environment and health supplementation products are the exposure. Despite frequent therapeutic use of silver and silver compounds evidence of silver acting as a mutagen or carcinogen. Significant toxicity argyria from chronic silver use is essentially a permanent manifestation. T effective means for removing accumulated silver and reversing argyria.

<5 Âµg/L (<24.5 nmol/L)

A 21-year-old woman developed mild, but persistent abdominal pain with intermittent, severe, colicky pain. Three days after the initial painful episode, her hair began to fall out. She became

constipated and noted a delay in the onset of her menses. Within 5 days of her initial symptoms, she was completely bald. On day 18, she was hospitalized. Physical examination was only remarkable for horizontal white (Mees) lines on her fingernails. Her routine blood studies and several special studies for autoimmune disease were all normal. Her overall condition responded to nutritional support, her symptoms gradually resolved, her hair regrew, and she was discharged almost 2 months after the onset of symptoms, but without a clear diagnosis.

The patient returned to school. One month later, she felt pain in both her hands and feet, and developed difficulty speaking, blurred vision, tremulousness, and vertigo. Again, she was taken to the hospital. On admission, her blood pressure was 140/110 mm Hg; other vital signs were normal. Examination of her extremities showed good muscular strength in her legs but poor muscle coordination, and hyperesthesias in a stocking-and-glove distribution. Her deep-tendon reflexes were hypoactive in both legs, but normal in her upper extremities. Cranial nerve examination revealed horizontal and vertical nystagmus, and palsies of the abducens (VI) and facial (VII) cranial nerves. Electrolyte, hepatic enzymes and analysis of cerebrospinal fluid were all normal.

Four days later, still without a diagnosis, her symptoms of vertigo and tremulousness worsened. She developed an oculogyric crisis, and her mental status deteriorated. Her alopecia returned. A magnetic resonance image of her brain was interpreted as normal, and an electroencephalogram was nondiagnostic. Her condition progressed very rapidly with the development of bulbar palsy, involuntary chewing movements of her mouth, and spastic clonus of both upper limbs. Her level of consciousness changed from mild agitation to lethargy. Tonic movements of both upper extremities and episodic oculogyric crises were noted.

Five days after her hospitalization, she became comatose.

Investigative studies for arsenic, antinuclear antibody, antidouble-stranded DNA antibody, rheumatoid factor, HIV, and Lyme disease were negative. Routine urinalysis was normal. She was treated with several broad-spectrum antibiotics, antiviral agents, hormones, and intravenous injections of Î³-globulin, none of which had any appreciable effect on her clinical manifestations.

Because her spontaneous respiratory efforts became progressively weaker and irregular, a tracheostomy was performed and she was placed on a ventilator. At that point, the diagnosis of acute disseminated encephalomyelitis was considered. Plasmapheresis was initiated and 7 exchanges, for a total of 10 L, were completed over the following 3 weeks. No change in her condition was noted.

Ultimately, the diagnosis of thallium toxicity was considered. Blood, urine, and cerebrospinal fluid thallium concentrations were reported as 275, 532, and 31 Âµg/L, respectively. Nail and hair concentrations were 22, 824, and 532 Âµg/kg, respectively. A regimen of intravenous potassium (100 mEq/d), oral Prussian blue (250 mg/kg/d divided q4h in 50 mL of 15% mannitol), and daily hemodialysis was initiated. Her symptoms slowly improved. About 2 months after hospitalization she began to intermittently regain consciousness.

One year after her initial presentation, her orientation and memory improved and her IQ was estimated at 128, with good mathematical and verbal abilities. The patient was able to sit in a wheelchair for a prolonged period of time and could move herself 20â€“30 meters. She still could not move her legs. Her vision remained poor, but periodically she was able to see clearly.

History and Epidemiology

Thallium, a metal with atomic number 81, is located between mercury and lead on the periodic table. It is a commonly found constituent

of granite, shale, volcanic rock, and pyrites used to make sulfuric acid, and is also recovered as flue dust from iron, lead, cadmium, and copper smelters.[23] Thallium is a soft, pliable metal that melts at 572Â°F (300Â°C), boils at 2699.6Â°F (1482Â°C), and is essentially nontoxic. However, thallium forms univalent thallous and trivalent thallic salts, which are highly toxic. Thallium has been used in alloys as an anticorrosive, in optical lenses to increase the refractive index, in artists' paints, in lamps to improve tungsten filaments, in extreme cold thermometers, in imitation jewelry, as a catalyst, and in fireworks.

