Many opinions exist as to the exact role of lymphadenectomy in the management of early cervical cancers. The lymphadenectomy itself clearly plays a role in prognosis as nodes are found to be apparently free of disease. Radiotherapy given as adjuvant treatment to pN1 patients decreases the chance of recurrence; however, it can produce iatrogenic complications such as radiation enteritis, which is increased if radiation follows surgical dissection (230). Taking these facts into account, some oncologists abort surgery as soon as they know that lymph node involvement exists. Others may proceed with radical surgery in spite of nodal disease, and in such cases, these surgeons deny any value to laparoscopic staging. The former group may have interest in laparoscopic staging, but the question remains of how to adopt this in the pN1 cases. The proposed algorithms (Figs. 13.33 and 13.34) represent a compromise taking into account the truth in surgical dissection for patients with limited nodal involvement and the necessity of radiotherapy in all pN1 cases. If bulky nodes are noted at laparoscopy, debulking probably is useful (238,239), but it appears to be safer to do such by laparotomy.

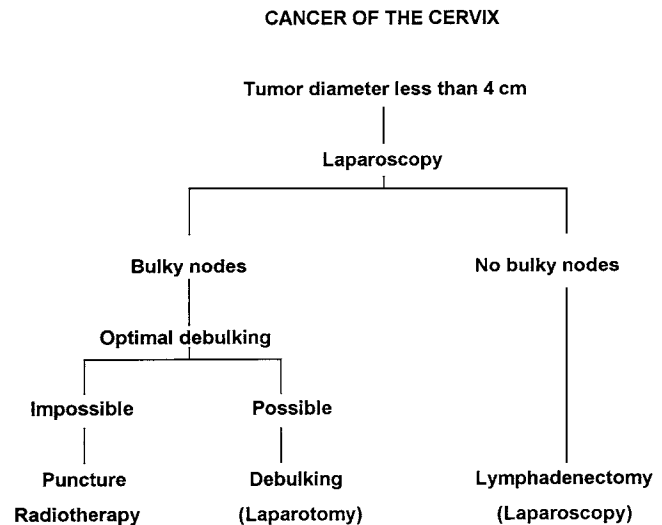

FIGURE 13.33. Algorithm for laparoscopy in early cervical cancer (1).

If the nodes appear to be endoscopically normal but are involved on frozen section, the decision depends essentially on the number of involved nodes. If this number is less than three, radical surgery is a reasonable choice. We prefer performing it by laparotomy for safety (and rapidity) reasons. If the number of positive lymph nodes exceeds two, primary chemoradiotherapy is the best option, and we recommend aborting the radical hysterectomy.

If the nodes are normal, radical surgery is the treatment of choice. The laparoscopically assisted and the purely laparoscopic radical hysterectomies are offered as alternatives to classic ARH.

Laparoscopic Assistance to Radical Surgery

After deciding to use the laparoscopic approach for performing radical hysterectomy, one must decide between the various forms of laparoscopic assistance to VRH and purely laparoscopic radical hysterectomy. The data concerning both types of approaches have been addressed in the previous sections of this chapter. We favor the combined approach for three reasons. The first is that the purely laparoscopic approach requires a large degree of manipulation of the tumor, whereas in the laparoscopically assisted operation there is no tumor

* pN1A = 1 or 2 Positive Lymph Nodes

** pN1B = 3 or more Positive Lymph Nodes

FIGURE 13.34. Algorithm for laparoscopy in early cervical cancer (2).

manipulation during the laparoscopic step and the tumor is protected inside the vaginal cuff at the beginning of the vaginal step. The second reason is that the vaginal approach allows easy management of the juxtaterine tissues, especially the vesicovaginal spaces, bladder pillars, and parametrium. Additionally, delineation of the vaginal cuff is much more precise using the vaginal route. The third and most important reason favoring the mixed approach is that this is good training for performing radical vaginal trachelectomy.

Advanced Cases and Recurrences

Radiotherapy given for advanced cervical cancers fails in two of three cases because of extrapelvic recurrences. These recurrences arise mostly in the abdominal cavity either extraperitoneally (aortic nodes) or intraperitoneally. One way of tackling this problem could be to give systematic extended-field radiotherapy. However, a prospective study (240) in which extended-field radiotherapy was given either routinely or after lymphangiographic selection did not yield the expected results. Moreover, extended-field radiotherapy includes a risk of severe complications close to 20% (241). Thus, the indications for its use must be limited to appropriately selected cases.

Staging laparotomy was devised as an answer to the question of selection of the indications for extended-field radiotherapy. It has some success in spite of its drawbacks, which include intraoperative and postoperative complications and enhanced risk of radiation enteritis because of peritoneal adhesions resulting from surgery. A GOG study (242) demonstrated that an extraperitoneal approach decreases these drawbacks, and laparoscopy may produce an even better result.

Laparoscopic staging of advanced cervical cancer can be performed using the classic transumbilical transperitoneal approach, which enables the surgeon to assess the peritoneal cavity and perform pelvic and aortic dissections. A more conservative approach could be limiting dissection to the pelvic area and going further only in the cases where the pelvic nodes are involved. Another approach entails using transumbilical laparoscopy only for assessing the peritoneal cavity and guiding digital preparation preceding extraperitoneal aortic dissection (discussed above). Most important in the selection of extended-field radiotherapy are (a) peritoneal cytology and (b) the status of the aortic nodes. The status of the pelvic lymph nodes does not alter pelvic radiation fields. This highlights the benefits of the combination of transumbilical laparoscopy and extraperitoneal dissection. It is the ideal way to perform laparoscopic staging in the management of advanced cervical cancer (Fig. 13.35). The benefits of this staging should

not be overestimated since using laparoscopy in place of laparotomy avoids the deleterious effects of operative adhesions but does not increase survival.

An additional benefit of pretherapeutic laparoscopy is the possibility of performing ovarian transposition for patients less than 40 or 45 years of age. Studies demonstrate that laparoscopic transposition is both feasible and effective (243).

An additional indication for combined laparoscopic assessment is selection for pelvic exenteration in patients diagnosed with pelvic recurrence of cervical cancer (227,228). Both positive peritoneal cytology and positive aortic nodes are contraindications to exenteration. As previously mentioned, it is advantageous to identify these findings without having to perform a laparotomy.

Laparoscopic Surgery and Endometrial Cancer

Surgery remains the cornerstone for the treatment of endometrial cancer. Hysterectomy and bilateral salpingo-oophorectomy are part of all traditional treatment protocols. Total hysterectomy has been traditionally performed through an open approach to completely assess the peritoneal cavity and perform lymph-node sampling or lymphadenectomy. Vaginal hysterectomy has been used in the management of endometrial cancers in certain situations (244). However, the vaginal route does not allow for the evaluation of the peritoneal cavity or the retroperitoneal lymph nodes. Since the introduction of laparoscopic lymphadenectomy, minimally invasive surgery has become increasingly popular in the management of gynecologic malignancies. With the development of improved instruments and surgeons' skills, laparoscopic surgeons began to perform more complicated procedures for the management of gynecologic malignancies. Case series began to appear in the literature, and recently, more prospective studies have been reported, with the largest one being the GOG LAP-2 study.

Using a combined laparoscopic and vaginal approach, all the procedures required for endometrial cancer surgery can be accomplished. Complete assessment of the peritoneal surfaces and retroperitoneal dissection are possible. Thus, the addition of laparoscopy transforms the basic transvaginal hysterectomy into an oncologic complete operation. Minimally invasive management of endometrial cancer is appealing, and does not require long training. This explains why the use of LAVH in the treatment of endometrial cancer gained popularity long before LAVRH in the treatment of cervical cancer.

Feasibility studies concerning minimally invasive surgery in endometrial cancer are becoming more numerous. In addition to the two early publications regarding laparoscopic management (81,137), there have been many additional reports (244,245) that confirm the feasibility. Recently, the GOG completed the largest prospective, randomized trial to date (LAP-2) in patients with clinical early-stage uterine cancer comparing a traditional open surgical approach to laparoscopic management (246). Although survival data are not available, the study did demonstrate that laparoscopic staging can be completed in 76.3% of patients. The patients undergoing laparoscopic staging were less likely to have their para-aortic nodes sampled but the node positivity rate and International Federation of Obstetrics and Gynecology (FIGO) stage were the same in both arms.

The advantages of laparoscopically assisted vaginal hysterectomy (LAVH) have been illustrated when compared to abdominal hysterectomy for the management of early-stage endometrial cancer in several retrospective studies. In a retrospective review of 320 patients, Gemignani et al. (247) demonstrated that LAVH was associated with a decreased

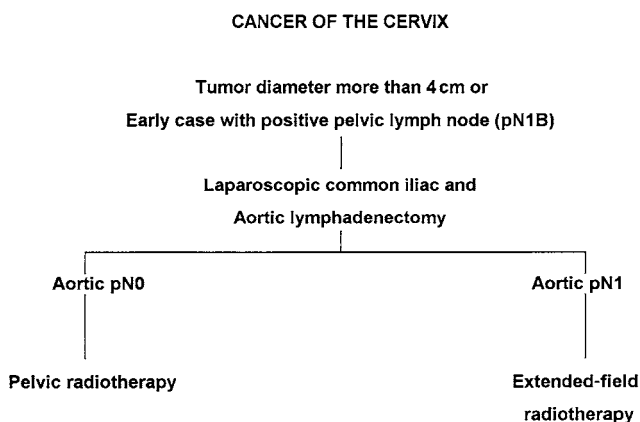

FIGURE 13.35. Algorithm for laparoscopy in advanced cervical cancer.

hospital stay, fewer complications, and resulted in lower overall hospital charges. Others have also demonstrated significantly lower hospital costs when patients with early endometrial cancer are managed by laparoscopy (151), but total costs may be higher when surgeons' fees are added (248). Cost savings are most likely a direct result of the significantly shorter hospital stay and have been consistently reported in both single institutional retrospective and prospective series (249,250). The multi-institutional GOG LAP-2 study also demonstrated a shorter hospitalization with a median hospital stay of 3 days for patients treated with laparoscopy versus a median of 4 days in those patients treated with open surgery (246).

Patients who undergo laparoscopic surgery seem to report a higher level of satisfaction with laparoscopy when compared to patients treated with total abdominal hysterectomy. They benefit from a shorter recovery time and are able to return to work and full activity more quickly (248). In a recent prospective, randomized study comparing laparoscopy to laparotomy in the management of endometrial cancer, Zullo et al. (250) prospectively demonstrated that patients treated with laparoscopy did indeed have improved quality of life for the first 6 months after surgery. Improved short-term quality of life was also demonstrated in the GOG LAP-2 study, which employed the Functional Assessment of Cancer Therapy-General (FACT-G) tool. At the 1-, 3-, and 6-week postoperative intervals, scores were higher for the patients treated with laparoscopic surgery, illustrating that quality of life was better. However, at the 6-month postoperative interval, scores were the same, signifying that improved quality of life was generally seen within the first 6 weeks after surgery (251).

When evaluating the two techniques in regard to their oncologic adequacy, both appear to be comparable. In a prospective comparison of the two techniques, Malur et al. (252) demonstrated that there was no significant difference in the number of pelvic or para-aortic lymph nodes obtained. Oncologic outcomes also appear comparable in small prospective and retrospective studies of women with early-stage endometrial cancer treated by either laparoscopy or laparotomy (250,253). Tozzi et al. reported on the survival of 122 women prospectively randomized to either laparoscopy or laparotomy. With a median follow-up of 44 months (range, 5 to 96), cause-specific survival was similar in the two groups: laparoscopy, 90.5% versus laparotomy, 94.9% ($p = 0.47$) (253).

Prospective comparisons between the combined laparoscopic and vaginal approach and the abdominal approach are available in the literature. Malur et al. (252) compared 37 patients treated by a laparoscopic and vaginal approach to 33 patients treated by laparotomy. All patients underwent pelvic and aortic lymph node dissection except for patients with well-differentiated tumors that invaded to less than the inner third of the myometrium. There was no difference in the mean Quetelet index (QI), mean number of lymph nodes, and mean operation time. The laparoscopic group did have less blood loss, fewer transfusions, and shorter hospital stay. With a mean follow up of 16.5 (range, 2 to 43) and 21.6 (range, 2 to 48) months for the laparoscopic and laparotomy groups, respectively, the recurrence-free and overall survivals were not significantly different (97.3% vs. 93.3% and 83.9% vs. 90.9%, respectively). Other small prospective trials have demonstrated the association of laparoscopy with less blood loss and shorter hospital stay in the management of endometrial cancer (254,255).

Since obesity is a major risk factor for the development of endometrial cancer, many patients will present with a high QI. Performing a staging procedure in an obese patient can be difficult, but may not be an absolute contraindication. Scribner et al. (256) reported on their experience of laparoscopic pelvic and para-aortic lymphadenectomy in the obese patient. In 55 patients, laparoscopic staging was completed in 44% of

patients with a QI ≥ 35 compared to a completion rate of 82% in patients with a QI < 35 ($p = 0.004$). In spite of this difference, the authors concluded that obesity is not an absolute contraindication to laparoscopic staging. Similarly, the same authors studied the surgical management of a group of patients 65 years or older with endometrial cancer. Although the operating room time and transfusion rate were significantly higher in the patients managed by laparoscopy compared to laparotomy, laparoscopy was associated with decreased hospital stay, less postoperative ileus, and fewer infectious complications with comparable blood loss and node counts. The authors concluded that older age was not an absolute contraindication to laparoscopic staging (257).

One potential drawback to laparoscopic management was the potential for retrograde seeding with the use of a uterine manipulator, which was suggested in a retrospective study of 377 patients undergoing either LAVH or total abdominal hysterectomy (TAH) for early-stage endometrial cancer (258). The authors found that patients in the LAVH group had a significantly higher incidence of positive peritoneal washings (10.3% vs. 2.8%, $p = 0.002$). A subsequent report by Vergote et al. (259) similarly reviewed the experience with endometrial cancer patients treated with either TAH or LAVH without the use of a uterine manipulator, and no difference in positive peritoneal cytology was observed. In a prospective study of patients with clinical stage I endometrial cancer undergoing laparoscopic surgery, Eltabbakh et al. demonstrated that routine use of a uterine manipulator does not result in an increased incidence of positive peritoneal cytology (260).

Laparoscopic surgery for the management of endometrial cancer undoubtedly has its limitations. Large fibroid uteri that cannot be removed without morcellation should not be operated on using laparoscopic surgery if endometrial cancer is present. Placing such unusual situations aside, the preliminary results from the GOG LAP-2 trial are encouraging and support many of the benefits of laparoscopic surgery identified in the studies to date. If equivalency in cancer outcomes is demonstrated, it is likely that laparoscopy will become a mainstay in the surgical management of early-stage endometrial cancer.

LAPAROSCOPY IN OVARIAN CANCER

Laparoscopy can be used in several different ways in the management of ovarian cancer depending on the stage of the disease and the anticipated goals of the procedures.

Advanced Ovarian Cancer

In patients with advanced ovarian cancer characterized by ascites, carcinomatosis, and omental cake, optimal surgical debulking may not be feasible even by laparotomy. Unfortunately, there is no perfect tool to determine preoperatively whether patients can be optimally debulked surgically. CT scan often underestimates the extent of the disease, in particular the extent and location of carcinomatosis. Nelson et al. have proposed a set of criteria that appear to accurately predict the inability to surgically debulk patients (261). They found that CT scan was highly sensitive for detection of ascites, mesenteric, and omental disease, but was poor for detection of liver involvement, omental attachment to the spleen, gallbladder fossa disease, and peritoneal nodules smaller than 2 cm (262). In the early 1990s, Schwartz et al. pioneered the concept of neoadjuvant chemotherapy in patients with advanced disease with the goals of chemoreducing the tumor bulk then using surgical debulking for those who

show a good response to the chemotherapy (262,263). Recent studies suggest that quality of life is improved with this approach (264). However, other malignancies, particularly of gastrointestinal (GI) origin (such as colon, pancreas, stomach, and others) can mimic ovarian cancer. In some series, up to 20% of patients with presumed advanced ovarian cancer had a GI primary (265) due in part to inconclusive cytologic examination of ascitic fluid. Some, however, have argued that it is extremely accurate and helpful (266).

In cases where the diagnosis remains unclear, histologic confirmation of an ovarian primary is critical before initiation of chemotherapy. However, an adequate biopsy specimen cannot always be safely obtained under radiologic guidance. This is where laparoscopy becomes a valuable diagnostic tool. Indeed, the laparoscopic exploration of the abdominal cavity allows the surgeon to determine whether the disease can be optimally surgically debulked or not. If so, then a laparotomy can be performed to complete the surgery. If not, an adequate tissue specimen can be obtained for histologic confirmation. In a recent series of 18 patients with ovarian cancer explored laparoscopically, 7 (40%) were found to have unresectable disease and were spared a laparotomy. In the remaining patients, a laparotomy was performed and complete debulking was accomplished (267). In patients with advanced disease, diagnostic laparoscopy is an accurate diagnostic tool that may obviate the need for unnecessary laparotomies and thus contribute to a better quality of life in patients found to have unresectable disease (268).

In a recent series, 87 patients with advanced ovarian cancer underwent first a diagnostic open laparoscopy (269). In 61% of patients, optimal cytoreductive surgery was deemed possible and those patients underwent a laparotomy and debulking surgery. The goal was correctly achieved in 96% of cases. Conversely, in 39% of cases, optimal debulking appeared impossible. These patients then underwent neoadjuvant chemotherapy followed by interval debulking and adjuvant chemotherapy. Of note, the first cycle of chemotherapy was quickly initiated the day following the laparoscopic surgery. Overall, 80% of patients could be optimally debulked following three cycles of chemotherapy. The authors concluded that diagnostic open laparoscopy is a valid diagnostic tool to evaluate the extent of disease and avoids unnecessary laparotomies in patients where optimal debulking cannot be accomplished (269). To that extent, Fagotti et al. proposed a simple laparoscopy-based scoring system to estimate the chances of achieving optimal cytoreduction based on the presence of an omental cake, diaphragmatic carcinomatosis, mesenteric retraction, etc. A score of >8 predicted a suboptimal surgery with a specificity of 100%, a positive predictive value of 100%, and a negative predictive value of 70% (270).

However, the diagnostic laparoscopic procedure can have some pitfalls: first, the presence of a large amount of ascites may lead to a reduced visibility; second, the GI anatomy can be distorted, or the colon and/or small bowel may be adherent to the anterior abdominal wall or omentum, which may increase the risk of bowel injury. An open laparoscopic approach may be preferable in such cases, although a recent large trial does not seem to indicate that open laparoscopy reduces the risk of major complications (40). Lastly, the issue of trocar-site implantation remains controversial, particularly in patients with adenocarcinoma, ascites, and carcinomatosis (see section on port-site metastasis). However, when trocar sites are carefully closed after the procedure and the chemotherapy is initiated within 1 week, the risk of trocar-site metastasis can be reduced substantially (271,272). In cases of advanced ovarian cancer, laparoscopy appears to be a good triage method to select out patients who would not benefit from a laparotomy and can thus be spared the associated morbidity.

Second-Look Surgery

For those who perform second-look evaluation following first-line chemotherapy, laparoscopy may be a valuable approach to reduce the morbidity of the procedure. The magnification of the view allows a good evaluation of the peritoneal surfaces, in particular the costodiaphragmatic recessus and pelvic cul-de-sac. However, laparoscopy may be less accurate in the prerenal and porta hepatis regions, as well as in the root of the mesentery where small implants may go unnoticed. It is reassuring that the rate of negative evaluations and the rate of recurrences in patients with negative laparoscopic second looks are equivalent to those described in studies of second-look assessment by laparotomy (273). Conversely, in a prospective comparative study, a French group found the laparoscopic second-look evaluation to be suboptimal when compared to the abdominal approach, mainly because of the presence of adhesions which appeared to limit the thoroughness of the evaluation (274). In that study, the positive predictive value was 100%, but the negative predictive value was 86% (two false-negative cases) (274). Clearly, if residual tumor implants are readily confirmed at laparoscopy, then a laparotomy can be avoided in those patients. In patients with negative laparoscopic evaluation, it remains uncertain if laparotomy is more accurate, particularly in patients with diffuse adhesions. Large randomized trials are not available to answer this important question.

However, in a recent study 99 patients who had achieved a complete clinical response following first-line chemotherapy underwent second-look surgery. Nearly 70% had a negative second-look laparoscopy and were converted to a planned laparotomy, whereas 32% had positive findings at laparoscopy and thus were spared a laparotomy. In that study, the negative second-look laparoscopy predicted a negative laparotomy in 91% of the cases and was associated with a lower complication rate. The authors concluded that the small increase in sensitivity offered by laparotomy does not warrant the increased morbidity (275).

In terms of morbidity, a pilot study from Memorial Sloan-Kettering demonstrated that the laparoscopic approach results in less morbidity, shorter operating time, shorter hospital stay, less blood loss, and lower total hospital charges (276). In a series of 150 cases, Husain et al. also concluded that the complication rate of the laparoscopic approach is low and that it is a safe approach even in patients who had a prior abdominal surgery (273). Clough et al. have also reported similar findings (274). Concerns about the effect of CO₂ pneumoperitoneum on the risk of tumor dissemination have been raised (see section on gasless laparoscopy). However, a recent study including 131 patients operated on by laparoscopy does not seem to indicate that laparoscopic surgical procedures with CO₂ pneumoperitoneum reduce overall survival of patients with metastatic intra-abdominal carcinoma of ovarian/peritoneal origin (89). Lastly, in the context of second-look surgery, laparoscopy may be used to place intraperitoneal catheters under direct laparoscopic guidance in patients found to have residual disease at the time of the second-look operation (277).

Staging Procedure in Early-Stage Disease

On occasion, despite thorough preoperative investigation, patients are operated on for a presumed benign ovarian mass, yet an unexpected diagnosis of ovarian cancer occurs on final pathology, or the operating surgeon does not feel comfortable completing the staging procedure. In such situations, a complete surgical staging at a second surgery should be performed

to determine the true stage. This information is critical for recommendations of adjuvant chemotherapy. Roughly, in presumed stage I disease, the chances of finding more advanced disease is in the range of 20% to 30% and the most frequent sites of metastasis are the lymph nodes (278,279). Laparoscopy may be an excellent alternative to complete the staging in such cases since a complete pelvic and para-aortic node sampling, an infracolic omentectomy, and a complete peritoneal assessment (+/- contralateral bilateral salpingo oophorectomy [BSO] and vaginal hysterectomy in older women), can be safely performed laparoscopically (280–283). Early studies showed that the morbidity of the laparoscopic procedure is low and the results are accurate (280–283). In the early 1990s, Querleu and Leblanc even demonstrated that a complete laparoscopic infrarenal lymph node dissection could be accomplished in the context of restaging ovarian or fallopian tube cancers (15). In a more recent study including 46 cases, infrarenal lymphadenectomies were performed laparoscopically (156). The morbidity was low and the authors noted that the number of lymph nodes obtained was doubled compared to the number of lymph nodes obtained by the more frequently performed inframesenteric lymphadenectomy (156).

Over a 10-year experience, Leblanc et al. laparoscopically restaged 42 patients with apparent early ovarian cancer and 7 with fallopian tube cancers. Only one patient had to be converted to a laparotomy because of adhesions and 19% were upstaged as a result of the staging procedure. They concluded that laparoscopic surgery meets the standards of a complete staging procedure, spares the patients the inconvenience of a laparotomy, and accurately identifies patients with more advanced disease who require adjuvant chemotherapy (284). In a recent GOG trial, Spirtos et al. completed the staging of incompletely staged gynecologic malignancies including ovarian and fallopian tube cancers. They noted a conversion rate of 20% to laparotomy, most often due to the presence of adhesions. Nevertheless, nearly 70% of patients had a successful complete laparoscopic staging and 11% were found to have more advanced disease (285).

Although there are no randomized trials comparing both approaches, it would appear that a comprehensive laparoscopic restaging of patients with early-stage ovarian cancer is feasible, accurate, and the morbidity is lower compared to the same procedure done by laparotomy. However, this procedure should only be performed by experienced and skilled laparoscopists capable of performing advanced and complex oncologic laparoscopic procedures.

With regard to borderline tumors, the value of a restaging procedure is controversial since the prognosis of patients with presumed stage I disease is excellent, and the value of adjuvant treatment is questionable even in more advanced disease. In a series of 56 patients referred with a suspected stage IA disease, only 4 (7%) were upstaged (286). Conversely, in a recent series of 30 patients who underwent complete laparoscopic staging for presumed ovarian cancer, 26.6% of patients were upstaged as a result of the staging procedure (287). However, all the patients are alive with the exception of only one patient who developed a recurrence (287). The authors concluded that whenever staging of a patient with a borderline tumor is considered, laparoscopy appears to be the method of choice since the procedure is accurate, the complication rate and the morbidity are low, and, very importantly, the incidence of infertility in young patients is minimized (287). It would appear, however, that laparoscopic ovarian cystectomy only for borderline tumor is associated with a higher risk of recurrence compared to a complete oophorectomy (131). Indeed, Darai et al. recently published their results regarding the laparoscopic restaging of borderline tumors and confirmed the feasibility of that surgical approach. In their series, there were no conversions and no intraoperative or postoperative

complications. As expected, they noted that ovarian cystectomies were associated with a higher risk of persistent lesions, and the risk of upstaging was higher in cases of serous borderline tumors (288).

Laparoscopic Surgical Management of Early-Stage Ovarian Cancer

It is uncommon for gynecologic oncologists to knowingly operate on women with ovarian cancer laparoscopically unless it is to determine the resectability of patients with advanced disease (see section above). Thus, in most instances the ovarian cancer is diagnosed inadvertently at the time of surgery for a presumed benign ovarian mass. There are two options: (a) complete the surgery laparoscopically or (b) convert to a laparotomy.

In experienced hands, the surgery can technically be completed laparoscopically, particularly when the cancer appears to be limited to the ovary and when there is no evidence of gross metastatic disease (39). In a recent series reported by Havrilesky et al., the ovarian malignancies discovered at the time of laparoscopy for pelvic masses were managed laparoscopically and this was not associated with an adverse outcome (109). A recent study comparing 15 cases of early ovarian cancer managed by laparoscopy to 19 cases managed by laparotomy shows no difference in outcome between the two groups. Complication rate and shorter hospital stay were in favor of the laparoscopy group (289). Lecuru et al. found no deleterious influence of laparoscopy as first surgical access on outcome of patients with early-stage cervical cancer (290). However, in a recent survey, Leblanc et al. concluded that complete laparoscopic management of early-stage ovarian cancer is feasible in selected cases, but should be reserved to surgeons with advanced skills in laparoscopic surgery (291). Obviously, when faced with the discovery of an ovarian malignancy, another option is to convert the laparoscopy to a laparotomy to complete the surgery if surgeons do not feel comfortable performing the whole staging laparoscopically (106,292).

Whether or not laparoscopy compromises outcome in patients managed laparoscopically for a pelvic mass compared with patients managed by laparotomy is not clear (293). Unfortunately, there are no prospective, randomized trials with a large number of patients and long-term follow-up to answer this very important question. There are several uncertainties that are still not well answered with regard to the safety and efficacy of minimally invasive surgery in early-stage ovarian cancer (294). Until such solid data are available, oncologists should remain very cautious with regard to the use of laparoscopy in the management of suspicious complex adnexal masses and early-stage ovarian cancer. Caution should be used when counseling such patients. First and foremost, minimal access surgery should not compromise outcome, particularly for patients with early-stage disease who have an excellent prognosis.

There are a few concerning reports of trocar-site recurrences following laparoscopic surgery. For instance, an isolated abdominal wall metastasis has been reported in a woman operated on for early-stage ovarian cancer 10 years earlier (295). Port-site metastasis at the trocar site of a previous endocholecystectomy performed 7 months prior to abdominal surgery for advanced ovarian cancer has also been reported; the metastasis appeared after completion of platinum-based chemotherapy (296). These two reports suggest that cancer cells can probably be trapped at the level of trocar sites and remain dormant for several years. Trocar-site metastasis may also be only the tip of the iceberg. Indeed, CT scan may show more extensive spread either within the abdominal wall

tracking or associated with intra-abdominal carcinomatosis (297). Huang et al. also recently reported that port-site metastasis that appears during chemotherapy or after adequate chemotherapy is associated with a very poor prognosis (298). Trocar-site metastasis associated with laparoscopic surgery is a very serious condition and all efforts should be made to reduce its occurrence.

Despite the above, the risk of malignancy in patients operated on for presumed benign pelvic masses is relatively low (Table 13.1) (39,94–109) but will always be present despite adequate and thorough preoperative evaluation. The majority of women will benefit from the minimally invasive laparoscopic approach, which is clearly associated with lower morbidity and cost. In the event of a malignancy discovered at the time of surgery, clear mechanisms have to be in place to minimize the risk of tumor dissemination, particularly at the level of trocar sites: appropriate surgical technique to prevent tumor spillage (avoid cyst puncture or morcellation, use of endobag, proper closure of trocar sites, etc.), conversion to immediate laparotomy if satisfactory surgery cannot be adequately completed laparoscopically, and rapid referral to proper centers to either complete surgery or for adjuvant chemotherapy. Proper teaching following strict oncologic and surgical principles is thus essential to promote safe laparoscopic surgery (299). If strict guidelines are followed, in the end, women will benefit from the minimally invasive laparoscopic surgery for the management of benign masses, and outcome should not be jeopardized for those found to have a malignancy discovered inadvertently.

Hand-Assisted Laparoscopy

Hand-assisted laparoscopy (HAL) has been introduced as an adjunct to conventional laparoscopic surgery to facilitate the surgery and reduce the rate of conversion to laparotomy. It is used more frequently by GI and genitourinary (GU) surgeons, and procedures such as splenectomy, pancreatectomy, hepatectomy, nephrectomy, prostatectomy, and colectomy have been successfully performed by HAL. The HAL approach implies a 6 to 8 cm skin incision in order to place the gel port through which the surgeon's hand and the laparoscopic instruments can be introduced while maintaining the pneumoperitoneum. HAL confers several advantages over laparoscopy alone: return of tactile sensation, improved spatial relationships, rapid exploration of the abdomen, palpation of intra-abdominal organs and masses, retraction and reflection of tissue planes, atraumatic blunt dissection, rapid control of bleeding, and lysing of dense adhesions. Even though a longer incision has to be made, HAL appears to maintain all the benefits of conventional laparoscopic surgery, i.e., less postoperative ileus and pain, less blood loss, and shorter hospital stay. In addition, HAL frequently reduces the operating time and shortens the learning curve.

HAL seems underused in gynecologic oncology surgery, and only a few groups have reported their experience so far. Spannuth et al. recently reported their experience with the management of 29 patients with a pelvic mass by HAL versus 41 managed by conventional laparotomy. The two groups were comparable in terms of age, body mass index (BMI), and size of the mass, and they found that HAL was associated with statistically lower blood loss, shorter hospital stay, and fewer postoperative complications (300). Krivak et al. approached 25 patients with ovarian cancer by HAL. Of the 19 with apparent early-stage disease, 10 (53%) were up-staged as a result of the full staging procedure done by HAL, and 88% of the cases were successfully completed by HAL (301). HAL has also recently been used to manage recurrent disease. The ideal situation is one where the recurrence appears to be an isolated mass.

Chi et al. recently described the technique for HAL splenectomy in five patients with an isolated recurrence in the spleen. The procedure was safely performed without complications (302).

VIDEOENDOSCOPIC SURGERY AND CANCER OF THE VULVA AND VAGINA

Surgery for the management of cancers of the vagina and/or vulva includes lymph node dissection. For cancers of the upper half of the vagina, the management is similar to that of patients with cervical cancers. Open surgery is the standard, but laparoscopically assisted vaginal radical surgery can be used as well (303). The best indication for laparoscopy may be for the reoperation of patients with incidental cervical cancer discovered at simple hysterectomy. This "Schauta *sine utero*" (304) seems to be safer than the classic open restaging. In a series of 17 patients managed between 1987 and 2003, no recurrence was observed among the 4 patients considered as being free of disease after laparoscopic vaginal restaging versus 1 of 4 patients who underwent only laparoscopic restaging and 1 of 3 patients who underwent abdominal restaging and were considered to be disease-free (DFD, unpublished data).

CONCLUSIONS

The most difficult question to answer is the actual benefit both the patient and the surgeon garner from the use of laparoscopic surgery rather than classic open surgery. For extirpative surgery, this benefit remains purely hypothetical as there is a paucity of level one evidence on this subject. The GOG has launched a trial to assess the advantages of laparoscopic surgery in the management of endometrial cancer. A French group has done the same for the management of early cervical cancer. Both organizations have met similar difficulties in enrolling patients owing to the public awareness that laparoscopic surgery is more patient friendly. This concept may deter patients from participating in randomized trials that could result in patients foregoing laparoscopy for laparotomy. However, without such randomized trials, the questions surrounding the laparoscopic approach, which include quality of life, will never be answered. The only truly recognized improvement is radical trachelectomy. Although no births were reported after the initial attempts of the pioneers using an abdominal approach, one birth was reported by the new supporters of the older method (305). This one success is in contrast to the numerous births reported after the laparoscopic vaginal operation. In regard to staging surgery, laparoscopically assisted staging surgery greatly reduces morbidity without sacrificing accurate assessment of disease spread. A brief operative procedure and hospitalization can now provide definitive information upon which appropriate treatment can be prescribed. Here may be the future of laparoscopic oncosurgery. However, even with this indication where the superiority to open surgery looks clear, we still require prospective evidence upon which it can be justified.

CHAPTER 14 ■ BIOLOGIC AND PHYSICAL ASPECTS OF RADIATION ONCOLOGY

BETH A. ERICKSON-WITTMANN, JASON ROWND, AND KEVIN KHATER

RADIATION ONCOLOGY AS A SPECIALTY

Radiation oncology is a specialty focused primarily on the treatment of malignancies, although there are a number of benign diseases for which radiation can be used. Training in radiation oncology begins with internship followed by 4 years of residency. Board certification follows, requiring successful completion of both written and oral exams. Residency training includes an in-depth understanding of the natural history and treatment of all malignancies including the roles of surgery and systemic therapy in this era of multimodality therapies. An in-depth understanding of surgical procedures, pathology, and radiologic anatomy, as well as the efficacies and toxicities of systemic therapy, are required. Formal instruction in physics and radiobiology is also part of the residency training. Subspecialization can follow with a specific practice focus on gynecologic or other cancers. Only a few centers sponsor fellowships, which are usually focused on brachytherapy or other special procedures. Brachytherapy skills are especially important in the curative treatment of patients with gynecologic cancer. In addition, contemporary treatment of gynecologic malignancies requires mastery of rapidly evolving technology for delivering external beam irradiation with techniques such as intensity-modulated radiation therapy (IMRT) and image-guided radiation therapy (IGRT). Radiation oncologists are important contributors in the management of individual patients and in multidisciplinary tumor boards. Having a knowledgeable and subspecialized radiation oncologist and gynecologic oncologist paired is a great benefit to all. In addition to radiation oncologists, other allied health professionals are integral to the radiation oncology department and treatment delivery. Radiation therapists are the individuals who actually operate the radiation equipment and deliver the radiation treatments. Some of them will obtain a Bachelor of Science degree followed by a 13-month training program in radiation therapy. Alternatively, a 2-year associate degree in diagnostic radiology can be obtained followed by 1 to 2 years in radiation therapy training. Dosimetrists are primarily responsible for doing the radiation therapy planning or dosimetry prior to treatment delivery. Most of these individuals are former radiation therapists. An additional 1 to 2 years of training under a physicist and board certified dosimetrist, as well as additional years of practice, are required to be eligible for board certification. Radiation physicists supervise and review the work of dosimetrists. Physicists are also integral to the introduction and maintenance of the rapidly evolving technology in radiation oncology departments. They are very involved with quality assurance and radiation safety. They can be Master's level or PhD level physicists and should be board certified.

INTRODUCTION TO RADIOBIOLOGY

Radiobiology is the study of the action of ionizing radiations on living things (1). It is important for radiation oncologists to know the most appropriate dose to potentially irradiate the tumor and the normal tissue tolerance doses for those organs in the radiation field. The published literature includes clinical and laboratory data to support various dose/fractionation schemes as well as acceptable dose ranges to the normal tissues. The size and histology of the tumor as well as the relationship of the tumor to the normal organs within the radiation field will help to determine the total dose and the dose per fraction. Almost every radiation oncologist approaches treatment planning by considering whether the therapy is curative versus palliative. If curative, then the focus becomes identifying the location of the disease and how best to irradiate it. Typically, radiation and chemotherapy treatments take place over many months, and upon completion of treatment, if there is still a clonogenically viable cell that remains, then the tumor will ultimately recur. Clinical radiobiology focuses on steps that maximize the chance for cure and decrease the chance for side effects.

As in pharmacology, radiation effects exhibit a sigmoidal dose-response curve. In the case of radiation, the interpretation of the curve becomes far more complex because multiple independent processes govern responses to radiation. Pharmacology, on the other hand, tends to be simpler because classic examples can be described by a ligand binding to a group of receptors initiating subsequent events. Keeping this in mind, consider the following theoretical dose-response curve for tumor control probability and normal tissue complications in the presence and absence of chemotherapy (Fig. 14.1). Ideally, there is a great deal of separation between the curve on the left, representing chances of tumor control, and the curve on the right, representing the chance for toxicity. An intolerable situation is where the curves are close together since, as they approach one another, the chances of control and toxicity become equal and the therapeutic range (TR) narrows. Therefore, the most important goal of radiobiology is to understand the basic science behind the interaction of radiation and cells with the hope of maximizing the risk-benefit ratio for patients.

Models for Cell Kill

Tumor Control Probability

The simplest model one can envision for the sterilization of cancer cells by radiation in a given volume is the log cell kill model. A typical course of radiation therapy is given in 10 to

FIGURE 14.1. Theoretic curves for tumor control and complications as a function of radiation dose both with and without chemotherapy. TR, therapeutic range, or the difference between tumor control and complication frequency. *Source:* Reprinted from Perez CA, Thomas PRM. Radiation therapy: basic concepts and clinical implications. In: Sutow WW, Fernbach DJ, Vietti TJ, eds. *Clinical Pediatric Oncology*. 3rd ed. St. Louis: Mosby; 1984:167, with permission from Elsevier.

40 fractions administered over 2 to 8 weeks. Each fraction kills a fixed percentage of cells. We are trained at a young age to mathematically think in base 10, and therefore a convenient number to consider is the D_{10} or the dose which kills 90% of the cells. If there are 100 cells and a D_{10} dose is administered, 10 viable cells remain. D_0 , a commonly used term, is the dose of radiation that kills 63% of cells. D_0 is related to the more convenient parameter D_{10} by the following formula: $D_{10} = 2.3 \times D_0$. Consider a tumor 1 g in size, which has 10^9 cells. If the D_{10} for this tumor is 3 Gy, how many fractions are required for a 90% chance of sterilization? The log cell kill model gets slightly more complicated when dealing in fractions since 1/10 of a viable cell does not exist. Instead, 0.1 cells represent a 10% chance that a viable cell will exist at the end of therapy. Therefore, a tumor with 10^9 cells requires 10 decades of cell kill for a 90% chance of tumor control. Three Gy \times 10 fractions = 30 Gy total dose. This model makes a number of invalid assumptions such as D_{10} remaining constant throughout the course of radiation. As discussed later, there are data that support D_{10} both increasing and decreasing throughout treatment.

When it comes to actually treating patients, physicians do not actively engage in the above mental exercise. However, the basic concepts of the log kill model are reflected in the administered treatments. Consider, for example, curative therapy for cervical cancer. Radiation oncologists begin treatment planning by first identifying the targets GTV (gross target volume) and CTV (clinical target volume) (Fig. 14.2). The CTV is any region that has a high likelihood of harboring malignancy, but otherwise appears normal. For cervical cancer, this could be normal-sized pelvic and possibly paraaortic lymph nodes or an area of positive margin. The CTV typically requires a lower dose of radiation for control, ranging from 45 to 54 Gy. The GTV is defined as any disease that is identified either radiographically or by physical exam and requires a higher dose of radiation, such as 80 to 90 Gy in cervical cancer patients. Attaining these doses of radiation while respecting normal tissue tolerance is not feasible with external beam radiation therapy alone and brachytherapy is required. If a patient undergoes a hysterectomy where bulk tumor is removed, then there is not a GTV and brachytherapy is often not needed. So, while the cell kill model is of little practical importance, it is used nonquantitatively for almost every patient receiving radiation treatments.

FIGURE 14.2. Target definition in radiation treatment planning for cervical cancer. The solid circle represents the gross target volume (GTV), which is the cervical primary defined both clinically and radiographically. The clinical target volume (CTV) is the pelvic lymph nodes, which have a high probability of at least microscopic involvement. The planning target volume (PTV) is shown as the outer solid line and represents the margin added to the CTV to account for organ motion and daily setup error.

Cell Survival Curves

The log cell kill model describes cell kill in very simplistic terms such that a given radiation dose will kill a certain percentage of cells and that a tumor receiving a fractionated course of radiation gets progressively smaller with time. This approach looks at behavior in a population of cells, which is practical, but gains very little insight into events at the molecular level. The reason is that measuring the diameter of the tumor is not a very accurate way of estimating cell kill. Additionally, tumor cells may have undergone clonogenic cell death, wherein they are still present but unable to reproduce. Therefore, one does not necessarily have to kill all cancer cells in order to achieve cure if the remaining ones are unable to reproduce.

In order to understand events at the molecular level, one needs to accurately measure cell kill. The technique used most commonly first involves creating a suspension containing the target population of cells at a known concentration (Fig. 14.3). An aliquot with a known number of cells is plated on agarose growth media and allowed to incubate. As one would expect, not all the cells successfully form a colony, and so plating efficiency must be calculated by dividing the number of formed colonies by the starting number of cells. The experiment is repeated, but after plating and before incubation, the petri dish is irradiated. The number of colonies formed is divided by the starting number of cells, which is then divided by plating efficiency to yield the ratio of surviving cells. This experiment is repeated over a range of doses of radiation and under various conditions to yield a cell survival curve. The first feature to notice about a cell survival curve is that it uses a logarithmic scale on the y-axis such that as survival approaches 0, the curve goes to negative infinity. The benefit of plotting the data on a logarithmic scale is that, visually speaking, we are able to interpret whether the events driving cell kill are simple or complex. Consider the analogy of a completely different process, such as the decay of a pure radioisotope over time.

FIGURE 14.3. Cell culture technique used to generate a cell survival curve. A cell suspension is used to plate Petri dishes with a known number of cells, which are subsequently irradiated. Viable cells will form colonies after incubation. The number of viable cells divided by the plating efficiency is used to calculate the surviving fraction. The experiment is repeated over a wide range of doses to produce the cell survival curve.

Plotting this on a linear scale over time would yield an exponential curve, which is difficult to interpret. However, plotting this on a logarithmic scale would yield a perfect straight line indicating that a single isotope is involved. Consider a slightly more complex situation where the decay is represented by two radioactive isotopes with similar half-lives. Plotting this on a linear scale would also reveal an exponential curve, which is unrevealing by inspection. However, creating a plot on a logarithmic scale would yield two lines superimposed on one another, clearly indicating that two radioisotopes are involved.

Two theoretical experimental cell survival curves are shown in Figure 14.4 under LDR (low dose rate) and HDR (high dose rate) radiation conditions. The curve for LDR is best fit by a straight line, while the HDR curve is shown to have two components, an earlier linear component mirroring

FIGURE 14.4. Cell killing by radiation is largely due to aberrations caused by breaks in two chromosomes. The dose-response curve for high dose rate (HDR) irradiation is linear-quadratic: the two breaks may be caused by the same electron (dominant at low doses) or by two different electrons (dominant at higher doses). For low dose rate (LDR) irradiation, where radiation is delivered over a protracted period, the principal mechanism of cell killing is by the single electron. Consequently, the LDR survival curve is an extension of the low-dose region of the HDR survival curve.

the LDR curve followed by a quadratic component. At higher doses of radiation, the HDR curve always has a higher proportion of cell kill than the LDR curve for any given dose.

The rate at which radiation is delivered causes dramatic differences in the shape of the cell survival curve. This is best described by considering the linear-quadratic model with DNA as the lethal target. The evidence for DNA as one of the targets for radiation is substantial: (a) incorporation of radioactive tritium into DNA causes cell death at greater rates than cytoplasmic tritium (2); (b) halogenated pyrimidines, when present in DNA, increase the cell's inherent radiosensitivity in an amount proportionate to the degree of incorporation; (c) a correlation between radiation, DNA double-stranded break repair, and clonogenic survival has also been observed; (d) the concentration of DNA in the nucleus correlates positively with radiosensitivity (3); (e) microirradiation techniques have shown the nucleus to be the most radiosensitive organelle (4).

In most instances, radiation must cause DNA damage that results in a net loss of genetic material, thereby causing a lethal outcome. Radiation exerts most of its deleterious effects by causing breaks in the DNA backbone. Figure 14.5 shows possible outcomes of photon interaction with the DNA backbone. Because DNA is composed of a double helix with multiple local base pairs acting cooperatively, a single-strand nick is thought to be inconsequential and is repaired by the cellular machinery (Fig. 14.5b). In fact, multiple single-strand nicks can occur, and if they are remote from one another, a normal cell can repair the damage with little chance of a deleterious outcome (Fig. 14.5c). However, two opposing single-strand breaks locally disrupt cooperativity, and a double-stranded break (DSB) develops.

Once a DSB develops, the cell attempts repair by rejoining the cut ends, as shown in Figure 14.6. There are two possible outcomes with repair of the DSBs: the lethal outcomes are shown at the top of Figure 14.6, wherein the chromosomes rearrange such that a portion lacks a centromere, an acentric fragment. When the cell undergoes mitosis, these acentric fragments are eventually lost and may be identified in micronuclei, a smaller "sub-nucleus" found in the cytoplasm in a separate compartment from the chromosomes (5–7). The nonlethal

FIGURE 14.5. Diagrams of single- and double-strand DNA breaks caused by radiation. **a:** two-dimensional representation of the normal DNA double helix. The base pairs carrying the genetic code are complementary (i.e., adenine pairs with thymine, guanine pairs with cytosine). **b:** a break in one strand is of little significance because it is readily repaired, using the opposite strand as a template. **c:** breaks in both strands, if well separated, are repaired as independent breaks. **d:** if breaks occur in both strands and are directly opposite or separated by only a few base pairs, this may lead to a double-strand break, where the chromatin snaps into two pieces. *Source:* Courtesy of Dr. John Ward. From Hall EJ. *Radiobiology for the Radiologist*. 4th ed. Philadelphia: JB Lippincott Co.; 1994.

outcomes are shown at the bottom of Figure 14.6, where repair results in a reciprocal translocation and preservation of the genetic information. In some instances, the reciprocal translocation results in activation of an oncogene, which may manifest as a malignancy. It is worth noting that a “bystander effect” has been described using microbeam irradiation techniques (8). In this approach, a nanoscale α -particle beam is directed

at the nucleus of a single cell. DSBs can be seen to develop in immediately adjacent unirradiated cells. This is just one notable example where classic radiation DNA damage models fail to explain an observation.

With the above information, the differences in the shape of the cell survival curve under HDR versus LDR conditions can be more easily understood. Referring back to Figure 14.4, in the inset is shown the linear-quadratic model depicting two DSBs that develop as result of a photon ejecting an electron, which interacts with DNA. Recall from Figure 14.6 that two separate chromosomal breaks are necessary for a potentially lethal outcome. Above the quadratic model is the linear model represented as a single ejected electron causing both DSBs and described mathematically by $\epsilon\alpha D$ where ϵ and α are both constants and D is dose. The important point is that the degree of the linear component of cell kill, also known as α kill, is proportional to D since only one photon/electron is involved. The quadratic model also shows two chromosomal breaks. This is caused by two separate ejected electrons and is described by $\epsilon\beta D^2$ where ϵ and β are constants and D is again dose. Cell kill accounted for by the quadratic model, or β kill, is proportional to D^2 because two photons/electrons are involved. Looking at the HDR curve at low doses of radiation, there is very little β kill; however, at higher doses the β component increases exponentially because of D^2 . Under LDR conditions, the β component is absent, leaving only α kill. This is best explained by the idea that β kill involves damage to one chromosome and so is more easily repaired provided that the radiation dose rate and rate of DSB formation is not significantly greater than the cell’s repair capacity.

DNA Damage Repair and the Shape of Cell Survival Curves

The concept that DNA damage repair drives the shapes of cell survival curves is well illustrated by experiments showing the effectiveness of oxygen as a sensitizer. Oxygen is known to chemically modify radiation-induced DNA damage making it irreparable (8). This is known as the oxygen fixation hypothesis. Therefore, under anoxic conditions, DNA damage repair would be expected to increase considerably. Figure 14.7 shows an experiment on cultured human embryo liver cells irradiated under 100% oxygen and nitrogen conditions. Hypoxia causes the cell survival curve to shift to the right and change shape.

FIGURE 14.6. Most biologic effects of radiation are due to the incorrect joining of breaks in two chromosomes. For example, the two broken chromosomes may recombine to form a dicentric (a chromosome with two centromeres) and an acentric fragment (a fragment with no centromere). This is a lethal lesion resulting in cell death. Alternatively, the two broken chromosomes may exchange broken ends, called symmetrical translocation, which does not lead to death of the cell, but in a few special cases activates an oncogene by moving it from a quiescent to an active site.

FIGURE 14.7. Influence of oxygen tension on radiosensitivity. Survival curve for human embryo liver cells in tissue culture irradiated with and without oxygen. Source: From Johns HE, Cunningham JR. *The Physics of Radiology*. 3rd ed. Springfield, IL: Charles C Thomas; 1972, with permission.

Up to this point, the linear-quadratic model has been used to describe cell survival curve experiments. Another way to describe the observations is using the multi-target single hit model, which simply states that multiple targets within a cell must be damaged for a lethal outcome. Therefore, at very low doses of radiation there will be nearly 100% survival. The model is described mathematically by $\text{Survival} = 1 - (1 - e^{-D/D_0})^n$, where D is dose delivered, D_0 is the amount of radiation to achieve approximately 63% cell kill. The parameter n is the extrapolation coefficient or the number of targets in each cell, and is identified by where an imaginary straight line drawn back from the linear portion of the cell survival curve crosses the y-intercept. It is important to note that this model makes no statement about what the targets actually are. Since we already know that the primary target is DNA, which can trigger multiple complicated events such as repair and apoptosis, the single hit multi-target model falls short of perfection. Nevertheless, it is a good model for understanding the general shapes of survival curves. Contrast this model to the single-target single hit model, which states that a cell needs only to sustain a single hit for lethality, and is described mathematically by $\text{Survival} = e^{-D/D_0}$. Therefore, even at very low doses of radiation, there will be cell kill. Note that this model does not have an extrapolation coefficient.

Referring back to Figure 14.7, the cell survival curve under anoxic conditions can be interpreted as having a higher extrapolation coefficient when compared to 100% oxygen. The extrapolation coefficient is shown diagrammatically by following the dotted lines of the survival curves back to the y-intercept. n is where the dotted line crosses the y-intercept.

The inset shows a dose-response relationship between oxygen and radiosensitivity. The typical sigmoidal relationship is lost because oxygen is extremely effective at fixing DNA damage even at low pressures. In fact, only approximately 20 mm Hg or 2% to 3% oxygen is required to achieve the maximum oxygen effect. The half-maximum sensitization is typically observed at 3 mm Hg or 0.5% of oxygen.

The linear-quadratic model is stated more explicitly by the following equation:

$$-\ln S = \alpha D + \beta D^2$$

where S is the surviving fraction and the remaining parameters α , β , and D are the same definitions as above. The formula was used to generate Figure 14.8. The dashed line represents the α component and is generated by extrapolating the initial slope of the curve to higher doses of radiation. The point at which the α and β kill are equal is shown, and the dose at which this occurs is called the α/β ratio. It is worth noting that the α/β ratio is a bit of a misnomer since ratios typically are unitless values. However, α/β has the units of Gy^{-1} . The α/β ratio for early side effects is thought to be higher, around 10 Gy^{-1} , than for tumor control and late side effects, which is around 3 Gy^{-1} .

FIGURE 14.8. At a dose equal to the α/β ratio, the log cell kill due to the α process (nonreparable) is equal to that due to the β process (reparable injury): α/β is thus a measure of how soon the survival curve begins to bend over significantly. Source: Reprinted from Fowler JR. Fractionation and therapeutic gain. In: Steel GG, Adams GE, Peckham MJ, eds. *Biologic Basis of Radiotherapy*. Amsterdam: Elsevier Science; 1983:181-194, with permission from Elsevier.

Biologically Equivalent Dose

It is clear from Figure 14.4 that both the total dose of radiation and how fast it is delivered can produce very different outcomes. The same holds true for fractionated courses of radiation. For example, 16 Gy delivered in a single treatment, as is the case for radiosurgery, can sterilize a small tumor of cancer cells. However, the same treatment delivered over 8 days would be clinically insignificant. Figure 14.9 shows theoretical cell survival curves for early and late reactions under two separate experimental conditions, single fraction and multi-fraction regimens. Note that by breaking up the radiotherapy in fractions, the shoulder of the cell survival curve is repeated. A formula that would normalize a biologic endpoint under various dose fractionation schemes is necessary. The linear-quadratic equation can be used to derive an equation to be used as a guide to predict various biologic endpoints and is given by the following equation:

$$\text{BED} = D[1 + d/(\alpha/\beta)]$$

Where:

BED = biologically equivalent dose

D = total dose

d = dose per fraction

α/β = dose where the α component of cell kill equals the β component

A good example where the formula aided the design of a randomized trial, RTOG 8305, is shown below (9). This trial investigated two different fractionation schemes in the treatment of metastatic melanoma.

Early Side Effects (assumes an α/β of 10)

Arm 1 (32 Gy at 8 Gy/fxn):

$$\begin{aligned}\text{BED} &= D[1 + d/(\alpha/\beta)] \\ &= 32 \text{ Gy} (1 + 8 \text{ Gy}/10 \text{ Gy}) \\ &= 57.6 \text{ Gy}\end{aligned}$$

Arm 2 (50 Gy at 2.5 Gy/fxn):

$$\begin{aligned}\text{BED} &= D[1 + d/(\alpha/\beta)] \\ &= 50 \text{ Gy} (1 + 2.5 \text{ Gy}/10 \text{ Gy}) \\ &= 62.5 \text{ Gy}\end{aligned}$$

Late Side Effects/Tumor Control (assumes an α/β of 3)

Arm 1 (32 Gy at 8 Gy/fxn):

$$\begin{aligned}\text{BED} &= D[1 + d/(\alpha/\beta)] \\ &= 32 \text{ Gy} (1 + 8 \text{ Gy}/3 \text{ Gy}) \\ &= 117 \text{ Gy}\end{aligned}$$

Arm 2 (50 Gy at 2.5 Gy/fxn):

$$\begin{aligned}\text{BED} &= D[1 + d/(\alpha/\beta)] \\ &= 50 \text{ Gy} (1 + 2.5 \text{ Gy}/3 \text{ Gy}) \\ &= 92 \text{ Gy}\end{aligned}$$

In this instance, the BED calculations predict that arm 1 will have slightly more early and late side effects but better tumor control. BED calculations are used as a guide for determining doses. Oftentimes the calculations do not translate directly into the clinical setting outcomes. For example, RTOG 8305 was not able to detect a difference between the two dose fractionation schemes.

The Cell Cycle

The cell cycle is an ordered set of events, resulting in cell growth and division into two daughter cells. The steps, pictured in the middle of Figure 14.10, are G_1 -S- G_2 -M. The G_1 stands for “gap 1,” and S phase stands for “synthesis” and is the point at which DNA replication occurs. Late S phase is the most radioresistant phase of the cell cycle since the DNA repair machinery for replication can also repair radiation damage.

FIGURE 14.9. Difference in cell survival curves for acute and late radiation effects with single or multifractionated doses of irradiation. Source: Reprinted from Fowler JF. Fractionation and therapeutic gain. In: Steel GG, Adams GE, Peckham MT, eds. *Biologic Basis of Radiotherapy*. Amsterdam: Elsevier Science; 1983:181, with permission from Elsevier.

The G_2 stage stands for “gap 2,” and M phase stands for “mitosis” and is when nuclear division occurs. M phase is also the most radiosensitive phase of the cell cycle since this is an all or nothing event. In other words, once the cell enters into M phase, it will attempt to complete this phase of the cycle without arresting. Therefore, any DNA damage caused generally will be passed along to the daughter cells and may be fatal. This is one important reason why rapidly dividing cells such as cancers are radiosensitive. Not shown in Figure 14.10 is G_0 , which is a stable state of the cell and is typically observed with well-differentiated cells that have reached end stage of development and are no longer dividing (i.e., neuron).

There are three major classes of proteins that orchestrate the cell cycle in mammalian cells: (a) cyclins, (b) cyclin-dependent kinases (cdk in mammals, cdc in yeast), (c) proteins that regulate (a) and (b). Cyclins are generally synthesized and degraded for each phase of the cell cycle. Alone they have no intrinsic enzymatic activity; rather, they bind to and activate cdks. Monomeric cdks are protein kinases that are inactive and require association with a specific cyclin and phosphorylation of a series of conserved threonine residues to become active. Cyclin D/cdk4 is involved with G_1 phase of the cell cycle, cyclin E/cdk2 with G_1 to S phase, cyclin A/cdk2 with S to G_2 , and cyclin B/cdk1 with M.

Cellular Response to Radiation

When a cell is irradiated, there are, in general, four possible outcomes. The cell can survive, undergo apoptosis, undergo a mitotic death, or senesce. Survival requires cell cycle arrest and repair of damaged DNA. Apoptosis requires intact molecular biologic pathways that favor an ordered process of programmed cell death within hours of exposure to radiation. Unfortunately, most tumors have mutations in these pathways, but in malignancies such as lymphoma where these pathways are intact, the tumors can respond after only a couple of radiation treatments. Cells that die a mitotic death undergo a catastrophic event when trying to replicate and so responses may take days. Tumors that die via this mechanism are more radioresistant and result in necrotic masses on imaging after completing a course of radiation. Senescence is a state in which proliferation is irreversibly arrested and the cell may eventually die. Note that senescence is a metabolically active state, which is different from G_0 , which is typically metabolically inactive.

Inherent to the cell is a type of thermostat, which influences the radiation responses to favor any of the above processes. Protooncogenes are regulator proteins that, due to

FIGURE 14.10. The cell cycle and important molecular biologic pathways driving cell cycle arrest, apoptosis, and survival are shown. The solid pentagon denotes a net inhibitory step and the open circle indicates a downstream step.

either overexpression or mutation, have a higher activity level, thereby promoting unregulated division. Because this mechanism is a net gain of function, only one allele need be affected in order to see phenotypic expression. Tumor suppressor genes keep the cell cycle in check, and so loss of function of both alleles is typically required for dysregulation to be observed.

Cell Cycle Arrest

As previously mentioned, when a cell is irradiated, repair of the DNA backbone is attempted, and in order for this process to occur the cell cycle must typically arrest. There are two prototypical points in the cell cycle during which arrest occurs: G_1 and G_2 (10,11). A major regulator of the cell cycle is the transcription factor p53, which is a tumor suppressor gene that has many pathways both upstream and downstream and is important for G_1 arrest (Fig. 14.10) (12). For example, breaks in the DNA backbone are rejoined via the nonhomologous end-joining (NHEJ) repair mechanisms (top left of Fig. 14.10) (13). One critical gene, the ataxia telangiectasia gene (ATM) has a net positive regulatory effect on p53, which, via p21 (CCDKN1A), has a net inhibitory effect on cyclin D/cdk4, thereby favoring arrest. This is the p53-dependent pathway of cell-cycle arrest. An alternative pathway, independent of p53, operates via chk1/2 and 14-3-3 α gene products and has a net inhibitory effect on cyclin B/cdk1, which promotes arrest during G_2 (14).

Retinoblastoma Gene, E2F, and Human Papillomavirus

Retinoblastoma protein (Rb) is another critical regulator of the G_1 phase of the cell cycle (15). This gene is located on chromosome 13 and mutations can cause a number of tumors, the earliest of which to manifest is retinoblastoma. Knudson et al. developed the two-hit hypothesis for the inheritance pattern of this disease (16). He recognized that there were two forms: (a) sporadic, which comprises 60% of the cases of retinoblastoma, whereby mutations occur as random events in both alleles. Patients typically have unilateral disease and a marginal risk for developing second malignancies in response to radiation. (b) Inherited, where a germ-line mutation results when an abnormal allele is inherited from a parent. Patients with this form of retinoblastoma are more likely to develop bilateral disease and have a profound sensitivity toward developing radiation-induced second malignancies. Rb acts by binding and inhibiting E2F, a transcription factor essential for G_1 . Phosphorylation of Rb results in release of inhibition of E2F and subsequent cell cycle progression. Human papillomavirus gene product produces an oncogene, E7, which binds to Rb and releases inhibition of E2F, thereby promoting cell division (17).

Apoptosis

Apoptosis can begin in two distinct manners: (a) extrinsic pathway, where the apoptotic stimulus occurs extracellularly, or (b) intrinsic pathway, where the cascade of events is contained intracellularly. Figure 14.10 shows both pathways converging on caspase 8 (cysteine aspartic acid-specific proteases). Caspases are expressed as inactive precursors (procaspases), which are proteolytically cleaved to an active state following an apoptotic stimulus. Upstream from caspase 8, the pathways diverge. The extrinsic pathway begins by binding of a specific ligand such as Fas-L or tumor necrosis factor (TNF) to a membrane bound death receptor. The intrinsic pathway, on the other hand, requires disruption of the mitochondrial membrane, release of mitochondrial cytochrome to the cytoplasm. Cyt c then combines with two other cytosolic protein factors, Apaf-1 (apoptotic protease activating factor-1) and procaspase-9, to promote the assembly of a caspase-activating complex termed

the apoptosome, thereby promoting the apoptotic caspase cascade. Bcl-2 and its family member proteins are important regulators of apoptosis. Bcl-2 is anti-apoptotic by inhibiting proapoptotic factor bax and inhibiting the release of cyt c into the cytoplasm. p53 is an important inhibitor of bcl-2. All of these pathways interact to determine whether a cell will survive or apoptose in response to an insulting stimulus such as radiation.

Radiation Effects on Embryo and Fetus

In Utero Exposure to Ionizing Radiation

There are two models that describe the negative clinical sequelae of exposure to radiation to a developing fetus or embryo. (a) Deterministic effects describe how radiation affects a large population of cells resulting in end organ damage. A large number of cells must die in order to induce organ failure. As such, deterministic effects tend to have a sigmoidal dose-response relationship with a threshold dose. As long as the threshold dose is respected, there is very little chance of a given toxicity. (b) Stochastic effects describe events at the cellular level and how radiation induces malignancies. Stochastic effects have more of a constant, steep dose-response relationship. As such, there is no threshold dose, i.e., exposure to even miniscule amounts of additional radiation theoretically increases the chance of inducing a malignancy.

Deterministic Effects—End Organ Damage and Failure

The most sensitive phase of the cell cycle to ionizing radiation is M phase because little repair to the DNA backbone occurs during this period. Most of the cell molecular machinery is geared toward completing mitosis and any DNA double-stranded breaks are passed along to the daughter cells and are typically fatal. Since embryos and fetuses are composed of rapidly dividing cells, they are exquisitely sensitive to radiation and exhibit an extremely low threshold dose. Gestational age is also a key determinant when predicting outcomes of radiation exposure. As Figure 14.11 shows, exposure of several gray during the first 1 to 2 weeks of gestation (peri-implantation stage) results in loss of the embryo. However, if the embryo survives the insult, it will go on to develop without obvious abnormalities. This phenomenon is termed the “all or nothing effect.” During weeks 2 to 6, the period of organogenesis is occurring and exposure at this point results in congenital anomalies, neonatal death, and temporary growth retardation. Doses as low as 2 Gy have a 70% mortality. The fetal period occurs beyond 6 weeks and exposure results in permanent growth retardation. Irradiation during weeks 4 through 16 may produce severe eye, skeletal, and genital organ abnormalities as well as microcephaly and mental retardation. According to the Japanese survival data, the risk is approximately 40% per gray. Exposure during weeks 16 through 20 may cause a less severe form of stunting of growth, microcephaly, and mental retardation. After 30 weeks, low doses of radiation do not typically result in gross abnormalities.

Stochastic Effects—Cancer Induction

The Oxford Survey by Kneale and Stewart suggested that there was an association between leukemia risk and *in utero* exposure to diagnostic x-rays (18). Doll and Wakeford summarized the data with the following general conclusions: Low-dose irradiation increases the risk of childhood malignancies, particularly in the third trimester (19). An x-ray exam increases the risk by approximately 40% above the spontaneous rate. Doses as low as approximately 10 mGy increase the risk, and the excess absolute risk is around 6% per gray.

FIGURE 14.11. Summary of the effects of radiation on the developing embryo and fetus from three principal sources: medical radiation, laboratory animal studies, and survivors of the atomic bomb attacks during organogenesis, whereas the principal effect observed in humans is reduced head diameter with or without severe mental retardation. *Source:* Modified from Hall EJ. *Radiobiology for the Radiologist*. 4th ed. Philadelphia: JB Lippincott Co.; 1994.

Solid tumors have a longer latency period of approximately 20 to 40 years, whereas leukemias have an average latency of around 7 years. When counseling the pregnant patient or worker, it is important to let them know the magnitude of and potential for side effects. According to the International Council of Radiation Protection (ICRP) Publication 84, doses less than 1 mGy may be considered negligible, which is the approximate dose of normal background radiation (20). Exposures above 1 mGy require a more in-depth discussion with the patient. ICRP Publication 84 provides detailed risk assessments and counseling guidelines for *in utero* exposure.

Occupational Exposure

Once a pregnancy has been declared, the employee is encouraged to formally inform her employer. Further, the radiation safety officer should interview her, her employment should be evaluated for exposure history, and steps should be taken to minimize exposure. The National Council on Radiological Protection recommends that the embryo/fetus have limited exposure to less than 0.5 Sv/month (21).

INTRODUCTION TO RADIATION PHYSICS

Radiation physics is the study of the interaction of radiation with matter. In the treatment of patients with radiation, this matter is either tumor tissue or normal tissues such as the skin, the internal organs, or the supporting tissues and structures.

Units Used in Radiation and Radiation Therapy

Radiation is an abbreviation for electromagnetic radiation. It can occur in numerous forms. The most common forms used in radiation therapy are x-rays, γ -rays, and electrons. X-rays and γ -rays are also known as photons or packets of energy and are used to treat most body sites where radiation is deemed efficacious. Other particles or forms of radiation, such as protons, neutrons, and heavier alpha particles, are less commonly used in radiation therapy except in select clinical situations. Protons are used increasingly in the treatment of prostate cancers, choroidal melanomas, skull base and paraspinal tumors, and pediatric tumors. Neutrons have been used for salivary gland tumors, sarcomas, and prostate cancers.

X-rays and γ -rays are forms of electromagnetic radiation, similar to visible light, but with a much smaller wavelength, i.e., greater energy. The difference between x-rays and γ -rays is only their respective origins. X-rays are derived from interactions in the atom that are outside the nucleus, typically by bombardment of the atom or target with high-speed electrons. This is the source of radiation produced by most modern radiotherapy treatment machines termed linear accelerators or linacs. Their name derives from acceleration of these electrons. γ -rays arise from a process within the nucleus of the atom called radioactive decay, which occurs in brachytherapy sources and cobalt (^{60}Co) teletherapy treatment machines. This type of electromagnetic radiation can penetrate several millimeters to centimeters of normal tissue, in close proximity to tumors or tissues at risk. There is increased penetration as

FIGURE 14.12. Schematic drawing illustrating the process of the Compton effect. The incident photon interacts with one of the atom's outer electrons, and the energy is shared between the ejected electron and a scattered photon. *Source:* From Purdy JA. Principles of radiologic physics, dosimetry, and treatment planning. In: Perez CA, Brady LW, eds. *Principles and Practice of Radiation Oncology*. 3rd ed. Philadelphia: Lippincott-Raven Publishers; 1998, with permission.

the energy of the gamma rays is increased. The x-rays produced by linear accelerators are much more penetrating than ^{60}Co gamma rays and are used to treat tumors or tissues at a distance from the linear accelerator such as deep within the pelvis or abdomen.

Electrons are small, negatively charged particles. Because of their inherent charge, these particles interact more strongly with the atoms found in tissue. Electrons will usually only penetrate a few millimeters to centimeters in tissue. Similar to photons, the higher the energy of the electron, the farther it will penetrate into the tissue. Electrons are used to treat tumors or tissues close to the skin surface such as superficial inguinal nodes and tumors of the skin, including vulvar cancers.

Regarding photon interactions with tissue, the dominant process at energies used in radiation therapy is termed the Compton effect (Fig. 14.12). The probability that a photon will interact with a target atom is inversely proportional to the energy of the incident photon and nearly independent of the atomic number of the target material. As a result, at the energies used in radiation therapy, termed megavoltage (MV), the absorbed dose in normal tissues is comparable to that in nearby bone. At much lower energies, termed kilovoltage (kV), the absorbed dose would scale with the atomic number of the target with higher absorbed dose in bone compared to normal soft tissues.

At the second International Congress of Radiology in 1928, the basic unit of exposure, the roentgen (R) was defined (22). Although the original definition evolved over time, the fundamental idea remained the same. The roentgen is the amount of photon radiation that causes 0.001293 g of air to produce one electrostatic unit of positive or negative charge (esu). The value of 0.001293 g is the mass of 1 cc of air at a temperature of 0°C and a pressure of 760 mm Hg. The definition of the roentgen can also be expressed in other equivalent terms:

$$1 \text{ R} = 2.58 \times 10^{-4} \text{ C/kg air}$$

or, conversely, expressed in SI units, the unit of exposure is defined by

$$1 \text{ C/kg} = 3,876 \text{ R}$$

Table 14.1 lists some basic units of radiation and radiation therapy, both in historic context and in terms of modern SI units. Kerma (kinetic energy release per unit mass) defines the transfer of energy from photons to directly ionized particles. These directly ionized particles, in turn, transfer some of their energy to the medium (usually tissue). This transfer of energy is defined as the absorbed dose to the medium from the radiation beam. The SI unit for kerma is joule per kilogram (J/kg) or gray (Gy). In a slightly confusing definition, the SI unit for absorbed dose is also joule per kilogram or gray. The term gray has replaced the previously used term "rad". Oftentimes the term centigray (cGy) is used. The cGy is equivalent to the rad and 1 gray equals 100 cGy.

Another rationale to think and communicate in SI units is that the roentgen was defined explicitly for photon interactions and not charged particles. Kerma and absorbed dose, although they have equivalence to the roentgen and exposure, can be defined equally for photons and charged particles.

RADIATION PRODUCTION

Radioactive Isotopes

As mentioned before, γ -rays are typically derived from radioactive isotopes, e.g., ^{60}Co . Electrons or beta particles also come from radioactive isotopes. In fact, most radioactive material produces a combination of photons (gamma rays) and electrons during the decay process. Radioactivity is the result of an atom changing its "energy" state, usually to a lower "energy" state, by the emission/absorption/internal conversion of photons or electrons in the atom. These processes result in disintegrations or radioactive decay whereby the atom releases photons or electrons or both during the change in "energy" states. The release of these particles is a form of radiation (or energy) that can be used to irradiate tissues. The absorbed dose resulting from this radiation depends on the energy and particle type as mentioned above, as well as the tissue in which it interacts.

Radioactivity, or activity, is denoted by the symbol A and is defined as the number of disintegrations per unit of time. The following relationship defines activity, the decay constant, and ultimately the half-life for a radioactive material:

$$A = N/t = \lambda N$$

This equation is solved using an exponential solution:

$$A = A_0 e^{-\lambda t}$$

where A is the initial activity, λ is the decay constant, and t is some unit of time later. Other important units for radioactivity and radioactive decay are the half-life, $T_{1/2}$, and the average life, T_a . The half-life is the amount of time necessary to reduce the original amount of material by half. This is also equivalent to reducing the original activity by half. $T_{1/2}$ is related to the decay constant by $T_{1/2} = 0.693/\lambda$. The average life represents

TABLE 14.1

SI UNITS FOR RADIATION THERAPY

Quantity	SI unit (special name)	Non-SI unit	Conversion factor
Exposure	C kg^{-1}	roentgen (R)	$1 \text{ C kg}^{-1} \approx 3876 \text{ R}$
Absorbed dose, kerma	J kg^{-1} (gray [Gy])	rad	$1 \text{ Gy} = 100 \text{ rad}$
Dose equivalent	J kg^{-1} (sievert [Sv])	rem	$1 \text{ Sv} = 100 \text{ rem}$
Activity	s^{-1} (becquerel [Bq])	curie	$1 \text{ Bq} = 2.7 \times 10^{-11} \text{ Ci}$

the period of time that a hypothetical source would need, if it retained its original activity for a fixed period of time (T_a) before suddenly decaying to zero activity, to produce the same number of disintegrations over an infinite amount time by the same source if it decayed exponentially. T_a is related to the decay constant and the half-life by $T_a = 1/\lambda = 1.44 T_{1/2}$.

Radioactive isotopes can occur naturally or be created artificially. Artificially created isotopes are usually created by neutron bombardment of otherwise stable isotopes. The resulting interactions produce atoms that are inherently unstable and will decay to a more stable form with a predictable half-life, releasing energy or radiation through this decay. Naturally occurring radioactive isotopes originally come from one of three

standard series—the uranium series, the actinium series, and the thorium series—so named because of a dominant radioactive isotope in each series. In general, the higher the atomic number, the more likely an isotope will be radioactive. Table 14.2 lists many of the more common radioactive isotopes and their physical properties. For gynecologic cancers, use of radium 226 (^{226}Ra) sources is now historic. Though cost-effective because of its long half-life (1,622 years), radium releases a by-product, radon gas, if the integrity of the source capsule is compromised. This could require closure of hospital wards due to radon gas contamination. Cesium 137 (^{137}Cs) has replaced radium as a safer yet effective radioisotope. Less shielding is required for cesium than radium, and there is no

TABLE 14.2**PHYSICAL PROPERTIES AND USES OF BRACHYTHERAPY RADIONUCLIDES**

Element	Isotope	Energy (MeV)	Half-life	HVL-lead (mm)	Source form	Clinical application
OBSOLETE SEALED SOURCES OF HISTORIC SIGNIFICANCE						
Radium	^{226}Ra	0.83 (avg)	1,626 years	16	Radium salt encapsulated in tubes and needles	LDR intracavitary and interstitial

Iodine	^{131}I	0.61 MeV β_{max} 0.364 MeV γ	8.06 days	—	Capsule NaI oral solution	Thyroid cancer
Phosphorus	^{32}P	1.71 MeV β_{max}	14.3 days	—	Chromic phosphate colloid instillation; Na ² PO ₃ solution	Ovarian cancer seeding; peritoneal surface; polycythemia vera, chronic leukemia

Note: LDR, low dose rate; HDR, high dose rate.

risk of radon gas leakage. With a half-life of 30 years it is also cost-effective due to the infrequent need for replacement. Cesium can be used clinically for years without replacement, but the treatment duration must be adjusted to allow for radioactive decay (23). It is typically used for low dose rate gynecologic brachytherapy in tandem and ovoid and cylinder applicators. Iridium 192 (^{192}Ir) comes in various activities and can be used for interstitial and intracavitary gynecologic implants. Its half-life of 74.2 days requires frequent replacement and, typically, this is custom ordered individually for each implant rather than stored in the radiation oncology department like ^{137}Cs sources. High activity ^{192}Ir (^{10}Ci) sources are used for high dose rate brachytherapy and are replaced every 3 months, and lower activity ^{192}Ir sources are used for low dose rate brachytherapy.

Linear Accelerators

Linacs are another method of producing radiation for treatment of malignancies. Linacs can produce both photon and electron beams of different energies depending on their construction. The principles behind a linac involve accelerating an initial beam of electrons across a variable electric field. The greater the strength of the electric field, the more energetic the electron beam. This electron beam can be adjusted to control its shape and intensity before delivery to the patient. Alternatively, the electron beam can be directed to a tungsten target. The electron-target interaction creates a forward scattered photon beam or x-ray. The resulting photon beam can then be modified by the machine using filters and collimators to produce the desired radiation field shape.

Photon beams of different energies have a different absorbed dose pattern within tissues. This pattern is normally characterized as a percent depth dose or variation of dose as a function of depth within tissue, as shown in Figure 14.13 and Figure 14.14, and by dose profiles, or variation of dose as a function of lateral distance at a given depth (Fig. 14.15). The key feature in all of the figures is that higher energy photons deposit dose at greater depths. Because of the way dose is deposited and absorbed in tissue, the higher the photon energy, the less dose is deposited at shallow depths toward the

FIGURE 14.13. ^{60}Co to 25-MV x-rays. Source: From Velkley DE, Manson DJ, Purdy JA, et al. Build-up region of megavoltage photon radiation sources. *Med Phys* 1975;2:14-19, with permission.

FIGURE 14.14. Typical x-ray or photon beam central-axis percentage depth-dose curves for a 10×10 cm beam for 230 kV (2 mm Cu HVL) at 50 cm SSD, ^{60}Co and 4 MV at 80 cm SSD, and 6 MV, 10 MV, 18 MV, and 25 MV at 100 cm SSD. The last two beams coincide at most depths but do not coincide in the first few millimeters of the build-up region. The 4-MV, 6-MV, 18-MV, and 25-MV data are for the Varian Clinic 4, 6, 20, and 35 units, respectively, at the Department of Radiation Oncology, Washington University in St. Louis. Source: From Cohen M, Jones DEA, Greene D. Central axis depth dose data for use in radiotherapy. *Br J Radiol* 1972;11:21, with permission.

surface of the patient. This is called “skin sparing” and is a characteristic of high-energy photons. In fact, the higher the photon energy, the deeper the point at which the maximum absorbed dose is deposited. After this D_{max} , the absorbed dose decreases because the photon beam is attenuated by the tissues through which it passes.

Figure 14.16 shows a simplified drawing of a linac. The gantry (or part of the linac where radiation exits the machine) can rotate 360° around the patient on the treatment table. The table can also be rotated about the vertical axis of the radiation beam. This combination of angles allows the radiation to be directed to almost any part of a patient’s body.

Modern linacs come equipped with multileaf collimators (MLCs) and asymmetric jaws to control the shape of the radiation beam directed before it reaches the patient (Fig. 14.17). Prior to asymmetric jaws and MLCs, photon beam shaping was achieved using poured blocks mounted below the lowest machine jaws. The composition and thickness of the poured block material are sufficient to block more than 97% of the radiation, allowing less than 3% of the radiation to penetrate the block and reach the patient. MLCs have mostly replaced poured blocks, but in some cases poured blocks are still necessary for detailed field shaping.

MLCs are small (projected size at the patient ~ 1 cm), adjustable collimators built into the linac gantry that work together to create a shaped opening mimicking the effects of a poured block. Because each MLC is adjustable, a new field shape can be “programmed” into the gantry without the necessity of pouring a different block for every treatment field. With the advent of computer-controlled motion of the MLCs,

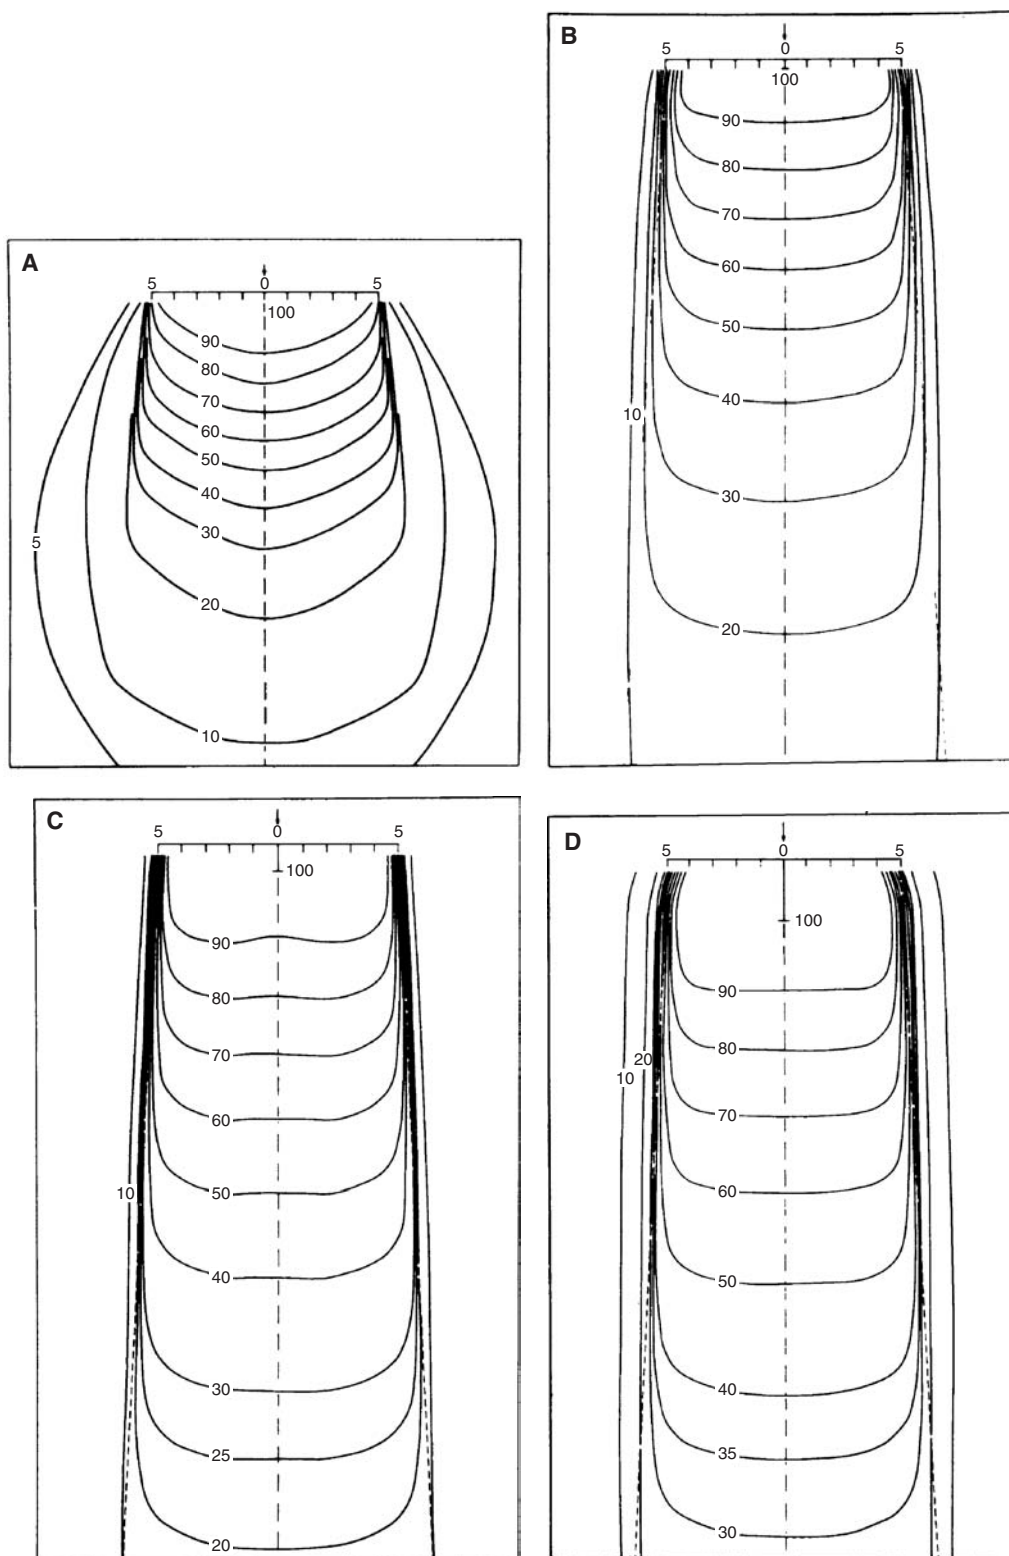

FIGURE 14.15. Isodose distributions for different quality radiation. **A:** 200 kVp, SSD = 50 cm, HVL = 1 mm Cu, field size = 10 × 10 cm. **B:** ^{60}Co , SSD = 80 cm, field size = 10 × 10 cm. **C:** 4-MV x-rays, SSD = 100 cm, field size = 10 × 10 cm. **D:** 10-MV x-rays, SSD = 100 cm, field size = 10 × 10 cm. *Source:* From Khan FM. *The Physics of Radiation Therapy*. 2nd ed. Baltimore: Williams & Wilkins; 1994, with permission.

the radiation field can be further controlled to produce an intensity modulated radiation therapy (IMRT) treatment. In IMRT treatments, the MLCs are used to create many small fields of radiation within a larger treatment field. By opening and closing these small fields, the intensity at any point within

the large field can be modulated to give more or less dose to the tissues directly exposed to the radiation. At one gantry angle, the IMRT field may need to spare a critical normal structure but still treat the target to a lower dose, while in another gantry angle, that same critical structure may be out

FIGURE 14.16. Example of multifield radiation therapy using parallel opposite beams with an isocentrically mounted radiation source.

of the field and the target can get a higher intensity to compensate for the lowered intensity in the first field. This adaptability allows the radiation treatment planner to create and deliver very complex treatment fields that improve target coverage while attempting to spare normal tissues. In practical terms, IMRT treatment plans are an improvement of the more conventional three-dimensional (3D) conformal treatment plans. 3D conformal treatment plans use fewer fields to achieve nominal coverage of the treatment target. At each gantry angle, the radiation is either hitting the target/normal tissue or not with a simple shaped treatment field. Normal tissues may be impossible to spare relative to adjacent targets. IMRT treatment plans may use similar gantry angle setups, but with the additional intensity modulation, the IMRT fields can create a complicated dose distribution within the patient. In some cases, where the normal tissues are relatively far from the target tissues, there may be no benefit or rationale for the more complex IMRT treatment plan compared to 3D conformal treatment plans. In cases where the proximity of normal tissues and target vary across a field and between gantry angles, IMRT may prove the more efficient treatment plan to protect normal tissues while focusing dose onto the target (Fig. 14.18).

IMRT is being explored for the treatment of gynecologic cancers. The setting where it may be the most helpful is in the postoperative setting for select endometrial and cervical cancer presentations. In this setting, there is often a significant amount of small bowel in the pelvis that can be avoided to a greater degree with IMRT than 3D conformal radiation techniques (24–27) (Fig. 14.19). Bone marrow sparing can also be improved over a 3D conformal approach (24). Bladder and rectosigmoid doses can also be reduced. Margin size around the target and bladder and rectal filling are important considerations as are immobilization techniques when using IMRT. RTOG 0418 has defined parameters for contouring of targets and normal organs, margin size, and dose volume constraints in the postoperative setting in early cervical or endometrial cancers. An online atlas has been developed to improve consistency between multiple contouring physicians (28). Other atlases are available to guide radiation oncologists in defining these structures of interest (29–30). When using IMRT to treat the intact uterus, bladder filling can have even more influence on the position of the uterus, and the vagina and uterus can move several centimeters as a result. Stool in the rectosigmoid can also cause movement of the adjacent pelvic organs and

alter the dose distribution in the rectosigmoid. Use of IMRT in the definitive management of cervical cancer has been piloted at the University of Chicago (31–33). In their series, IMRT has reduced both acute and late gastrointestinal (GI) toxicities (34–35). The University of Chicago experience also revealed that IMRT in the setting of concurrent chemotherapy and radiation can also spare bone marrow during treatment (36). Use of IMRT for extended field irradiation, used for treating the pelvic and paraaortic regions, is also being explored to decrease dose to the small bowel, kidneys, liver, spinal cord, and bone marrow (Fig. 14.20). Selective boosting of gross nodal disease may allow for safer dose escalation (37–40). IMRT techniques are also being explored for whole abdominal irradiation to reduce doses to the gastrointestinal tract, liver, kidneys, and bone marrow and increase dose to the peritoneal surfaces and lymph nodes (41–42).