In the early 1900s, thallium salts were used medicinally to treat syphilis, gonorrhea, tuberculosis, and ringworm of the scalp, and as a depilatory.[5 , 62] Although the usual oral dose given for epilation in the treatment of ringworm of the scalp was 7â€“8 mg/kg, fatal doses ranged from 6â€“40 mg/kg.[13 , 51] Many cases of severe thallium poisoning (thallotoxicosis) resulted from the treatment of ringworm, with one author summarizing nearly 700 cases and 46 deaths.[65]

Because thallium sulfate is odorless and tasteless, it was also successfully used as a rodenticide. Commercially available as Thalgrain, Echol's Roach Powder, Mo-Go, Martin's Rat Stop liquid, and Senco Corn Mix, thallium sulfate was a very efficient rodenticide. As a consequence of numerous case reports of unintentional poisonings,[64 , 65 , 76] the use of thallium salts as a household rodenticide was restricted in the United States in 1965. Ultimately, even the commercial use of thallium salts as a rodenticide was banned in the United States in 1972, because of continued reports of human toxicity.

Life-threatening unintentional poisoning continues in other countries where thallium salts are still commonly used as rodenticides.[12 , 74 , 82 , 97] Additional cases of thallium poisoning are reported in the United States and other countries as a result of

the use of thallium as a homicidal agent,[19,56,60,68,70,79,86] and through contamination of herbal products[83] and illicit drugs such as heroin[73] and cocaine.[38] Although occupational exposures to consequential amounts of thallium salts are uncommon, toxicity is well described in this setting.[32] Diagnostically, trace amounts of thallium salts are used as a radioactive contrast agent to image tumors and to visualize cardiac function.[62]

The following discussion of thallium toxicity refers to toxicity resulting from exposure to inorganic thallium salts, because this source represents virtually the entire literature on thallium poisoning. Although exceedingly rare, cases of poisoning with organic thallium compounds are reported,[1] and should be assessed and managed in a fashion similar to that used for patients with inorganic exposures.

Toxicokinetics

Exposures usually occur via one of three routes: *inhalation* of dust, *ingestion*, and *absorption* through intact skin. Thallium is rapidly absorbed following all routes of exposure. Bioavailability is greatest following ingestion, and exceeds 90%.[35] Distribution follows 3-compartment toxicokinetics[75] (Chap. 9), into a final volume of distribution that is estimated to be about 3.6 L/kg.[18] Thallium can be found in all organs, but it is distributed unevenly, with the highest concentrations found in the large and small intestine, liver, kidney, heart, brain, and muscles.[5,46] In animals, the highest concentrations of thallium are found in the kidneys.[2,46]

The toxicokinetics of thallium can be described in the following 3-phase model. The first phase, occurs rapidly in the 4 hours following exposure during which thallium is distributed to a central compartment and to well-perfused peripheral organs such as the kidney, liver, and muscle. In the second phase, which can last between 4 and 48 hours, thallium is distributed into the central

nervous system.[75] Whereas previous literature suggests that this distribution phase is generally completed within 24 hours of ingestion,[75] a recent human case suggests slower distribution into the CNS as evidenced by increasing cerebrospinal fluid (CSF) concentrations days following exposure when blood concentrations were declining.[86] The third, or elimination, phase starts within 24 hours after ingestion. The primary mechanism of thallium elimination is secretion into the intestine, but enteral reabsorption of thallium that is present in the bile subsequently reduces the fecal elimination.[18, 60] Thallium is excreted primarily via the feces (51.4%) and the urine (26.4%).[50] It is filtered by the glomerulus, with approximately 50% being reabsorbed in the tubules. Thallium is also secreted into the tubular lumen in a manner similar to potassium.[3] The duration of the elimination phase depends on the route of exposure, dose, and treatment. Unlike many other metals, thallium does not have a major anatomic reservoir. As such, reported elimination half-lives are as short as 1.7 days in humans with thallium poisoning.[36]

Pathophysiology

The mechanism of thallium toxicity is not well established. Thallium behaves biologically in a manner similar to potassium because they have similar ionic radii (0.147 nm for thallium and 0.133 nm for potassium). Because cell membranes cannot differentiate between thallium and potassium ions, thallous ions accumulate in areas with high potassium concentrations, such as central and peripheral nervous system and hepatic and muscle tissue.[57, 97] This accumulation is the fundamental principle that governs the use of radioactive thallium in cardiac imaging studies. Thallium replaces potassium in the activation of potassium-dependent enzymes.[57] In low concentrations, thallium stimulates these enzyme systems, but in high concentrations, it inhibits them.[7, 59] Thallium also inhibits several potassium-dependent systems. Pyruvate kinase, a magnesium-dependent glycolytic