A relatively new feature for radiotherapy treatments is image-guided radiation therapy (IGRT). Historically, treatment setups were verified by orthogonal radiographs and treatment fields by port films or x-rays of the treatment fields superimposed on the patient. Modern linacs have added on-board imaging (OBI) that allows the treatment fields to be recorded electronically at every treatment setup using an electronic portal imaging device (EPID). By comparing computer generated

radiographs (DRRs, or digitally reconstructed radiographs) with the actual patient images, discrepancies in field shape and patient setup can be corrected before the delivered treatment. This type of corrective behavior before treatment is the foundation of IGRT. The latest variation on IGRT is the addition of computed tomography (CT) scanners within the linear accelerator to verify more completely the correct alignment of the patient on the treatment table prior to treatment. CT scans are obtained prior to each treatment. In some cases, the CT scans are constructed based on the photon beams (MV) that will be used for treatment. In other cases, a different photon source (kV) is used to reconstruct the CT scan. Because cone beam CT (CBCT) or megavoltage CT (MVCT) uses a high-energy photon beam to gather the information for reconstruction, the image quality suffers because of poor soft-tissue contrast. kVCT or normal CT images, because they use a lower energy photon beam to reconstruct the patient image, have better soft-tissue contrast but are prone to distorting artifacts from high density objects within the patient, i.e., hip prostheses. In either case, the CT image at the time of treatment and its corresponding isocenter location are compared to the treatment planning CT and isocenter for agreement. Adjustments for rotation, lateral, vertical, and longitudinal discrepancies are made prior to treatment. The intent of these

FIGURE 14.20. A: Contours of enlarged paraaortic nodes with margin are shown in close proximity to small bowel. B: IMRT plan for extended field irradiation in axial, coronal, and sagittal projections.

IGRT treatments is to improve the accuracy of the treatment setup on a daily basis relative to the original treatment plan. This enables decreasing the size of the radiation fields, as there is not as much need for a large margin on the target, which can decrease normal tissue irradiation and even allow for dose escalation to the target.

TomoTherapy (Fig. 14.21) is special type of linac/CT combination. TomoTherapy units were the first commercially available treatment machines that directly combined CT (MVCT in this case) with highly complex MLCs to deliver IMRT using IGRT. Each day, the patient receives an MVCT, a comparison using 3D fusion to the original treatment plan is made, adjustments to the patient position are made, and IMRT treatment is delivered without the patient needing to change machines. Corrections to the delivered dose can even be modeled based on the patient's current anatomy as visualized by the MVCT built into the TomoTherapy machine.

In addition to photon beams, many linacs also provide the option to treat patients with electron beams of various energies (e.g., 4 to 21 millionelectron volts [MeV]). Compared to photon

beams, electron beams have different depth dose and dose profiles (Fig. 14.22), when electrons, even at the same energy as photons, do not penetrate as far as photons do within tissues. While electron depth doses have a D_{\max} that increases with increasing energy, unlike photons, the higher the electron energy, the higher the surface dose to tissue, i.e., loss of “skin sparing.”

Simulation

The conventional simulator used in radiation oncology departments reproduces all the gantry, collimator, and table rotations used in a linac treatment, and therefore “simulates” the actual treatment. Instead of a therapy (MV) photon beam, the conventional simulator uses a diagnostic (kV) photon beam to simulate the treatment beam. Previously, the conventional simulator (Fig. 14.23) allowed the radiation oncologist to determine beam direction and treatment fields that would be needed for a radiotherapy treatment based on x-ray fluoroscopy. The radiographic visualization of internal structures allowed special

FIGURE 14.21. A: Helical TomoTherapy device commercially available for IMRT. B: Diagrammatic representation of the device. *Source:* Courtesy of TomoTherapy Inc., Madison, Wisconsin, USA.

shielding (poured blocks) to be constructed. All the geometric parameters of the conventional simulator are nearly identical to the actual treatment linacs. The intersections of the gantry rotation axis, collimator rotation axis (the machine isocenter), and patient location are identified and marked on the patient's skin with removable ink or a permanent series of tattoos. These marks facilitate the reproduction of the same clinical setup for the patient each day of treatment. Hard copy radiographs can also be used to document the expected treatment fields for comparison with port films obtained on the treatment linac.

CT-based simulators ("CTSim") have largely replaced conventional simulators in most radiation oncology departments. CTSims (Fig. 14.23) combine a diagnostic CT scanner with a software package that allows for the simulation of the patient setup in the virtual world of the computer. All of the necessary gantry angles and table angles are modeled in the computer.

Computer controlled room lasers tied into the CTSim software allow the simulator therapist to identify the treatment isocenter in a fashion similar to the conventional simulator. DRRs are created for later comparison to actual treatment images. The treatment isocenter and the full CT images can then be transferred to the computer planning system for further treatment planning.

Computerized Dosimetry

In a modern radiotherapy department, computers are necessary to accurately calculate the absorbed doses to tissues. These absorbed doses within tissues are termed isodoses, or lines of the same dose. To initiate this process, CT images are acquired of the area of interest at a pretreatment planning

FIGURE 14.22. Electron beam central axis isodose curves for a 10×10 cm field at 100 cm SSD. session or simulation. These scans are typically obtained on the CT simulator. Treatment targets such as pelvic lymph nodes, the uterus, or vagina are identified through contouring on these images, as are normal tissues such as the rectosigmoid, bladder, and small bowel. Dose goals are identified for the targets and normal tissues. A dosimetrist uses this information to design the radiation treatment plan. Treatment beams are planned and the resulting dosimetry is reviewed by the treating physician and a physicist and altered as needed to best address the tumor and avoid the normal organs and tissues. In order for a computer treatment planning system to do all this, the depth dose and dose profiles for all the treatment beams (photons and electrons) must be accurately entered into the planning system.

There are varying complexities of treatment plans that might be used. For simple targets, e.g., metastatic cancer to the spine, a simple single field or parallel opposed, two-dimensional

(2D) plan might be all that is required. Complexities of internal anatomy and external surface contours can be ignored while still successfully delivering a palliative treatment plan to the patient. More complicated target definitions might require specific and accurate knowledge of adjacent internal anatomy and the details of the patient's surface in order to accurately deliver a successful treatment plan. In these cases, a 3D conformal treatment plan is developed. In still more complicated target/normal tissue regions, IMRT treatment planning might be required in order to give sufficient dose to the target while minimizing the dose to an adjacent normal tissue. The goal for most treatment plans is to treat the target to a specified dose while minimizing dose to adjacent normal tissues.

In all of these examples, the word “target” is used. The goal is to encompass the target with the desired dose. Targets are more formally defined in ICRU 50 (43). Figure 14.24 illustrates the gross target volume (GTV), the clinical target volume (CTV),

DEFINITION OF "VOLUMES" IN RADIATION THERAPY

FIGURE 14.24. Schematic representation of “volumes” in radiation therapy. The treatment portal volume includes the gross target volume, potential areas of local and regional microscopic disease around the tumor (clinical), and a margin of surrounding normal tissue (planning). *Source:* From Perez CA, Purdy, JA. Rationale for treatment planning in radiation therapy. Philadelphia: Lippincott-Raven Publishers; 1998:1, with permission.

the planning target volume (PTV), and the treated volume. Each of the target or tumor volumes is larger than the previous target volume by some margin. The CTV includes all of the GTV plus possible microscopic extensions. The PTV includes all of the CTV plus a margin to account for possible geometric uncertainties of the patient or treatment margin. The irradiated volume includes all of the PTV plus any margins that might be included in the treatment plan to provide minimum dose coverage to the PTV.

Brachytherapy Principles

Brachytherapy is a term with Greek roots where “brachy” means “short distance.” With brachytherapy, a highly concentrated dose of radiation is delivered to immediately surrounding tissues within millimeters to several centimeters of the applicators that carry the radioactive sources. This allows for a high dose of radiation to be delivered to closely approximated tumor and to relatively spare surrounding normal tissues such as the rectosigmoid, bladder, and small bowel. This is in comparison to teletherapy, where “tele” means “far distance” and refers to external beam irradiation where the radiation source is at a greater distance from the patient (~100 cm) than with brachytherapy. With external beam irradiation, the tumor and/or tumor bed are typically irradiated along with adjacent tissues at risk such as lymph nodes. External beam irradiation typically is much more penetrating than brachytherapy unless electron beam external irradiation is used. With electron beam therapy, superficial structures such as the skin and or superficial lymph nodes are optimally treated unlike the deep abdominopelvic tissues, which are best irradiated with the penetrating photons produced by a linear accelerator.

There are different types of brachytherapy or radioactive implants. Temporary implants are used most frequently and are categorized as interstitial or intracavitary. With interstitial brachytherapy, the radioactive sources are transiently inserted into tumor-bearing tissues directly through placement in hollow needles or tubes. With intracavitary brachytherapy, radioactive

sources are placed into naturally occurring body cavities or orifices such as the vagina or uterus using commercially available hollow applicators such as a vaginal cylinder or tandem and ovoids. Temporary surface applications or plesiotherapy for ophthalmic or skin tumors and intraluminal applications in the esophagus, bronchus, and bile duct are other possible approaches. Permanent interstitial implants entail insertion of radioactive seeds (iodine 125 [^{125}I]; gold 198 [^{198}Au]; palladium 103 [^{103}Pd]) directly into tumor-bearing tissues to emit radiation continuously as they decay to a nonradioactive form (44). Radioactive sources are also sealed or unsealed, referring to whether they are solid (^{137}Cs ; ^{192}Ir) or liquid radioisotopes (phosphorus 32 [^{32}P]). The most common sealed radioactive sources used for gynecologic brachytherapy are ^{192}Ir and ^{137}Cs . Historically, unsealed radioactive sources such as ^{32}P have been used to treat the entire peritoneal cavity in ovarian cancer. The limitation of this source was that the beta rays emitted only penetrated a distance of 3 mm, making it useful only for patients with microscopic or very thin residual tumor deposits following debulking.

Dose rate is also an important variable in brachytherapy. Traditional low dose rate (LDR) irradiation has been used for decades in gynecologic cancers using ^{226}Ra and ^{137}Cs sources for intracavitary insertions and low activity ^{192}Ir sources for interstitial insertions. High dose rate (HDR) brachytherapy has gradually been introduced over the last several decades and entails the use of a highly radioactive (^{10}Ci) ^{192}Ir source. There are several definitions for the dose rates used in brachytherapy. The ICRU 38 classifies LDR as 0.4 to 2 Gy/hr, MDR (medium dose rate) as 2 to 12 Gy/hr, and HDR as >12 Gy/hr (45). More standard ranges for LDR are 40 to 100 cGy/hr, and for HDR 20 to 250 cGy/min, which is 1,200 to 15,000 cGy/hr. Pulsed dose rate (PDR) is increasingly popular with the scarcity of available new ^{137}Cs sources. Rather than using a high activity ^{10}Ci ^{192}Ir source with short dwell times as in HDR, PDR uses a medium strength ^{192}Ir source of 0.5 to 1.0 Ci with dose rates of up to 3 Gy/hr. The radiation with PDR is typically delivered in a “pulsed” method over only 10 to 30 minutes of each hour as opposed to LDR techniques, which deliver 30 to 100 cGy/hr continuously over several days (46). PDR delivers the same total dose over the same total time at the same hourly rate as LDR, but with an instantaneous dose rate higher than LDR. PDR brachytherapy was developed to combine the isodose optimization of HDR brachytherapy with the biologic advantages of LDR.

The term “afterloading,” whereby an unloaded applicator is inserted first and the radioactive sources introduced later, was popularized by Henschke (47–49). Nearly all modern brachytherapy exploits afterloading. An ideal implant is established with the appropriate applicator before being loaded with the radioactive sources. This sequence allows for more careful and accurate applicator placement than inherent to earlier “hot loaded” applicators, which were placed in the operating room preloaded with radium. Radiation exposure to medical personnel is reduced and exposure of operating room personnel is totally eliminated. Remote afterloading, which eliminates all personnel exposure, entails the use of a computer-driven machine to insert and retract the source(s), which are attached to a cable. During treatment, the source is transported from its shielded safe to the patient’s applicators via a transfer tube. Sources are retracted automatically whenever visitors or hospital personnel enter the room. With modern remote afterloading techniques, a single cable-driven radioactive source is propelled through an array of dwell positions in needles, plastic tubes, or intracavitary applicators within an implanted volume. Through computerized dosimetry, the source stops for a specified duration at a preselected number of locations during its transit, delivering a specified dose to a defined volume of tissue. This dose may be delivered rapidly in a large fraction, as in the case of HDR brachytherapy, or a series of small “pulsed doses”

delivered at a given frequency over a period of days, as in PDR brachytherapy (46). Typically, these treatment units are housed in shielded rooms in the hospital (LDR or PDR) or the radiation oncology department (HDR) to further eliminate radiation exposure (44).

Radiation Protection

The amount of radiation that a person other than patients under treatment can receive is governed by state and federal regulations. The actual values depend on whether the person is considered part of the general public or an occupationally exposed worker. These values can change with different regulations. The National Council on Radiation Protection and Measurements (21) set the following recommendations for limits on exposure to ionizing radiation:

- Public exposures <1 mSv or 0.1 rem annually
- Occupational exposures <50 mSv or 5 rem annually

Additionally, NCRP Report #91 placed limits on embryo-fetus exposures:

- Total dose limit <5 mSv or 0.5 rem
- Dose equivalent limit in 1 month <0.5 mSv or 0.05 rem

These recommended limits were adopted by the Nuclear Regulatory Commission (10 CFR 20, Standards for Protection Against Radiation).

Linacs produce radiation using electrical power. Once the linac is turned “off,” there is little, if any, radiation exposure risk to staff. Radioactive isotopes, used most often for brachytherapy, however, do not have an “off” switch. They are always undergoing radioactive decay with the resultant radiation production of x-rays, γ -rays, electrons, and other particles.

Radiation safety is an important focus for patient and health care workers. All hospitals that house radioactive sources or linear accelerators will have a special department termed radiation safety. Radiation personnel are responsible for monitoring radiation exposure in hospitals and clinics. All health care workers exposed to radiation must wear badges that track radiation exposure. There are three words that encompass all of the important aspects of radiation safety and protection: time, distance, and shielding. All three can be used to reduce radiation exposure. The dose delivered to a target from a radioactive source is directly proportional to the amount of time the target is exposed to the radioactive source (50). The dose delivered to a target is inversely proportional to the square of the distance from the radioactive source double the distance and the dose is reduced by a factor of four.

$$\begin{aligned} \text{Dose} &\sim \text{time} \\ \text{Dose} &\sim 1/t^2 \end{aligned}$$

This is the inverse square rule. The relationship between shielding and absorbed dose is more complicated. The simplest explanation is that the absorbed dose is reduced in an exponential relationship to the physical amount of shielding. The exact relationship (μ) depends on the energy of radiation and the specific material, e.g., concrete or lead, used to provide the protection. More material (x) means more protection. Less energy means more protection for the same thickness (x) of material.

$$\text{Dose} \sim e^{-\mu x}$$

Minimizing time, maximizing distance, and maximizing shielding will reduce one's absorbed radiation dose. Fortunately, there is relatively little exposure to radiation for most health care providers. The linear accelerators in radiation oncology are strategically located and shielded to minimize radiation to anyone other than the treated patient. Many brachytherapy insertions are typically performed with remote afterloading to

minimize exposure, and often outpatient brachytherapy can be realized because of high dose rate techniques. This takes the patient off the hospital ward and thereby avoids exposure to the health professional caring for inpatients. The shielded rooms in the radiation oncology department protect the attendant staff from exposure as well.

CLINICAL APPLICATIONS

Historical Background

The use of radiation in the treatment of gynecologic cancers has a rich history. Roentgen rays were used externally as early as 1902 to treat cervical carcinoma and “radium rays” in 1906. In Europe, the use of intracavitary radium was reported in 1903 for the treatment of inoperable uterine cancers (51). Dr. Margaret Cleaves reported one of the first uses of intracavitary radium along with roentgen rays for the treatment of cervical carcinoma in New York in 1903 (52). In October of 1903, Dr. James Morton reported the use of a radium applicator “to be introduced within cavities where it had been heretofore impossible to practically introduce the X-ray” (53,54). In 1913, Robert Abbe was the first to report a true cure with a patient alive and well after 8 years of follow-up (54,55). In these early years, there was little knowledge of the biologic effects of radiation on the normal and tumor tissues. Typically, a uterine tandem was used alone without vaginal colpostats. There was little understanding of the dose distribution in the tumor and surrounding normal tissues, and implant duration, and thereby dose, was entirely empirical. Complications and failures were common.

Brachytherapy Systems for the Treatment of Cervical Cancer

Intracavitary brachytherapy for cervical carcinoma was profoundly impacted by the development of various “systems” that attempted to combine empiricism with a more scientific and systematic approach. A dosimetric system refers to a set of rules concerning a specific applicator type, radioactive isotope, and distribution of the sources in the applicator to deliver a defined dose to a designated treatment region (45,56). Within any system, specification of treatment in terms of dose, timing, and administration is necessary to implement the prescription in a consistent manner. Three systems were developed in Europe, including the Paris system, the Stockholm system, and the Manchester system (57,58). The Manchester system principles are an integral part of modern brachytherapy.

The Manchester System

The Manchester system was developed in 1932 by Tod and Meredith (59–61), and was later modified in 1953 (62) at the Holt Radium Institute. It standardized treatment with predetermined doses and dose rates directed to fixed points in the pelvis. The fixed points A and B were selected on the theory that the dose in the paracervical triangle impacted normal tissue tolerance rather than the actual doses to the bladder, rectum, and vagina. The paracervical triangle was described as a pyramidal-shaped area with its base resting on the lateral vaginal fornices and its apex curving around with the anteverted uterus. “Point A” was defined as 2 cm lateral to the central canal of the uterus and 2 cm from the mucous membrane of the lateral fornix in the axis of the uterus (Fig. 14.25). It often correlates anatomically with the point of crossage of the

FIGURE 14.25. The Manchester system. Definitions of points A and B in the classical Manchester system are found in the text. In a typical application, the loading of intrauterine applicators varied between 20 and 35 mg of radium and between 15 and 25 mg of radium for each vaginal ovoid. The resultant treatment time to get 8,000 R at point A was 140 hours. Source: From Meredith WJ. *Radium Dosage: The Manchester System*. Edinburgh: Livingstone, 1967, with permission.

ureter and uterine artery and was taken as an average point from which to assess dose in the paracervical region. “Point B” was located 5 cm from midline at the level of point A and was thought to correspond to the location of the obturator lymph nodes. To achieve consistent dose rates, a set of strict rules dictating the relationship, position, and activity of radium sources in the uterine and vaginal applicators was devised. The amount of radium would vary based on ovoid size and uterine length such that the same dose in roentgen would be delivered to point A regardless of the size of the patient or the size and shape of the tumor, uterus, and vagina. The vaginal ovoids were available in three sizes: small (2.0-cm diameter), medium (2.5-cm diameter), and large (3.0-cm diameter) and were preloaded or “hot loaded” with radium. The amount of radium per ovoid varied by size to get a uniform dose rate at the ovoid surface. It was recommended to use the largest ovoid size possible and place the ovoids as far laterally as possible in the fornices to carry the radium closer to point B and increase the depth dose. Vaginal packing was used to limit the dose to the bladder and rectum to <80% of point A. Two intracavitary applications of 72 hours with a 4- to 7-day interval between them were given to deliver a dose of 8,000 R at 55.5 R/hr to point A and 3,000 R to point B. External beam irradiation with a midline block in place was later used to deliver a total cumulative dose of 6,000 R to point B.

The Manchester system underlies contemporary intracavitary techniques and dose specification (59–62). With current LDR applications using cesium rather than radium, it is considered standard to have a point A dose rate of 50 to 60 cGy/hr and to deliver a total dose of 85 Gy to point A and 60 Gy to point B when combined with external beam therapy.

FIGURE 14.26. Fletcher Suit Delclos low dose rate applicators. Left to right: Afterloading colpostats, mini ovoids, tandems, cylinders, and source inserters. Source: Reprinted with permission from Fletcher, Gilbert H, eds. *Textbook of Radiotherapy*. 3rd ed. Philadelphia: Lea & Febiger; 1980:741 (Fig. 18A).

The Fletcher (M.D. Anderson) System

The Fletcher system was established at M.D. Anderson Hospital in the 1940s (63). The Fletcher applicator was subsequently developed and remains an integral part of gynecologic brachytherapy (Fig. 14.26) (64). The initial dosimetric work at M.D. Anderson was done prior to the development of computerized dosimetry in the 1960s (65–69). As in the Paris system, milligram-hours (mg-hrs) were used for dose prescription with the premise that with any geometric arrangement of specified sources, dose at any point is proportional to the amount of radioactivity and the implant duration. Though previous systems (Paris and Stockholm) had used mg-hrs, clinical experience alone determined the amount of radium tolerable to the tissues. Fletcher predicted that better results and less morbidity could be obtained if knowledge of the energy absorbed at various points in the pelvis (“measured data”) such as the bladder and rectum and pelvic lymph nodes could be determined (70). According to Fletcher, a dosimetric approach should meet the following requirements: (a) ensure that the primary disease in the cervix and fornices and immediate extensions into the paracervical triangle are adequately treated; (b) guide treatments in such a way that the bladder and rectum are not overdosed (respect mucosal tolerance); and (c) determine the dose received by the various lymph node groups. Individualization to fit the anatomical situation was an essential aspect of this system (71).

The primary prescription parameter in the Fletcher system was tumor volume and prescription rules were based on maximum mg-hrs and maximum time, taking into account the total external beam dose and the calculated sigmoid dose. An application was left in place until either of these two maximums was reached. Large mg-hr implants were halted by the mg-hr prescription while smaller mg-hr implants were terminated by time. A set of maxima of mg-hrs was established for combinations with external irradiation, which were published in tables (72,73). Standardized source arrangements and limits on the vaginal surface dose and mg-hrs were all used to help specify treatment.

Despite a more elaborate dosimetry system, the Fletcher system combined many elements of the Paris and Manchester systems, including using the largest size ovoid possible positioned as far laterally and cephalad as possible to give the

highest tumor dose at depth for a given mucosal dose. By using a larger ovoid, the radium-mucous membrane distance was increased, allowing a greater increase in the total number of mg-hrs and a greater volume of adequate irradiation (63). The Fletcher colpostats were actually a further evolution of the Manchester ovoids and were made with the same diameters of 2, 2.5, and 3 cm but were more cylindrical than Manchester "ovoids" and were attached to handles, with shielding in the direction of the bladder and rectum. Initially these were preloaded with radium, but later an afterloading model was developed and loaded instead with ^{137}Cs (74-77). Recommended loadings were 15, 20, and 25 mg of radium for the 2, 2.5, and 3 cm colpostats, respectively, and 5 to 10 mg for the mini-ovoids (74). Like the earlier systems, it was also recommended to use the longest tandem available and load the tandem so that sources reached the uterine fundus to give an adequate distribution in the lower uterine segment and paracervical areas and to increase the dose to the obturator lymph nodes. Additionally, a high position of the applicator in the pelvis and a wide separation of the ovoids were thought to increase the dose to the pelvic wall (63,78). Tight packing was also recommended to displace the system upward and centrally and to decrease the dose to the bladder and rectum (63). Recommended tandem loadings were usually 15-10-10 mg of radium with the amount of radium in the tandem usually greater than that in the ovoids (71). The distal source in the tandem was to be positioned to produce an even pear-shaped dose distribution with no drop in dose rate between the tandem and ovoids, without excessive overlap that would cause a hot spot on the adjacent bladder or rectal mucosa. With the ovoids well positioned, this was usually accomplished by placing the physical end of the distal source at or a few millimeters beyond the external os of the cervix. A 10-mg protruding source was recommended if the vaginal ovoids were separated by more than 5 cm or displaced caudally, with each ovoid then decreased by 5 mg.

A careful review of implant films was outlined (Figure 14.27). It was recommended to keep the tandem in the axis of the pelvis, equidistant from the sacral promontory and pubis and the lateral

pelvic walls to avoid overdosage to the bladder, sigmoid, or one ureter. The tandem was recommended to bisect the ovoids on the AP films and bisect their height on the lateral films (79). The flange of the tandem was to be flush against the cervix and the ovoids surrounding it, verified by confirming the proximity of the applicators to radio-opaque cervical seeds. Radio-opaque vaginal packing was used to hold the system in place and displace the bladder and rectum. Scrutiny of implant films prior to treatment remains an important tenant of brachytherapy. Two or more intracavitary insertions were thought to make more efficient use of the inverse square law such that the second and third implants would deliver intense radiation to the tumor periphery because of interval tumor regression. A recent retrospective review of implant geometry has confirmed the consistency of the M.D. Anderson approach and the good outcomes achieved when attention is paid to applicator position in the pelvis (80).

The current M.D. Anderson approach to treatment specification reflects a policy of treating advanced cervical carcinoma to normal tissue tolerance (81). This includes integrating standard loadings and mg-hrs with calculated doses to the bladder, rectum, sigmoid, and vaginal surface. The activity in the ovoids is limited by the vaginal surface dose, which is kept below 140 Gy. Calculated bladder and rectal doses are noted and are sometimes used to limit the duration of the intracavitary system, with the combined external beam and implant doses for the bladder kept at <75 to 80 Gy and for the rectum at <70 to 75 Gy. Mg-Ra-eq-hrs are usually limited to 6,000 to 6,500 after 40 to 45 Gy external beam. Though mg-hrs have usually been used to guide and report doses at M.D. Anderson, recent retrospective reviews have also reported point doses, though these have not been used to plan or prescribe treatment. With the implant loadings and durations outlined by Fletcher, typical dose rates at point A are approximately 57 cGy per hour and vaginal surface dose rates are 100 cGy/hr (80,82). The median doses to point B and to the International Commission on Radiation Units & Measurements (ICRU) rectal and bladder reference points averaged 28%, 59%, and 60% of the point A doses, respectively (80). The median total dose to point A from external beam and intracavitary irradiation

FIGURE 14.27. Ideal position of tandem and ovoid applicator on an AP radiograph (A) and a lateral radiograph (B). Philadelphia: Lea & Febiger; 1980:745 (Fig. 11-24).

was 87 Gy, and the median doses to the bladder and rectum were 68 and 70 Gy. The total dose delivered to the vaginal surface was limited to 120 to 140 Gy or 1.4 to 2.0 times the point A dose (80). These total doses to point A and the vagina, bladder, and rectum are used as contemporary guidelines for determining implant duration and therefore dose.

Point A Redefined

The failure of localization radiographs to show the surfaces of the ovoids made implementation of the initial definition of point A difficult. The definition of point A was modified in 1953 to be "2 cm up from the lower end of the intrauterine source and 2 cm laterally in the plane of the uterus, as the external os was assumed to be at the level of the vaginal fornices" (Fig. 14.28) (62). This definition of point A is currently used at many institutions (83,84). A seed or marker ball placed near the exocervix and coincident with the tandem flange is used to identify the exocervix on the localization films. This definition, however, becomes problematic when the cervix protrudes between the ovoids (Fig. 14.29). This causes a resultant increase in dose rate at point A because point A lies in the higher dose "bulge" around the ovoids (78). The variation of point A often occurs in a high-gradient region of the isodose distribution. A consistent location for dose specification should fall sufficiently superior to the ovoids where the dose distribution runs parallel to the tandem (Fig. 14.30) (85,86). In patients with deep vaginal fornices, reverting to use of the ovoid surface rather than the exocervix can help to solve this problem (85,87).

American Brachytherapy Society recommendations for low-dose rate brachytherapy for carcinoma of the cervix. *Int J Radiat Oncol Biol Phys* 2002;52(1):38 (Fig. 2).

Limitations of Brachytherapy Systems: Point A

It has become clear over time that points A and B are not anatomic sites. The actual specification is related to the position of the intracavitary sources rather than to an anatomical structure. Lewis et al. also demonstrated that point A does not maintain a constant relationship to any specific structure and its position varies with the type of applicator, individual tumor anatomy, and age of the patient. No correlation was found between point B and the pelvic wall (88,89). Potish also questions the validity of point A as its position bears no fixed relationship to tumor or normal tissue anatomy and is in a steep dose gradient and sensitive to displacement (83,84,90,91). Point A can be identical for implants that differ in fundamental ways and deliver different overall 3D dose distributions.

Limitations of Brachytherapy Systems: Mg-Hr Systems

The use of mg-hr systems also continues at many institutions to guide the choice of source strength and duration of the implant, estimate the risk of complications, compare treatment between patients and institutions, and estimate efficacy (92,93). In the past, little attempt was made to obtain dose information to anatomical structures, and mg-hr prescriptions were not necessarily accompanied by isodose distributions so that the dose prescription was not related to patient anatomy.

Contemporary Dose Specification for Cervical Cancer

The advent of afterloading applicators and computerized dosimetry has brought about a dramatic change in dosimetric analysis (65,66,94). For cervical cancer, there continue to be two basic systems of dose prescription, mg-hrs and the Manchester point A and B systems, and many prescription systems combine both Fletcher and Manchester elements. The basic principle of intracavitary prescription is to leave a specific loading of sources in for a definite time, determined by empirical experience, prescription rules, and computerized dosimetry. At present, the dose at several anatomic points is evaluated, and the isodose distributions are generated by computer (Fig. 14.31). The intracavitary dose is based on the extent of disease and may have to be altered if computer calculations indicate high doses to surrounding critical structures. The rectum and bladder are viewed as tolerance points, compared to point A, which is a treatment dose reference point (78,95). Further work is needed to routinely implement 3D-image-based brachytherapy to relate these isodose distributions and doses to individual tumor volumes and critical normal organs such as the bladder and rectosigmoid. CT-based dosimetry can be used instead of 2D film-based dosimetry to better understand the relationship of the applicator and the dose distribution to the bladder and rectosigmoid (Fig. 14.32) (96,97). MRI-based brachytherapy is under investigation to assess and modify the dose to the actual tumor volume rather than relying on point A alone (98–100) (Fig. 14.33). This should give additional insight into the reasons for local failures and complications and allow for improvement in local control and late toxicities.

Dose Specification Points for Cervical Cancer

At institutions using a derivation of the Manchester system, dose is typically specified at various points such as A and B.

FIGURE 14.31. A: Anteroposterior view of intracavitary insertion for carcinoma of the uterine cervix. B: Lateral view of same implant. Isodose curves (cGy/hr) are superimposed. *Source:* From Perez CA, Grigsby PW, Williamson JF. Clinical applications of brachytherapy. I: low dose-rate. In: Perez CA, Brady LW, eds. *Principles and Practice of Radiation Oncology*. 3rd ed. Philadelphia: Lippincott-Raven Publishers; 1998:487, with permission.

A combination of both mg-hrs and point doses is used at some institutions to guide implant duration (81,101). Though these definitions vary from institution to institution, most will attempt to quantify doses in the paracervical region (point A), and at either point B or the pelvic wall (C or E), and the rectum and bladder (83,84). Unfortunately, intracavitary point dose calculations are not recorded as often for the sigmoid, vaginal mucosa, or cervix. Dose evaluation at these points is

also recommended. Maruyama et al. defined a point T (tumor dose) located 1 cm above the cervical marker and 1 cm lateral to the tandem, which is usually 2 to 3 times the dose at point A (102) and has been used at other institutions (103,104). Vaginal surface dose rates, defined at the lateral ovoid surface, will vary based on applicator diameter and available source strengths and should be in the range of 1.4 to 2.0 (the point A dose) (80,105).

Though frequently confused, the ICRU 38 system (Dose and Volume Specification for Reporting Intracavitary Therapy in Gynecology) is a dose reporting system, not a dose specification system (Fig. 14.34) (45). This was developed so that comparisons could be made between centers using different brachytherapy systems. It provides definitions for determining dose to the bladder and rectum in addition to other characteristics of the implant.

Importance of Brachytherapy in Cervical Cancer

When curative treatment is planned, patients with cervical carcinoma treated with definitive irradiation should receive a combination of external beam irradiation and brachytherapy. As revealed in the Patterns of Care Studies (PCS) and the retrospective series of Perez et al., recurrences and complications are decreased when brachytherapy is used in addition to external beam (82,101,106–108). Use of an intracavitary implant was the single most important treatment factor in multivariate analysis for stage IIIB cervical cancer with respect to survival and pelvic control in the 1973 and 1978 PCS (109,110). Retrospective series with external beam alone have proven marginal outcomes with this approach. The efficacy of brachytherapy is attributable to the ability of radioactive implants to deliver a higher concentrated radiation dose more precisely to tissues than external beam alone, which contributes to improved local control and survival. At the same time, surrounding healthy tissues such as the bladder and rectosigmoid are relatively spared due to the rapid fall-off of dose around the applicators with distance. The external beam component of treatment is also very important as it addresses tissues at a distance from the applicator such as the pelvic lymph

nodes. The external beam also brings about tumor regression in intact cervical and vaginal cancers such that the residual tissue is brought within the range of the pear-shaped or cylindrical-shaped radiation dose distribution around standard applicators (44).

Brachytherapy Applicators

Given the importance of brachytherapy, it is important to select the appropriate applicator to accommodate patient anatomy and the disease and shape the associated isodose distribution to encompass the disease. Tumor volume and patient anatomy are key in this decision. Tumor size and shape are variable, and there are a multitude of applicators available to address these diverse presentations.

INTRACAVITARY APPLICATORS: CERVICAL CANCER

Low Dose Rate

There are varieties of low dose rate applicators available for intracavitary brachytherapy. The best known are the Fletcher-Suit and Henschke tandem and ovoid (colpostat) applicators (Fig. 14.26). In 1953, Fletcher published an article introducing his preloaded radium applicator, which was designed to produce the largest possible volume of adequate radiation in each of the common directions of spread of disease—the uterine body, parametria, and perivaginal tissues—with relative sparing of the bladder trigone and anterior rectum due to the addition of shielding (63,64). The applicator was modified in the 1960s for afterloading (Fletcher-Suit applicator) (74,76,77,111) and in the 1970s to accommodate ^{137}Cs sources (75,76). In the 1970s, the Delclos mini-ovoid was developed for use in narrow vaginal vaults (Fig. 14.26) (74, 6,112,113). The mini-colpostats have a diameter of 1.6 cm and a flat inner surface. The mini-ovoids do not have shielding added inside the colpostat, and this together with their smaller diameter produces a higher surface dose than regular ovoids with resultant higher doses to the rectum and bladder. Appropriate source strength and treatment duration adjustment are important considerations to prevent complications. Fletcher tandems are available in four curvatures, with the greatest curvature used in cavities measuring >6 cm and lesser curvatures used for smaller cavities (Fig. 14.26). A flange with keel is added to the tandem once the uterine canal is sounded, which approximates the exocervix and defines the length of source train needed. The keel prevents rotation of the tandem after packing. The distal end of the tandem near the cap is marked so that rotation of the tandem after insertion can be assessed.

The Henschke tandem and ovoid applicator was initially unshielded (111,114) but later modified with rectal and bladder shielding (103,104). It consists of hemispheroidal ovoids with the ovoids and tandem fixed together. Sources in the ovoids are parallel to the sources in the uterine tandem (103). The Henschke applicator may be easier to insert into shallow vaginal fornices in comparison to Fletcher ovoids.

The Fletcher-Suit-Delclos tandem and cylinder applicator was designed to accommodate narrow vaginas where ovoids may be contraindicated and to treat varying lengths of the vagina when mandated by vaginal spread of disease. The cylinders vary in size from 2 to 5 cm to accommodate varying vaginal sizes (Fig. 14.26) (112). A narrow vagina poses a therapeutic challenge. Use of vaginal cylinders may lead to a higher rate of local failure as the dose to the lateral cervix and pelvic sidewall is reduced in the absence of ovoids, which produce the optimum

FIGURE 14.35. MRI/CT compatible tandem and cylinder applicator with associated isodose distribution in (A) axial and (B) sagittal views, demonstrating the close proximity to the rectum due to the absence of packing or rectal retraction.

pear-shaped distribution. These patients also tend to receive lower total doses due to the proximity of the rectum and bladder (Fig. 14.35) (81). There is less of a dose gradient between the vaginal mucosa and the bladder and rectum than in a patient with a wider vagina (115). Additionally, packing cannot be used with cylinders to decrease the rectal and bladder doses (116–119). Vaginal cylinders increase the length of vagina and rectum treated, with an associated increase in complications (120,121). Vaginal fistulae, rectal ulcers, and strictures are reported with increased frequency when vaginal cylinders are used (122–124). Pourquier et al. indicated that doses should be reduced with the use of vaginal cylinders and mini-ovoids to reduce complications as these applicators have no shielding (125,126). Interstitial implantation should also be a consideration for patients with a narrow vagina or with distal vaginal disease.

The Importance of Optimal Applicator Placement

Geometrically optimal intracavitary implants improve outcome over suboptimal implants. Corn et al. reported an analysis of the 1978 and 1983 PCSs, which attempted to analyze the outcome

of cervical cancer patients by the technical quality of the implant. A technically good implant correlated significantly with improved local control, with a trend toward improved survival (127). Perez et al. observed that “inadequate” insertions increased the incidence of pelvic failures (101) and that the quality of the intracavitary insertion had a measurable impact on the incidence of complications (128). Attention to the details of implant geometry has been linked to improved outcome in the series of Katz and Eifel at M.D. Anderson (80). Prior to afterloading, it was much more difficult to obtain adequate applicator placement due to the need to complete the insertion quickly to avoid excessive exposure to the sources in the preloaded applicators. In the era of afterloading, applicator placement can be more methodical. Orthogonal films or other imaging (CT, magnetic resonance imaging [MRI]) should always be obtained following applicator placement to assess applicator geometry and the need for adjustment to ensure optimum placement. It is imperative that geometrically favorable applicator placement, as described in detail previously by Fletcher, be achieved in as many patients as possible.

Optimum applicator placement is pivotal in maximizing local control. Placement of the brachytherapy applicators in direct proximity to the cervix is necessary to avoid underdosage. There will be a cold spot if the ovoids or other vaginal applicators are displaced away from the cervix (Fig. 14.36). Proper applicator selection is important in avoiding malpositioning. It is extremely important to place metallic markers on the cervix so that the flange of the tandem and the ovoids/cylinder dome are positioned in close proximity to these markers as confirmed on orthogonal check films (80).

Likewise, suboptimal applicator placement can increase the risk of complications. Applicators that are too close to the bladder and rectum can increase rectal and bladder complications. Sources in the tandem can give very high doses of radiation to the small bowel (ileum), sigmoid, and upper bladder, often not

FIGURE 14.36. Lateral radiograph of a poorly positioned HDR tandem and ovoid applicator. Note that the tandem does not bisect the ovoids and that the ovoid appears to be displaced inferiorly from the cervical marker balls.

revealed by orthogonal x-rays. Tandems that have perforated through the uterus can cause tremendous hot spots in the nearby normal organs (79).

Interstitial Applicators: Cervical and Vaginal Cancers—LDR and HDR

The size of the reference pear-shaped isodose achieved with tandem and ovoids is not variable except by increasing the duration (dose) of the implant. The shape of the reference pear-shaped isodose can be altered to some degree by varying the source strengths and applicator type, but it may not be able to encompass a bulky tumor, particularly when there is bulky parametrial or vaginal disease. In these settings, the disease may be better accommodated by an interstitial application (Fig. 14.37). Patients with large, bulky lesions will have a higher rate of local failure because of a decrease in dose to the periphery of the tumor due to the rapid fall-off of dose beyond the relevant pear-shaped distribution. The use of higher doses of external beam prior to implantation and interstitial techniques are important considerations. These patients should not be treated with external beam alone, as achieving the curative radiation doses required may be impossible because of the limited tolerance of the interposed small bowel, rectum, and bladder. Standard intracavitary applications may be sub-optimal or prohibited either by tumor bulk or distorted normal anatomy, and these patients should not be treated with geometrically unfavorable intracavitary implants.

The limitations of intracavitary techniques contrast with the strengths of interstitial techniques in certain settings. Determine which approach is best on a patient-by-patient basis. Interstitial implantation is appropriate in select patients with bulky tumors, anatomical distortion such as an obliterated endocervical canal or narrow vagina, or recurrent disease (129).

The development of prefabricated perineal templates, through which stainless steel needles were inserted and afterloaded with ^{192}Ir or ^{125}I , was pivotal in advancing interstitial techniques for the treatment of cervical and vaginal cancers. With these interstitial techniques, rather than doing a freehand implant, the template concept allows for a predictable distribution of needles inserted across the entire perineum through a perforated template according to an optimum pattern. Commercially available and institution-specific templates are used in these patients to accommodate varying disease presentations. Stainless steel and plastic needles are used, which are

afterloaded with low- or high-activity ^{192}Ir sources. The MUPIT (Martinez Universal Perineal Interstitial Template, Beaumont Hospital, Royal Oak, Michigan, USA) template (Fig. 14.38) accommodates implantation of multiple pelvic-perineal malignancies (prostate, anorectal, gynecologic) (129–133). In this system, one template accommodates many different disease presentations. Recent modifications of this template and needle system enabling HDR implants have become available (134). The Syed-Neblett (Best Industries, Springfield, Virginia, USA) is the other well-known commercially available template system (129,135–139). Currently, there are three LDR Syed-Neblett templates of varying size and shape for use in implantation of gynecologic malignancies (GYN 1-36 needles, GYN 2-44 needles, GYN 3-53 needles), as well as templates for implantation of the anus, prostate, and urethra (Fig. 14.39). There is also a disposable template for gynecologic presentations that accommodates HDR needles (140,141).

The Syed-Neblett and MUPIT templates are particularly suited for treatment of vaginal disease as the vaginal obturator needles can be strategically loaded to encompass disease from the fornices to the introitus. Additionally, the obturator needles can be advanced directly into the cervix, along with a uterine tandem, and may be essential to deliver tumorcidal radiation doses to the cervix by preventing a central “cold spot,” especially if an intrauterine tandem is not used. The more peripheral needles are used for implantation of the parametria, which is often underdosed in intracavitary approaches. Modifications of these standard templates have evolved and other innovative templates have been developed for vulvar, vaginal, and cervical carcinomas (129).

Individualized computer-generated dosimetry is an integral part of interstitial dose delivery. CT imaging following needle implantation has proven very helpful to identify tumor volume and critical normal structures, confirm the adequacy of needle placement in relation to these structures or needed adjustments, analyze and manipulate the dose distribution related to these structures, and assist with dose specification and the integration of external beam irradiation (129,142). Post-procedure epidural anesthesia provides optimal pain control and allows the needles and tandem to be manipulated outside the operating room if necessary. Modification of the planned source placement based upon the location of specific needles and critical structures can therefore be made before or after source loading.

With LDR techniques, traditional low dose rates are the goal (142), achieved through differential loading (core sources $\leq 1/2$ activity of peripheral sources) of low-activity sources. “Reference” dose rates of 60 to 80 cGy/hr are optimal. The implant dose rates as well as the dose homogeneity and distribution can be manipulated by selectively changing the activity associated with a particular needle or needles or by selectively unloading, either immediately or during the implant, strategic needles in the pattern. With HDR techniques, optimization of the dose distribution with predetermined parameters for the reference dose, normal organ doses, and dose homogeneity can produce even more ideal implant dosimetry (Fig. 14.40). Typically, total LDR doses to the tumor volume or reference isodose from the implant range from 23 to 40 Gy over 2 to 4 days (142). The total HDR dose will be approximately 60% of the total LDR dose and will be given in divided fractions. With either approach, careful attention to significant hot spots within the implant and doses to the bladder, rectosigmoid, and vaginal surface are requisite to obtaining the best outcome.

External whole pelvic irradiation (39.6 to 45.0 Gy) generally precedes implantation. For either LDR or HDR, one or two template implants can be done 1 to 2 weeks following external beam. With HDR, one to two fractions can be delivered per day over a period of 2 to 5 days, whereas with LDR, continuous hourly

radiation is delivered. After the implant, selective external irradiation boosting can be done as needed. The total LDR dose to the reference volume from the combined implant and external beam approximates 70 to 85 Gy over 8 weeks.

High Dose Rate Brachytherapy for Cervical Cancer

Though LDR techniques have been the traditional standard for decades for gynecologic brachytherapy, there appear to be some inherent advantages with the implementation of HDR techniques (143). Because the treatment time is very short, treatment is performed on an outpatient basis without the need for several days of bed rest, with greater patient acceptance and comfort. This allows treatment of some patients with medical comorbidities, which would prohibit LDR techniques because of the prolonged bed rest. With the shorter

treatment time, the implant reproducibility is superior to traditional LDR approaches as more stable positioning of applicators is possible. The shortened treatment time provides a greater degree of certainty that the sources will remain in the 3D positions documented in the isodose distributions, and that applicator displacement as a function of time will be decreased (56). The use of external applicator fixation devices allows more constant and reproducible geometry of source positioning (56,144–146). The newer systems, which allow a single source to “dwell” at a site for a calculated period of time, combined with dose optimization software programs, provide a significant further improvement in the ability to shape the dose distribution. The small source size allows for finer increments in source location and relative weighting for each source location than with the fixed source sizes and activities inherent to the LDR ^{137}Cs sources (86,146,147). This allows for greater precision coupled with greater flexibility and perhaps a reduction in normal tissues doses. Additionally, the

FIGURE 14.39. LDR Syed-Neblett templates (top to bottom) Gyn 1, Gyn 2, Gyn 3. Source: Reprinted with permission from Erickson B, Gillin M. Interstitial implantation of gynecologic malignancies. In: Nag S, ed. Principles and Practice of Brachytherapy. New York: Futura; 1997:518 (Fig. 1).

rectal retraction devices available with the HDR applicators maximize displacement of the rectum for short periods of time and may give superior and more predictable displacement than traditional vaginal gauze packing (56,144–146). These two factors lead to improved dose delivery to the tumor relative to surrounding normal tissues (148). There is also increased integration of external beam with HDR as external beam irradiation can be given three to four times per week and HDR one to two times per week. This can lead to a shorter overall treatment duration, which may be pivotal in maximizing cure (149,150). Additionally, due to the small physical size of the ^{192}Ir source, the HDR applicators are

FIGURE 14.40. Axial CT scan with needles inserted into the cervical and paracervical tissues between the bladder and rectum. Isodose curves shown are 80%, 100%, and 120% of the prescription dose.

lighter and smaller than bulky LDR applicators and are easier to insert, particularly if there is vaginal narrowing. Many institutions use only one LDR implant so that if the applicator geometry is poor, there is not the opportunity to perform multiple implants and improve the geometry or change applicators in future insertions as realized with HDR techniques. The remote afterloading also provides a lack of radiation exposure to health-care givers. Contrastingly, on a radiobiologic basis, HDR lowers the therapeutic ratio compared to LDR as there may be more late effects of radiation if the rectosigmoid and bladder receive as much radiation as the tumor than with LDR techniques. For HDR to succeed, the geometric advantages must overcome the radiobiologic disadvantages (146). Himmelmann et al. concluded that with HDR regimens, reoxygenation of hypoxic cells can take place between fractions, and this may in fact be a radiobiologic advantage of HDR (151). Disadvantages of HDR may include loss of the radiobiologic advantage of LDR, a potential increase in late tissue effects with large fraction sizes, and an increase in the number of implants per patient from 1–3 to 3–6 (range: 2–16), which is labor intensive for all involved. The need for sedation may still exclude high-risk patients even though bed rest is not required.

Conversion from LDR to HDR

There have been numerous suggestions regarding how to convert total LDR doses to HDR doses in order to implement reasonable dose-fractionation schemes. Efforts have been made by many investigators to compare the biologic effects of LDR with HDR regimens using various dose conversion models. The linear-quadratic model has typically been used, but this does not address the optimal number of fractions. A basic concept is that the total dose with HDR must be less than with LDR and the number of fractions must increase (151–155). This concept comes from early radiobiologic studies. The Equivalent Radiation Dose (ERD) mathematical model can be used to determine the HDR dose per fraction (156,157). The ERD is a biologic dose unit, which utilizes the linear-quadratic model. To determine an appropriate dose for high dose rate

FIGURE 14.41. HDR tandem and ovoids. *Source:* Courtesy of Nucletron.

treatments based upon low dose rate techniques, the ERDs are assumed to be equal. The alpha/beta for tumor is assumed to be 10, while μ is assumed to be 1.4 hours^{-1} . For this calculation, the LDR total dose, LDR dose rate, and desired number of HDR fractions are required to calculate an HDR fraction size. These calculations have shown that one must give approximately 60% of the LDR dose with HDR (143,156,157).

High Dose Rate Applicators

The tandems and ovoids used with HDR are variations of the traditional Fletcher and Henschke LDR applicators but are lighter, narrower, and smaller (Fig 14.41). The ovoids are 2.0, 2.5, and 3.0 cm in diameter with and without shielding. The relationship of the colpostat to the handle is different between HDR and LDR colpostats so that the cable-driven HDR source can negotiate the angle between the handle and the colpostat. The Selectron colpostats are angled at 60° to the applicator handles. Standard Fletcher-Suit LDR colpostats are angled most often at 15° and sometimes at 30° with respect to the colpostat handles (Fig 14.42). This can lead to a different

FIGURE 14.42. LDR versus HDR ovoid angles. The low dose rate ovoids are positioned at a 15° or 30° angle to the vaginal axis versus 60° in the HDR ovoids. *Source:* Courtesy of Nucletron.

relationship between the tandem and the colpostats and between the colpostats and the cervix, best seen on the lateral orthogonal x-rays taken for dosimetry after applicator insertion.

The ring applicator, which is an adaptation of the Stockholm technique, has become a popular applicator (147,158–161) (Fig. 14.43). The plastic caps that come with the ring applicator place the vaginal mucosa 0.6 cm from the source path, compared to the caps for the ovoids, which distance the vaginal mucosa from the source path by 1 to 1.5 cm. The short distance from the ring to vaginal mucosa can result in very high surface doses if fixed weighting, nonoptimized techniques are used (144,145,160). The bladder and rectum may also receive higher doses with fixed weighting nonoptimized dosimetry (159). It is important not to activate all the positions in the ring, as this will increase the dose to the rectum, bladder, and vaginal

FIGURE 14.43. Tandem and ring applicator with associated rectal retractor. *Source:* Courtesy of Nucletron.

FIGURE 14.44. Tandem and cylinder applicator. *Source:* Courtesy of Nucletron.

mucosa (159). Typically, four dwells are activated on each side of the smallest ring (36 mm), five on each side of the medium ring (40 mm), and six on each side of the large ring (44 mm). The tandems are available in lengths of 2 to 8 cm. Four ring-tandem angles are available including 30°, 45°, 60°, and 90°. The shape of the isodose curves comparing the ring with tandem and ovoids will also have a different shape and the volume of tissue irradiated will also differ (159,160). The ring applicator is ideal for patients without lateral vaginal fornices. Its ease of insertion and predictable geometry make it a popular alternative to tandem and ovoids.

Tandem and cylinder applicators are used in the setting of a narrow vagina or vaginal extension of disease and are available in diameters of 2.0 to 4.0 cm (Fig. 14.44). In most cases, rectal and bladder displacement are not possible with this applicator, although some of the cylinders have built-in shielding. A posterior speculum blade to displace the rectum can be used if there is not posterior vaginal disease. As with LDR tandem and cylinder applicators, the bladder and rectal doses may increase with this applicator, and the dose distribution will be more cylindrical than pear-shaped, which can underdose bulky tumors (Fig. 14.35). Careful attention to normal tissue doses and target coverage is necessary in this setting.

HDR Treatment Planning

The dose distribution with HDR tandem and ovoids and tandem and ring applicators model the LDR pear-shaped isodose distribution. Most HDR regimens use a paracervical dose specification point (A) rather than mg-hrs. Rectal, bladder, sigmoid, and vaginal surface doses should always be specified or documented, and some assessment of dose to the pelvic lymph nodes and lateral parametria should be documented.

The HDR system utilizes special vocabulary to describe certain functions and applications. A “dwell position” is a position at which the source is driven to stop or dwell. Dwell positions can be 2.5 and 5 mm apart. Up to 48 dwell positions can be specified per channel. The physicists will ask for the active length and convert the active length into a number of dwell positions. “Patient points” are points of interest at which the dose is calculated; they are defined on the orthogonal implant films. Examples include bladder, rectum, and sigmoid. “Applicator points” are points of interest at which the dose is calculated; they are defined by manually inputting the coordinates. Typically, applicator points include point A and points on the lateral surface of a ring, ovoid, or cylinder. “Dose points” are points at which the dose is optimized. In general, doses are specified using dose points. The optimization program then attempts to give the prescription dose at each of these points. With the tandem and ring, a similar system is used. The entire ring should never be activated, as this will cause high rectal, bladder, and vaginal doses. For the tandem and cylinder, again, a similar system is used with the

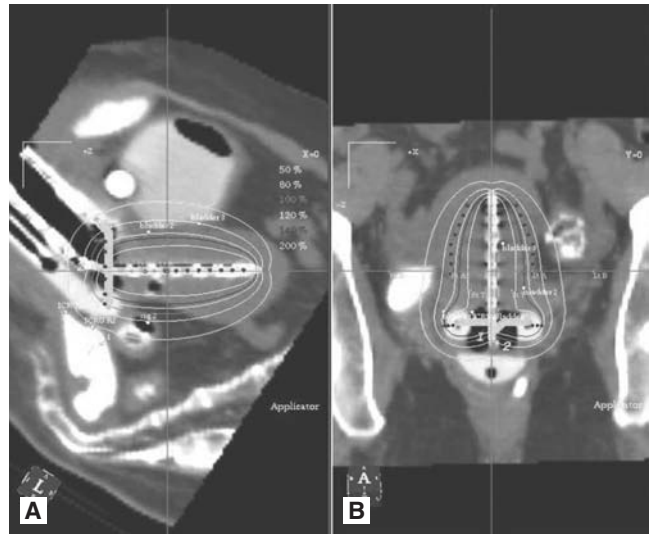

FIGURE 14.45. Dose distribution around a tandem and ring applicator in (A) sagittal and (B) coronal projections with dose specified at the ring surface and at the level of point A.

exception that at the cylinder interface, dose points are entered laterally from the dwell positions at the distances representing the cylinder surface. Due to the close proximity of the bladder and rectum in women requiring vaginal cylinders because of a narrow vagina, it may be wise to decrease the vaginal surface dose to 100% to 120% of the point A dose rather than 140% to 200% of the point A dose, as recommended with tandem and ovoid or ring applications.

Dose specification at point A alone can result in underdosing of target tissue and overdosing of dose-limiting tissues (162). In addition to point A, specifying dose at the vaginal applicator surface and use of optimization may allow for design of an optimal dose distribution (Fig. 14.45). Optimization is a term used in HDR dosimetry planning. With optimized plans, dose points are defined relative to the applicators and are used by the planning system to determine the dwell times necessary to deliver the specified dose to the points. With nonoptimized plans, fixed relative dwell weights are input into the planning system and are used to calculate the dose distribution. By altering the dwell times and dwell weights, it is possible to alter the dose distribution, and thereby optimize tumor volume coverage, and minimize normal tissue exposure. Excessive optimization can alter the pear shape to a less desirable configuration with the same point A dose (163,164). When altering the standard dwell times and weights, it is important to also monitor point T (defined at 1 cm superior to the cervical os and 1 cm lateral to the tandem with a dose two to three times the point A dose), and the vaginal surface (defined at the lateral radius of the ovoid and ring applicator with a dose 1.4 to 2.0 times the point A dose) (80,102,105). In addition, doses to the rectum, sigmoid, and bladder should be carefully monitored and adjusted if they are above the threshold tolerance.

HDR Dosimetry Generation

It is important to perform dosimetry for each fraction of an HDR regimen even if the same applicator is used, as there may be quite a bit of variation in applicator position with each fraction (165–173). There is also applicator deformation of the adjacent structures, which varies with applicator position (168). Variables that impact applicator position are vaginal packing, the presence and effectiveness of sedation/anesthesia, as well as use of the dorsal lithotomy versus legs down position. The bladder and rectosigmoid may also change configuration

Variation in Anatomy by Fraction

FIGURE 14.46. Variation in anatomy between fraction 2 (A) and fraction 3 (B) of a 5 fraction high dose rate (HDR) course. Note the difference in the position of normal organs at the level of point A between fractions 2 and 3.

due to changes in filling and position, and doses to these organs will vary from fraction to fraction. Uterine and sigmoid mobility may also impact the dose distribution in these organs. Additionally, disease regression and vaginal narrowing will vary from fraction to fraction and can also result in changes in dose distribution. A change in applicator can also result in changes in dose distribution as can changing the ovoid or ring size, ovoid separation, and tandem curvature. The ovoids may also change in separation and their relative position to the tandem over time if there is not a fixed relationship between the tandem and ovoids (167,169–172). Jones et al. found that when treatment planning was not performed for each fraction and only the initial dosimetry was used, there was increased dose to at-risk normal organs (172). This is also true when using a tandem and ring, even though it has a fixed geometry. The applicator position relative to the pelvic organs is the important factor rather than the relationship of the tandem to the ring (Fig. 14.46).

Dose-Fractionation Schemes

In the 1990 literature review by Fu and Phillips of the randomized and nonrandomized studies of HDR, multiple dose-fractionation schemes were tabulated. Most centers used point A as a reference point, although the definition of point A varied. The dose per fraction at point A varied from 3 to 10.5 Gy, the number of fractions varied from 2 to 13, and the number of fractions per week varied from one to three. At that time, most centers used a schedule of 7 to 8 Gy/frac for three to six fractions. The external beam dose was variable and in most centers was carried out concurrently with or after intracavitary brachytherapy (174). The 1991 Orton et al. survey of 56 institutions reported treatment of over 17,000 cervix patients with HDR and found that the average fractionation scheme was five fractions of 7.5 Gy to point A. Fractionation of the HDR treatments significantly influenced toxicity as morbidity rates were significantly lower for point A doses per fraction of ≤ 7 Gy compared with > 7 Gy (175,176). Fraction sizes < 7.5 Gy are recommended by the American Brachytherapy Society (86). In a literature analysis by Peterit and Pearcey of the HDR fractionation schedules, a dose-response relationship could not be identified for tumor control or complications (177). There is no consensus as to the optimal number of fractions and dose per fraction except that the choice will depend

on the external beam dose and on whether central shielding is used, normal tissue doses, medical comorbidities, and the stage of disease. The linear-quadratic model was suggested as a guide to formulate the regimens chosen at each institution (86,178). Currently, Gynecologic Oncology Group (GOG) protocols define a dose/fractionation scheme of 6 Gy \times 5 to point A (87). Radiation Therapy Oncology Group (RTOG) protocols allow more variation depending on the external beam dose with fraction sizes of 5.3 to 7.4 Gy when using four to seven fractions. Tables for combining various external beam doses with varying HDR fractions using the linear-quadratic formula and normal-tissue-modifying factor have been provided with these protocols (179). Currently, the most common approach in the United States is to use five fractions of 5 to 6 Gy in combination with whole pelvis irradiation of 45 to 50 Gy (180).

Sequencing with External Beam

In nonbulky disease presentations, HDR insertions are often integrated early in the treatment course after approximately 20 Gy of external beam RT. Alternatively, some institutions choose to take the whole pelvis to 40 to 45 Gy initially, preceding the five HDR insertions, unless the patient has very early disease or evidence of early vaginal stenosis. When delivering 40 to 45 Gy to the whole pelvis before initiation of HDR, it is important to avoid treatment prolongation by giving two HDR fractions per week to complete the radiation within 50 to 56 days (86,87). Compressing the duration of treatment to < 60 days may be desirable (149,181–183).

Midline blocks are used at variable points in time at many institutions (Fig. 14.47). It is important to understand when the midline block is placed as this will influence the HDR fraction size. Higher whole pelvis doses can be utilized without a midline block (56,145,146), but the HDR doses have to be appropriately reduced. HDR and external beam fractions should not be given on the same day.

Brachytherapy for Endometrial Cancer

Hysterectomy is the cornerstone of treatment for endometrial carcinoma. Selective use of vaginal brachytherapy, external beam irradiation, or both in the postoperative setting is based

FIGURE 14.47. Midline blocks. (A) A custom cerrobend block protecting the area previously treated by the tandem and ring implant. (B) A midline block defined by the leaves of the multileaf collimator.

on the histopathologic risk factors identified in the tissues removed at the time of surgical staging. Vaginal brachytherapy is typically performed using Fletcher colpostats, or a variety of vaginal cylinders (Delclos, Burnette). Both LDR and HDR techniques are used (Fig. 14.48). The choice of ovoids versus cylinders is individual and both have relative advantages and disadvantages (184). Vaginal ovoids are available in diameters of 2 to 3 cm with associated caps and shielding. Vaginal cylinders are available in diameters of 2 to 5 cm, with or without shielding. Vaginal ovoids generally require sedation for insertion, whereas cylinders do not. The length of the vagina treated with vaginal ovoids is approximately the upper third, whereas vaginal cylinders can treat a portion of or the entire vagina. Though rare, when present, distal vaginal metastases tend to be located in the periurethral area (185,186). Poorly differentiated

tumors may recur earlier and present in the distal vagina or distant disease sites, whereas well-differentiated lesions tend to recur later and are often in the upper vagina (187). Distal vaginal recurrences or metastases, however, are rare after radiation and occurred in 0.5% to 1% of patients when the upper vagina was treated (188). It is therefore not suggested to treat more than the upper half of the vagina routinely. Typically, the length of vagina treated with vaginal cylinders is between 4 and 5 cm, perhaps favoring a longer length when using brachytherapy alone (189). Packing is typically used to displace the rectum and bladder with ovoids and not with cylinders. Due to the longer length of vagina treated and the lack of packing, a larger volume of rectum and bladder will be treated with cylinders. Vaginal ovoids may be prohibited in a narrow vagina, whereas vaginal cylinders may not be in close approximation with all of the vaginal mucosa in the setting of a wide vaginal apex or if the cuff has been closed with “dog ears” rather than in a cylindrical shape.

Most vaginal brachytherapy for endometrial cancer is performed with vaginal cylinders using HDR techniques (Fig. 14.48) (189). The dose distribution should ideally conform to the shape of the cylinder (190). Dose is typically specified either at the vaginal applicator surface (mucosal surface) or at a depth of 0.5 cm from the applicator or vaginal mucosal surface. Dose prescription at 0.5 cm can lead to excessively high mucosal doses and surface doses should also be tracked (191,192). Additionally, careful assessment of dose to the rectum and bladder through use of computerized dosimetry should also be performed for the first fraction of radiation delivered (Fig. 14.48). Choo et al. have revealed that 95% of the vaginal lymphatic channels are located within 3 mm of the vaginal surface and that dose prescription to a depth of less than 5 mm may be adequate (193). For LDR insertions, dose rates at the surface of the applicator should be in the range of 80 to 100 cGy/hr, and perhaps 50 to 70 cGy/hr if the prescription is at 0.5 cm (190). Total vaginal surface doses of 50 to 80 Gy are reported most frequently in the literature. When used with external beam, cumulative doses of 60 to 100 Gy at the vaginal surface are reported in the literature. Doses in excess of 80 Gy to the vaginal mucosa are not necessary in the setting of adjuvant therapy and can be associated with increased morbidity. For a vaginal recurrence of endometrial cancer, doses of 80 Gy and higher may be needed when combining external beam and brachytherapy (194).

Vaginal brachytherapy alone is generally considered an option for patients treated with hysterectomy, with either no or selective lymph node sampling, who are thought to be at low risk for lymph node metastases. These patients typically have grade 1 or 2 disease without significant myometrial invasion (<1/3) (195,196). Additionally, vaginal brachytherapy alone is considered an option at some institutions in the setting of a negative pelvic lymph node dissection, even when high-risk factors such as high grade or deep myometrial invasion are present (196–198).

There is great debate if a vaginal cuff boost is routinely necessary in addition to external beam irradiation for early-stage endometrial cancer and little data to support it (199,200). Practice patterns are based more on institutional tradition and individual preference rather than prospective randomized trials. The rationale for use of a vaginal boost is the supposition that there may be a critical dose needed at the vaginal apex to optimally decrease the likelihood of a vaginal apex recurrence. Doses in excess of the 45 to 50 Gy typically delivered with external beam may be necessary if there are microscopic tumor cells embedded in the hypoxic vaginal cuff.

There are some clinical situations in which more complex brachytherapy procedures are required in the treatment of endometrial cancer. Patients with bulky stage II endometrial cancers may benefit from preoperative radiation with external beam alone, brachytherapy alone, or a combination of the

two. Tandem and ovoids or tandem and ring or cylinder applicators are used in this setting. Medically inoperable endometrial cancer is a rare phenomenon in the current era of aggressive surgical staging. When encountered, it can require the use of sophisticated radiation techniques. Either external beam alone or brachytherapy alone or a combination of the two may be appropriate for some patients. Tandem and ovoids or a tandem and ring or cylinder may be appropriate if the uterine cavity is small. If the uterus is large or if there is more extensive disease, special uterine applicators such as dual and triple tandems or Heyman-Simons capsules may be helpful (Fig. 14.49). There is better coverage of the entire endometrial cavity with these applicators, and dose can be delivered through the uterine wall to the serosa of the uterus (201–203). HDR and LDR techniques can be used.

Patients with recurrent endometrial cancer usually benefit from both external beam and brachytherapy. Doses in excess of 80 Gy may lead to better local control in these patients (194). In patients with residual vaginal disease less than 0.5 cm in maximum thickness, vaginal cylinders or ovoids can be used, whereas in patients with thicker lesions following external beam, interstitial techniques are needed. For apical lesions, laparotomy or laparoscopy may be required for optimum needle placement and to avoid small bowel tethered to the pelvic floor (129,204–206).

EXTERNAL BEAM IRRADIATION FOR GYNECOLOGIC CANCERS

Cervical and Vaginal Cancers

In cervical and vaginal cancers, the role of external beam irradiation is to shrink bulky tumor prior to implantation to bring it within range of the high-dose portion of the intracavitary dose distribution, improve tumor geometry by shrinking tumor that may distort anatomy and prevent optimal brachytherapy, and sterilize paracentral and nodal disease that lies beyond reach of the intracavitary system (72,85). Some institutions maximize the brachytherapy component of the treatment regimen and perform the first intracavitary insertion after 10 to 20 Gy with subsequent external beam delivered with a central block (207). Other institutions treat the whole pelvis to 40 to 50 Gy and perform brachytherapy once the external beam is completed. The total dose at point A or to the vaginal dose specification point(s), however, should remain the same, stage for stage. Implementing brachytherapy early with subsequent reliance on only the implant to treat the central disease may be considered an advantage as a greater portion of the central dose is delivered with the implant, with relative sparing of the bladder and rectum, perhaps permitting delivery of a higher central dose over a shorter period of time. More reliance, however, is placed on the extremely complex match between the intracavitary system and the edge of the midline block, making good implant geometry imperative when brachytherapy contributes a large portion of the central dose. Those who prefer to deliver an initial 40 to 45 Gy of external beam first believe that the ability to deliver a homogeneous distribution to the entire region at risk for microscopic disease and the ability to have more shrinkage of central disease prior to intracavitary irradiation outweigh other considerations. The brachytherapy dose is accordingly decreased to respect normal tissue tolerance. In addition to causing regression of central disease, the external beam fields are also directed at the regional lymph nodes at risk. In cervical and vaginal cancer, the risk of pelvic lymph node involvement is related to the stage of disease, tumor size, and lymphatic vascular space invasion. Other histomorphologic

FIGURE 14.49. Brachytherapy plan for a patient with medically inoperable endometrial cancer in (A) coronal, (B) sagittal, and (C) axial dimensions. Note dual tandems on the coronal image (A).

factors influencing lymph node involvement in cervical cancer include pathologic tumor diameter, depth of stromal invasion, uterine body involvement, parametrial spread, and the number of cervical quadrants involved by tumor (208). Early necropsy studies reported the lymphatic pathways for patients with cervical cancer (209). The primary lymphatic pathway is to the parametrial and paracervical nodes, and the obturator and internal and external iliac nodes. Secondary spread can occur to the sacral and common iliac nodes, with subsequent spread to the paraaortic nodes. Unlike in endometrial cancer,

paraortic lymph node involvement in the absence of pelvic lymph node involvement is rare. Inguinal lymph node involvement occurs with distal vaginal spread of disease or via the round ligament if there is extensive involvement of the corpus. The cervical lymphatics are located in three plexuses in the mucosa, muscularis, and serosa of the cervix and anastomose extensively with the lymphatics of the uterine isthmus. This interconnected lymphatic supply is one of the reasons why the entire uterus should be within the external beam fields when treating cervical cancer. Additionally, there may also be lower uterine segment and endometrial extension of tumor. There are lymph vessels running posteriorly in the uterosacral ligaments to lymph nodes located in the sacrum between the rectum and internal iliac vessels. These posterior nodes may terminate in the common iliac, subaortic, or paraaortic lymph nodes (208,210,211). Recent CT studies have added further information on the location of these lymph nodes and variants of spread (212).

For all gynecologic cancers, these patterns of lymphatic spread influence the external beam field borders. Traditionally, design of “standard” pelvic fields, as shown in many radiation oncology textbooks, has been thought to be quite simple and straightforward and based primarily on skeletal landmarks. The skeletal landmarks are not sufficient for field design (213–215). Traditionally, many institutions have used the “four-field box” technique to treat the pelvis with typical AP-PA field sizes of 15×15 cm and lateral field widths of 8 to 9 cm (Fig. 14.50) (79). The intent of the four fields is to use rather narrow lateral beams to avoid some of the small bowel anteriorly and a portion of the rectum posteriorly. As radiation technique must be “predicated on knowing where things are as opposed to where they ought to be,” there exist no such entities as “standard” radiation treatment volumes, “standard” portal design, or “standard” field sizes. Surgical and imaging series using CT, MRI, and Lymphangiogram (LAG) have revealed that fields of these sizes can easily miss the primary tumor and its extensions and the regional lymphatics at risk, and design of the pelvic fields needs to be done with care and use of confirmatory imaging (214,216–222). Plain films do not visualize the important soft tissues such as the cervical tumor and its extensions, the uterus, or the lymph nodes at risk. Additionally, bladder and rectal contrast and a vaginal obturator or cervical markers have been used to guide field design but are not sufficient (218,223). As with the brachytherapy component of treatment, the adequacy of the external beam fields and margins has a direct relationship with local and regional control (217). What may be considered a mysterious failure following definitive irradiation, perhaps caused by “radiation resistance,” may actually be the result of a marginal miss due to external beam field design. Placement of radiation fields must take into account the alteration of the spatial relationship between the tumor and normal anatomy due to individual anatomic, tumor-induced, or treatment-related positional variations of the uterus and cervix, as well as a knowledge of the location of the regional lymphatics (218,220). Radiation oncologists must be aware of these patterns of disease spread as well as have an in-depth understanding of CT anatomy when designing radiation fields following CT simulation. Identification and contouring of enlarged nodes in nodal regions at risk as well as identification of the iliac vessels, which serve as surrogates for the location of unenlarged lymph nodes, are important in subsequently defining radiation field borders (Fig 14.51). Additionally, contouring of the entire uterus and portions of the vagina will also ensure that these tissues are included in the radiation fields (Fig. 14.51).

Generally, the superior border of the pelvic fields is at the S1-L5 interspace for early-stage disease (i.e., nonbulky IB or IIA) or at the L4-5 interspace for more advanced disease. The latter is used if one wants to cover the common iliac lymph nodes. Interestingly, Greer et al. evaluated “standard” pelvic fields

FIGURE 14.50. Traditional four field pelvic box technique with short and narrow fields with the potential to miss the uterine fundus and the pelvic lymph nodes. *Source:* Reprinted with permission from Fletcher, Gilbert H, eds. *Textbook of Radiotherapy*. 3rd ed. Philadelphia: Lea & Febiger; 1980:761–762 (Fig. 37B and D).

(Anterior-Posterior [AP] - Posterior-Anterior [PA], 15×15 cm; lateral, 8 to 9 cm wide) for the treatment of cervical cancer in relationship to intraoperative findings. Based on intraoperative measurements of the location of the aortic bifurcation and the bifurcation of the common iliac arteries relative to the lumbosacral prominence (the anterior caudal border of L5), Greer et al. concluded that anterior and posterior treatment fields with a superior border at the L4-5 interspace are required to cover the internal iliac, external iliac, and obturator nodes as the bifurcations of the common iliac arteries were above the lumbosacral prominence in 87% of the patients studied. Coverage of the common iliacs could require extending the upper field border to the L3-4 interspace or even the L2-3 interspace in some patients (224). In a later series, Greer et al. treated 38 patients with cervical carcinoma with these expanded fields (AP-PA fields: median length and width of 20 and 17.5 cm; lateral fields: median width of 16.5 cm, posterior border including the entire sacrum), with an acceptable late

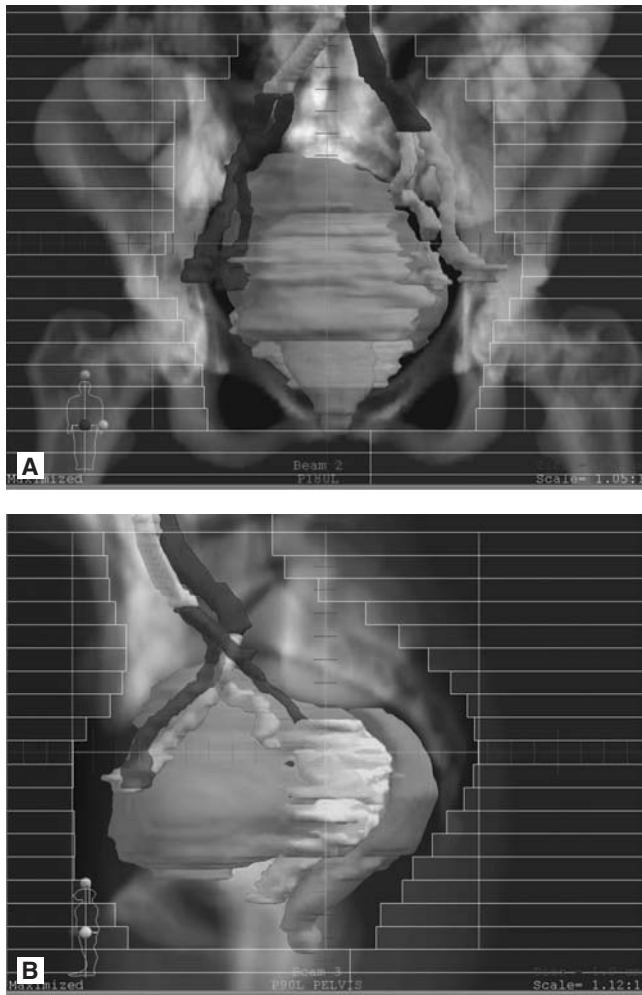

FIGURE 14.51. Digitally reconstructed AP (A) and lateral (B) radiographs with associated contoured targets including the pelvic lymph nodes and uterus. Note the multileaf collimator leaves defining the field shape in accordance with coverage of the targets of interest.

actuarial severe complication rate of 14.8% (223). Obviously, with CT-based dosimetry, it is imperative to outline the vessels and/or nodes in these areas to determine the appropriate field borders as unnecessary irradiation of bowel could occur if all patients were treated to the L2-3 interspace based on this assumption (Fig. 14.51). CT is an excellent tool to either identify pathologically enlarged nodes, multiple small lymph nodes that by increased number rather than size are suspicious, or in the absence of nodes, the aortic and iliac bifurcations and the iliac vessels (212,214). Finlay et al., using CT-based planning, found that 79% of patients treated with conventional fields had inadequate coverage. For adequate coverage, the superior border may need to be as high as L3-4 to cover the common iliac nodes. Using CT-based planning, Finlay et al. reported that 95.4% of the patients who had “conventional” pelvic fields had inadequate coverage of nodes when these were contoured on treatment planning CT scans (225). The inferior border of the pelvic field is usually at the bottom of the ischial tuberosities or 3 to 4 cm below the most distal vaginal component of disease. Inguinal nodes are included if there is distal vaginal spread, in which case treatment of the vaginal introitus with margin would also be required. MRI is especially helpful in imaging vaginal tumor extension (218). The lateral borders of the AP-PA fields are important to design carefully as the 1.5- to 2.0-cm margin from the pelvic brim standardly recommended may be too narrow. Using lymphangiography, Pendlebury et al.

found that in order to cover the lymphatic channels in the pelvis in 90% of cases, the lateral margins of the AP-PA fields would need to be 2.5 cm lateral to the pelvic brim (range of medial margins to cover lymph nodes: 0.5 to 3.0 cm) (215), and Bonin et al. found a margin of 2.6 cm (213). Intraoperative measurements have confirmed these findings (224). The lateral fields are even more prone to marginal misses than the AP-PA fields, as demonstrated in multiple series that have compared the standard textbook lateral fields (8 to 12 cm wide) to fields designed based on CT and MRI images (Fig. 14.52) (214,216,217, 219–221,226). For the lateral fields, a commonly employed guideline is to place the posterior border in a horizontal line, parallel to the treatment couch that divides the mid-rectum and intersects the sacrum between the second and third sacral segments (S2-3 interspace), and the anterior border by a horizontal line, parallel to the treatment couch from the anteroinferior lip of L5 to the anterior aspect of the pubic symphysis (219). These “standard” lateral fields are too narrow. For the lateral fields, careful consideration needs to be given to the anterior border to include the external iliac nodes. Based on lymphangiography, Pendlebury et al. found that to cover the external iliac nodes, the anterior border of the lateral field was sometimes as much as 2 cm anterior to the pubic symphysis (215), which was later confirmed by Bonin et al. (213). Chun et al. found that based on CT definition of the external iliac lymph nodes, when using standard lateral fields, only 50% of the patients studied had adequate coverage of these nodes (214). Additionally, the anterior border must also be drawn to include the entire uterus, given the interconnecting lymphatics of the uterus and cervix and the possibility of lower uterine segment/endometrial extension (Fig. 14.52) (211,216,220). Enlargement of the uterine fundus by the presence of hematometra or massive fundal extension of cancer can displace the fundus anteriorly and cephalad, as can an anteverted or retroverted uterus (216, 221,227). The prone position may accentuate this displacement (218,220). The anterior field border should be based on CT or MRI delineation of the tumor and/or normal anatomical variants to avoid underdosing of these structures (214,216,218, 219,221,226,227). The posterior border of the lateral fields must be designed carefully. Based on intraoperative findings, Greer et al. showed that the cardinal and uterosacral ligaments extend posterior to the rectum and sigmoid in their attachments to the sacrum. As part of the parametria, these tissues often contain nodes, even in early disease (IB and II, 22.5%) or are involved by direct extension and need to be covered in most patients by including the entire sacrum in the lateral fields (223). If there is uterosacral ligament involvement, it is especially important to include the entire sacrum in the lateral fields, although some institutions will use this as a criterion for AP-PA fields alone (210). The internal iliac lymph nodes can also lie very close to the rectum and splitting of the rectum can result in a marginal miss of these nodes (Fig. 14.53) (212). For posterior cervical lesions, there can also be direct extension to the superior rectal nodes or sacral lymph nodes (208). Tumor can also extend directly around the rectum. Kim et al. found that the most common site of an inadequate margin was near the portion of the lateral field blocking the rectum. On CT, it was found that tumor often fell along the lateral aspect of the rectum. The second most common site of inadequate margin was the posterior border at the S2-3 interspace (216). Zunino et al. also found inadequate posterior border margins when the uterus was both retroverted and anteverted (Fig. 14.52) (221). The reason for narrow lateral fields is typically concern over the rectum and the small bowel. Russell et al. have included the entire sacrum in the lateral fields of all patients with cervical cancer treated at their institution, and they have reported no increase in acute or late morbidity. When present, all rectal injuries observed have been on the anterior rectal wall due to the proximity of the implants used in the definitive management

FIGURE 14.52. (A–B): Traditional lateral fields are superimposed on sagittal MRI scans to evaluate target coverage with traditional fields. Note in (A) that the traditional lateral fields would not completely cover the uterine fundus, and that in (B) the traditional lateral field would cut through cervical tumor within the anteverting uterus. *Source:* Reprinted with permission from Zunino S, Rosato O, Lucino S, et al. Anatomic study of the pelvis and carcinoma of the uterine cervix as related to the box technique. *Int J Radiat Oncol Biol Phys* 1999;44(1):56–57 (Figs. 2 and 3).

FIGURE 14.53. A: The location of the presacral lymph nodes mandates including the entire sacrum to cover disease in the uterosacral and cardinal ligaments and superior rectal (pre-sacral) nodes. The right lateral sacral node (solid arrow) is medial to the hypogastric vessels (open arrow). B: Note the proximity of the internal iliac lymph node (solid arrow) to the rectum. This spatial relationship would exclude partial blocking of the rectum on the lateral fields. *Source:* Reprinted with permission from Park J, Charnsangavej C, Yoshimitsu K, et al. Pathways of nodal metastases from pelvic tumors: CT demonstration. *Radiographics* 1994;14(6):1311 (Figs. 2 and 3).

of these patients (219). Greer et al. also reported no increase in late rectal complications when including the entire sacrum in the field (223). It may also be a mistake to avoid the chance of a marginal miss by treating just with anterior and posterior fields, as in most cases some of the small bowel can be omitted from the lateral fields when using imaged-based planning (219). Gerstner et al. found that by using beam's eye view–based 3D treatment planning, though the rectal volume treated increased to avoid a marginal miss, there was an overall reduction in the lateral field treatment volume as compared to standard treatment fields due to beam shaping to exclude portions of the

bladder and small bowel and bladder distention (226). MRI has been found to be an invaluable tool for delineating normal anatomy and the extent of cervical tumor involvement because of its superior soft-tissue contrast when compared to CT. MRI also allows direct imaging in sagittal, coronal, and transverse planes (221). Sagittal MRI images are exceedingly helpful in designing radiation fields (Fig. 14.52). Design of the anterior and posterior borders of the lateral fields can be especially influenced by these images (218–221,227). Thomas et al. performed MRI rather than CT in the treatment position, and found better delineation of the tumor volume due to the superior contrast resolution (220). Lymphangiograms are very helpful in defining the location and architecture of lymph nodes when designing radiation fields, and are especially helpful in designing the lateral fields and subsequent nodal boost fields (213,215, 221,228). They do not routinely image the internal iliac lymph nodes, although sometimes these will fill in a retrograde manner. Unfortunately, lymphangiography is available at only a few institutions due to the fact that it is time consuming for both the radiologist and patient, and it is rather radiologists are trained in such procedures (213). Positron emission tomography (PET)/CT scans have largely replaced lymphangiograms at most institutions with Medicare approval in 2005 and can detect involved pelvic and paraaortic lymph nodes better than CT alone (229–232). PET does not rely on lymph node size alone, unlike CT, but rather metabolic alterations for detection of disease. PET has better accuracy than can be achieved with CT or MRI with a sensitivity of 85% to 90%, a specificity of 95% to 100%, and overall accuracy of 90% to 95%. Nodes as small as 6 mm can be imaged with PET, providing information to guide therapy and predict outcome.

Midline Blocks

A midline block is used during external beam to avoid regions of excessive dose adjacent to the implant and to deliver an adequate dose to potential tumor-bearing regions outside of the implant. When using a midline block early in the treatment course, more reliance is placed on the extremely complex match between the intracavitary system and the edge of the midline block. Some institutions customize the midline shield for each patient by defining the Cerrobend block edges as the contour of the isodose line passing through point A (233), or the 50% isodose line. Other institutions further customize this by stepping or altering the block thickness at specific isodose level intervals to achieve a dose “feathering” effect between the external beam and brachytherapy doses. The step-wedge or variable thickness transmission block used at Mallinckrodt (MIR) was initially designed to correspond to the various isodoses of the intracavitary insertions with various tandem and ovoid configurations (128,234,235). Over time, a customized step-wedge was not fabricated for each patient, but a number of standard prefabricated sizes were made available for repeated use. Several other institutions have published use of customized step-wedge midline blocks based on individual implants (236). Most institutions use rectangular blocks 4 to 5 cm in width rather than production of blocks based on the isodose distributions (Fig. 14.47) (233,237).

There are some important safety issues when using midline blocks. The midline block position should be based on films with similar isocenters. If patients receive external beam irradiation in the prone position, it may be wise to simulate them in the supine position for their parametrial boosts so that they are in the same position as they are for their implants. Midline blocks can be positioned to account for applicator deviation. Wolfson et al. found that most institutions using the standard rectangular midline blocks align the superior-inferior central axis of the block along the midplane of the patient's pelvis,

while those using customized midline blocks usually align the midline block along the axis of the tandem (233). The step-wedge corrects for the lateral gradient of the intracavitary system and not the rapid dose gradient anterior and posterior to the plane of the implant or for variations in the positions of the implants. The contribution of scattered radiation may increase the dose under narrow midline blocks, which may exceed the anticipated 5% of the primary pelvic dose when using a 5 to 6 half-value layer (HVL) midline block. Midline blocks that are too narrow may not adequately shield the bladder and rectosigmoid given their ability to move in and out of the blocked field. Filling and emptying of these organs may also alter their position relative to the block. Eifel et al. point out that the distance between the distal ureters is usually 4 to 5 cm. A narrow block may fail to shield a portion of the ureters during external beam (238). Reviewing the M.D. Anderson experience, Eifel et al. detected an increase in complications in patients with midline blocks (4 cm) used throughout the course of external beam. Since the ureters are typically 2 to 3 cm from midline, the explanation for the ureteral stenosis could have been an overlap between the external beam fields and the high dose region of the intracavitary implants (238). A margin of 0.5 cm lateral to the lateral ovoid surface is recommended in designing the width of the midline block for each patient to protect the implanted volume. If the intracavitary system is broad, a wide midline block may potentially shield the external iliac lymph nodes. If tissues immediately adjacent to the colpostats and tandem tip are not shielded, portions of the ileocecal junction and rectosigmoid may be overdosed (239,240). Huang et al. recommended avoiding a combination of parametrial boost doses of ≥ 54 Gy and a cumulative rectal biologically effective dose (CRBED) ≥ 100 Gy₃ to decrease the risk of radiation-induced bowel complications (240). Chun et al. also found increasing rectal complications with parametrial boosts > 55 Gy (241). When a midline block is inserted prior to 40 Gy, it should not extend to the top of the field since it will shield the common iliac and presacral lymph nodes, which will be underdosed (228,233). Kuipers notes that the uterus can be displaced cranially toward the sigmoid during intracavitary irradiation because of vaginal packing. It may be important to make the midline block high enough to protect the sigmoid so that it does not receive further radiation during external beam (242). The inferior edge of the midline block should be coincident with the caudal aspect of the whole pelvis fields to avoid overdosage of the distal vagina (233). When there is suspicion of uterosacral ligament involvement, it is safer to avoid early placement of the midline block, which will shield disease lying posterior to the implant (210). Due to concern over rectal tolerance, the rectum is shielded after a certain amount of external beam radiation therapy, which can block tumor in the perirectal area and uterosacral space. The geometric configuration of the intracavitary implant emphasizes lateral rather than posterior coverage and does not effectively treat the perirectal and uterosacral space effectively. This can lead to underdosing of tissues in this area and an increased risk of central recurrence. Higher whole pelvis external beam doses, interstitial implantation, or addition of a supplemental posterior oblique external beam boost may offer ways to compensate dose in this area (210). As there may be some disparity in implant position if multiple fractions are used over time, such as with HDR, it is necessary to reassess the midline block configuration after each implant (243).

Parametrial/Nodal Boosting in Cervical Cancer

Parametrial boosting is often recommended for patients with bulky parametrial or sidewall disease, after completion of the whole pelvis field and midline block fields, as the parametria are

a common site of failure. The need for boosting is usually based on the status of disease regression following whole pelvis irradiation. MRI may be helpful in making this assessment both before and during radiation. Mayr et al. found MRI imaging useful in the localization of parametrial tumor extension and enlarged their parametrial boost fields based on these MRI images to include the disease and exclude small bowel (218). Logsdon and Eifel suggest boosting residual lateral pelvic wall disease after 40 to 45 Gy whole pelvis to 60 to 62 Gy to small volumes (82). Perez et al. found a trend toward increased pelvic control with point B doses (defined at 6 cm lateral to the central axis) >45 Gy (101,244). In the 1973 and 1978 PCS, there was no relationship between lateral dose >60 Gy and either infield pelvic control or survival, but the lateral dose did impact complications with an increase above 50 Gy (107,109,110). There was a trend toward decreased failure with increasing parametrial doses in stage III disease (108). Perez et al. found that the incidence of pelvic recurrence was correlated with tumor size and dose of irradiation delivered to the lateral parametrium. There was an increase in the incidence of pelvic recurrence in patients receiving less than 50 Gy, but no correlation with increasing doses of irradiation (245). Doses needed to eradicate parametrial disease in the literature are typically around 60 Gy, combining the external beam doses with the implant doses. The proximity of small bowel can make this a risky proposition. Perez et al. noted that with doses below 50 Gy to the lateral pelvic wall, the risk of small bowel complications was about 1% and somewhat higher with larger doses (128). In a later series, grade 3 small bowel sequelae were 1% with doses of 50 Gy and 2% to 4% with doses over 60 Gy ($p = 0.04$) (246). At present, Perez et al. recommend limiting the small bowel doses to less than 60 Gy (246). Ferrigno et al. found an increase in small bowel complications when parametrial boosts were above 59 Gy. They recommended dropping the superior border of the parametrial fields to the S2-3 level and limiting the total dose to 54 Gy (181). The use of concurrent chemoradiation may allow a decrease in these doses, but data is too preliminary to conclude what this dose should be. When there is uterosacral space involvement, thought should be given to the use of a supplemental posterior oblique external beam boost (210). Grigsby et al. used PET/CT scans to evaluate lymph node size, irradiation dose, and patterns of failure. The parametrial and lymph node boost doses used were in the range of 9.0 to 14.4 Gy following large field doses of 50.4 Gy. Radiation dose and lymph node size were not significant predictors of lymph node failure. The risk of an isolated lymph node failure was $<2\%$ (247). A reoperation series following definitive irradiation and chemotherapy was reported by Houvenaegel et al. After 45 Gy and whole pelvis and selective parametrial or nodal boosting to 55 to 60 Gy, 15.9% of patients had biopsy-proven residual disease in the pelvic nodes and 11.7% of paraaortic nodes (248). Use of IMRT may be a method to increase dose to bulky nodes or residual parametrial disease while sparing adjacent normal structures (37,40,249).

EXTERNAL BEAM IRRADIATION FOR GYNECOLOGIC CANCERS

Endometrial Cancer

For endometrial cancer, many of the same nodes are at risk as in cervical cancer, but the spread of disease is not as predictable with the paraaortic nodes independently at risk. The presacral nodes are also not at risk unless there is cervical involvement. Both the pelvic and paraaortic nodes are at risk in all sites of uterine involvement, and grade, myometrial invasion, and lymphatic vascular space invasion are more predictive of risk than

location (250–254). Cervical and lower uterine segment involvement also increases the likelihood of pelvic and paraaortic lymph node metastases compared to fundal location, as do increasing histologic grade and myometrial invasion. In the surgical staging series of Boronow et al., 18 of 222 patients had lower uterine segment involvement and six (33%) had pelvic lymph node metastases (253,255). In the final GOG surgical staging series report, by location, patients with fundal lesions had a 4% risk of paraaortic and 8% risk of pelvic lymph node involvement, whereas patients with lower uterine segment involvement had a 16% risk of pelvic and 14% risk of paraaortic lymph node involvement (254).

In endometrial cancer, external beam irradiation is generally recommended for patients thought to be at significant risk for lymph node metastases and/or a vaginal cuff recurrence. This has traditionally been recommended in the absence of a lymph node dissection or a limited lymph node sampling. External beam irradiation is also still delivered at many institutions in the setting of a negative lymph node dissection when high risk features such as deep myometrial invasion, high grade, lymphatic vascular space invasion, lower uterine segment involvement, or cervical invasion are present (256,257).

External beam irradiation typically covers the upper one half to two thirds of the vagina, the pelvic lymph node regions, and the surgical bed (Fig. 14.54). External beam field design must necessarily include the pelvic lymphatics with exclusion of as

FIGURE 14.54. Digitally reconstructed AP (A) and lateral (B) radiographs with nodal volumes contoured as well as the vaginal apex and the fields defined by the leaves of multileaf collimator. This is a standard field design for patients with endometrial cancer.

FIGURE 14.55. A: Utility of the prone technique for small bowel displacement as shown on a sagittal and axial CT scan of a patient with endometrial cancer planned in the prone position. B: Radiographs of the pelvis showing significant amount of small bowel in the radiation fields.

much small bowel as possible. Treatment of the patient in the prone position with a full bladder will help to exclude at least some small bowel in most patients unless these loops are fixed in the pelvis (Fig. 14.55). It is important, however, for the lateral fields to also cover the course of the external iliac nodes, which are quite anterior in the pelvis and require inclusion of some small bowel in the lateral fields to be adequately covered. Doses of 45 to 50.4 Gy are typical with some institutions treating to 40 Gy and as high as 60 Gy to reduced fields in the setting of nodal disease. Whole pelvic fields are generally reduced or a midline block is added after variable doses.

Prone techniques have been used in the treatment of many other pelvic malignancies to attempt to exclude small bowel from the field. Use of a belly board device to further enhance small bowel displacement has become standard practice for many pelvic malignancies (258–260). Use of prone position with or without a belly board for the treatment of patients with cervical cancer has been reported in a few series, in the postoperative (258,259,261–263) and definitive settings (258–260,263,264). Prone positioning with the belly board has been used extensively for patients with rectal cancers when using a PA and two lateral fields. Concern over use of this technique for patients with gynecologic malignancies when adding a fourth field (AP) to cover the external iliac nodes has been raised by Ghosh et al.

due to the uncertainty in source to skin distance (SSD) and variation in tissue thickness from the anterior field. In patients who underwent postoperative irradiation for cervical cancer, they observed that the small bowel was best excluded from the AP-PA fields when the patient was positioned prone without the belly board, thereby compressing the small bowel laterally out of the AP-PA fields. They recommended an alternating routine (261). Bladder distention can also help to optimally displace bowel when using the belly board (258,260). Concern over use of the belly board in patients treated with definitive versus postoperative irradiation for cervical cancer is also raised due to the potential change in position of the uterus when prone, the impact and variability of bladder filling, and the potential daily variation in the setup (261,263,264). There is also some concern that, in patients with intact uteri, the prone position may increase the volume of the rectum treated (263). CT-based dosimetry has documented that the prone position, particularly with bladder filling, can alter the position of the uterus within the radiation field (218,220,264). Hence, if patients are simulated prone, it is even more imperative to use CT- or MRI-based dosimetry in the prone position to make sure that the entire uterus is in the pelvic fields, and it is also imperative to consistently fill or empty the bladder (264,265). IGRT may also be helpful in ensuring that the daily setup is reproducible and reliable.

FIGURE 14.56. Axial CT scan demonstrating an enlarged periaortic lymph node near the left renal hilum.

Extended Field Irradiation

Extended field irradiation refers to inclusion of both the pelvic and paraaortic nodes in the radiation fields. Common indications for extended field irradiation in gynecologic cancers include patients with positive paraaortic nodes or those with positive pelvic nodes or bulky primary lesions feared to be at risk for microscopic paraaortic disease (Fig. 14.56). Extended fields include more normal organs than pelvic fields alone. Limitation of dose to the small bowel, kidneys, liver, stomach, and spinal cord are essential. Three-dimensional conformal techniques are helpful in achieving an acceptable therapeutic ratio. Use of IMRT has recently been piloted in this setting with further attempts to decrease acute and late toxicity (Fig. 14.20). Selective boosting of gross nodal disease may allow for safer dose escalation (37–39,249).

Whole Abdominal Irradiation

Whole abdominal irradiation is used to cover the entire abdominopelvic cavity in ovarian cancers or high-risk uterine cancers such as those with positive peritoneal washings or adnexal involvement (IIIA disease). This requires limiting the radiation dose to a maximum of 30 Gy to the entire abdomen and using lower fraction sizes of 150 to 170 cGy. This will reduce both acute and late toxicities. Careful attention to and limitation of the dose of radiation delivered to the liver and kidneys requires selective blocking of these structures at different doses (266,267). IMRT techniques are also being explored for whole abdominal irradiation to reduce doses to the GI tract, liver, kidneys, and bone marrow and increase dose to the peritoneal surfaces and lymph nodes (41,42).

Radiation-Induced Tissue Effects

Side effects that develop during the course of radiation and persist for 3 months or less following completion of radiation are termed acute side effects. Those toxicities that develop later than 3 months after the completion of radiation are termed late or chronic effects. The late effects of radiation are due to damage at the capillary level where there is endothelial cell proliferation resulting in less diffusion of oxygen into the tissues with resulting fibrosis. There is less resistance to infection, trauma, or functional stress due to this change in vasculature and circulation (268,269). When treating gynecologic

cancers, the normal tissues most often incidentally irradiated in the pelvis are the rectosigmoid, small bowel, bladder, vagina, and pelvic bones and bone marrow. In the upper abdomen, the kidneys, liver, stomach, small bowel, and spinal cord may be in the radiation field. The response of a tissue or organ to radiation depends on two factors: (a) the inherent sensitivity of the individual cells, and (b) the kinetics of the population as a whole of which the cells are a part. These factors combine to account for the substantial variation in response to radiation characteristic of different tissues (1). Additionally, the volume of tissue irradiated as well as the dose, dose rate, and fractionation scheme will affect both acute and late toxicities. The addition of chemotherapy or other systemic agents may impact toxicity, as may other medical comorbidities such as diabetes, hypertension, collagen vascular diseases, Crohn's disease, and ulcerative colitis, as well as social risk factors such as smoking. The most comprehensive data describing the effects of radiation on the normal tissues was published by Rubin and Casarett and later updated by Emani et al. (269,270). Rubin and Casarett defined tolerance doses (TD) for almost all of the tissues. The TD 5/5 is defined as the probability of a 5% risk of complications within 5 years of the completion of radiation, and TD 5/50 as the probability of a 50% risk of complications within 5 years (269).

Skin

When treating abdominopelvic tumors with radiation, often there will be minimal skin reactions due to the skin-sparing quality of the high-energy radiation beams used to treat these sites deep within the body. Contrastingly, when treating the vulvar and inguinal regions, where electrons or lower energy x-rays are more often used, there can be marked skin reactions. Skin reactions are also more likely to develop in skin folds such as the inguinal creases or intergluteal fold. The cells in the basal layer of the skin are very sensitive to radiation, but because of the time required for these differentiating cells to move from the basal layer to the keratinized layer of skin, there is a 2 to 3 week delay between the start of radiation and the appearance of skin reactions. Erythema is the first visible skin reaction due to dilation of the small capillaries and is usually seen about the 3rd week of radiation. Other skin reactions include dry desquamation and moist desquamation occurring after the 4th week of radiation. Moist desquamation occurs with transient loss of the epidermis and exposure of the dermis. Serous fluid often oozes from the exposed and inflamed dermis (269,271). These effects may be enhanced by the combination of irradiation and some chemotherapeutic agents, particularly actinomycin D and doxorubicin (Adriamycin) (272). It is also well known that chemotherapy agents such as Adriamycin or gemcitabine can "recall" radiation reactions after the original reaction has subsided. Radiation-induced skin reactions are treated with various topical ointments and creams as well as with sitz baths and special emphasis on cleansing all stool and urine gently from the perineum. Additionally, if the distal vagina or vulva is in the radiation field, patients may also complain of dysuria or painful defecation, which is due to the caustic effects of the urine and stool on the denuded epithelium of the distal vagina, perianal area, and vulva. Diarrhea control and use of barrier creams to protect the irritated skin from stool and urine will help to minimize discomfort and hasten skin healing. Sulfa-based creams and Domeboro soaks can be used to expedite healing. Return of the epidermis can take 10 to 14 days. Residual surviving basal cells form islands of regeneration, which proliferate to re-epithelize the area. Islands of skin forming in the desquamated skin herald skin renewal. The new skin is thin and pink with gradual return to normal in 2 to 3 weeks (269). Late manifestations of radiation on the skin

include depigmentation, subcutaneous fibrosis, dryness and thinning with loss of apocrine and sebaceous glands, thinning or loss of hair, and telangiectases. Necrosis of the skin is rare and generally occurs only with very high doses of radiation in excess of 60 Gy (269,272).

Vagina

There are few noticeable acute reactions when treating the upper two thirds of the vagina with radiation. Some patients may notice a white-yellow vaginal discharge, which is due to mucositis of the vaginal mucosa. This can be evident during radiation and continue for several months after radiation (269). The lower third of the vagina, however, will become quite irritated when irradiated, in part due to irradiation of the vulva and urethra as described above. The distal vagina is less tolerant of radiation than the proximal and the tolerance doses are in the range of 80 to 90 Gy versus 120 to 150 Gy, respectively (273). Vaginal narrowing and shortening is a late sequela of radiation, which can alter and impede sexual function. Combined brachytherapy and external beam irradiation will cause more late effects than either modality alone. Use of a vaginal dilator or intercourse 2 to 3 times/week can help to keep the vagina open. Use of lubrication with intercourse as well as estrogen creams to build up the vaginal mucosa can also make intercourse more comfortable (272,274). Rarely, with excessive doses of radiation, patients can develop vaginal necrosis. This is due to a change in blood supply to the vaginal tissues and is much more common at the introitus than at the vaginal apex, perhaps due to the vascular supply of the vagina. The posterior vaginal wall is most frequently involved (273). Interstitial implants are more likely to cause necrosis than intracavitary implants. Hydrogen peroxide douches, antibiotics, and hyperbaric oxygen therapy can help the vaginal tissues to heal (275,276). Narcotics are often necessary to control the associated pain until healing has occurred. Trental (pentoxifylline) can also help soft-tissue necrosis to heal (277). The uterus is very resistant to high doses of radiation as is evident in patients treated with external beam and brachytherapy for cervical cancer. Rare cervical necrosis can occur and will respond readily to hyperbaric oxygen treatments and pentoxifylline (269,276,278). Necrosis can also be caused by recurrent tumor, and distinguishing recurrent disease from necrosis can be very difficult and sometimes will mandate surgical intervention (269).

Bladder/Ureters/Urethra

The bladder and ureters have a rapidly renewing transitional epithelium. The effect of radiation is early denudation similar to the skin due to injury to the rapidly dividing basal cells. Epithelial desquamation leads to focal ulcerations, hyperemia, and edema of the bladder wall, which is visible at cystoscopy (269,271,279). Acute and transient radiation cystitis may be observed with moderate doses of irradiation (>30 Gy) and usually requires no specific treatment. Patients will report urinary frequency and urgency as well as mild dysuria, as well as decreased bladder capacity. However, with higher radiation doses, more severe symptoms of cystitis develop, such as severe dysuria and hematuria, which may require treatment. Agents such as Pyridium may help lessen these symptoms. Significant spasms of the bladder musculature, which may be improved with administration of smooth muscle relaxants, may also occur. It is important to rule out the presence of a concomitant bacterial infection, which may exacerbate the symptoms. Infections are seen at an increased rate in irradiated patients, perhaps in part due to radiation-induced diarrhea and contamination of the

perineum. Urinalysis and urine cultures obtained under sterile conditions, when indicated, should be obtained before institution of antibiotic therapy. Radiation cystitis is characterized by the presence of white cells and red cells without bacteria on urinalysis.

With doses above 60 Gy, chronic cystitis and hematuria may be observed due to telangiectasias, which can develop in the bladder lining. With higher doses, more severe chronic cystitis, fibrosis, and decreased bladder capacity can occur. Rarely, bladder neck contractures as well as fistulas may occur, which can necessitate surgical intervention. Fistulas are more likely to occur if there is invasion of the bladder wall by tumor or in the setting of interstitial implants. Surgery may be required to deal with some of these complications (269). Hyperbaric oxygen therapy can be very helpful with hemorrhagic cystitis as can the drug pentosan polysulfate (Elmiron), which has been used for interstitial cystitis (276,280,281). Studies have demonstrated that with doses below 75 to 80 Gy to limited volumes of the bladder, the incidence of grade 3 or 4 complications is 5% or less, whereas with higher doses, a greater incidence of sequelae is noted (238,246). The ureters are quite resistant to radiation and rare ureteral stenosis is reported in some series (238,269,279,282). This can require stenting or rarely diversion. Interstitial implants are more likely to cause this than intracavitary implants, as can early placement of a narrow midline block (238). Urethral stenosis is also rare and is also more likely to occur with interstitial than intracavitary approaches. Careful dilation can be helpful in sustaining bladder outflow (279).

Small and Large Intestine, Stomach

The acute effects of radiation on the small intestine are due to the inherent radiation sensitivity of the rapidly dividing undifferentiated crypt of Lieberkuhn cells. The normal lining of the GI tract is a self-renewing tissue. These undifferentiated stem cells normally migrate and differentiate upward from the lower half of the crypts to the tips of the intestinal villi as they mature, providing a continuous supply of surface cells as they divide. Their function is to primarily form absorptive cells but also mucous-secreting goblet cells and endocrine cells (268,269,271). The mature cells at the surface of the villi are repeatedly sloughed and replaced by the cells, which originate in the crypts. These undifferentiated crypt cells are the most sensitive to radiation and are preferentially depleted, leading to loss of mature replacement cells at the surface of the villi. When these mature mucosal cells cannot be replaced, the villi shorten and the loss of absorptive function of the small intestine occurs. This loss of function results in fluid and nutrient wasting, diarrhea, and dehydration. This constellation of symptoms is termed acute radiation enteritis. Fortunately, re-epithelialization occurs within several days due to recovery of the rapidly dividing crypt cells (271). Mucosal healing will occur within 10 to 14 days if radiation is terminated, and symptoms will accordingly improve and resolve in most patients. It is common to observe watery diarrhea with intermittent abdominal cramping starting in the 2nd or 3rd week of abdominal or pelvic irradiation. Increased peristalsis, disturbance of the absorption mechanisms, and a decreased transit time also occur. Patients will report increased flatulence and noisy bowel sounds. Rarely patients will report nausea. Implementation of a low residue diet, hydration, and use of antimotility agents can be very helpful. Some patients may be lactose and fat intolerant as well. Judicious use of narcotics to calm the bowel can also be helpful. Concurrent 5-FU or gemcitabine can worsen small bowel toxicity with diarrhea from the 5-FU often appearing before the radiation enteritis has had time to evolve. The late effects of radiation on the small bowel

can be a continuation of the acute effects. Some patients will experience chronic diarrhea that will require a permanent change in diet. Certain foods may trigger diarrhea such as those high in fiber or fat. Spicy foods and MSG may also trigger diarrhea. Areas of narrowing corresponding to regions of high dose or adhesions can occur in the small bowel loops and lead to partial obstruction of the small bowel. Patients may report abdominal pain and distention followed by diarrhea and relief of these symptoms. A complete bowel obstruction would also be characterized by abdominal pain and distention in addition to vomiting and lack of bowel movements. Small bowel obstructions occur in approximately 5% of irradiated patients and surgical intervention is required in some to relieve these obstructions. Prior surgeries or a history of a perforated appendix or pelvic abscess as well as inflammatory bowel disease can increase the risk of small bowel toxicity. Hypertension and diabetes can also be risk factors as can thin body habitus. Radiation to large volumes of bowel or high doses to even small volumes of bowel can lead to bowel obstructions. The ileum is the most common loop of bowel involved (269). Malabsorption of fats, carbohydrates, protein, B12, and lactose can occur in some patients. Excessive bile salts can reach the colon and act as a cathartic, and medications such as cholestyramine can be helpful in controlling the resultant loose stools.

The rectosigmoid mucosa is also a rapid renewal system similar to the small bowel. When the rectum is included in the irradiated volume, there is rectal discomfort with tenesmus and mucous production, sometimes mixed with blood in the stools. Patients may report frequent and sometimes painful evacuations of only small amounts of stool mixed with mucus. Hemorrhoids may worsen during radiation. This constellation of symptoms is termed "proctitis." Medications to decrease the number of stools as well as antispasmodic agents can be helpful. Suppositories or foams with steroids can be helpful, as can topical perianal skin ointments and lotions. Uncontrolled radiation enteritis can worsen radiation proctitis due to frequent stooling through the irritated rectum. For late effects, if the dose of radiation is large enough, it may cause temporary or permanent ulceration and bleeding due to telangiectasias (Fig. 14.57). Cortisone-containing rectal suppositories and foams or sulfasalazine instillations can also help to heal the

FIGURE 14.57. Radiation-induced telangiectasias of the rectum consistent with radiation proctitis.

FIGURE 14.58. Radiation-induced sigmoid stricture noted on a contrast study ([A] full view, [B] magnified view) following definitive chemoradiation.

bleeding and ulcerated rectal mucosa as can argon laser ablation of the telangiectasias.

Hyperbaric oxygen therapy can be helpful in controlling bleeding when severe (276,280,283,284). Fibrosis, stenosis, perforation, and fistula formation are more rare (Fig. 14.58). In general, doses in excess of 60 Gy are necessary to produce this more advanced radiation damage to the small bowel and rectosigmoid. Fecal diversion may be necessary in the setting of stenosis, necrosis, or fistula formation. Retrospective analyses have shown that limited volumes of the rectum can tolerate about 75 Gy (external beam and brachytherapy) with acceptable morbidity (238,246).

The stomach is also lined with a mucous membrane, which is columnar epithelium and sensitive to radiation. Like the small and large bowel reactions, the stomach lining develops

erosions and thinning and subsequent edema and ulceration. Symptoms can include nausea, vomiting, reflux, and pain. Use of prophylactic antiemetics and proton pump inhibitors can decrease the acute effects of radiation. Acid production can be decreased during radiation and for up to 1 to 2 years after. Late effects can include gastritis and ulceration with associated bleeding. Progressive fibrosis can lead to gastric outlet obstruction and rarely perforation, all of which are dose and volume dependent (269).

Ovaries

In premenopausal patients treated with definitive irradiation, the ovaries will be irradiated incidentally and ovarian failure will occur. Hot flashes and other menopausal symptoms can begin to develop during radiation. Hormone replacement therapy is an important consideration in women younger than 50. Alternatively, midline oophorectomy has been used in young women requiring irradiation for Hodgkin's disease in an effort to spare the ovaries. The ovaries can also be elevated out of the radiation field and placed above the true pelvis to attempt to avoid them when treating cervical cancer. The radiosensitivity of the ovarian cells varies considerably with age. The dose necessary to castrate a woman depends on her age. A larger dose is required during the period of more active follicular proliferation. A single dose of 4.0 to 8.0 Gy or fractionated doses of 12 to 20 Gy (depending on age) are known to produce permanent castration and sterility in most patients (268,269,272).

Bone Marrow/Pelvic Bones

The lymphocytes are the most radiosensitive cells in the bone marrow. The rate of fall of the various components of the marrow is a function of the half-lives of the mature cells. These half-lives are as follows: erythrocytes, 120 days; granulocytes, 6.6 hours; platelets, 8 to 10 days (269). Pelvic irradiation may cause transient lymphopenia. This is even more of an issue when whole abdominal or extended field irradiation is used due to the increased bone marrow in the radiation fields. This decrease in lymphocytes is thought to be the result of irradiation of the lymphocytes circulating through the vascular bed and may not be indicative of bone marrow reserve depletion. Prior or concurrent chemotherapy will also lead to increased bone marrow toxicity. Frequent monitoring of the CBC is considered standard of care with pelvic or abdominal irradiation. Permanent chronic changes are noted even when small segments of the bone marrow are irradiated to doses over 30 Gy, and recovery may take up to 18 months or longer in a proportion of patients with good reparative capacity.

Insufficiency fractures can also develop in irradiated pelvic bones (285–287). These most commonly involve the sacrum and ileum, followed by the pubic bones, and rarely the acetabulum. Patients may complain of sudden onset of back or groin pain, which worsens with weight bearing and changes in position. MRI is the best imaging modality to detect them and also rule out recurrent disease. Sometimes edema will be reported in the absence of actual fractures, and in other cases actual fractures will be seen. It is important not to confuse these changes with metastatic disease, as further palliative irradiation would worsen the integrity of the bone. Symptoms from these changes in the pelvic bones will often improve over time, but patients may also suffer future symptoms from exacerbation of these fractures or development of new fractures over time. Sacroplasty can be used if patients remain symptomatic. Narcotics and changes in activity are often required. Femoral neck complications can include avascular necrosis as well as

fracture. This is a rare complication following irradiation of the inguinal nodes. Hip replacement surgery is required to resolve this problem (278).

Liver

During whole abdominal irradiation or paraaortic irradiation, the liver is in the radiation field and dose must be limited to this critical organ. Clinical and pathologic studies have shown that the liver is not a radioresistant organ. Venocclusive disease is the pathologic entity caused by radiation. Necrosis and atrophy of the hepatic cells result from this change in blood supply. CT scanning following radiation can show changes in perfusion of the liver corresponding to the radiation fields. These changes are not always associated with toxicity. The clinical course and liver changes depend on the dose and volume of irradiation as well as the presence of chemotherapy and preexisting liver disease. During radiation, the liver enzymes may be elevated. This can continue following completion of radiation. Signs of radiation hepatitis can include a marked elevation of alkaline phosphatase (3 to 10 times normal) with much less elevation of the transaminases (normal to 2 times normal) (269,288). Liver enlargement and varying amount of ascites can also evolve. If the doses and volumes are high enough liver failure can occur. The TD 5/5 for whole liver is 30 Gy. Small portions of the liver can receive up to 70 Gy (269).

Kidney

The kidneys are very sensitive to small doses of radiation, and a common goal is to avoid greater than 18 to 20 Gy whole kidney dose. When delivering whole abdominal irradiation the kidneys are at risk and must be blocked at acceptable doses to prevent renal failure. When delivering paraaortic irradiation, the kidneys are also at risk and treatment planning CT scans can help to define which beam angles are best to irradiate the nodal regions yet miss, in part, the kidneys. When planning radiation fields, sometimes one kidney will need to be irradiated more than the other and the equivalent of one kidney must be spared. Functional renal studies prior to radiation are important in documenting unexpected perfusion or excretion abnormalities and in determining how much each kidney contributes to total renal function. Functional changes have been described after exposure of the kidney to more than 20 Gy, and signs and symptoms of renal dysfunction can follow including hypertension, leg edema, and a urinalysis showing albuminuria and low specific gravity. A normocytic, normochromic anemia may also appear. Renal function studies will ultimately show decreased blood flow and filtration rates. CT scans may reveal a small kidney if one kidney has been preferentially irradiated to protect the other (269).

Bladder and Rectosigmoid—LDR

The bladder and rectosigmoid are the organs of concern in the setting of combined external beam irradiation and brachytherapy. Dose and volume are considered two important variables related to complications. Dose has been thought to be an important determinant of normal tissue complications. Attempts have been made to determine the maximum tolerable normal tissue dose with an acceptable risk of complications. There is no consensus as to what these values should be. Point doses may or may not coincide with complication risk, as they do not account for the volume of organ irradiated. They are also not defined consistently. Maximum bladder doses of 75 to 80 Gy and rectal doses of 70 to 75 Gy are guidelines (79,246). Small bowel doses

should be limited to 45 to 50 Gy with 60 Gy maximum (246). Additionally, the ratio of dose to the rectum and bladder and dose to point A is also important with a low incidence of rectal (0.3% vs. 5%) and bladder (2% vs. 2% to 5%) complications when this ratio was less than 80% (246). Other factors such as external beam dose and intracavitary dose rate are also important in the etiology of complications. The volume of rectum and bladder irradiated is an important variable in the development of complications in addition to the cumulative dose (289). Both external beam and use of tandem and cylinder applicators can increase the volume of bladder and rectum treated (116,290). Stage, patient age, and medical comorbidities such as hypertension, diabetes, diverticulitis, or inflammatory bowel disease may also increase the risk of complications. Individual radiosensitivity may also impact complication risk (291).

Bladder and Rectosigmoid—HDR

Acceptable normal tissue doses are even more debatable in HDR than LDR (177). Using HDR techniques, the therapeutic range is narrower and the risk of complications seems to rise faster than the rate of improved tumor control. Available clinical data also suggests that in addition to total HDR dose, the most important factor in late complication development is the dose per fraction and the number of fractions (56,291,292). The organ most at risk for complications is the rectosigmoid, whereas the bladder complication risk is comparatively low (150,174,293,294). Rectal and sigmoid complications occur earlier than bladder complications (291,292). Rectal bleeding is the most frequent rectal morbidity occurring in approximately 30% of patients (241,293–295). To avoid excessive morbidity, better physical dose distributions must be achieved with HDR to reduce doses to critical normal structures. This implies the use of rectal and bladder displacement. Fowler has speculated that if only 80% of the tumor dose is received by the critical normal tissues, then 4 to 6 HDR fractions can be used safely, whereas 12 to 16 fractions would be required if the normal structures receive 90% of the point A dose, and 30 fractions if the normal structures received 100% of the HDR dose (56,296).

Various disparate recommendations concerning normal tissue fraction size and total dose exist in the literature. Sakata et al. found that the probability of rectal complications increased dramatically above a maximal rectal dose (Deq) of 60 Gy (297). Cheng et al. found that patients with >62 Gy of summed external beam and intracavitary doses to the proximal rectum and >110 Gy maximal proximal rectal BED had significant increase in complications (298). Takeshi et al. noted that radiation dose significantly impacted rectal dose complication rate with an increase above 65 Gy (299). Teshima et al. noted a marked increase in rectal reactions beyond a rectal time-dose fractionation (TDF) factor value of 80 (300,301), and Ogino et al. noted no grade 4 rectal complications below a TDF of 130 and a BED below 147. The calculated incidence of complications ranged from 5% to 10% at TDF values from 104 to 124 and BED values from 119 to 146 (294). Sood et al. found that a rectal or bladder BED₃ <100 Gy₃ was associated with negligible late toxicity (302). Chun et al. noted increasing complications with an ICRU 38 CRBED >100 Gy (241). Chen et al. found the risk of rectal complications to increase with cumulative rectal doses >65 Gy and a CRBED >110 Gy (303). When using 45 Gy to the whole pelvis, Chen et al. found that complications were increased with cumulative ICRU 38 HDR rectal doses >16 Gy and cumulative ICRU 38 HDR bladder doses >24 Gy (304). Ferrigno et al. found that patients treated with a cumulative BED at rectum points above 110 Gy₃ and at bladder points above 125 Gy₃ had a higher risk of complications (181). Correlation of bladder BED with radiation

complications has been unreliable (225,304). Toita et al. suggested that the cumulative BED at the rectal point should be kept below 100 to 120 Gy₃ (305). In the series of Lee et al., late rectal complications increased with cumulative rectal BED ≥ 131 (306). Huang et al. recommended cumulative rectal BED ≤ 100 Gy₃ when using parametrial boosting, and recommended boost doses of <54 Gy to the parametria (240). Van Lancker and Storme have not found point A or normal tissue dose points helpful as predictors of complications, but rather that volume calculations were extremely helpful in predicting complications, and they found a significant correlation between rectal complications and the ICRU reference 60 Gy isodose volumes (307).

Rectal retractors have become an integral component of insertion techniques and perhaps improve the effectiveness and reproducibility of rectal displacement over gauze vaginal packing (56,144–146). Whatever the case, a rectal retractor, vaginal speculum blade, or gauze packing should be used to displace the rectum (157,175).

FIGURE 14.59. Radiograph of the pelvis with a tandem and ovoid applicator in place demonstrates the circuitous course of the sigmoid (A). The axial CT scan (B) demonstrates a more accurate relationship of the sigmoid to the uterine tandem and the need to limit dose to this loop of sigmoid positioned very close to the high dose region of the implant.

FIGURE 14.60. A: MRI compatible applicators. *Source:* Courtesy of Nucletron. B: MRI of the pelvis with an MRI/CT compatible applicator in place. Note the associated dose distribution relative to visible tumor within the cervix, in axial (B,C) and sagittal (D) orientations.

It is very important to choose points related to critical structures very carefully on the orthogonal films. Rectum above the level of the vaginal applicators and rectal retractor should be identified and sigmoid in addition to rectal points should be evaluated, as should bladder and vaginal points. Various methods for determining normal tissue doses have been described. When possible, the doses to the normal critical structures should be less than the dose at point A, perhaps in the range of 50% to 80%. The portions of the rectum and sigmoid that are above the range of the rectal retractor are most often the hot spots, and every effort must be made to decrease the dose to the rectosigmoid relative to the point A dose. Consideration to decreasing the dwell times or turning off dwell positions in the tandem should be given. To avoid underdosing endometrial extension of tumor, at least treating 4 cm above the exocervix so that point A is not in a region of dose constriction may be wise. Tandem lengths of 6 to 8 cm are typical. If there is endometrial extension, a longer tandem may be needed. Additionally, use of a tapered tandem will decrease sigmoid, bladder, and small bowel doses (162). Contrast in the sigmoid is helpful in making these decisions. CT scanning after applicator placement is exceedingly helpful and much more reliable in assessing the proximity of the sigmoid to the tandem and in manipulating the dose distribution (Fig. 14.59). Assessment of the anterior and posterior uterine wall thickness measured on CT with the applicator in place, along the course of the tandem, as well as the measured distances from the tandem to the rectosigmoid, small bowel, and bladder, can help to guide dose prescription and potentially decrease toxicity if the distribution is altered appropriately (308). Sigmoid doses can often be higher than the rectal ICRU doses (298).

FUTURE FOCUS

Reduction of morbidity and improvement in local control and cure is a common goal in the treatment of patients with gynecologic cancers. Use of 3D and functional imaging will be increasingly important to define tumor and normal tissues. This can perhaps allow escalation of dose to the tumor and reduction of dose to the critical normal tissues. There has been, however, a reluctance to vary from traditional dose specification as good outcomes have been published at institutions skilled in the care of gynecologic patients. It is potentially dangerous to optimize therapy to such an extent that the dose distribution looks dramatically different from the traditional "pear shape," which effectively encompasses the primary tumor and parametria in cervical cancer presentations. Making this pear too narrow to avoid critical structures may lead to a higher rate of local recurrence. Yet it is important to treat the disease and not just strive for an ideal dose distribution. Preliminary studies using CT indicate that we underestimate normal tissue doses with the present 2D dosimetric analysis used at most institutions (96,291,309). Whether this information should change the way we prescribe doses remains debatable. Directly relating the intracavitary system to the anatomy through use of CT and MRI seems to be the next step in the lineage of dosimetric systems (Fig. 14.60) (96,97,309–312). The GEC ESTRO Gyn Working Group has developed guidelines for defining and contouring tumor volumes and normal tissues on MRI scans with the brachytherapy applicators in place (99–100). The excellent soft-tissue resolution of MRI allows visualization of residual tumor in relation to the isodose distribution around the MRI compatible brachytherapy applicators (Figs. 14.33 and 14.60) (98,313). Data from Potter et al. has shown a decrease in complications and an increase in local control with the use of MRI-guided brachytherapy for cervical cancer (314). Additionally, the use of dose-volume histogram

analysis may add new insight into optimizing local control and decreasing morbidity with a better understanding of the importance of dose/volume relationships (311,312,315). This may be a powerful tool to help improve the therapeutic ratio in patients with gynecologic cancer and will best be achieved through collaboration of radiation oncologists, gynecologic oncologists, and diagnostic radiologists.

CHAPTER 15 ■ PRINCIPLES OF CHEMOTHERAPY IN GYNECOLOGIC CANCER

MICHAEL A. BOOKMAN

HISTORICAL OVERVIEW OF CANCER CHEMOTHERAPY

The first report of a drug-mediated tumor response was noted over 125 years ago using Fowler's solution (arsenic trioxide in potassium bicarbonate) in patients with Hodgkin's disease and leukemia (1). Arsenic compounds had been used for various medicinal purposes for over 2,000 years, and it was not surprising that they were tested in patients with cancer. Cyclic hematologic toxicity was observed following arsenic administration in normal individuals and patients with leukemia (2), establishing a close association between tumor response and host toxicity that still exists today. Cumulative dose-limiting toxicity (arsenic poisoning) was also described following expanded utilization of arsenic in chronic myelogenous leukemia (3), coinciding with a transition toward radiation therapy for the management of leukemia and lymphoma around 1940.

The term *chemotherapy* has been attributed to Paul Ehrlich, a Nobel laureate physician and bacteriologist, who developed *in vivo* rodent models of infection, including the introduction in 1910 of Salvarsan, an organic arsenical originally used to cure syphilis and still used in the management of trypanosomiasis. His early *in vivo* modeling also encouraged the development of inbred transplantable rodent tumors, thereby establishing a paradigm that has been widely adopted for screening new antitumor agents.

Although the topical vesicant properties of sulfur mustard received much attention during World War I, multiple systemic effects, including leukopenia, bone marrow aplasia, and mucosal ulceration, emerged with further study, and would ultimately have greater importance. Cancer chemotherapy, in the traditional sense, began with the demonstration that nitrogen mustard had reproducible activity against transplanted lymphoma in mice, prompting clinical trials as early as 1942 (4). However, owing to World War II, much of the research remained classified until 1946. Following the demonstration by Farber in 1948 that aminopterin, an antifolate, could induce temporary remission in childhood leukemia (5), antimetabolites became the next major category of agents to be developed, and were ultimately associated with cures in women with choriocarcinoma (6). Research during the 1940s also included the Nobel Prize-winning observations of Huggins and others (7) regarding the antitumor effect of estrogens in prostatic cancer.

Between 1945 and 1965, many important chemotherapeutic agents, such as actinomycin D, cyclophosphamide,

5-fluorouracil, Vinca alkaloids, and progestogens, were developed and demonstrated to have antitumor activity in clinical trials. Between 1965 and 1975, the pace of new drug discovery and development continued. During this period, cisplatin was shown to have activity in testicular and ovarian tumors, and doxorubicin, bleomycin, etoposide, and tamoxifen entered our clinical arsenal. This was followed by identification of analogs, such as carboplatin, idarubicin, and vinorelbine, with antitumor activity similar to the parent compound but with a reduction in nonhematologic toxicity. The 1990s and beyond have brought important new agents into clinical practice, including the taxanes (paclitaxel and docetaxel), non-taxane microtubule binding agents (epothilones), camptothecins (topotecan and irinotecan), nucleoside analogs (gemcitabine and capecitabine), alternative organoplatinums (oxaliplatin, satraplatin), an inhibitor of the proteasome complex (bortezomib), and an agent that binds to the minor groove of DNA, distinct from other alkylating agents (ecteinascidin).

Attention has also been directed at alternative formulations of standard agents, including liposomal or polymer-based encapsulation, protein conjugation, nanoparticles, or lipid solubilization, to modify drug disposition, tumor targeting, and the potential for host toxicity. In addition, conventional agents have been utilized for regional (intraperitoneal) administration, prolonged intravenous infusion, continuous oral administration, high-dose therapy with hematopoietic progenitor cell support, and weekly low-dose therapy, each with the goal of improving the therapeutic ratio, but with a variable impact on host toxicity and clinical outcomes.

With the availability of multiple agents, each with a different molecular target, mechanism of action, pattern of resistance, and spectrum of host toxicity, we have also seen frequent utilization of multidrug combinations, particularly as primary therapy for advanced disease. The use of adjuvant therapy, including concurrent chemoradiation for early-stage disease, has been greatly expanded in selected clinical situations, with the result that a larger proportion of patients is exposed to chemotherapy at an earlier point in the natural history of their disease. Based on a combination of intrinsic and acquired factors, the majority of advanced tumors eventually demonstrate broad resistance to conventional cytotoxic chemotherapy, and there has been renewed interest in novel biologic and immunologic approaches with non-cross-resistant mechanisms. In addition, with improved understanding of the mechanisms associated with drug resistance, newer agents have been developed that may partially reverse the resistant phenotype through blockade of specific pathways or promotion of cellular apoptosis.

Exploration of the biologic mechanisms associated with tumor invasion, metastasis, and angiogenesis has led to the development of inhibitors directed against metalloproteinases, adhesion molecules, and growth factors important for angiogenesis. As basic research in molecular biology uncovers specific genetic and growth-regulatory factors associated with tumorigenesis, targeted small molecules have been developed that modulate a number of intracellular pathways. These include inhibition of protein tyrosine kinases associated with specific growth-factor receptors and downstream components of signal transduction pathways, cyclin-dependent kinases associated with cell cycle progression, as well as interference with posttranslational protein modifications, such as farnesylation of the *ras* oncogene and other intracellular targets (8).

TUMOR BIOLOGY IN RELATION TO CHEMOTHERAPY

Tumor Growth and Cellular Kinetics

Many of the principles of modern chemotherapy are derived from knowledge of the growth characteristics of normal and tumor tissues. Each tissue has an innate capacity for growth that is regulated by internal and external factors. The growth characteristics of tumors differ from normal tissues, and the exploitation of these differences has provided the historical basis for utilization of radiation and chemotherapy. The cellular kinetics of normal tissues also explains many of the toxicities associated with chemotherapy. All normal tissues, particularly during fetal development and variably during adult life, possess the capacity for cellular division and growth.

The *static* population includes well-differentiated cells that arise from pluripotential fetal stem cells and rarely undergo cell division during adult life. Typical of this group are striated muscle, neurons, and nephrons, with oocytes representing a specialized subcategory. Damage to these cells can have long-term consequences, and has prompted interest in stem cell biology.

The *expanding* population of normal tissues retains the capacity to grow, but in their adult state, they are normally quiescent. Under stress, especially after injury, a proliferative burst is followed by return to quiescence. Typical of this pattern of growth are the components of liver parenchymal tissue, including hepatocytes, bile duct epithelium, and vascular endothelium.

The *renewing* cell population is in a continuous proliferative state with ongoing cell division balanced by cell loss and terminal differentiation. Typical renewing populations include the bone marrow, epidermis, gastrointestinal epithelium, and spermatocytes.

The patterns of normal cell growth partially explain some of the toxic effects of cytotoxic therapy and why some tissues are commonly spared (9). Renewing cell populations with constant turnover are most sensitive to acute injury from conventional chemotherapy or irradiation. This is reflected by the frequent occurrence of dose-limiting bone marrow suppression, mucositis, and azoospermia during cytotoxic drug treatment, with relative sparing of nonproliferative compartments, such as brain, muscle, kidney, bone, and oocytes. However, even nondividing tissues can experience late chronic effects related to DNA damage.

Dysregulated growth of cancer cells occurs because of altered growth-factor signaling and/or disruption of checkpoint mechanisms that exist in normal cells. Despite a capacity for continuous growth, the actual process of cancer cell division is not more rapid than division in normal cells.

Programmed cell death, or apoptosis, has emerged as a major mechanism for regulating growth and development of tissues. Furthermore, certain oncogenes, like *c-myc* and *bcl-2*, and tumor-suppressor genes (antioncogenes), including *Rb* and *TP53*, are central to the regulation of apoptosis. Expression of these genes can alter the sensitivity of cancer cells to treatment with chemotherapy and radiation. For instance, overexpression of functional *bcl-2* and nonfunctional p53 genes can render tumor cells resistant to a number of chemotherapeutic agents (10), suggesting that efforts to restore apoptotic signaling may improve chemosensitivity.

Antioncogenes, such as *Rb* or *TP53*, contribute to growth restraint in normal cells. Within the spectrum of gynecologic malignancies, their role is best illustrated in the setting of cervical cancer, where the papillomavirus E7 protein directly inhibits *Rb*, allowing cell cycle release (11). In addition, the papillomavirus E6 protein increases *TP53* degradation, promoting cellular proliferation.

Gompertzian Tumor Growth

During initial cell divisions, tumor growth seems to follow an exponential pattern. As the tumor grows larger, the rate of growth slows. This pattern of exponential growth with exponential growth retardation and is known as gompertzian growth (Fig. 15.1). As the tumor mass increases, the time required to double the tumor volume also increases. The kinetic explanation for this apparent paradox is illustrated in Figure 15.2, showing the effect of exponential growth by comparing the number of cells in the tumor mass with the number of doublings (12). In accordance with gompertzian kinetics, exponential growth is not strictly maintained throughout the entire growth history. For example, if a skilled radiologist recognized a 0.5-cm tumor on a chest radiograph, or a clinician palpated a 1-cm tumor mass, we might assume that the tumor had been detected quite early. In reality, the tumor has already

FIGURE 15.1. Hypothetical gompertzian tumor growth curve. Exponential tumor growth with exponential growth retardation. The vertical axis is tumor volume, and the horizontal axis is time.

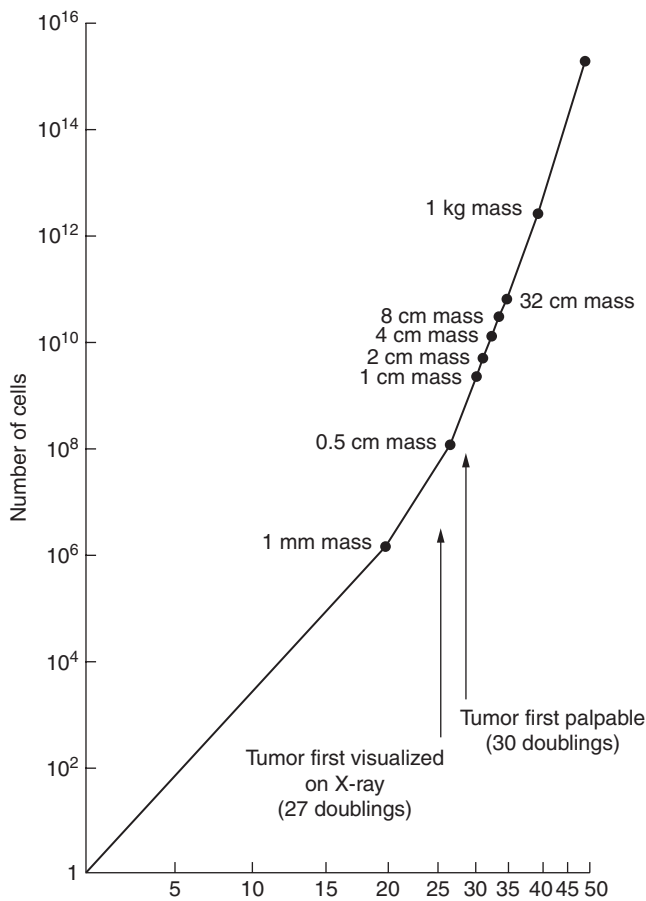

FIGURE 15.2. Theoretical tumor doubling curve assumes exponential tumor growth. The vertical axis is the number of cells, and the horizontal axis is the number of doublings.

undergone at least 30 doublings prior to detection (Fig. 15.2). If we adjust for ongoing cell loss, the number of actual cell doublings would be much greater.

Limited information exists regarding the actual doubling times of human tumors *in vivo* (13,14), as summarized in Table 15.1. For this analysis, tumors were relatively circumscribed and serially measurable by radiographic imaging, often as pulmonary metastases, representing a selective sample. It is clear that embryonal tumors, lymphomas, and mesenchymal

TABLE 15.1

DOUBLING TIMES OF HUMAN TUMORS

Tumor histology	Patients (n)	Doubling time (Mean \pm 2 SD, days)
Embryonal tumors (lung metastases)	76	27 \pm 5
Lymphomas	51	29 \pm 6
Malignant mesenchymal tumors	87	41 \pm 7
Squamous-cell carcinomas (lung metastases)	51	58 \pm 9
Squamous-cell carcinomas (primary tumors)	97	82 \pm 14
Adenocarcinomas (lung metastases)	134	83 \pm 12
Adenocarcinomas (primary tumors)	34	166 \pm 48

tumors have shorter doubling times than adenocarcinomas or squamous-cell carcinomas. In addition, metastases generally have faster doubling times than their corresponding primary lesions. The average doubling time observed in human tumors is approximately 50 days, with a broad range.

The model also suggests other conclusions of clinical relevance. First, metastatic spread may occur well before obvious evidence of the primary lesion. Second, at later stages of tumor growth, a small number of doublings can produce a marked change in tumor size with an increased potential for adverse clinical consequences. For instance, a 1-cm mass (at least 30 prior doublings) becomes a 4-cm mass after just two more doublings.

Host-Tumor Interactions

Ultimately, dysregulated growth exceeds local resources, and the tumor becomes dependent on the manipulation of host angiogenic pathways for delivery of oxygen, access to nutrients, and removal of waste products. In contrast, tumors generally grow without induction of host lymphatics, and are characterized by increased interstitial pressures as a consequence of disordered capillary proliferation with leaky vessels and accumulation of extracellular fluid. Together, these factors result in regional hypoxia, acidosis, and necrosis that can limit the effective delivery of chemotherapy and may protect viable tumor cells that are more distant from functional capillaries. One of the potential benefits observed with antiangiogenic therapy has been normalization of tumor vessels with reduced interstitial pressures and improved drug delivery (15).

Cell Cycle Kinetics

The kinetic behavior of individual tumor cells is also important in understanding tumor growth. Figure 15.3 is a schematic view of the cell cycle. Cells can remain in a noncycling postmitotic

FIGURE 15.3. Phases of the cell cycle, beginning with M (mitosis) and proceeding through G₁ (postmitotic phase), S (DNA synthetic phase), and G₂ (premitotic phase). As G₁ becomes progressively longer, it is known as G₀.

compartment (G_0) for extended periods of time, but retain the ability to reenter active cycling when triggered by growth factors or other local signals. The point of entry, or first gap phase (G_1), can be of variable length and associated with diverse cellular activities, including protein and RNA synthesis, DNA repair, and cell growth. After passing the first checkpoint in G_1 , the cell enters the DNA synthetic phase (S), during which a complete copy of the cellular DNA is created through replication. The second gap phase (G_2) provides another opportunity for checkpoint control before entering active mitosis (M), during which the nuclear membrane disappears and the chromosomes condense (prophase) and align (metaphase) in conjunction with the appearance of the mitotic apparatus, consisting of microtubules, centrioles, and the kinetochore. Mitotic alignment is associated with one final checkpoint prior to actual separation (anaphase), followed by dissolution of the mitotic apparatus (telophase) and creation of daughter cells through cytokinesis. The postmitotic period (G_1) is variable, and cells can further differentiate, enter a noncycling state (G_0), or initiate another cycle.

Cell cycle events have important implications for the patient, tumor, and cancer therapist. Most chemotherapeutic agents disrupt DNA, RNA, or protein synthesis. Rapidly proliferating cells (i.e., short G_1) are most sensitive to chemotherapy, whereas cells that slowly proliferate (i.e., G_0 or long G_1) are generally less sensitive. Nondividing cells, such as the differentiated elements of a mature teratoma, may occupy space and contribute to tumor bulk and symptoms, but are relatively insensitive to chemotherapy.

Cell cycle times may be estimated by performing labeled mitotic curves *in vivo* or *in vitro*, and appear to be relatively similar for many solid tumors, with cycle times ranging from 10 to 31 hours (16). Compared with the tremendous variation in human tumor doubling times, this is a relatively narrow range, suggesting that the primary reason for variations in clinical tumor growth cannot be ascribed to variations in the cell cycle.

Growth fraction and programmed cell death also influence the overall tumor growth rate and response to therapy. The growth fraction is the proportion of tumor cells that are actively cycling. In a typical solid tumor, only a fraction of the cells are rapidly proliferating, primarily those that are most proximal to small blood vessels. With the marked heterogeneity of human tumors at a microscopic level, growth fractions are quite variable, ranging from 25% to 95%. Although it may seem paradoxical, cell loss is very high in human tumors, ranging from 70% to more than 95%, and small changes in cell loss could produce major changes in overall tumor growth (17).

Log Cell Kill

In principle, the rational use of chemotherapy relies on basic concepts of cellular kinetics, but the translation from preclinical models to solid tumors has been challenging. In animals, the curability of transplanted tumors is inversely proportional to the tumor cell number, size, and timing of treatment initiation. In part, this is the result of important tumor-host interactions, such as the time required to establish a blood supply. However, this is also an illustration of first-order cell-kill kinetics, whereby a constant fraction of exposed cells is killed, rather than a constant number. Using first-order kinetics, a single treatment for a tumor weighing 1 g (approximately 10^9 cells) might yield 90% cell kill and would only decrease the tumor population by one log, leaving 10^8 viable cells. Without further treatment, the tumor would grow back at a constant rate, with only a modest delay in lethality. Only when the log cell kill is very large (>99%) and the therapies are repetitive can chemotherapy be curative. Although certain

unusual cancers, such as choriocarcinoma, can be cured with a single application of a single drug, most human cancers are intrinsically less sensitive, and more sophisticated therapeutic techniques are needed to achieve adequate tumor response. This is one reason why multidrug combinations have been developed. In addition, chemotherapy is usually distributed over multiple cycles to allow for host recovery and achieve the cumulative cell kill required for tumor regression and cure.

It is thought that prolonged survival or cure can be achieved only when the cell population is reduced to between 10^1 and 10^4 cells. In most circumstances, cell burdens of this size are not clinically detectable. This realization has led to the use of adjuvant chemotherapy in the early stages of cancer, where microscopic residual disease is suspected. It has also been used to rationalize the continuation of active chemotherapy for several cycles beyond clinical evidence of tumor remission.

Cell Cycle Specificity

Chemotherapeutic agents have complex mechanisms of action and can affect tumor cells through multiple pathways. Nevertheless, certain anticancer drugs are known to be proliferation dependent and cell cycle specific. Other drugs are cycle non-specific, and are capable of killing in all phases of the cell cycle, generally without dependence on the proliferative rate. Examples of cycle-nonspecific drugs include alkylating agents, particularly nitrogen mustard, which are effective against a variety of solid tumors, including those with low growth fractions. Cell cycle-specific agents depend on the proliferative fraction of the tumor and phase of the cell cycle. A typical example is hydroxyurea, which inhibits ribonucleotide reductase. Not surprisingly, cell cycle-specific drugs tend to be more effective against tumors with a high proliferative rate and growth fractions. The interaction of specific cytotoxic agents with the cell cycle is summarized in Table 15.2.

PHARMACOLOGIC PRINCIPLES OF CHEMOTHERAPY

General pharmacologic principles should be considered by the physician in selecting individual drugs and managing their administration according to standards of dose and schedule. Many factors may influence the effectiveness and/or toxicity of chemotherapy, including absorption, distribution, metabolism, and excretion, as well as clinical complications, such as renal impairment, malnutrition, or drug-drug interactions.

Absorption, Distribution, and Transport

Drugs may be given orally, intravenously, intramuscularly, intraarterially, or intraperitoneally. Selection of the route of administration depends on solubility, requirements for drug activation, local tissue tolerance, feasibility for an individual patient, and optimal tumor drug exposure, which is estimated as the area under the concentration-time curve (AUC) for the drug and active metabolites. The ultimate effectiveness of any chemotherapeutic agent depends on optimizing the AUC at critical tumor sites. However, there are no established techniques for noninvasive measurement of active drug concentration at these critical sites, and we are forced to extrapolate tumor drug exposure from preclinical models and plasma concentrations over time. Promising research in magnetic resonance spectroscopy and positron emission tomography may soon provide clinically relevant information on drug distribution and tumor metabolism using selected agents.

TABLE 15.2

RELATIONSHIP OF CHEMOTHERAPY AGENTS TO INTRACELLULAR TARGETS AND CELL CYCLE PROGRESSION

Classification	Cell-cycle arrest	Cellular targets and mechanisms	Examples
Inhibition of DNA synthesis and repair	G ₁ , S	Inhibition of nucleotide synthesis and metabolism. Inhibition of thymidylate synthase, thymidylate phosphorylase, dihydrofolate reductase, ribonucleotide reductase	Antifolates (methotrexate, pemetrexed), nucleoside analogues (6-mercaptopurine, 5-fluorouracil, cytarabine, fludarabine, gemcitabine), hydroxyurea
	S	Stabilization of DNA-topoisomerase II cleavable complex, DNA intercalation, +/- free radical formation	Anthracyclines (doxorubicin, daunomycin, idarubicin, epirubicin), anthracenediones (mitoxantrone), epipodophyllotoxins (etoposide), actinomycin-D
Alkylating agents and related compounds	G ₁ , G ₂ , S	Stabilization of DNA-topoisomerase I cleavable complex	Camptothecins (topotecan, irinotecan)
Antimicrotubule reagents	M	Direct DNA damage, DNA adduct formation, free radical production, strand breakage	Radiation, platinum compounds (cisplatin, carboplatin, oxaliplatin); bleomycin, mitomycin C, nitrogen mustard, nitrosoureas, ecteinascidin
Cell cycle agents	G ₁ , S, G ₂ , M	Inhibition of tubulin polymerization Promotion of tubulin polymerization Kinesin spindle proteins	Vinca alkaloids (vinristine, vinblastine, vinorelbine), colchicine Taxanes (paclitaxel, docetaxel), epothilones Investigational agents
Signal transduction modulators	G ₀ , G ₁ , S, G ₂	Mitotic checkpoint control, cyclin-dependent kinases (CDK), aurora kinases	Flavopiridol, investigational agents
		Growth factor sequestration, receptor blockade Inhibition of tyrosine kinase mediated signal transduction Modulation of protein kinase C Inhibition of hormonal pathways	Trastuzumab, cetuximab, pertuzumab, VEGF-trap, bevacizumab Erlotinib, gefitinib, dasatinib, imatinib, sorafenib, sunitinib, lapatinib Bryostatins, enzastaurin Tamoxifen, raloxifene, anastrozole, letrozole, fulvestrant, megestrol, mifepristone, flutamide, leuprolide
Gene regulation	NA	Gene regulation by inhibition of methylation, DNA methyltransferase, inhibition of histone deacetylase	Azacitidine, suberoylanilide hydroxamic acid (vorinostat)
Protein modifications	NA	Post-translational protein modifications, inhibition of farnesylation Inhibition of the proteasome complex and clearance of ubiquitinated proteins	Tipifarnib, bisphosphonates Bortezomib

The increasing utilization of oral chemotherapy and development of oral molecular targeted agents has renewed interest in bioavailability in the setting of meals and other factors that can modulate local intestinal transport. Most often, dose and schedule information from Food and Drug Administration (FDA)-approved package inserts reflects data from large phase 3 trials, rather than smaller studies that might examine dietary or drug interactions. For example, the bioavailability of one tyrosine kinase inhibitor could be increased over threefold in the setting of a high-fat meal (18), but the package insert recommends taking the drug on an empty stomach, at least 1 hour before or after meals. With the high cost of chronic medication, it is apparent that there could also be substantial economic implications to these pharmacokinetic observations (19).

Another interesting association concerns ingestion of grapefruit juice, which contains compounds that can inhibit local compounds within the intestinal mucosa, particularly the cytochrome P450 isozyme, CYP3A4 (20), and possibly the drug efflux pump, p-glycoprotein. Drugs that are substrates for either of these compounds can be more efficiently absorbed after ingestion of grapefruit juice, due to reduced local metabolism, leading to increased serum levels that may have clinical consequences, including cyclosporine, erythromycin, calcium channel blockers, and benzodiazepines.

The extent of drug binding to serum proteins, as well as physical properties, such as lipid solubility, diffusion, or molecular weight, may have an impact on tumor drug exposure. In addition, some areas of the body, particularly the brain, are actively protected from drug exposure and can serve as pharmacologic tumor sanctuaries, where sequestered cancer cells may survive otherwise curative systemic therapy. Although uncommon with solid tumors that disrupt the blood-brain barrier, this was a common problem in acute leukemia until effectively managed with intrathecal drug delivery and/or high peak plasma levels. In addition to achieving local delivery, most drugs must be internalized within tumor cells to achieve cytotoxicity. Internalization can be accomplished by passive diffusion, active transport, pinocytosis, or receptor-mediated endocytosis.

Many chemotherapeutic agents are lipophilic and highly protein bound in plasma, particularly to albumin. Commonly used agents with greater than 95% protein binding include cisplatin, paclitaxel, docetaxel, etoposide, and the active metabolite of irinotecan (SN-38). Agents with less protein binding include doxorubicin (75%), topotecan (35%), gemcitabine (10%), carboplatin (<5%), and ifosfamide (<5%). It is generally the unbound "free" drug that mediates toxicity, and any condition associated with variability in protein binding can have an impact on cumulative drug exposure. For example, the toxicity of chemotherapy is frequently accentuated in patients with poor nutritional status, which is associated with reduced protein levels and other metabolic changes (21). Docetaxel offers an interesting example for potential interactions, due to extensive binding to albumin, lipoproteins, and α -acidic glycoprotein (AAG), which has been correlated with changes in drug clearance, prompting further evaluation of optimized dosing (22).

Intraperitoneal Chemotherapy

Although most chemotherapy is administered by the systemic route, there are unique situations in which the regional use of chemotherapy has been studied, with intraperitoneal administration a specific example. If primary tumors or their metastases are anatomically confined to specific organs or particular regions of the body, or if unique pharmacokinetic circumstances exist that favor regional clearance, there is a theoretical rationale for regional chemotherapy. For example, intraarterial

drug administration has been studied in cervical cancer, localized recurrence of rectal carcinoma, and head and neck cancer. Local complications are potentially serious, including arterial thrombosis, wound slough, lymphedema, and osteonecrosis caused by the shared arterial blood supply between the tumor and neighboring normal tissues. While high response rates can be achieved in selected patients, larger randomized trials are needed to evaluate overall risks and long-term outcomes.

Intracavitary chemotherapy has been used for tumors confined to the peritoneum, pleura, or pericardium. The rationale for this approach is based on the fact that clearance from a body cavity is delayed compared to the systemic circulation, achieving more prolonged exposure to higher regional concentrations of active agents. This technique has been most extensively studied in ovarian cancer, with evaluation of many agents, including 5-fluorouracil, doxorubicin, cisplatin, carboplatin, cytarabine, melphalan, etoposide, and paclitaxel (23,24). Phase 1-2 studies have uniformly demonstrated a pharmacologic advantage favoring the intraperitoneal compartment, but have not documented enhanced drug delivery to actual sites of disease. Of key importance, penetration of peritoneal tumor nodules by passive diffusion is limited by fibrotic adhesions, tumor encapsulation, and high interstitial pressures as a consequence of intratumoral capillary leak without functional lymphatic drainage. In addition, both cisplatin and carboplatin are rapidly cleared from the peritoneal compartment and recirculate through the blood, limiting the window for direct tumor penetration, exposing the host to systemic toxicity, and raising questions about the clinical importance of the local pharmacokinetic advantage. Based on these observations, it has been postulated that the major role for intracavitary therapy would be in patients with minimal residual disease.

Cisplatin has received the greatest attention for intraperitoneal delivery in ovarian cancer, achieving a laparotomy-confirmed response rate of greater than 32% at doses between 50 and 150 mg/m², using systemic thiosulfate rescue at the higher dose levels (25). One long-term analysis reported an actuarial 2-year survival rate of 74% for patients with minimal residual disease treated with a variety of intraperitoneal therapies (26), although this may partially reflect the biology of small-volume disease, which can also be managed effectively with observation followed by systemic therapy. In view of the risk of systemic toxicity from cisplatin, there has been renewed interest in the substitution of carboplatin, which differs in terms of protein binding and overall time required for activation (via aquation), suggesting that biologic and clinical properties could be different from intraperitoneal cisplatin.

In contrast to cisplatin, paclitaxel was poorly absorbed from the peritoneal compartment, suggesting that patients might benefit from combined intravenous and intraperitoneal administration to optimize tumor drug exposure. As a single agent, intraperitoneal paclitaxel demonstrated a 61% pathology-confirmed complete response rate among 28 assessable patients with initial microscopic disease (27). However, only 1 of 31 patients (3%) with greater than microscopic disease achieved a complete response, emphasizing the limitations of drug access and penetration by diffusion from the peritoneal space.

Intraperitoneal therapy could also have an impact on the tumor-host relationship through alterations in local cytokine production, angiogenic potential, or immunoregulation. Hopefully, future studies will evaluate some of these biologic parameters to assist with optimization of therapy.

Biotransformation

Some agents, such as cyclophosphamide, ifosfamide, and capecitabine, are administered as true prodrugs and must undergo irreversible metabolism to the active form, most

commonly in the liver, but also in tumor or other host tissues. For many of these agents, intraperitoneal or intraarterial administration would be ineffective, as it would achieve high local concentrations of the native compound, but without an opportunity for bioconversion. Other agents are in reversible equilibrium with reactive intermediates, such as irinotecan and SN-38 (7-ethyl-10-hydroxycamptothecin), with dependencies on local pH and presence of specific enzymes, such as carboxyesterase. Cisplatin and carboplatin require activation through irreversible aquation to a reactive intermediary before they can initiate DNA adduct formation. Although the final reactive compounds are identical, the rate of aquation and adduct formation is much slower with carboplatin (28), but can be accelerated in the presence of activating nucleophiles, such as glutathione (29), even though the same nucleophiles can partially block cisplatin adduct formation at higher concentrations.

Renal Excretion and Physiologic Age

Drug inactivation, elimination, or excretion can dramatically influence cumulative exposure, which significantly affects antitumor activity and host toxicity. Inactivation and excretion of chemotherapeutic agents occurs primarily through the liver, kidneys, and body tissues, with lesser elimination through the stool. While any impairment of normal liver or kidney function can disturb drug metabolism and excretion, the most common problem encountered in the setting of gynecologic cancer is acute or chronic renal insufficiency due to tumor-mediated obstruction, drug-induced toxicity, advanced age, or preexisting comorbidities.

The use of combination chemotherapy in the elderly patient can pose a number of challenges related to bone marrow reserve and vital organ function (30). Although the risk of hematologic toxicity is generally increased, overall benefits from active chemotherapy regimens can still be demonstrated, as illustrated by the analysis of data from several breast cancer trials (31). Studies in ovarian cancer have indicated that age is an adverse prognostic factor, but it seems reasonable to expect

that delivery of effective treatments can still have an incremental benefit regardless of age. From that perspective, it is important to define tolerable and effective treatment regimens that can be safely administered in elderly patients, incorporating adjustments for age-related changes in vital organ function.

In surveying the general nondiabetic female population, the incidence of moderate renal insufficiency dramatically increases with advancing age, which is of particular relevance to the care of women with gynecologic cancer (32). For example, in the 60 to 69 year age group, over one third of women have an estimated glomerular filtration rate (GFR) of less than 60 mL/min/1.73 m² (Fig. 15.4). In addition, serum creatinine levels can be inappropriately low in women with gynecologic cancer, as a consequence of reduced muscle mass, malnutrition, or alterations in fluid balance, and any of the standard formulae will overestimate GFR, with potential clinical consequences. Clearly, universal caution in dosing drugs with high renal clearance, especially carboplatin, is required.

Several methods are available to estimate GFR and classify the extent of renal injury based on age, sex, serum creatinine, and other factors. In general, serum creatinine is the dominant factor, and it remains unclear if minor differences between formulae might have meaningful and/or consistent clinical consequences with regard to drug dosing. In most cases, it is sufficient to estimate the magnitude of renal injury rather than obtain a precise measure of GFR. However, all of these formulae are based on stable normalized biologic parameters, and are less useful in the setting of dynamic changes following acute renal injury, or nonrenal fluctuations in serum creatinine and fluid status, such as might occur in the postoperative setting or in the presence of large-volume ascites or in patients with abnormal muscle mass. While urine collection for measurement of creatinine clearance may provide a better estimate of GFR, it is also subject to variability, and the use of ⁵¹Cr-ethylenediamine tetraacetic acid (EDTA) clearance remains the standard for measurement of GFR, but is rarely used in clinical practice due to the cost and complexity associated with radioisotopes. A nonradioactive alternative is the measurement of iodine in blood after administration of iohexol (a nonionic contrast agent), but this has not yet gained wide clinical acceptance (33).

FIGURE 15.4. Distribution of renal function in nondiabetic adults. Weighted distribution of predicted GFR (mL/min/1.73 m²) based on the MDRD formula from the Third National Health and Nutrition Examination Survey (NHANES III). *Source:* From Clase CM, Garg AX, Kiberd BA. Prevalence of low glomerular filtration rate in nondiabetic Americans: Third National Health and Nutrition Examination Survey (NHANES III). *J Am Soc Nephrol* 2002;13:1338–1349.

TABLE 15.3**COMMONLY UTILIZED FORMULAE TO ESTIMATE CREATININE CLEARANCE**

Formula name	Estimation of creatinine clearance (CrCl)
Cockcroft–Gault formula (35)	$\text{CrCl (mL/min)} = (140 - \text{age}) \times \text{weight (kg)} \times (0.85 \text{ if female}) / \text{serum Cr (mg/dL)} \times 72$
Jelliffe formula (36)	$\text{CrCl (mL/min)} = \{98 - [0.8 \times (\text{age} - 20)]\} \times (0.9 \text{ if female}) / \text{serum Cr (mg/dL)}$
MDRD formula (34)	$\text{GFR (mL/min/1.73 m}^2) = 170 \times [\text{serum Cr (mg/dL)}]^{-0.999} \times (\text{age})^{-0.176} \times (0.762 \text{ if female}) \times (1.180 \text{ if African American}) \times [\text{SUN (mg/dL)}]^{-0.170} \times [\text{Alb (g/dL)}]^{+0.318}$

Note: Alb, serum albumin concentration; Cr, creatinine; GFR, glomerular filtration rate; MDRD formula, the Modification of Diet in Renal Disease study equation; SUN, serum urea nitrogen concentration.

For characterization of chronic renal dysfunction, there is emerging support for the formula derived from the Modification of Diet in Renal Disease (MDRD) study, which has also been incorporated in standardized laboratory reports (34). The Cockcroft–Gault (35) and Jelliffe (36) formulae are also commonly used (Table 15.3). Staging of chronic renal disease has been used to reflect overall severity and guide management decisions, including dose modifications. The most commonly used staging system is from the National Kidney Foundation (http://www.kidney.org/professionals/kdoqi/guidelines_ckd/toc.htm) (37).

Specific guidelines exist for modifying drug doses for patients with renal impairment (38), with special attention to a growing list of agents with renal-dominant clearance (Table 15.4). Dosing parameters for patients on dialysis receiving individual drugs, such as cisplatin (39) and carboplatin (40), are also available. However, owing to the rapid introduction of new

agents, clinicians are urged to consult updated prescribing information and online database resources.

Metabolism and Pharmacogenomics

Modifications of drug doses may also be required for patients with liver disease (41), particularly for paclitaxel, docetaxel, nanoparticle albumin-bound paclitaxel (42), doxorubicin, and the Vinca alkaloids (vincristine, vinblastine, and vinorelbine), which are primarily metabolized in the liver and/or excreted in the bile. Excessive toxicity may occur with doses that would ordinarily be acceptable, and guidelines for treating patients with impaired liver function should be consulted. However, variability in nonhepatic clearance and compensatory host adaptations, such as increased renal clearance, make these recommendations less rigid than those provided for patients with

TABLE 15.4**MODIFICATIONS IN THE SETTING OF RENAL AND HEPATIC DYSFUNCTION**

Agents that should be considered for modification in the presence of moderate to severe renal dysfunction	Agents that generally do not require modification in the presence of moderate renal dysfunction	Agents that should be considered for modification in the presence of hepatic dysfunction
Actinomycin D	Anastrozole	Docetaxel
Bleomycin	Bevacizumab	Doxorubicin
Capecitabine	Cetuximab	Epirubicin
Carboplatin	Docetaxel	Mitoxantrone
Cisplatin ^a	Doxorubicin	NAB-paclitaxel
Cyclophosphamide	Epirubicin	Paclitaxel
Etoposide	Erlotinib	PEG-liposomal doxorubicin
Ifosfamide	Fluorouracil	Vinblastine
Irinotecan	Gefitinib	Vincristine
Methotrexate	Gemcitabine	Vinorelbine
Topotecan	Letrozole	
	Leucovorin	
	Leuprorelin	
	Megestrol	
	NAB-paclitaxel	
	Oxaliplatin

renal dysfunction. For example, dose reduction of etoposide in the setting of biliary obstruction remains controversial and may not be required (43).

With expanded knowledge of metabolic pathways and awareness of polymorphisms in key enzymes, it has also been possible to identify individuals with a dramatic increased risk of toxicity. For example, dihydropyrimidine dehydrogenase (DPD) controls the rate-limiting step in fluoropyrimidine metabolism, and approximately 10 variant DPD alleles can occur with sufficient frequency to merit consideration of screening, as patients can be at risk for life-threatening mucosal injury and bone marrow suppression after receiving a single standard dose of 5-fluorouracil. While methods are available for screening, current assays can be expensive, and the potential reduction in risk needs to be balanced against the costs of a widespread screening program (44). The use of 5-fluorouracil during primary treatment of gynecologic cancer has declined, with the exception of some chemoradiation strategies and occasional palliative management of recurrent disease.

Uridine diphospho-glucuronosyl-transferase 1A1 (UGT1A1) is responsible for glucuronidation of bilirubin and a number of drug metabolites, most notably SN-38, the major active metabolite of irinotecan. As such, patients with a deficiency in UGT1A1 are at increased risk for life-threatening diarrhea and bone marrow suppression after receiving irinotecan, and potentially other camptothecin derivatives with SN-38 metabolites (45). While the UGT1A1*28 promotor mutation has been studied most extensively, mutations in the coding region can also occur, particularly in Asian populations, and may predict for efficacy in addition to toxicity (46). Gilbert's syndrome is associated with a mild unconjugated hyperbilirubinemia and reduced activity of UGT1A1 that is also associated with an increased risk of toxicity in both homozygous and heterozygous patients (47). The family of adenosine triphosphate-binding cassette (ABC) proteins is involved in biliary transport and conjugation of camptothecins. Polymorphisms of ABCB1, also known as p-glycoprotein or multidrug resistance protein 1 (MDR1) as well as ABCC2, also known as canalicular multispecific organic anion transporter (cMOAT)

TABLE 15.5

PHYSIOLOGIC AND PHARMACOLOGIC INTERACTIONS IN CANCER CHEMOTHERAPY

Interaction	Cause and/or agent	Impact
Renal dysfunction	Obstruction, renal dysfunction, hypovolemia, hypotension, nonsteroidals, nephrotoxins (aminoglycosides, cisplatin)	Decreased clearance of methotrexate, carboplatin, and other agents
Hepatobiliary dysfunction	Biliary obstruction, hepatic dysfunction Gilbert's syndrome, glucuronidation polymorphisms (UGT1A1)	Decreased clearance of doxorubicin, mitoxantrone, vincristine, vinblastine, etoposide, paclitaxel, docetaxel Increased exposure to SN-38 (irinotecan)
Microsomal activation	Hepatic dysfunction	Impaired activation of cyclophosphamide and ifosfamide
Altered protein binding	Carrier displacement (sulfonamide, salicylates, phenytoin) Reduced carrier proteins (malnutrition)	Increased toxicity, higher free drug levels (methotrexate) Increased toxicity, higher free drug levels (cisplatin, paclitaxel, docetaxel, etoposide, SN-38)
Altered intestinal absorption	Oral antibiotics (neomycin) High-fat meal Grapefruit juice (intestinal CYP3A4 inhibition)	Decreased absorption of methotrexate Increased bioavailability (lapatinib) Decreased bioavailability (capecitabine) Increased bioavailability (cyclosporine, erythromycin, benzodiazepines)
Decreased metabolism	Allopurinol Dihydropyrimidine dehydrogenase (DPD) deficiency	Delayed clearance (6-mercaptopurine) Lethal toxicity (5-fluorouracil)
Cholinesterase inhibition	Cyclophosphamide, glucocorticoids	Decreased clearance (succinylcholine)
Monoamine oxidase inhibition	Procarbazine	Neurotoxicity and seizures (tricyclic antidepressants and phenothiazines)
MDR-1 competition	Natural products and other substrates, including verapamil, cyclosporine, tamoxifen	Decreased efflux and increased toxicity from natural products (doxorubicin, vincristine, paclitaxel, docetaxel)
CYP2C9	Inhibition Capecitabine	Increased AUC (warfarin)
CYP3A4	Induction Glucocorticoids, barbiturates, rifampin Inhibition Ketoconazole, itraconazole, fluconazole, erythromycin Substrate competition Cyclophosphamide, ifosfamide, paclitaxel, docetaxel, etoposide, vincristine, vinblastine, tamoxifen, gefitinib	Increased activation (cyclophosphamide) Decreased metabolism of substrates (potentially significant) Decreased metabolism of other substrates (usually not clinically significant)

or MRP2, also appear to have an impact on the clinical efficacy and toxicity (neutropenia and diarrhea) associated with irinotecan therapy in Asian patients (48).

Other gene polymorphisms have been described with an impact on DNA repair or detection of DNA damage, as described in subsequent sections. Techniques for screening and identification of pharmacogenomic elements are expanding, with potential implications for individualized drug selection, dosing, prediction of efficacy, and risk of toxicity.

Drug Interactions

During routine care, patients may receive a variety of drugs, including antiemetics, antihistamines (H₁ and H₂), steroids, nonsteroidal anti-inflammatory agents, anticoagulants, narcotics, and anti-infective agents. In addition, adult patients are frequently receiving medication to manage underlying comorbidities, such as diabetes, hypertension, and elevated cholesterol. In view of the number and diversity of medications in common use, it is somewhat surprising that most drug interactions with cytotoxic chemotherapy appear to be of little consequence. However, prospective studies of chemotherapy administration in noncancer volunteers are impractical, and many potential interactions have not been fully explored. Although recent clinical trials acknowledge that these interactions may exist, patients are likely to be excluded from enrollment on the basis of concomitant medications, rather than prospectively collecting valuable data to document safety or the need for treatment modifications. In clinical practice, the occurrence of excessive hematologic and/or nonhematologic toxicity in an individual patient treated with chemotherapy is usually attributed directly to the chemotherapy and managed with treatment modifications, rather than ascribed to a potential drug interaction.

In some instances, interactions may be critical, and some of the more important drug interactions are listed in Table 15.5. Particular attention should be placed on drugs that could alter renal function, such as aminoglycoside antibiotics, nonsteroidal anti-inflammatory agents, and diuretics, in patients

with reduced fluid intake. Typical of *in vivo* interactions relevant in gynecologic cancer chemotherapy are the displacement of methotrexate from its transport protein by aspirin or sulfonamides, suppression of pseudocholinesterase by alkylating agents with increased apnea duration during succinylcholine-assisted general anesthesia, impairment of doxorubicin clearance by preadministration of paclitaxel, and impairment of paclitaxel clearance by preadministration of cisplatin.

Increased attention has been focused on drug metabolism and potential interactions at the level of cytochrome P450 (CYP) isozymes, particularly CYP3A4, which is potentially linked to the metabolism of nearly half of all pharmaceutical agents (49). These interactions are guided by several common principles. Drugs that are *substrates* for the same isozyme may competitively inhibit metabolism, but these interactions are usually not of clinical consequence. Drugs that *directly inhibit* CYP isozymes without being a substrate for that isozyme are more likely to have clinical consequences. In this regard, itraconazole, ketoconazole, and fluconazole can inhibit CYP3A4 at low concentrations, and erythromycin can inhibit CYP3A4 via covalent binding and inactivation. Other drugs act as *inducers* of CYP isozymes by increasing gene expression or protein levels, such as glucocorticoids, barbiturates, and rifampin, which can increase the net activity of CYP3A4, resulting in decreased concentrations of susceptible compounds. In addition, many drugs that interact with CYP3A4 are natural products and may also interact with the MDR-1 multidrug resistance transporter P 170 (see mechanisms of multidrug resistance). Among the anticancer agents that are substrates for CYP3A4 are cyclophosphamide, ifosfamide, docetaxel, etoposide, paclitaxel (also CYP2C8), docetaxel, vincristine, vinblastine, tamoxifen, and gefitinib (50). CYP2C9 and CYP2D6 are inhibited by imatinib, and doxorubicin can inhibit CYP2D6. Cyclosporine and verapamil can increase concentrations of doxorubicin and etoposide, probably through blockade of the P-170 drug efflux pump (Table 15.6).

Owing to the diversity and rapid adoption of new chemotherapy and nonchemotherapy compounds, information regarding drug interactions is best obtained from online

TABLE 15.6

SPECIFIC MECHANISMS OF TUMOR DRUG RESISTANCE

Mechanism	Examples	Specific target or effects
<i>Impaired activation</i>	5-Fluorouracil Methotrexate Doxorubicin Cyclophosphamide, ifosfamide Gemcitabine	Reduced levels of thymidylate synthase, thymidylate phosphorylase, or dihydropyrimidine dehydrogenase Reduced intracellular polyglutamation Low P450 enzymes Decreased microsomal function Decreased deoxycytidine kinase
<i>Increased drug efflux</i>	Natural products Topotecan, mitoxantrone	Increased <i>MDR 1</i> (P 170) Increased <i>BCRP</i> (ABCG2)
<i>Increased drug inactivation</i> <i>Accelerated DNA repair</i> <i>Increased damage tolerance</i> <i>Transport defects</i>	Alkylating agents, platinum Alkylating agents, platinum, radiation Alkylating agents, platinum, radiation Melphalan Gemcitabine Platinum	Elevated glutathione and other cellular thiols Induction of DNA repair enzymes Loss of DNA mismatch repair Reduced carrier-mediated uptake Decreased nucleoside transporter Decreased copper transporter-1
<i>Target alterations</i>	Methotrexate Vincristine, paclitaxel Hydroxyurea, gemcitabine Glucocorticoids Camptothecins Anthracyclines, etoposide	<i>DHFR</i> gene amplification Altered beta-tubulin binding Decreased ribonucleotide reductase Decreased receptor binding Decreased topoisomerase-I Decreased topoisomerase-II

DRUG RESISTANCE AND TUMOR CELL HETEROGENEITY

The curative potential of chemotherapy is limited by the emergence of drug resistance, which can be either intrinsic or acquired, and may involve one drug or multiple agents (pleiotropic resistance). Of interest, tumors with intrinsic or primary drug resistance to natural products often arise from duct cells or cells lining excretory organs (51). These cells, which normally detoxify, transport, and excrete a wide variety of toxic compounds, may retain these normal functions after transformation, manifesting as chemoresistance. With few exceptions, attempts to differentiate prospectively drug-responsive tumors from their resistant counterparts using morphologic, cytogenetic, immunologic, or molecular biologic techniques have not yet been successful. However, within the next few years, high-throughput molecular profiling by gene expression or proteomic array is expected to identify patterns that are predictive of tumor resistance or response to specific chemotherapeutic agents.

The presence of intrinsic drug resistance is inferred based on clonal survival of tumor populations after initial chemotherapy exposure. Solid tumors are thought to consist of a mixture of clonal variants with different mutations and patterns of resistance. Following repetitive cycles of chemotherapy, a process of clonal selection can occur, enriching for resistant populations, even while there could be a reduction in clinical tumor volume associated with elimination of more sensitive tumor elements. From a clinical perspective, the end result of this process is indistinguishable from acquired resistance, which develops from cumulative mutations, or phenotypic alterations, over a period of time. However, acquired resistance is more likely to have a reversible component that could influence the timing and selection of subsequent chemotherapy. The most well-documented specific example is amplification of the dihydrofolate reductase (*DHFR*) gene, which is associated with acquired resistance to methotrexate (52). *DHFR* gene amplification is not generally observed prior to methotrexate exposure and can be reversed in the absence of drug exposure.

From the perspective of gynecologic oncology, there are two major patterns of drug resistance that emerge with continued treatment. The first is broad-based multidrug, or pleiotropic, drug resistance that has been associated with overexpression of *MDR 1* (P 170 glycoprotein) and/or other membrane-associated transport proteins (53,54). This multidrug resistance phenotype has maximal impact on natural products and their analogs, including the anthracyclines, Vinca alkaloids, and taxanes. The second is resistance to alkylating agents, especially platinum compounds, mediated through a completely different set of cellular mechanisms, including reduced cellular uptake due to loss of membrane transport proteins, increased detoxification of reactive intermediates by glutathione production, increased damage tolerance due to defective detection and/or apoptotic signaling, and expanded capacity for DNA repair (55).

Mechanisms of Multidrug Resistance

After exposure to a potential *MDR 1* substrate, tumor cells will develop cross resistance to a variety of structurally and functionally unrelated agents derived from natural products. This pleiotropic resistance is associated with increased drug

efflux and a net lowering of intracellular drug concentration. Although relatively uncommon in ovarian cancer (56,57), with increased utilization of natural products, including taxanes, etoposide, and liposomal doxorubicin, this pattern of resistance may become more prevalent. Mutations in the β -tubulin subunit have been associated with paclitaxel resistance in preclinical models, but this does not appear to be a common mechanism in the clinical setting (58), and expression of *MDR 1* has been more frequently observed as a potential marker of resistance (59).

Other chemotherapeutic agents are not substrates for *MDR 1* and remain unaffected by increased expression. For example, several cell lines with multidrug resistance mediated by *MDR 1* demonstrated increased uptake, phosphorylation, and sensitivity to gemcitabine, a nucleoside analog, which could be reversed by verapamil, an inhibitor of *MDR 1* (60). This has potential implications for optimal timing, sequence, and combination of agents in the clinical setting.

Other energy-dependent transporter proteins have been identified in drug-resistant cell lines that do not overexpress *MDR 1*. These include the multidrug resistance-associated protein (MRP), which is representative of a family of cMOAT proteins (61). Similar to *MDR 1*, these proteins include multiple transmembrane domains, but appear to have more broad tissue distribution and greater association with intracellular membrane-bound compartments. Another member of the family with relevance to gynecologic cancer is the breast cancer resistance protein (BCRP) or adenosine triphosphate-binding cassette protein G2 (ABCG2) that dimerizes to form a membrane-associated energy-dependent drug efflux pump responsible for atypical multidrug resistance following exposure to mitoxantrone or camptothecins, including topotecan. Overexpression of BCRP has been documented in ovarian cancer cells resistant to topotecan (62).

Platinum Resistance and DNA Repair

Although a number of DNA alkylating agents and radiation are used in the treatment of gynecologic cancer, platinum derivatives are the most important compounds utilized in clinical practice. The dramatic success of platinum-based therapy is nearly overshadowed by the emergence of platinum resistance, and this observation has stimulated a substantial body of research over the last 30 years.

As a highly polar compound, cisplatin enters cells relatively slowly, and uptake can be influenced by local cation concentrations, pH, and the presence of reducing agents, prompting a search for membrane transporter proteins that could supplement passive diffusion. The major transporter involved in copper homeostasis, copper transporter-1 (CTR1), has now been shown to have a substantial role in cisplatin influx (63). Down-regulation of CTR1 expression can reduce cisplatin uptake, leading to one mechanism of resistance. Targeted methods to safely and selectively increase platinum uptake in tumors are not yet available. However, it has been observed that ovarian cancer cell lines can rapidly down-regulate membrane CTR1 after cisplatin exposure, followed by proteasomal-mediated degradation (64), suggesting that sequence and schedule of drug administration could have an impact on platinum uptake. An orally active analogue of carboplatin, satraplatin or bis-acetato-amine-dichloro-cyclohexylamine platinum (IV), has shown promising activity in the treatment of prostate cancer (65) and undergoes biotransformation to JM118 or cis-amine-dichloro-cyclohexylamine-platinum (II), which retains activity in tumor cells that have lost CTR1 (66), suggesting another avenue for clinical development.

Human ovarian cell lines resistant to alkylating agents, cisplatin, and irradiation contain elevated levels of cellular

glutathione (GSH). Using resistant cell lines, it has been possible to demonstrate a restoration of drug sensitivity by exposure to the synthetic amino acid buthionine sulfoximine (BSO), which inhibits gamma-glutamylcysteine synthetase, causing GSH depletion (67). The exact mechanism by which GSH and other thiol compounds modulate cytotoxicity is unknown, although they can interfere with the formation of DNA-platinum adducts (68). There is also evidence of increased drug metabolism through GSH-linked transferases, which can vary for specific platinum compounds (69), and which may also contribute to cisplatin-mediated nephrotoxicity (70). Although clinical trials of BSO with melphalan have documented an 80% to greater than 90% reduction in tumor-associated GSH levels (71,72), this approach has not yet been demonstrated to improve the outcomes of platinum-based therapy.

In view of the prominent role of thiols in mediating a subset of platinum resistance, a sterically hindered platinum complex, picoplatin (JM473, ZD0473), was developed with the expectation that it would favor interacting with DNA rather than glutathione or metallothioneins (73). A phase 2 trial in recurrent ovarian cancer documented response rates of 8.4% in platinum-resistant disease and 32.4% in platinum-sensitive disease, similar to expectations with cisplatin or carboplatin (74). Of interest, there was no documented peripheral neuropathy or nephrotoxicity even in this group of patients with prior platinum therapy, implicating thiol reactions in the generation of these nonhematologic toxicities.

Enhanced capacity for DNA repair can play a role in drug resistance to alkylating agents and cisplatin. Human ovarian cancer cell lines resistant to melphalan demonstrate increased ability to repair melphalan damage, and this phenotype can be reversed by aphidicolin, a potent inhibitor of alpha and beta DNA polymerase (75). Increased damage tolerance is another mechanism that contributes to resistance, and is perhaps best illustrated by the mismatch repair system. Errors in DNA replication following platinum adduct formation can be detected by the postreplicative DNA mismatch repair system, which contains several well-characterized genes, including *MLH1* and *MSH2*. Of note, cellular attempts to repair platinum alkylation by this mechanism are not successful as the repair is directed at the nascent daughter DNA strand rather than the platinated parental strand. Eventually, abortive attempts at repair are associated with apoptotic cell death. Thus, loss of mismatch repair can actually promote cell survival by ignoring DNA damage in noncritical areas of the genome and has emerged as another mechanism of drug resistance.

Loss of *MLH1* or other mismatch repair genes is not uncommon in ovarian cancer and appears to increase after exposure to carboplatin or cisplatin (76). In addition, functional loss of *MLH1* activity in patients with ovarian cancer can also occur through hypermethylation-mediated silencing of the *MLH1* gene following exposure to platinum, and has been correlated with poor survival (77). Preclinical models with platinum-resistant cell lines have shown improved treatment outcomes following exposure to 2'-deoxy-5-azacytidine (decitabine), which blocks DNA methylation, unmasking expression of *MLH1* (78), providing a basis for exploratory clinical trials.

Oxaliplatin is one of several diaminocyclohexane (DACH) platinum derivatives that forms platinum adducts that differ in three-dimensional structure from the more established diamine compounds, such as cisplatin and carboplatin (79). As a consequence of these structural differences, oxaliplatin adducts are not detected by the mismatch repair system (80), and there was hope that oxaliplatin would retain clinical activity in patients with platinum-resistant tumors. However, in phase 2 studies, the response rate among ovarian cancer patients with less than a 6-month platinum-free interval was less than 7% (81,82).

Nucleotide excision repair (NER) is the primary mechanism to remove platinum-DNA adducts from genomic DNA. Excision repair cross-complementing 1 (*ERCC1*) is a critical gene on the NER pathway. Platinum resistance has been linked to *ERCC1* mRNA levels in tumors, including ovarian cancer (83). In lung cancer, immunohistochemical evaluation of *ERCC1* levels was also predictive for survival following cisplatin-based adjuvant therapy, with improved survival in patients with *ERCC1*-negative tumors (84). However, *ERCC1* may also have prognostic significance independent of chemotherapy, as lung cancer patients assigned to observation with *ERCC1*-positive tumors had better survival compared with those with *ERCC1*-negative tumors (85). These observations have prompted randomized trials to prospectively assign chemotherapy for lung cancer based on *ERCC1* status, with the suggestion of higher response rates among patients receiving customized therapy, but without a difference in progression-free or overall survival (86). The role of *ERCC1* in selecting treatment for women with ovarian cancer remains to be established, but optimal selection will probably require information from additional cellular pathways.

Other Mechanisms of Agent-Specific Resistance

A number of specific alterations have been identified in the setting of individual drugs (Table 15.6). For example, *DHFR* gene amplification was demonstrated in a patient with methotrexate-resistant ovarian cancer who had localized *DHFR* gene copies on an abnormally staining region of chromosome 4q (87). Methotrexate resistance has also been associated with defects in polyglutamation, limiting intracellular methotrexate accumulation (88).

The action of nucleoside analogs, such as gemcitabine (2,2-difluorodeoxy-5-azacytidine), is dependent on active membrane transport for uptake, which is followed by double phosphorylation and potential incorporation in DNA. This complex process offers several opportunities for development of resistance, such as decreased activity of specific nucleoside transport proteins or reduced phosphorylation by depletion of deoxycytidine kinase (89). In addition, the main enzymatic target of phosphorylated gemcitabine, the M2 subunit of ribonucleotide reductase, can undergo gene amplification in resistant cell lines (90) similar to the primary mechanism of resistance to hydroxyurea, an inhibitor of ribonucleotide reductase. Of interest, sensitivity to gemcitabine can actually be increased severalfold by prior exposure to flavopiridol, an inhibitor of cyclin-dependent kinase activity, which has been shown to accelerate catabolism of the M2 subunit protein through the proteasome complex (91). Increased levels of target gene expression or protein, including thymidylate synthase, thymidylate phosphorylase, and dihydropyrimidine dehydrogenase, have also been associated with resistance to 5-fluorouracil in colon cancer, and have been correlated with clinical outcomes following 5-fluorouracil treatment (92,93). Even a superficial analysis of these specific examples would suggest potential strategies for screening of tumor tissue to guide the selection of optimal chemotherapy regimens, providing a basis for the application of tissue, gene, and protein arrays.

Tumor Heterogeneity and Assays of Chemotherapy Response

Solid tumors have traditionally been considered to be a homogeneous collection of clonally derived cells with similar features, but it is now clear that tumors are composed of subpopulations

with diverse biologic characteristics. Through genetic instability and regulatory processes, such as gene methylation, these subpopulations may exhibit different kinetic properties, angiogenic potential, receptor content, immunogenicity, and susceptibility to chemotherapy. In addition, there can be variability in the potential for metastatic spread among cells that appear to be similar at a morphologic and genetic level (94). Recognition of tumor heterogeneity has altered our understanding of tumor behavior with implications for multiagent and multimodality treatment programs.

Following the development of model systems for screening new anticancer compounds, it is not surprising that attention was focused on the process of screening actual human tumor cells for sensitivity and resistance to chemotherapy agents (95). A variety of methods have been developed utilizing clonogenic survival, ³H-thymidine incorporation, vital dye exclusion, treatment of transplanted tumor xenografts, and colorimetric analysis of adenosine triphosphate levels. Although there is relatively good correlation between high-level resistance to individual agents demonstrated *in vitro* and lack of a clinical response *in vivo*, it is more difficult to predict sensitivity to specific agents, or to guide the utilization of drug combinations (96), reflecting tumor cell heterogeneity, assay complexity, and inability to evaluate the tumor-host relationship, including angiogenesis. A nonrandomized phase 2 trial in recurrent epithelial ovarian cancer has suggested good correlation between *ex vivo* assay sensitivity and clinical response (97). Wider adoption of these approaches will need to address the lack of prospective randomized data, as well as the complexities of obtaining and shipping fresh tumor tissue, delay in receiving assay results, and substantial costs. In addition, with the rapid development of gene expression and proteomic arrays, it is possible that adequate predictions can be obtained from profiling existing frozen tumor specimens, as opposed to assays on fresh tumor biopsies.

Dose Intensity and Density

The dose and frequency of drug administration can contribute to the overall effectiveness of a treatment regimen, as well as the spectrum and severity of host toxicity. Dose intensity is a standardized measure of the amount of drug administered over time, most commonly expressed as mg/m² per week.

Preclinical studies demonstrate a sigmoidal relationship between dose and tumor response. This is characterized by a *lag phase* and a lower-limit *threshold* for observing benefit; a *linear phase*, where increases in dose are matched by improved efficacy; and a *plateau*, where toxicity continues to increase but there is no incremental improvement in response. In highly responsive tumors (e.g., choriocarcinoma, dysgerminoma), the entire dose-response curve is shifted to the left, with the result that standard chemotherapy doses are already situated near the upper plateau, and further dose increases are unlikely to achieve any improvement in clinical outcomes. In resistant tumors (e.g., previously treated cervical cancer), the curve is shifted to the right, and is also flattened, reducing the maximal potential benefit. For heterogeneous tumors with sensitive and resistant populations, such as epithelial ovarian cancer, it is unlikely that increased dose intensity would achieve long-term clinical benefit. However, lower than standard doses are potentially suboptimal, and arbitrary dose reductions or delays for nonphysiologic factors should be avoided. True dose-intense regimens have not been demonstrated to improve long-term clinical outcomes in women with gynecologic cancer, with the possible exception of recurrent germ-cell tumors.

The dose intensity hypothesis has been extensively evaluated in the setting of advanced ovarian cancer, beginning with

a series of retrospective studies (98) suggesting a correlation between actual delivered dose intensity and clinical outcomes. However, within practical dose ranges that can be achieved in the clinical setting, prospective randomized trials have not demonstrated significant improvements in either disease-free or overall survival (99). While front-line studies focused on platinum dose intensity, the question of paclitaxel dose intensity was also addressed in the setting of recurrent disease, again without evidence of improved outcomes.

Dose intensity is limited by acute (single-cycle) and cumulative (multi-cycle) non-hematologic and hematologic toxicity. Although multiple cycles of high-dose carboplatin and paclitaxel (with or without topotecan or gemcitabine) can be safely administered with hematopoietic progenitor and growth factor support, it is more difficult to overcome serious non-hematologic toxicities. Thus far, there is no evidence that a two- to threefold increase in carboplatin dose intensity and cumulative dose delivery is associated with a substantial improvement in clinical outcomes (100–102), and it is unlikely that this approach will be further evaluated.

In contrast, there is renewed interest in “dose-dense” therapy, in which a series of two or three individual single agents are sequentially administered at maximal tolerated doses using short cycle intervals. This approach has been favorably evaluated in the adjuvant therapy of breast cancer (103), although it has not been clearly established if the clinical benefit is secondary to dose density or weekly scheduling of specific components. Short cycle intervals may offer a safer approach for intensification by reinforcing normal biologic rhythms that can accelerate repair and minimize host toxicity.

GENERAL PRINCIPLES OF CHEMOTHERAPY

Treatment Objectives

Although certain general principles guide the clinician in choosing the appropriate classes of drugs or combinations, the decision to use these agents *at all* must be considered carefully. The critical factors involved in formulating a recommendation are reviewed in Table 15.5.

Natural History

Antineoplastic agents should be used only in patients whose malignancy has been established histologically, with consideration of the expected natural history, based on the primary tumor site, extent of disease, and rate of progression. Individual factors that could have an impact on tolerance for therapy must be evaluated in the context of treatment goals, including physiologic age (as reflected by vital organ function), general health, performance status, desire for treatment, and the presence of underlying illness. Prior history, including any previous cancer treatment and residual functional impairment, as well as patterns of recurrence, should also be considered. Finally, the emotional, social, and financial concerns of the patient and family must be respected (Table 15.7). Recommendations and goals should be presented to the patient and family in conjunction with a reasonable analysis of potential risks and benefits, which contributes to the process of informed consent, and which should be followed by sharing of written information for future reference.

Clinical Assessment

Chemotherapy should not be instituted unless the physician is prepared to monitor tumor response (if applicable) carefully while managing expected and unexpected toxicities. If proper

TABLE 15.7**IMPORTANT CONSIDERATIONS BEFORE USING ANTINEOPLASTIC DRUGS***Natural history of the malignancy*

- Biopsy proof of malignancy
- Identification of primary site
- Rate of progression or grade
- Stage of disease, patterns of spread

Patient characteristics

- Physiologic age, nutritional status, performance status
- Vital organ function; bone marrow reserve
- Comorbid conditions
- Extent of previous treatment

Supportive care

- Adequate facilities to evaluate, monitor, and treat potential drug toxicities
- Emotional, social, and financial status; support from family
- Collaboration with referring physician

Treatment goals

- Parameters to monitor objective response to treatment
- Potential benefits
 - Curative intent
 - Improved or sustained quality of life
 - Control of disease
 - Palliation of symptoms

facilities are not readily available, and the decision is made to begin therapy, the patient should be referred to a physician or facility that can provide integrated care.

In view of the potential for serious toxicity, it is desirable to have some objective means of measuring tumor response by physical examination, radiographic imaging, and/or analysis of serum tumor markers. However, it is not uncommon to administer multiple cycles of adjuvant or postoperative chemotherapy without any direct means of documenting tumor response. In these circumstances, the physician should be alert for any clinical evidence of tumor recurrence or progression during treatment. In patients with evaluable disease, continued administration of chemotherapy requires verification of ongoing benefit.

Expectations

The likelihood of achieving long-term benefit influences the choice of treatment and the acceptance of potential toxicity. Primary tumors (and recurrence after surgical resection or radiation without prior chemotherapy) can generally be grouped according to the likelihood of achieving a durable response. However, chemotherapy is also being utilized more frequently in the setting of early-stage disease, including postoperative adjuvant therapy of ovarian cancer, concurrent chemoradiation in cervical cancer, and postoperative treatment (with or without sequential radiation) in endometrial cancer. While the use of chemotherapy in each of these scenarios is supported by data from phase 3 clinical trials, it is also apparent that more patients are being exposed to platinum-based therapy at earlier points in their natural history, with an increased risk of treatment-resistant disease at the time of recurrence.

Most importantly, there is a group of tumors for which primary chemotherapy has been curative in the majority of patients, including choriocarcinoma and ovarian germ cell tumors. These patients should be treated aggressively with curative intent. Toxicity in this setting is acceptable, assuming that it is reversible, as the probability of long-term survival is high.

A second group, including advanced epithelial ovarian carcinoma, has high response rates to primary therapy (exceeding 75%), with prolongation of disease-free and median overall survival, but with only a modest improvement in overall mortality. Patients with these tumors usually benefit from therapy in terms of extended survival or quality-adjusted survival, and they should receive primary treatment at full doses unless contraindicated.

A third group of cancers, including advanced (or recurrent) endometrial cancer, cervical cancer, and uterine mixed müllerian tumors, have intermediate or lower response rates to primary chemotherapy, with shorter duration of remission and limited improvement in overall survival. Treatment with an initial course of therapy is reasonable, with careful monitoring of toxicity and response.

Other tumors, including uterine leiomyosarcoma, are more resistant to primary therapy, achieving a low frequency of objective response without prolongation of survival. In this setting, the use of chemotherapy should be restricted and particular emphasis placed on including these patients in well-structured clinical trials to evaluate innovative treatments.

In patients with recurrent or progressive disease after prior chemotherapy, the expectations of response are reduced due to the emergence of drug resistance and the impact of prior therapy and/or disease on performance status and vital organ function. As such, treatment goals are usually palliative, with attention to quality of life and control of symptoms. In this population, the frequency of stable disease usually exceeds the objective response rate. With appropriate chemotherapy regimens that avoid cumulative toxicity, patients without further disease progression may remain on therapy for prolonged periods of time with an acceptable quality of life. Most patients are best managed with single-agent chemotherapy with regular assessment of ongoing response and management of toxicity. However, patients with epithelial ovarian cancer and a prolonged treatment-free interval generally receive a platinum-based combination.

The decision to embark on antineoplastic drug therapy is obviously complex. Optimal patient care demands careful

review of the multiple factors affecting therapy to maximize any opportunity for improving survival and quality of life.

Choice of Specific Chemotherapeutic Regimens

After the decision to use chemotherapy has been made, the appropriate regimen must be selected. The physician is aided in this task by the results of randomized trials and evolving standards of care, including published practice guidelines. However, not every patient can receive “standard” therapy because of idiosyncratic reactions, vital organ dysfunction, prior treatment, or other factors. Practical individualized decisions are facilitated by the logical grouping of chemotherapeutic agents in several classes with similar pharmacologic properties, mechanisms of action, and spectrum of toxicity. The most important classes are the platinum-based alkylating agents, non-platinum alkylating agents, antimetabolites, anti-tumor antibiotics, antimicrotubule agents, nucleoside analogs, hormones, and newer molecular targeted therapies.

A number of combinations have been evaluated in the management of gynecologic cancer, and some have been widely adopted as “standard of care” for primary management of advanced-stage or recurrent disease. Phase 3 trials have demonstrated the superiority of specific regimens, such as paclitaxel with either cisplatin (104) or carboplatin (105) in ovarian cancer; a triplet combination of paclitaxel, cisplatin, and doxorubicin with granulocyte colony-stimulating factor (G-CSF) in endometrial cancer (106); cisplatin with either paclitaxel (107) or topotecan in cervical cancer (108); and ifosfamide with paclitaxel in uterine mixed müllerian tumors (109).

However, none of the standard combinations for advanced ovarian, endometrial, or cervical cancer has been directly compared to sequential therapy with the best active single agents, and the superiority of combination therapy has not been fully established. In the setting of ovarian cancer, phase 3 trials have suggested that sequential therapy with platinum followed by paclitaxel may offer similar long-term outcomes to a combination of platinum and paclitaxel (110,111). Although the initial frequency of tumor response is often increased with combination therapy, long-term outcomes such as overall survival and symptom-adjusted quality of life can be similar for patients who receive optimal sequential therapy with single agents. This is primarily related to the advanced stage of disease at the time of initial treatment with systemic chemotherapy and the lack of curative therapy for the majority of patients. As such, if individual patient circumstances contraindicate the use of a standard combination regimen, it remains a reasonable option to begin therapy with one of the active single agents. In addition to their application as primary therapy for advanced disease, combinations can also be employed as adjuvant therapy for patients with early-stage disease at increased risk for recurrence and for patients with late recurrence after good response to initial therapy.

Adjuvant chemotherapy refers to the initial use of systemic chemotherapy after surgery and/or radiation therapy has been performed with curative intent and there is no evidence of residual disease. Adjuvant chemotherapy is considered if the subsequent risk for recurrence after initial definitive therapy is relatively high (generally greater than 20%), but it is not routinely recommended when the risk of recurrence is less than 10%. In the adjuvant therapy of epithelial ovarian cancer, long-term results from randomized trials have documented a reduction in the risk of recurrence after platinum-based chemotherapy (112,113). However, in carefully staged patients (to exclude occult advanced-stage disease), it has been difficult to establish an advantage in overall survival. Phase 3 studies in

endometrial cancer (114) and uterine mixed müllerian tumors (115) have documented improved survival with the use of adjuvant combination chemotherapy compared to whole abdomen radiation in selected patients with high-risk disease, increasing the overall proportion of patients who receive adjuvant therapy.

Concurrent chemotherapy with radiation (chemoradiation) refers to the use of chemotherapy to sensitize tumor to the effects of radiation delivered with curative intent. This has been most extensively studied in the primary management of locally advanced cervical cancer, where platinum-based chemoradiation has been proven to be superior to radiation alone (116). In general, the duration of chemotherapy coincides with the duration of external beam radiation. Although the preferred weekly dose of cisplatin might appear to be low, these regimens generally exceed the overall dose intensity of cisplatin when used to treat advanced disease, and patients require monitoring to avoid cumulative toxicity and treatment interruptions.

Neoadjuvant chemotherapy generally refers to the use of chemotherapy in the management of locally advanced disease in situations where it would be difficult or impractical to perform immediate surgery or radiation. Following a response to initial chemotherapy, there is an expectation that morbidity associated with the overall treatment program can be minimized in conjunction with a reduction in radiation treatment volume or extent of surgery. This approach is most often considered in advanced cervical cancer, where high initial response rates to neoadjuvant therapy have been observed. However, the long-term benefit of this approach has not been established. Neoadjuvant therapy is also a consideration in advanced ovarian cancer, particularly in patients with large-volume ascites, pleural effusions, diffuse small-volume disease, or comorbidities that might increase surgical risk. In this setting, it has been difficult to conduct randomized neoadjuvant trials owing to impaired performance status, the desire to establish a definitive tissue diagnosis, and the bias toward initial cytoreductive surgery.

Monitoring of Tumor Response

Generally accepted criteria for evaluation of response are necessary to facilitate treatment decisions and comparisons among different regimens. Several standards have been used, including those developed by the World Health Organization (WHO). However, in 2000, an international working group including the European Organization for Research and Treatment of Cancer (EORTC), the National Cancer Institute of Canada (NCIC), and the National Cancer Institute (NCI) of the United States developed, validated, and published new Response Evaluation Criteria in Solid Tumors (RECIST), which have subsequently been widely adopted within clinical trials (117). RECIST is based on the prospective designation of at least one “target lesion” that measures at least 2 cm in one dimension, as well as “nontarget lesions” that are used to corroborate response. Radiographic imaging by helical computed tomography (CT) or magnetic resonance imaging (MRI) are the preferred techniques to monitor tumor response, and the same technique that is used for initial assessment should be used for subsequent measurements. The use of physical examination is restricted to cutaneous lesions or superficial adenopathy that can be directly measured. The omission of findings on bimanual pelvic examination posed a particular challenge for monitoring regional disease in patients with gynecologic tumors, and the criteria were subsequently modified by the Gynecologic Oncology Group (GOG) to include pelvic lesions measurable by physical examination, as summarized in Table 15.8.

TABLE 15.8

OVERALL DISEASE RESPONSE CATEGORIES (RECIST)

Complete response (CR) ^a	Disappearance of all <i>target</i> ^b and <i>non-target</i> lesions, and normalization of tumor marker levels (if appropriate).
Partial response (PR)	Disappearance of all <i>target</i> lesions without progression of <i>non-target</i> lesions, without appearance of new lesions, and persistence of abnormal tumor marker levels. Or At least a 30% decrease in the sum LD of <i>target</i> lesions (taking as reference the baseline sum LD) without progression of <i>non-target</i> lesions or appearance of new lesions. <i>Note:</i> In the case where the only <i>target</i> lesion is a solitary pelvic mass measured by physical exam (not radiographically measurable), a 50% decrease in the LD is required.
Progressive disease (PD)	At least a 20% increase in the sum LD of <i>target</i> lesions, taking as reference the smallest sum LD recorded since the start of treatment, or the appearance of one or more new lesions, or progression of any <i>non-target</i> lesion. <i>Note:</i> In the case where the only <i>target</i> lesion is a solitary pelvic mass measured by physical exam (not radiographically measurable), a 50% increase in the LD is required.
Stable disease (SD) ^c	Neither sufficient shrinkage of <i>target</i> lesions to qualify for PR nor sufficient increase to qualify for PD, taking as reference the smallest sum LD since the start of treatment. No appearance of new lesions (<i>target</i> or <i>non-target</i>).

Note: Measurable lesions—lesions that can be accurately measured in at least one dimension with longest diameter (LD) ≥ 20 mm using conventional techniques or ≥ 10 mm with spiral CT scan. *Non-measurable lesions*—all other lesions, including small lesions (longest diameter < 20 mm with conventional techniques or < 10 mm with spiral CT scan), i.e., bone lesions, leptomeningeal disease, ascites, pleural/pericardial effusion, inflammatory breast disease, lymphangitis cutis/pulmonis, cystic lesions, and also abdominal masses that are not confirmed and followed by imaging techniques.

^aTo be assigned PR or CR, changes in tumor measurements must be confirmed by repeat assessments no less than 4 weeks after the criteria for response are first met. The duration of overall response is measured from the time that criteria are met for CR or PR (whichever status is recorded first) until the first date that recurrence or PD is objectively documented, taking as reference for PD the smallest measurements recorded since the treatment started.

^bAll measurable lesions up to a maximum of five lesions per organ and 10 lesions in total, representative of all involved organs, should be identified as *target* lesions and recorded and measured at baseline. *Target* lesions should be selected on the basis of their size (lesions with the longest diameter) and their suitability for accurate repeated measurements (either by imaging techniques or clinically). All other lesions (or sites of disease) should be identified as *non-target* lesions and should also be recorded at baseline. Measurements of these lesions are not required, but the presence or absence of each should be noted throughout follow-up.

^cIn the case of SD, follow-up measurements must have met the SD criteria at least once after study entry at a minimum interval (in general, not less than 6 to 8 weeks) that is defined in the study protocol. SD is measured from the start of the treatment until the criteria for disease progression are met, taking as reference the smallest measurements recorded since the treatment started.

The summary response designation within RECIST integrates the findings from target and nontarget lesions, as well as serum tumor markers (if applicable). Serum tumor markers are not sufficient to declare response, but if initially elevated, must normalize to designate a complete response. International criteria to declare disease progression on the basis of a serial elevation in CA125 have been widely adopted (118,119), but there is incomplete agreement on criteria to define a partial response during treatment (120). Overall, RECIST is more detailed and specific than previous response criteria, and is also more demanding of the clinical team and radiologist, particularly if there are a large number of target and nontarget lesions.

A *complete response* refers to the complete disappearance of all objective evidence of tumor and a resolution of all signs and symptoms referable to the tumor. Complete regressions of cancer are generally those associated with a prolongation of survival. A *partial response* refers to at least a 30% decrease in the sum of the longest diameter of all measurable lesions. Usually, this would be accompanied by some degree of subjective improvement and the absence of any new lesions during treatment. Partial remissions are generally accompanied by improved well-being for a period of time, but are not expected to improve overall survival. A variety of terms have been used to designate lesser responses (e.g., minor response, objective regression), but these are rarely associated with any significant clinical benefit. *Progressive disease* is defined as a 20% or greater increase in the sum of the longest diameter of all measurable lesions or the appearance of new lesions. *Stable disease* is the term applied to patients without measurable tumor response or progression

fitting one of the prior criteria. Disease stabilization is an acceptable goal in the setting of palliative therapy for recurrent disease provided that symptoms have not progressed and the patient can tolerate continued therapy.

Changes in the volume of ascites or pleural fluid are not usually considered in the measurement of response, as a number of factors unrelated to cancer can influence third-space fluid accumulation, such as nutritional status, renal function, and treatment-related toxicity. However, appearance of a new fluid collection with cytologic verification would represent progressive disease. Similarly, the appearance of new symptoms, such as a partial small bowel obstruction, does not always indicate progression of disease, but could be related to prior surgery, irradiation, chemotherapy, or infection. In general, it is preferable to base decisions regarding treatment on objective measures of response as described rather than subjective findings or symptoms.

MANAGEMENT OF CHEMOTOXICITIES

Toxicity Assessment, Dose Modification, and Supportive Care

Chemotherapeutic regimens are universally toxic, with a narrow margin of safety, and it is often necessary to adjust doses individually in accordance with patient tolerance. Initial

TABLE 15.9

CTCAE GRADING OF MYELOSUPPRESSION

Element	Grade			
	1	2	3	4
Leukocytes (per mm ³)	LLN to 3,000	<3,000 to 2,000	<2,000 to 1,000	<1,000
Granulocytes (per mm ³)	LLN to 1,500	<1,500 to 1,000	<1,000 to 500	<500
Hemoglobin (g/dL)	LLN to 10.0	<10.0 to 8.0	<8.0 to 6.5	<6.5
Platelets (per mm ³)	LLN to 75,000	<75,000 to 50,000	<50,000 to 25,000	<25,000

Note: LLN, lower limit normal (institutional).

chemotherapy dosing is based on body surface area, weight, renal function, and hepatic function, using guidelines from clinical trials. However, there are a number of other factors that could further influence host tolerance, including nutritional status, performance status, extent of disease, prior therapy, third-space fluid accumulations, metabolic polymorphisms, and uncharacterized drug interactions. Current dose algorithms generally fail to address these factors, although emerging pharmacodynamic and pharmacogenomic research has improved individualized dosing in selected cases. As such, it is necessary to monitor host toxicity with ongoing modifications to avoid serious acute and cumulative toxicity.

The Cancer Therapy Evaluation Program (CTEP) of the NCI has developed a detailed and comprehensive set of guidelines for the description and grading of acute and chronic organ-specific toxicity in collaboration with the FDA, international cooperative groups, and the pharmaceutical industry. Most clinical research protocols have incorporated these criteria, which are also applicable to the grading of toxicity for standard chemotherapy regimens outside of a clinical trial. The current version of the Common Terminology Criteria for Adverse Events (CTCAE) is available in electronic format from CTEP (<http://ctep.info.nih.gov>). Basic hematologic parameters have been summarized in Table 15.9.

An unintended consequence of our current regulatory environment is that most new medications receive single-agent FDA approval at a dose and schedule that is close to the maximally tolerated dose (MTD), essentially maximizing the risk of host toxicity. The association between dose and toxicity is usually dramatic at levels close to the MTD. As such, a modest reduction in dose, or an adjustment in schedule, can have a substantial impact on acute and cumulative toxicities. The impact of these minor modifications on efficacy is generally unknown, but unlikely to be as dramatic as the impact on toxicity, and many clinicians frequently make modifications in the starting dose and/or schedule of single agents or combinations, essentially deviating from FDA-approved indications. As these modifications become integrated with clinical practice, limited supporting data emerge, usually from nonrandomized trials, but the primary FDA-approved dose and schedule is rarely changed. Many agents in common use today, including polyethylene glycol (PEG)-liposomal doxorubicin, topotecan, paclitaxel, docetaxel, and gemcitabine, are frequently modified in accord with emerging clinical experience, but without changes in the FDA-approved regimen. It is thus important for the clinician to be aware of emerging data, as well as data from pivotal trials that were used to support original FDA registration.

In view of the narrow safety margin for chemotherapy, it is important that all orders be reviewed by a nurse and

pharmacist with oncology experience. Height, weight, calculation of body surface area, pertinent laboratory values, and methods of dose calculation should be clearly indicated and verifiable. Pretemplated orders encourage systematic review and can reduce the risk of error. In addition, it is preferable to have predefined dose levels to account for expected treatment modifications rather than relying on percentage-based modifications. For example, it is not always obvious if a percentage refers to the degree of dose reduction or the amount of drug to be administered, which becomes compounded over multiple cycles, with the potential for more than one modification. One convenient method of structured dose modification is illustrated in Table 15.10. With this approach, modifications for the subsequent course of therapy are implemented according to the degree (grade), duration, and timing of toxicity experienced during the preceding course. Although treatment can be delayed on a week-by-week basis to allow for recovery, delays of greater than 2 weeks should be avoided through dose modification and utilization of hematopoietic growth factors. With expanded utilization of combination regimens, it is also helpful to know the patterns of toxicity associated with individual drugs, as it might be appropriate to modify one component rather than an entire regimen.

Bone Marrow Toxicity

Bone marrow toxicity is the most common dose-limiting side effect associated with cytotoxic drugs, and neutropenia is the most common manifestation of bone marrow toxicity, occurring 7 to 14 days after initial drug treatment and persisting for 3 to 10 days. CTCAE grading criteria are summarized in Table 15.9. For purposes of dose modification, the absolute neutrophil count (ANC) is preferred over total white blood count, as this more accurately reflects dose tolerance and risk of infection, which parallels the duration of grade 4 neutropenia (ANC \leq 500/mm³). Dose-limiting thrombocytopenia is less common than neutropenia, but has become more frequent with wider utilization of carboplatin and carboplatin-based combinations. A systematic approach to management of hematologic toxicity can help to reduce the risk of error and facilitate overall compliance with a treatment regimen (Table 15.10).

Radiation, alkylating agents (e.g., melphalan, carboplatin), and other DNA-damaging agents (e.g., nitrosoureas, mitomycin C), can have cumulative long-term effects on the bone marrow. Most other agents, including the taxanes and topotecan, show no evidence of cumulative toxicity and can be administered for multiple cycles without dose modification.

TABLE 15.10**REPRESENTATIVE DRUG DOSE MODIFICATIONS**

Category (timing)	Parameters	CTCAE grade	Dose or schedule modifications
Granulocytes (day of therapy)	>1,500/mm ³	0, 1	Full doses of all drugs.
	<1,500/mm ³	2, 3, 4	Delay until recovered. If already delayed, reduce dose by one level or add G-CSF.
Platelets (day of therapy)	WNL	0	Full doses of all drugs.
	< LLN to 75,000/mm ³	1	Delay until recovered.
	<75,000/mm ³	2	Delay until recovered. If already delayed, reduce dose by one level.
Granulocytes (cycle nadir)	>1,000/mm ³	0, 1, 2	Full doses of all drugs.
	<500/mm ³ for ≥ 7 days	4	Reduce dose by one level. If already reduced, add G-CSF.
	<1,000/mm ³ with fever	3, 4	Reduce dose by one level. If already reduced, add G-CSF.
Platelets (cycle nadir)	≥50,000/mm ³	3	Full doses of all drugs.
	<50,000/mm ³ with bleed	3, 4	Reduce doses by one level.
	<25,000/mm ³	4	Reduce doses by one level.

Note: CTC, common toxicity criteria; G-CSF, granulocyte colony-stimulating factor; LLN, lower limit normal; WNL, within normal limits.

In view of the frequent occurrence of neutropenia and the risk of infectious complications, utilization of G-CSF, including filgrastim or the longer-acting PEG-filgrastim, has increased. Although these agents promote more rapid granulocyte recovery, thus avoiding potential complications and facilitating the maintenance of dose intensity, their use has not been shown to improve long-term survival for patients with gynecologic cancer compared to conservative management with dose reduction and cycle delay. In addition, G-CSF is not effective in the management of thrombocytopenia and may actually increase the degree of thrombocytopenia by diversion of immature marrow elements, a particular problem after multiple cycles of carboplatin. Recombinant megakaryocyte growth factor is an option to maintain platelet counts (121). However, current treatment programs are not associated with a high frequency of complicated grade 4 thrombocytopenia, and the value of aggressive support would appear to be limited.

Moderate degrees of anemia are quite common in cancer patients receiving chemotherapy, which may contribute to chronic fatigue. With increased recognition of blood-borne viral pathogens and limited supplies of banked blood, frequent transfusions are not practical or recommended, and many patients will adapt to chronic anemia with minimal symptoms. The availability of recombinant erythropoiesis-stimulating agents (ESA), including erythropoietin (epoetin alfa) and darbepoetin, has provided a generally safe and effective alternative for the management of anemia associated with chemotherapy (122) and should be considered on a case-by-case basis, although financial costs at the recommended dose and schedule can be greater than the intermittent use of blood products (123). Emerging data with regard to the potential risks associated with ESA, including cardiovascular events, thrombosis, and reduced tumor-related survival in placebo-controlled, randomized trials (124), have prompted the FDA to reevaluate the role for ESAs in routine practice (125–127), including a Medicare decision memo (128) limiting reimbursement to patients with confirmed hemoglobin of less than 10 g/dL. Patients with anemia should undergo evaluation of iron stores, with appropriate use of iron replacement, prior to initiation of ESA. Based on available data, the initiation of ESA should be restricted to patients with hemoglobin of less than 10 g/dL, and should be avoided in patients

with a hemoglobin of greater than 12 g/dL to avoid thrombotic complications.

Gastrointestinal Toxicity

Most anticancer agents are associated with some degree of nausea, vomiting, and anorexia. There are three major categories of nausea and vomiting: *anticipatory*, occurring prior to actual administration of chemotherapy; *acute onset*, beginning within 1 hour of chemotherapy administration and persisting for less than 24 hours; and *delayed*, beginning more than 1 day after chemotherapy administration and persisting for several days. Prophylactic management of these adverse effects improves patient acceptance and facilitates completion of therapy with full doses on schedule.

The antiemetic regimen is tailored to the emetogenic potential of the treatment, which reflects the incorporation of specific drugs, as well as the dose and schedule of drug administration. Mild nausea and vomiting can often be managed effectively with H₁ antihistamines (diphenhydramine), phenothiazines (prochlorperazine or thiethylperazine), butyrophenones (haloperidol), steroids (dexamethasone or methylprednisolone), benzamides (metoclopramide), or benzodiazepines (lorazepam). These are likely to be sufficient with drugs such as bleomycin, docetaxel, paclitaxel, Vinca alkaloids, 5-fluorouracil, methotrexate, mitomycin C, gemcitabine, PEG-liposomal doxorubicin, and topotecan.

For drugs with more severe emetogenic potential, including cisplatin, carboplatin, cyclophosphamide, or dactinomycin, a more aggressive prophylactic regimen is required. In general, these patients should receive a 5-hydroxytryptamine (5-HT₃) receptor antagonist, such as ondansetron or granisetron, prior to chemotherapy and repeated at 8- to 12-hour intervals. Both compounds are also available in an oral formulation, which has been helpful in the management of delayed and/or chronic nausea after chemotherapy, or nausea associated with multi-day oral chemotherapy regimens. Longer acting 5-HT₃ antagonists have also become available, including palonosetron and dolasetron, which require only a single intravenous or oral dose prior to chemotherapy. As a group, the 5-HT₃ antagonists have been quite effective in controlling severe emesis

with few side effects, but are more expensive than prochlorperazine (129). Chronic nausea and vomiting can be a particular problem after several cycles of cisplatin, and occasionally carboplatin (130). The mechanism is poorly understood, and symptoms can be difficult to control with currently available medications, prompting the use of extended steroid administration, cannabinoids, or repeated dosing with 5-HT₃ receptor antagonists.

Anticipatory nausea and vomiting can become a significant problem during repeated cycles of chemotherapy, as patients associate environmental cues (such as odor, carpeting, or paint colors) with nausea. In addition to behavioral modification, it can sometimes be modulated by pretreatment with antiemetics and amnesic drugs, such as benzodiazepines, administered orally at home prior to arriving at the treatment center. Lorazepam (0.05 mg/kg) can also be given by slow intravenous push 1 hour before therapy, with doses being continued as needed every 4 hours for up to six doses (131). Unfortunately, this particular schedule produces significant sedation and can be used only in hospitalized patients or outpatients with independent transportation.

Diarrhea, oral stomatitis, esophagitis, and gastroenteritis are also potential problems. Patients with significant oral or esophagogastric symptoms may have symptoms managed with oral viscous lidocaine (2%), other topical anesthetics, or parenteral narcotics in severe cases. Randomized, controlled trials following 5-fluorouracil-based chemotherapy or radiation have failed to document any clinical improvement with sucralfate, which can bind to ulcerated mucosa (132,133). However, randomized, controlled trials have demonstrated that multiple intravenous doses of recombinant keratinocyte growth factor (palifermin) before and after treatment can reduce the incidence and severity of chemotherapy-induced oral stomatitis associated with bolus 5-fluorouracil (134) or high-dose chemotherapy. In general, dose-limiting mucosal injury is uncommon with platinum-based combinations, taxanes, and other single agents used in the treatment of gynecologic cancer. While many patients might develop some degree of diarrhea in the setting of concurrent chemoradiation, palifermin has not been specifically evaluated in that setting, although there are preclinical data to suggest benefit (135). In refractory cases, patients should be screened for secondary infectious complications, such as candidiasis and herpes simplex. Following treatment with irinotecan, noninfectious secretory diarrhea is a well-recognized dose-limiting toxicity associated with local exposure to the active metabolite SN-38, and is generally managed with prophylactic antimotility agents and intravenous hydration, with utilization of octreotide in severe cases. Diarrhea can also result from diffuse mucosal injury following administration of doxorubicin (including PEG-liposomal doxorubicin), 5-fluorouracil, methotrexate, and other agents. In the setting of recent surgery and chemotherapy, patients are also at increased risk for infectious diarrhea, and screening for *Clostridium difficile* is appropriate.

Alopecia

Scalp alopecia is one of the most emotionally taxing side effects of chemotherapy. Aside from long-lasting alopecia that follows cranial irradiation, it is almost always reversible, but it can be a major deterrent to successful chemotherapy. Total scalp alopecia is particularly common with drugs like doxorubicin and paclitaxel, and there is generally some degree of partial alopecia with cisplatin, carboplatin, cyclophosphamide, docetaxel, Vinca alkaloids, and 5-fluorouracil. In a minority of cases, patients treated with paclitaxel will also experience loss of eyelashes, eyebrows, and other body hair, which can be

particularly distressing. A variety of physical techniques have been devised to minimize alopecia, including scalp tourniquets and ice caps designed to decrease scalp blood flow. Although partially effective, they are rarely successful with extended chemotherapy.

Skin Toxicity

Skin toxicities that occur during chemotherapy include allergic or hypersensitivity reactions, skin hyperpigmentation, photosensitivity, radiation recall reactions, nail abnormalities, folliculitis, palmar-plantar erythrodysesthesia (PPE, hand-foot syndrome), and local extravasation necrosis. Many of these are drug specific and self limited, but occasionally they may be dose limiting.

PPE is a reversible but painful erythema, scaling, swelling, or ulceration involving the hands and feet. This occurs more often with chronic oral or intravenous medications, weekly treatment regimens, and formulations that increase drug circulation time, such as prolonged oral etoposide, weekly and continuous-infusion 5-fluorouracil, capecitabine, and PEG-liposomal doxorubicin, where it has emerged as a major dose-limiting toxicity (136).

Extravasation necrosis is a serious complication seen after tissue infiltration of vesicant drugs such as doxorubicin, dactinomycin, mitomycin C, and vincristine (137,138). These drugs should always be administered through a freely flowing intravenous line with careful monitoring. Caution is also required during utilization of central venous ports, as malfunctions in the needle, hub, or tubing can be associated with gradual extravasation that will not be apparent for several hours (139). Any suspected infiltration should prompt immediate removal of the intravenous line and application of ice packs to the infiltrated area every 6 hours for 3 days. Small series have reported a limited experience with local infiltration or topical application of steroids, *n*-acetylcysteine, dimethyl sulfoxide (DMSO), and hyaluronidase with variable results, and recommendations are imprecise. However, single or multiple intravenous doses of dexrazoxane, a topoisomerase II catalytic inhibitor, appears to offer specific protection against injury from anthracyclines, including doxorubicin and daunorubicin (140,141). Skin necrosis from some extravasations may eventually require surgical debridement and skin grafting.

Neurotoxicity

Peripheral neuropathy is the most common neurotoxicity encountered in gynecologic oncology, and is a particular risk with administration of cisplatin, paclitaxel, docetaxel, nanoparticle albumin-bound (NAB) paclitaxel, epothilones, Vinca alkaloids, and hexamethylmelamine (142,143). Although less common with carboplatin than cisplatin, neuropathy can still occur, particularly in combination with paclitaxel. Peripheral neuropathy generally begins with symptoms of paresthesia accompanied by loss of vibratory and position sense in longer nerves associated with the feet and hands. It then progresses to functional impairment, with gait unsteadiness and loss of fine motor coordination, such as trouble buttoning clothes and writing. This is closely followed by loss of deep tendon reflexes and eventual development of motor weakness. With paclitaxel and other nonplatinum agents, this is almost always reversible, but may require several months posttherapy for substantial improvement. In more severe cases, accompanied by neuronal injury or demyelination, recovery may require active neuronal regeneration over an extended period of time, and symptoms may persist for the lifetime of the patient.

In current clinical practice, neurotoxicity from widely utilized microtubule-stabilizing agents is predominant (144,145). The frequency of moderate to severe toxicity is more common with paclitaxel, compared to docetaxel or epothilones. Risk appears related to peak levels associated with individual doses, as well as cumulative doses over multiple cycles, which is further complicated by alternative schedules and newer drug formulations. For example, although the risk associated with NAB-paclitaxel on the FDA-approved 3-week schedule is at least as high as paclitaxel (146), the risk is reduced with NAB-paclitaxel administered on a weekly schedule, even with higher cumulative doses. In addition, as the primary means of assessment is clinical, reported frequencies vary widely in clinical trials, reflecting variability in documenting history, subjective and objective findings.

If related to cisplatin, neuropathy can continue to progress after therapy has been discontinued owing to ongoing axonal demyelination and loss, with long-term persistence of symptoms. Cisplatin has also been associated with permanent ototoxicity, and at higher doses, with loss of color vision (147) and autonomic neuropathy. Oxaliplatin can produce a long-term peripheral neuropathy similar to cisplatin (148), but is also associated with transient acute reactions, including paresthesia and cold-sensitive laryngeal dysesthesia (149), which may reflect blockade of membrane ion channels (150). Of interest is that, although infusions of calcium and magnesium have been used to ameliorate the acute oxaliplatin reactions (151), an ongoing phase 3 randomized trial was terminated due to concerns about a reduction in clinical response rates at interim analysis, illustrating the potential interplay of toxicity and efficacy for some agents (152).

Although some patients report transient distal paresthesia after a single dose of paclitaxel (153), the onset of persistent neuropathy is generally more gradual. Neuropathy can become clinically apparent after two to three courses of therapy, with mild symptoms that resolve between cycles. Careful questioning and examination may reveal subtle findings at an earlier stage, and functional assessments have been developed that demonstrate good concordance with actual neuropathy (154). Patients with underlying neurologic problems, such as diabetes, alcoholism, or carpal tunnel syndrome, are particularly susceptible, and substitution of docetaxel for paclitaxel can be a useful strategy in some situations. All patients who receive potentially neurotoxic therapy, especially cisplatin and paclitaxel, should be routinely queried regarding proprioception and fine motor tasks and examined for loss of vibratory sense, high-frequency hearing, and deep tendon reflexes.

In view of the frequency of neurotoxicity and the impact on daily life, there has been interest in agents that might prevent nerve damage, encourage recovery, or ameliorate symptoms. Amifostine has been reported to reduce the frequency and severity of platinum-mediated neuropathy (155) and is being evaluated as a treatment to promote resolution of established neuropathy. However, a nonrandomized study in patients receiving cisplatin and paclitaxel in combination with amifostine failed to achieve a targeted reduction in the incidence of neuropathy (156). Widespread substitution of carboplatin for cisplatin has reduced but not eliminated the risk, and the value of amifostine in combination with carboplatin and paclitaxel, or paclitaxel as a single agent, has not been established. Thus far, small studies with glutamine, vitamin E, and other agents have been inconclusive, and there are no agents that can be recommended for prevention of neuropathy in routine practice. Clinical management of painful paresthesia has been reported with amitriptyline and gabapentin (157), prompting the empiric use of similar agents for relief of symptoms.

Other neurotoxicities include acute and chronic encephalopathies, usually associated with intrathecal chemotherapy, acute cerebellar syndromes, autonomic dysfunction,

inappropriate secretion of antidiuretic hormone (SIADH), and cranial nerve paresis. Of particular relevance to the gynecologic cancer population, an acute reversible metabolic encephalopathy has been well described in association with ifosfamide and attributed to the toxic metabolite chloroacetaldehyde. Of note, this syndrome can potentially be prevented by infusion of methylene blue (158), which may act through inhibition of monoamine oxidase activity with reduced chloroacetaldehyde formation in the liver.

Genitourinary Toxicity

Renal toxicity is a well-recognized side effect of cisplatin (159), with implication of specific local metabolites, even though only a small fraction of cisplatin is cleared by renal excretion. In contrast, carboplatin undergoes extensive renal clearance with little risk of toxicity. Indeed, with increased substitution of carboplatin for cisplatin, and with a reduction in overall cisplatin dose intensity, there has been a decline in clinical familiarity with cisplatin-mediated nephrotoxicity. However, the expanded utilization of concurrent cisplatin and pelvic radiation for management of early-stage cervical cancer has renewed awareness of this potential problem, particularly as commonly utilized weekly dosing can exceed 100 mg/m² over a 3-week period. Careful attention to hydration status and saline-driven urinary output before, during, and immediately after therapy is required to reduce the risk associated with this serious complication (160).

Another troublesome side effect is hemorrhagic cystitis, which can be seen with cyclophosphamide or ifosfamide, attributed to the metabolite acrolein. With moderate-dose cyclophosphamide, this complication can be prevented by maintaining high urinary output, which reduces overall urothelial exposure to the toxic metabolites. However, patients receiving combination regimens often have reduced oral intake postchemotherapy, and selected patients receiving cyclophosphamide might benefit from supplemental intravenous hydration. The risk of cystitis is essentially 100% with ifosfamide, even with aggressive hydration, but this can be prevented with simultaneous administration of mesna, which binds and neutralizes acrolein in the urine (161).

Hypersensitivity Reactions

Increased utilization of paclitaxel, a natural product with poor solubility, has focused attention on the risk of hypersensitivity reactions (HSR). For intravenous administration, paclitaxel is formulated in Cremophor-EL, a mixture of polyoxyethylated castor oil and dehydrated alcohol, which has been associated with mast cell degranulation and clinical HSR. Over 80% of reactions occur within minutes during either the first or second cycle of drug administration and can usually be managed with prophylactic medication (corticosteroids, histamine H₁/H₂ blockade) followed by rechallenge beginning at a lower rate of infusion (162,163). Similar reactions have been reported with docetaxel and PEG-liposomal doxorubicin, but with lower frequency in the absence of Cremophor-EL. Emerging data with NAB-paclitaxel indicate a marked reduction in the risk of HSR, further emphasizing the role of formulation, vehicle, and carriers.

With improved survival and an increased utilization of second-line therapy, patients can also experience more traditional allergic reactions to selected chemotherapy agents. Carboplatin, an organoplatinum compound, has emerged as a major source of late allergic reactions. These occur most often during the second cycle of a second course of therapy, suggesting a process of antigen recall and priming of the

immune response (164). Patients receiving a second course of carboplatin-based therapy should be closely monitored for early signs of hypersensitivity to avoid more serious reactions. Unlike the situation with paclitaxel, carboplatin reactions are not readily prevented or circumvented with prophylactic medication, although inpatient (165) and outpatient strategies for desensitization have been reported (166) and successfully utilized for patients who are responding to retreatment. However, the desensitization routine must generally be repeated with each cycle of treatment.

Other Significant Toxicities

A comprehensive discussion of all potential toxicities for currently available chemotherapeutic agents is beyond the scope of this chapter, and additional information is available throughout the text. Nevertheless, a variety of other important toxicities are occasionally encountered in regimens commonly used in gynecologic oncology. These include cardiac toxicity from cumulative doxorubicin exposure, radiation recall vasculitis from doxorubicin, pulmonary fibrosis from bleomycin, gonadal dysfunction in premenopausal women from alkylating agents, and secondary acute leukemia from the chronic administration of alkylating agents, particularly melphalan in ovarian cancer.

DEVELOPMENTAL CHEMOTHERAPY

Background

The identification, evaluation, and regulatory approval of effective drugs for cancer treatment is a long, complicated, and expensive process. Of note, it has been argued that the expanded availability of only 17 existing generic chemotherapeutic agents would substantially improve worldwide mortality from cancer (167). However, most cases of advanced disease remain incurable with current treatments, and the search for new agents remains a high priority. Promising candidates are identified and prioritized through preclinical screening (168), utilizing derivatives of previously defined active agents or established drug classes or new compounds engineered to interact with a specific target. In addition, there continues to be broad screening of natural products isolated from terrestrial and marine sources (169). Some evidence of antitumor activity during screening must be demonstrated before clinical trials are undertaken. Thus far, all useful antitumor agents have demonstrated antitumor activity using *in vitro* or *in vivo* screening systems.

These traditional approaches are being increasingly challenged by the large number of new genes and potential targets identified through molecular biology, genomics, and proteomics. Principles of genomic libraries, solid-phase organic synthesis (170), and combinatorial chemical library generation (171) have been adopted by the pharmaceutical industry to promote high-throughput screening (172). As new targets are identified, a large number of related compounds can be created, beginning with lead natural products or known reagents (173), and then screened for improved target binding and/or inhibition of target function (174). Substantial bioinformatics resources are required to manage and analyze the large amount of data generated from these processes, but the accumulation of gene expression and proteomic data can facilitate “pre-discovery” modeling of potential targets and reagents prior to making decisions about actual development. To some extent, these processes have evolved in parallel, as it

is clear that agents generated from a library or a database will still require some form of biologic validation prior to entering complex and expensive clinical studies.

After antitumor activity has been identified, the new agent must be formulated for human use and produced in sufficient quantities to support clinical trials. This is never a trivial achievement, as was evident from the natural supply limitations and formulation problems encountered in early trials with paclitaxel (175) and the camptothecins (176). Clinical-grade material is then subjected to detailed preclinical toxicology tests in animals. These toxicology trials are done in several animal species and may explore different schedules of drug administration to provide a basis for clinical development. As such, they are time consuming, complex, and expensive.

After all of the steps of preclinical testing are completed, new agents can enter clinical evaluation. As such, clinical trials are the primary means utilized to evaluate new agents in a systematic manner. All physicians and patients are urged to consider participation in clinical trials, which are available for almost all diagnoses and treatment circumstances. Sponsors of clinical trials include the NCI in collaboration with individual institutions and national groups, such as the GOG, as well as the pharmaceutical industry and individual institutions.

Clinical Trials

Detailed rationale and methodology for clinical trials design has been covered in other sections. This material is provided to highlight key concepts related to investigational drug development.

Phase 1 Trials

Phase 1 trials are typically first-in-human studies for new compounds and employ a dose- and/or schedule-escalating design to determine the dose-limiting toxicity (DLT), maximally tolerated dose (MTD), and pharmacokinetic parameters applicable to each regimen. In the most common model, accrual is suspended when more than one DLT event occurs within a dose level (two of six patients), as this would generally exceed predefined limits for the MTD. Modifications of the standard dose-escalation schema have been developed to enroll fewer patients at lower dose levels with greater dose increments between successive dose levels in the absence of toxicity. As the MTD is approached, the dose level increments are reduced and accrual can be expanded. These newer methods aim to minimize the number of patients treated at very low (nonefficacious and nontoxic) doses, while providing greater precision for estimating the MTD and DLT at higher doses (177).

With the shifting focus from conventional cytotoxic agents to non-cytotoxic molecular-targeted agents, the traditional phase 1 paradigm needs to be reexamined. Many newer agents, such as human monoclonal antibodies, may not demonstrate traditional dose-limiting and dose-related toxicities, and phase 1 studies can reach their highest dose level without achieving a conventional MTD. In addition, these agents are frequently destined for chronic administration in conjunction with chemotherapy, and/or following chemotherapy, and cumulative toxicity over multiple cycles appears more important than acute toxicity during the first cycle. Finally, with an identified biologic target, it is also important to consider the optimal biologic dose that achieves a desired level of receptor blockade or signal transduction inhibition. With these considerations, it is apparent that a modified phase 1 design utilizing expanded cohorts treated for multiple cycles would provide better data to guide large randomized trials.

Tumor response is not a primary endpoint within a phase 1 trial, which will typically include patients representing a variety of primary tumor types and multiple prior therapies.

Comprehensive analysis of aggregate phase 1 data, often from multiple trials, will generally determine a dose, schedule, and disease site profile for evaluation in phase 2 studies. In selected situations where the toxicity and appropriate tumor targets are well defined, some phase 1 studies have included an embedded phase 2 component to conserve patient resources, avoid delays associated with activation of a stand-alone phase 2 trial, and accelerate the overall development process. With the increased number of compounds that merit early phase testing, it is also important to prioritize these studies carefully within the limited clinical resources that are available.

Phase 1 studies can also serve to evaluate new combinations that build on standardized chemotherapy regimens to establish feasibility and tolerability of the proposed regimen before embarking on larger trials. In certain situations, such as epithelial ovarian cancer, disease-specific phase 1 trials may enroll newly diagnosed patients without prior therapy, as the experimental combinations generally incorporate other known active agents, such as platinum and a taxane.

Phase 2 Trials

After the recommended dose and schedule have been defined, the regimen can receive focused evaluation in patients with a specific cancer diagnosis, usually in the setting of measurable disease after one (or two) prior chemotherapy regimens. Phase 2 trials are designed and powered based on a surrogate endpoint that is thought to reflect clinical benefit, such as response rate, disease stabilization rate, biologic (tumor marker) response rate, or the proportion of patients alive and progression-free at a specific time interval. Although each of these endpoints may reflect antitumor activity, they are viewed as surrogate endpoints in comparison with overall survival or quality-adjusted survival, which provide a true measure of clinical benefit. In general, each phase 2 trial tests a single hypothesis, such as response rate, to determine if the new agent or regimen crosses a threshold based on historical data in the same patient population with an appropriate degree of power (type II or β error) and precision (type I or α error). Through this process, new agents are “selected” for further development based on historical controls. In order to conserve patient resources and minimize the number of patients who might receive ineffective therapy, most phase 2 studies utilize a multi-stage accrual design with early-stopping parameters, as proposed by Gehan (178) and modified by Simon (179).

Although most phase 2 trials are single-arm nonrandomized studies, there are circumstances where randomized phase 2 evaluations are appropriate (180–182). Randomized phase 2 trials allocate patients among two or more treatment arms to minimize potential differences in prognostic factors or other variables. Each arm is then independently tested against the same historical threshold value. Using this approach, one or both arms can be “selected” for further clinical development. Such randomized trials are generally underpowered for direct comparison of response rate and survival between each arm owing to the limited number of patients. Examples include looking at two different schedules of drug administration with comparative analysis of toxicity and noncomparative reporting of response data to facilitate the selection of experimental arms for future studies. This approach has been used to select between two different schedules of topotecan administration in recurrent ovarian cancer (183).

The traditional phase 2 paradigm has also been challenged by the availability of new molecular-targeted or biologic agents that are thought best to work in combination with conventional cytotoxic chemotherapy. Given the number of combinations that need to be evaluated, it has been appealing to consider randomized designs to select promising combinations.

Indeed, in situations where the specific choice of chemotherapy might not be critical to evaluate clinical activity, pilot studies have allowed clinicians to select one of several chemotherapy regimens, and then randomly allocate patients to receive new agents in combination. In addition, where phase 2 data appear interesting but might not support a fully-powered phase 3 trial, there have been phase 3 designs that incorporate an embedded phase 2 study to confirm disease-specific activity and feasibility prior to enabling full accrual.

Phase 3 Trials

If a promising regimen is identified for further testing, it then moves toward a phase 3 randomized trial, in which it is directly compared with an existing standard regimen in a particular clinical setting, as defined by the type of cancer and stage at enrollment. Phase 3 trials generally require a minimum of 150 patients per arm to provide adequate *precision* for the comparison of primary study endpoints while avoiding false-positive conclusions (type I or α error) and adequate *power* to detect a difference while avoiding a false-negative result and potentially missing a true advantage of one arm over the other (type II or β error). In keeping with current drug registration guidelines of the FDA, the primary endpoint of most phase 3 trials is a true measure of clinical benefit, such as overall survival or quality-adjusted survival, with secondary endpoints of progression-free survival, response rate, and toxicity.

Owing to the large number of uniformly staged and treated patients required for a phase 3 trial, such studies are best conducted through a national clinical trials organization, such as GOG. To minimize potential sources of bias, phase 3 trials frequently stratify patients into groups according to key prognostic variables prior to randomization, such as stage or extent of residual disease, as well as other minor variables, such as location of the treating institution. Verification of patient diagnosis, stage of disease, eligibility, treatment delivered, and tumor response can further improve the reliability of results reported from clinical trials.

The traditional phase 3 endpoint of overall survival has been challenged by an increasing number of available treatment options for management of recurrent disease. This has prompted greater consideration of progression-free survival as the primary endpoint for phase 3 trials, as progression is not altered by secondary treatments. However, progression-free survival is subject to observer and detection bias, requiring better control over post-treatment monitoring. Regulatory authorities have also questioned if progression-free survival (as a surrogate endpoint) may not always translate into clinical benefit, and most registration trials include sufficient accrual to evaluate both progression-free and overall survival.

FDA Approval and Postmarketing Studies

Following a successful phase 3 trial or a group of trials, a sponsor can apply to the FDA for marketing approval for a specific disease indication. This triggers a detailed review of clinical trials and pharmaceutical data by the Oncology Drug Advisory Committee (ODAC), which then issues a recommendation to the FDA, followed by formal review and a decision by the FDA, which may grant approval or request additional data. In the United States, all marketing requires approval for at least one specific indication by the FDA. The average time from initial drug discovery to application for an FDA-approved indication is 10 to 12 years, involving considerable expense and effort, as noted above. Supplemental phase 4 or postmarketing studies can be required by the FDA as part of the approval process or be performed by the sponsor to evaluate alternative drug formulations or resolve questions regarding

dose, schedule, or toxicity. In addition, phase 4 studies may involve substitution of the new agent in combination chemotherapeutic regimens already established for the disease. These studies are not commonly employed in the development of new chemotherapeutic regimens, but can provide confirmatory postmarketing evidence of safety and efficacy.

Development of Combination Regimens

With some notable exceptions, such as choriocarcinoma and childhood Burkitt's lymphoma, single agents are not sufficient to achieve prolonged survival or cure. Development of combination regimens has been accelerated by our knowledge of cell killing, pharmacokinetics, molecular targets, tumor heterogeneity, and drug resistance. Combinations can approach maximal cell kill by including drugs with minimal overlap of toxicities, such that antitumor effects can be summed but the toxicities dispersed. Combinations are also more likely to demonstrate activity against heterogeneous tumor populations, and effective combinations would prevent the emergence of drug resistance. However, in practice it may also encourage greater resistance among surviving cell fractions.

No direct evidence currently exists to indicate whether optimal combinations should utilize sequential single agents, doublets, or triplets. Utilization of single agents generally precludes any biologic interaction between the various components of a treatment regimen, but permits administration of each agent at the full active dose. The use of sequential doublets generally permits higher doses of individual drugs compared to a triplet regimen, but over a smaller number of cycles with each agent. Doublets have the potential advantage of sequentially introducing more than one regimen with a different mechanism of action and/or pattern of resistance, which has been postulated to prevent the emergence of drug resistance.

Development of combination chemotherapy has been guided by several principles (Table 15.11). However, much of the reported experience has been derived from empiric combinations evaluated in conventional phase 1 dose-escalating trials. Ideally, each of the drugs employed in a new combination should have independent activity as a single agent, as verified in phase 2 studies. Generally, drugs that can produce complete remissions are preferred to agents that produce only

TABLE 15.11

PRINCIPLES OF COMBINATION CHEMOTHERAPY

Each component should have

- Activity against the target tumor as a single agent
- A different mechanism of action and cellular target
- A biochemical basis for additive or synergistic effects in combination with at least one of the other agents
- No evidence of antagonistic interactions
- Distinct patterns of resistance to discourage the emergence of drug-resistant phenotypes

Optimal dose, schedule, and sequence of drug administration should be determined from preclinical data and early clinical trials to maximize tumor response and minimize host toxicity.

Minimal overlap of nonhematologic toxicity is desirable to safely maintain full therapeutic doses of each component over multiple cycles.

partial regressions, but complete remissions are uncommon in previously treated patients with recurrent disease. An attempt should be made to use drugs with minimal overlap of toxicities to avoid excessive dose reduction. Although this may broaden the range of toxicities encountered with each combination, it avoids cumulative and serious toxicity within individual organ systems. Bone marrow recovery usually proves to be the most dominant factor in cycle timing, and in practice, cycles of most combinations can be repeated every 3 to 4 weeks.

Several of these strategies are currently under evaluation in epithelial ovarian cancer based on preclinical models that have suggested an advantage for combinations with platinum, which has been attributed to inhibition of DNA repair (Table 15.12). Each of the selected agents (topotecan, gemcitabine, and PEG-liposomal doxorubicin) has also demonstrated independent single-agent activity against recurrent ovarian cancer, adding to the overall potential benefit of the combination. However, based on available phase 3 data in ovarian cancer, none of the newer combinations have successfully translated into improved long-term clinical outcomes, providing additional support for a shift in developmental priorities toward molecular targeted agents and other novel approaches.

TABLE 15.12

REPRESENTATIVE AGENTS FOR DEVELOPMENT OF COMBINATION REGIMENS

Agent	Cellular target	Mechanism of action	Schedule-dependent effects	Patterns of resistance	Interaction with platinum
<i>Platinum</i>	DNA	DNA adduct formation	Independent	↑ GSH ↑ DNA repair ↑ Damage tolerance ↓ Accumulation	NA
<i>Paclitaxel</i>	β tubulin	↑ Tubulin aggregation	Dependent (toxicity)	↑ <i>MDR 1</i> (P 170) β tubulin mutations	↓ Heme toxicity, ↑ Neuropathy
<i>Topotecan</i>	Topoisomerase-I	Stabilize DNA-topoisomerase complex	Dependent (efficacy)	↓ Topoisomerase-I ↑ <i>BCRP</i> (ABCG2)	↑ Heme toxicity
<i>Gemcitabine</i>	Ribonucleotide reductase, DNA, nucleotide pool	↓ DNA synthesis ↓ Nucleotide pools Masked chain termination	Dependent (metabolism)	↑ Ribonucleotide reductase	↑ Heme toxicity
<i>PEG-liposomal doxorubicin</i>	Topoisomerase-II	↓ DNA synthesis	Prolonged clearance	↑ <i>MDR 1</i> (P 170)	↑ Heme toxicity

Drug Interactions, Scheduling, and Sequence

Drugs should be used in their optimal dose and schedule. However, new combinations have the potential to alter the pharmacokinetics, bioavailability, toxicity, and efficacy of individual components based on substrate-dependent effects, such as a reduction in nucleotide pools or altered metabolism. Therefore, the optimal dose and schedule for individual agents within a combination might differ from their use as single agents, and regimen development would benefit from preclinical models and phase 1 trials with pharmacodynamic endpoints.

The impact of sequence variations using platinum with either paclitaxel or topotecan has been explored in phase 1 clinical trials with somewhat surprising results. For example, prior administration of cisplatin can delay subsequent clearance of paclitaxel when administered as a 24-hour infusion (184). The mechanism for this effect is unknown, but is not attributable to platinum-mediated renal dysfunction. Instead, it has been postulated to occur following cisplatin-mediated inhibition of cytochrome P450 mixed-function oxidases that participate in paclitaxel metabolism. This enzymatic effect is not shared by carboplatin, and prior carboplatin exposure has not been demonstrated to interfere with clearance of paclitaxel. However, most combinations with carboplatin have utilized a shorter (3-hour) paclitaxel infusion, which would tend to blunt the impact of sequencing. Earlier preclinical models had demonstrated enhanced cytotoxicity when paclitaxel was administered prior to cisplatin and antagonism by the reverse sequence (185,186). Thus, the schedule ultimately adopted in clinical practice (paclitaxel followed by cisplatin) is both less

toxic and potentially more efficacious. Although this would appear to be firmly grounded in science, it is more likely due to practical considerations owing to the risk of acute paclitaxel HSR, which can require interruption of treatment in approximately 5% of cases, and it was more practical to administer the carboplatin after it was clear that the patient had already tolerated the paclitaxel.

A different pattern was observed with sequences of platinum and topotecan. Preclinical models have consistently favored the sequence of platinum followed by topotecan, which has been postulated to interfere with repair of platinum-mediated DNA damage. In a phase 1 clinical trial, treatment with cisplatin on day 1 was associated with increased bone marrow toxicity compared with the reverse sequence (187). In this instance, the sequence recommended for further clinical evaluation was clearly more toxic, but the question of antitumor efficacy remains to be resolved. When combined with carboplatin, the risk of hematologic toxicity was accentuated, and a similar sequence-dependent relationship was identified (188). Once again, higher doses of topotecan could be safely administered using the reverse sequence of drug administration (with carboplatin on day 3). Topotecan has also been evaluated in sequence with docetaxel (189), showing a reduction in docetaxel clearance associated with increased neutropenia when topotecan was administered prior to docetaxel, emphasizing that each new combination may require independent evaluation.

Even with a single drug, the schedule of administration can have a significant impact on host toxicity and potential efficacy (Table 15.13). Early studies with paclitaxel utilized an

TABLE 15.13A

IMPACT OF PACLITAXEL INFUSION DURATION AND SCHEDULE ON TOXICITY AND EFFICACY

Paclitaxel dose and schedule			Dose-limiting toxicities				Antitumor efficacy
Infusion duration (hr)	Dose interval (wk)	Single-agent unit dose (mg/m ² /d)	Neutropenia	Mucositis	Alopecia	Neuropathy	
96	3–4	80–120	+++	++	+++	+	+++
24	3	135	++	0	+++	++	+++
3	3	175	+	0	+++	+++	+++
1	1	60–80	0	0	+	+	+++

TABLE 15.13B

IMPACT OF TOPOTECAN INFUSION DURATION AND SCHEDULE ON TOXICITY AND EFFICACY

Topotecan dose and schedule			Dose-limiting toxicities				Antitumor efficacy
Infusion duration (days)	Dose interval (wk)	Single-agent unit dose (mg/m ² /d)	Neutropenia	Mucositis	Alopecia	Neuropathy	
21	4	0.40	+++	0	0	0	+++
5	3–4	1.25	+++	0	0	0	+++
3	3	2.00	+++	0	0	0	++
1	3	8.50	+++	0	0	0	+/-
1	1	1.75	++	0	0	0	+/-
1	1	4.00	+	0	0	0	(UA) ^a

^aUA, under evaluation.

arbitrary 24-hour infusion, which was selected to reduce the risk of hypersensitivity reactions. Preclinical data suggested that prolonged exposure (96 hours) might have greater efficacy. Owing to increased bone marrow and mucosal toxicity, the MTD was lowered, and the frequency of serious neuropathy was reduced. However, the 96-hour regimen was not demonstrated to have significant activity in patients with recurrent ovarian cancer (190). In addition, the efficacy of a 3-hour infusion was comparable to a 24-hour infusion in a phase 3 trial (191), reinforcing a clinical shift toward the convenient 3-hour schedule, which achieved a higher MTD, primarily due to a marked decrease in bone marrow toxicity, but with an increased incidence of neuropathy. This was followed by phase 1 evaluation of a weekly low-dose 1-hour infusion, which was almost devoid of serious toxicity, including a decreased incidence of alopecia, with maintenance of clinical efficacy (192). Thus, the optimal preclinical regimen (96-hour exposure) was superseded in the clinical setting by an unexpected series of observations from empiric phase 1 trials, yielding decreased toxicity, improved convenience, and the potential for increased efficacy.

With topotecan, a different relationship was defined (Table 15.13B). Initial studies utilized an inconvenient daily infusion for 5 consecutive days, which was based on preclinical data suggesting that prolonged exposure would be more efficacious. This 5-day regimen achieved a 33% response rate in a GOG phase 2 trial in recurrent platinum-sensitive ovarian cancer with expected dose-limiting neutropenia and thrombocytopenia (193). This was followed by the evaluation of a single 24-hour infusion once every 3 weeks, achieving only a 7% response rate in a similar population (194). An attempt to define an intermediate 3-day regimen achieved only a 14% response rate (195). Topotecan was also evaluated as a prolonged intravenous infusion for 21 days to maximize the duration of exposure (196). Although conducted in a different patient population, the overall response rate (35%) was similar to the 5-day regimen, and once again there was equivalent hematologic toxicity without dose-limiting non-hematologic toxicity. Finally, a randomized phase 2 trial conducted by the NCIC and EORTC determined that the 5-day schedule was more appropriate for further clinical development owing to limited activity of an experimental weekly schedule (183). However, this has been challenged on the grounds of inadequate dosing for the weekly regimen, which clearly has reduced hematologic toxicity, and studies are ongoing to evaluate a revised weekly treatment program. In this situation, changes in drug schedule, over a wide range, were associated with substantial differences in efficacy, but without any change in the spectrum or severity of host toxicity, with the exception of reduced hematologic toxicity on the weekly schedule. Thus, each new agent needs to be independently evaluated in the appropriate clinical setting to select the optimal dose and schedule for cancer treatment.

CHAPTER 16 ■ PHARMACOLOGY AND THERAPEUTICS IN GYNECOLOGIC CANCER

DAVID S. ALBERTS, LISA M. HESS, DANIEL D. VON HOFF, AND ROBERT T. DORR

The determinants of effective cancer drug therapies include drug disposition, tumor kinetics, and drug resistance. These factors profoundly influence the cytotoxicity of each anticancer drug and must be considered in designing therapeutic regimens. These principles are discussed in Chapter 15. In this chapter, we elaborate the basic and clinical pharmacology of cancer chemotherapeutic and biologic agents and provide a limited discussion of cytotoxic, molecularly targeted, antiangiogenesis, and modulating/supportive care drugs useful in the treatment of patients with gynecologic cancer.

DETERMINANTS OF EFFECTIVE DRUG THERAPIES

Drug Disposition Factors

The term *pharmacokinetics* describes the time course of drug disposition in body fluids and tissues through the use of mathematical models. These models use an equation or set of equations to describe the concentration versus time profile of a specific drug after administration into the body. The models are often illustrated by box diagrams, with each box or compartment corresponding to a region of the body, although the compartments may not represent real anatomic regions. A drug is considered to be uniformly distributed within a compartment if its concentration within tissues has reached homogeneity.

Pharmacokinetic models may be useful in predicting the plasma or tissue concentrations of drugs in the body after any one of several routes or methods of drug administration. The simplest model has one compartment into which the drug is assumed to be instantaneously introduced, and elimination occurs by one linear route. The disappearance of the drug from this compartment can be described by a straight line if plotted on semilogarithmic graph paper. As discussed by Tozer (1), no one-compartment pharmacokinetic model can be used to describe the disposition of commonly used anticancer drugs; nevertheless, the one-compartment pharmacokinetic model lends itself to an understanding of the concept of plasma half-life (i.e., $t_{1/2}$), which represents the time required for the concentration of a drug at any point on the plasma concentration · time elimination curve to achieve half its value. This constant may be applied repeatedly, so that, for instance, only 25% of the drug remains in two half-lives. The equation for plasma half-life that can be applied to any linear plasma concentration · time elimination curve is as follows: $t_{1/2} = 0.693/\text{slope of the linear elimination curve (i.e., } \lambda_z \text{ or rate constant for that part of the curve)}$. Unfortunately, the determination of the terminal half-life of a drug is often poorly reproducible because it is highly

dependent on measuring multiple plasma levels, often at the limit of drug assay sensitivity.

Pharmacokinetic Models

The pharmacokinetics of virtually all anticancer drugs require two- or three-compartment models for their mathematic description. These models are commonly referred to as biphasic or triphasic models (i.e., two or three phases observed on semilogarithmic plots). Conceptually, the one-compartment model relates to a drug that remains confined to the intravascular space after intravenous injection, and the two- or three-compartment model allows the pharmacokinetic description of anticancer drugs whose ultimate targets are beyond the intravascular space in tumor tissues.

Drug Clearance and AUC Concepts

Wisdom dictates using the simplest mathematical model that can provide the “best” fit of the actual plasma concentration · time data using nonlinear least squares regression. After the mathematic model is selected, it is possible to generate the important pharmacokinetic parameters that describe the disposition of a specific anticancer drug within the body. Besides the determination of the terminal-phase plasma half-life (i.e., half-life related to the second or third phase of biphasic or triphasic plasma concentration · time data), the area under the plasma disappearance curve ($AUC_{0-\infty}$) and total body plasma clearance (Cl_T) are the most significant and clinically useful pharmacokinetic parameters. The relationship between AUC and clearance is simplified to $\text{dose} = \text{clearance} \times \text{area}$.

Although the height of an anticancer drug’s peak plasma level (C_{\max}) generally correlates with peak dose and the degree of toxicity, the drug’s plasma AUC tends to correlate better with its ultimate antitumor activity and normal tissue side effects. For example, when identical doses of melphalan are administered first orally and then intravenously at a 1-month interval, because of its poor oral availability, the melphalan plasma AUC after the oral dose would be only one third of that after the intravenous dose (Fig. 16.1). As would be anticipated, the equivalent intravenous dose of melphalan was associated with a twofold to threefold deeper nadir in granulocytes and a greater than twofold increase in objective response rates in various cancer types (e.g., myeloma).

The plasma AUC (in $\text{mg/mL} \cdot \text{hour}$) can be estimated through the use of a pharmacokinetic model or measured directly by plotting the drug’s plasma concentrations against time on semilogarithmic graph paper. Then, it is possible to calculate the

FIGURE 16.1. Plasma disappearance curves for intravenous and oral (tablets) melphalan (0.6 mg/kg) in a patient with ovarian cancer. The melphalan plasma AUC associated with the bolus oral dose was only one third of that associated with the intravenous dose. *Source:* Reprinted with permission from Alberts DS, Chang SY, Chen HS, et al. Oral melphalan kinetics. *Clin Pharmacol Ther* 1979;26:737-745.

areas of successive trapezoids under the concentration · time curve wherein the upper surface of the trapezoid is a line that connects two successive plasma concentration data points. By convention, when the plasma AUC is measured in this way, the terminal part of the AUC is calculated using a triangular area, rather than a trapezoid.

After the plasma AUC has been determined, it is possible to derive the anticancer drug's total body clearance rate based on the following formula: $Cl_T = \text{dose}/\text{AUC}$ (mg/mL · hour). The resulting Cl_T is measured in units of milliliters or liters per minutes or hours, sometimes with normalization to the body surface area. The total body clearance of an anticancer drug depends on the drug's dose and plasma AUC and represents the rate at which the drug is eliminated from the entire body. The drug's total body clearance is made up of the combination of renal clearance (Cl_R) plus nonrenal clearance (Cl_{NR}). The renal clearance of a drug can be calculated by the following equation: $Cl_R = Ae_c/\text{AUC}$, where Ae_c is the total amount of the unchanged drug that is excreted in the urine. For many drugs that are glomerularly filtered but not reabsorbed, renal clearance is proportional to creatinine clearance. In a patient with severe renal impairment, if nonrenal clearance is unaltered, the total body clearance of the drug is diminished significantly. This phenomenon is observed in patients with relatively severe renal impairment who receive drugs like methotrexate and carboplatin, both of which are eliminated mainly through renal excretion.

Volume of Distribution

The volume of distribution (Vd) of an anticancer drug is another important pharmacokinetic parameter that relates the

drug plasma concentration (measured at the time of administration through extrapolation of the terminal phase of the concentration · time curve to 0 time) to the total amount of drug in the body. Thus, Vd_{area} represents the volume of distribution of a drug in the terminal phase of its elimination from the body and in its simplest form, $Vd = \text{amount of drug in the body} \div \text{plasma concentration}$. Since drug levels are typically measured only in the plasma compartment and not in tissues, most reported Vd values represent the "apparent" Vd of the drug in the plasma. Thus, these Vd values represent a theoretic plasma volume that would account for the drug's plasma levels after administration. The volume of distribution in the terminal phase can be derived using the following equation: $Vd_{\text{area}} = \text{dose}/\text{AUC} \cdot \text{slope} (\lambda_z)$, where λ_z is the rate constant in the terminal phase of a biphasic or triphasic elimination curve.

Linear and Nonlinear Kinetics

Most drugs exhibit linear pharmacokinetics, which in its simplest configuration means that the C_{max} and AUC are proportionate to the dose, and the $T_{1/2}$, Vd and clearance are constant, that is, they do not change with the dose. Linearity helps make predictions about the effects of changes in doses since the AUC (and the biological effects) of the drug should change in proportion to the dose. Drugs with nonlinear pharmacokinetics such as aspirin, ethanol, and phenytoin have saturable elimination patterns. This means that small dose changes can disproportionately increase the AUC and the drug's biologic effects. Drugs with nonlinear pharmacokinetic patterns may therefore have longer $T_{1/2}$ s and much lower clearance values when the dose is increased.

As discussed by Collins and Dedrick (2), there are at least two explanations for nonlinear kinetics. First, nonlinearity may be caused by changes in drug excretion at high doses. For example, at extremely high doses of methotrexate (i.e., 7 to 8 g/m²), the drug load outstrips renal tubular secretion capacity. Second, nonlinearity may be observed for drugs that depend almost completely on elimination through a specific degradative enzyme system (e.g., antimetabolites). Drugs like cytarabine and 5-fluorouracil administered in high doses may overcome the capacity of their respective degradative enzymes with a resultant decrease in their total body clearance rates and an increase in plasma levels that are more than proportionate to their doses.

Intraperitoneal Drug Pharmacokinetics

Intraperitoneal drug administration has become an increasingly important therapeutic strategy in the management of patients with advanced ovarian cancer who have minimal residual intraperitoneal disease after primary or secondary exploratory laparotomies. Three large phase 3 trials in the Gynecologic Oncology Group (GOG) and the Southwest Oncology Group (GOG-104/SWOG-8501, GOG-114, and GOG-172) comparing various cisplatin-based combination chemotherapeutic regimens administered intravenously (IV) or intraperitoneally (IP) have documented significant survival advantages for the intraperitoneal cisplatin treatment arms (3-5). Most recently, in GOG-172, an intraperitoneal regimen (intravenous paclitaxel on day 1, intraperitoneal cisplatin on day 2, and intraperitoneal paclitaxel on day 8) was associated with a 25% reduction in the risk of death as compared to the intravenously administered regimen (intravenous paclitaxel plus cisplatin) ($p = 0.03$) (4). A meta-analysis of IP cisplatin-based randomized trials found that both overall and progression-free survival were significantly improved with IP regimens ($p = 0.0007$ and $p = 0.001$, respectively) (6).

Despite the superior activity of this intravenous paclitaxel/intraperitoneal cisplatin-paclitaxel regimen evaluated in GOG-172, there was significantly more hematologic, gastrointestinal, metabolic, and neurologic toxicity in comparison to intravenous paclitaxel and cisplatin (7); however, the dose of cisplatin on the IP arm was 33% higher than on the IV arm. When combining the toxicity data across intraperitoneal randomized trials, only acute gastrointestinal toxicity ($p = 0.01$) and fever ($p = 0.04$) are significantly higher among patients treated IP, and ototoxicity is significantly higher among patients receiving IV treatment as compared to those receiving IP therapy ($p = 0.004$) (6). A study of patient quality of life within GOG-172 demonstrated that patient quality of life was significantly lower during IP treatment as compared to IV therapy, but 1 year after treatment, the overall quality of life of patients receiving IP or IV therapy was equivalent (8). However, long-term neurotoxicity remained higher among patients treated IP. These short- and long-term effects should be balanced against the documented 16-month improvement in survival as compared with intravenous cisplatin/paclitaxel ($p = 0.03$) (7). This increase in survival is similar to that which was achieved when intravenous cisplatin was initially added to primary combination chemotherapeutic regimens for the treatment of this disease (9).

The incremental increase in cisplatin efficacy associated with intraperitoneal administration likely results from the delivery of approximately 20-fold greater concentrations of cisplatin into the intraperitoneal space than are achievable with intravenous administration. Anticancer drugs with known activity against ovarian cancer that undergo slow clearance from the intraperitoneal space into the systemic circulation without causing significant chemical peritonitis are the favored intraperitoneal compounds. Clearly, paclitaxel falls into this category. Intraperitoneal administration of this large taxane molecule results in 1,000-fold greater concentration · time products in the intraperitoneal space than is achievable with intravenous administration (10). In contrast, cisplatin undergoes rapid clearance from the systemic circulation after administration by the intraperitoneal route. Caution must be taken when considering other agents for research-based intraperitoneal administration, as some cytotoxic agents have not demonstrated efficacy and have been associated with excessive toxicity when given IP (e.g., mitoxantrone, doxorubicin) (11–14).

As with intravenous administration of anticancer drugs, the drug clearance rate from the intraperitoneal space is the most useful pharmacokinetic parameter for comparing drugs that are administered by the intraperitoneal route in the treatment of ovarian cancer. The peritoneal clearance rate can be calculated by dividing the drug dose by its intraperitoneal concentration · time product, which must be measured with repeated intraperitoneal fluid content sampling. Intraperitoneal drugs with slow clearance rates are favored because they result in prolonged exposure of the intraperitoneal tumor bed to high concentrations of anticancer drug. It is also possible to assess the pharmacokinetic characteristics of drug doses by comparing their peak intraperitoneal concentration with peak plasma concentration after intraperitoneal dosing or comparing their intraperitoneal concentration · time product (AUC_{IP}), with their plasma concentration · time products (AUC_{IV}) after intraperitoneal dosing. Virtually all commonly used drugs administered intraperitoneally in patients with ovarian cancer have peak or concentration · time product ratios of more than 20. In some cases, the peritoneal exposures can be much greater. For example, paclitaxel intraperitoneal exposure with IP therapy is 300 to nearly 3,000 times greater than with IV treatment (15).

Except for drugs whose cytotoxicity depends on continuous exposure, such as cytarabine and methotrexate, drugs

used by the intraperitoneal route should be administered relatively rapidly in at least 2 L of peritoneal dialysate and remain within the peritoneal space without removal. For schedule-independent drugs, it is important to maintain high concentrations as long as possible within the intraperitoneal space to improve efficacy. It is of considerable interest that as the intraperitoneal dialysate volume decreases, a drug's intraperitoneal clearance rate increases rapidly. Thus, large volumes of intraperitoneal fluid increase the chances for uniform drug distribution throughout the intraperitoneal space and optimize the intraperitoneal clearance rates. Generally, it is suggested to administer the IP drug dose in the first liter of peritoneal dialysate, followed by a second liter of dialysate to the point of mild abdominal discomfort.

Ultimately, the effectiveness of intraperitoneal therapy depends on the inherent cytotoxic potency of the individual agent and its ability to penetrate from the outer surface to the inner core of intraperitoneal tumors. The degree of tumor penetration depends on the molecular weight, charge, and chemical structure of the compound. There is an inverse relationship between molecular weight and tumor penetration. The higher the molecular weight of the anticancer drug, the lower the degree of the tumor penetration. Indeed, one advantage of cisplatin over carboplatin as an intraperitoneal agent is its lower molecular weight. Los et al. (14) have demonstrated in intraperitoneal ovarian cancer animal studies that it requires almost 10 times more intraperitoneal carboplatin than cisplatin to achieve similar intratumoral concentrations; however, there is renewed interest to develop intraperitoneal carboplatin plus intraperitoneal and intravenous paclitaxel regimens to reduce the potential for cisplatin-paclitaxel-induced peripheral neuropathy (see Special Applications, in the Carboplatin section below).

CLINICAL PHARMACOLOGY OF ACTIVE DRUGS AGAINST GYNECOLOGIC CANCERS

We discuss below in alphabetical order the clinical pharmacology of cytotoxic, biologic/molecularly targeted, and modulating/supportive care drugs with demonstrated activity against gynecologic cancers. We also include several Food and Drug Administration (FDA)-approved drugs for other indications that may prove active against gynecologic cancers.

Cytotoxic Agents

Albumin-Bound Paclitaxel

Chemistry. Albumin-bound paclitaxel (Abraxane, ABI-007) is a protein-bound form of paclitaxel that measures approximately 130 nanometers. Each vial of albumin-bound paclitaxel contains 100 mg of paclitaxel and 900 mg of human albumin. The chemical name of paclitaxel is 5 β , 20-epoxy-1, 2 α , 4, 7 β , 10 β , 13 α -hexahydroxytax-11-en-9-one 4, 10-diacetate 2-benzoate 13-ester with (2*R*, 3*S*)-*N*-benzoyl-3-phenylisoserine and the empirical formula and molecular weight are C₄₇H₅₁NO₁₄ and 853.91, respectively. Albumin-bound paclitaxel is FDA approved for the treatment of breast cancer after failure of treatment for metastatic disease or recurrence within 6 months of adjuvant chemotherapy. Phase 3 trials have demonstrated superior efficacy to castor oil-based paclitaxel and a more favorable toxicity profile (16). Clinical trials in gynecologic cancer (e.g., ovarian and cervical cancer) are ongoing. Please refer to the Paclitaxel section for details on the mechanism of action of this agent.

Drug Disposition. According to the Abraxane package insert, comparison studies of the clearance of albumin-bound paclitaxel (260 mg/m² over 30 minutes) was larger (43%) than for the clearance of paclitaxel injection (175 mg/m² over 3 hours) and the volume of distribution of the albumin-bound form was 53% higher; however, there was no difference in the terminal half-life of the active agent.

Administration and Dosage. The recommended dosage of albumin-bound paclitaxel is 260 mg/m² IV over 30 minutes every 3 weeks. No premedication to prevent hypersensitivity reactions is needed. Albumin-bound paclitaxel should be carefully reconstituted following the manufacturer instructions. Each mL of the reconstituted formulation will contain 5 mg/mL paclitaxel. The exact total dosing volume of 5 mg/mL for the patient should be calculated using the following formula: total dose (mg) ÷ 5 (mg/mL). Reconstituted agent should be used immediately, but can be refrigerated for up to 8 hours. If precipitates are observed, the solution should be discarded.

Side Effects and Toxicities. Neutropenia and sensory neuropathy are dose dependent. In drug approval studies, grade 4 neutropenia occurred among approximately 9% of patients, as compared to 22% of patients receiving 175 mg/m² paclitaxel. Infection (generally oral candidiasis and respiratory system events) occurred in approximately 23% of patients receiving albumin-bound paclitaxel. Anemia occurred among 33% of patients (severe anemia in 1% of cases). Severe cardiotoxicity occurred in approximately 3% of patients. Dyspnea (12%) and cough (6%) were also reported among patients receiving albumin-bound paclitaxel. Patients with neutrophil counts of less than 1,500 cells/mm³ should not receive albumin-bound paclitaxel, as it may lead to bone marrow suppression, which can result in infection.

Altretamine

Chemistry. Altretamine (hexamethylmelamine, Hexalen), a synthetic cytotoxic antineoplastic s-triazine derivative, has FDA approval for treatment of persistent or recurrent ovarian cancer after first-line chemotherapy with cisplatin or other alkylating agents. The drug also exhibits antitumor activity against breast cancer, lymphomas, small cell carcinoma of the lung, and endometrial and cervical cancer. The empiric formula of altretamine is C₉H₁₈N₆ (molecular weight = 210.28).

Mechanism of Action. The mechanism of action of altretamine is not completely elucidated. Although it bears structural similarity to and cross reactivity with triethylene-melamine, a classic alkylating agent, evidence demonstrating altretamine to be an alkylating agent is inconclusive. Altretamine does not consistently demonstrate cross resistance with classic alkylating agents used in rodent tumors or in human cancer treatment, but its clinical antitumor spectrum resembles that of an alkylating agent. Altretamine is inactive against most common murine and human tumor cell lines *in vitro*. Ruty and Connors (17,18) presented definitive evidence that metabolic activation of altretamine is necessary for its cytotoxic activity. It is extensively demethylated *in vivo* in the presence of liver enzymes and these N-methylolmelamine derivatives are more cytotoxic than the parent compound (18). Additional studies have shown that the reactive methyl intermediates, formed during altretamine N-demethylations, covalently bind to tissue macromolecules, including DNA, and that the cytotoxicity against certain human solid tumor cells *in vitro* is dependent on the metabolic formation of the reactive intermediates or their direct addition to cell culture incubate (17).

Drug Disposition. Altretamine is practically insoluble in water and, therefore, it has only been administered orally in clinical studies, precluding absolute bioavailability studies. After administration of altretamine to laboratory animals by any route, urinary recovery of parent drug was very low (<1%), and

urinary recovery of total dose or total radioactivity after administration of ¹⁴C-labeled drug was as high as 90%. Ames et al. (19) determined that the bioavailability of the parent compound in rabbits after oral administration was 25% of that obtained after intravenous administration. Moreover, after giving the rabbits labeled altretamine by stomach tube, 85% of labeled drug equivalents was recovered in the urine. The high rate of recovery suggests efficient gastrointestinal absorption.

The urinary recovery and bioavailability data demonstrate that altretamine is well absorbed after oral administration and that the drug is extensively metabolized regardless of route of administration. The low bioavailability of intact altretamine is due to first-pass metabolism rather than to poor absorption.

After oral administration in doses of 120 to 300 mg/m², peak plasma levels, measured by gas chromatographic assay, from 0.2 to 20.8 mg/L are reached between 0.5 and 3.0 hours. The terminal-phase plasma half-life ranges from 4.7 to 10.2 hours (20). The interpatient variability of AUCs, ranging from 1.2 to 60.1 mg/L · hour, is most likely due to the differences in the rate at which the drug is metabolized.

Administration and Dosage. The recommended dose for altretamine as a single agent for use in the palliative treatment of patients with ovarian cancer is 260 mg/m²/day, orally, for 14 to 21 consecutive days in a 28-day cycle (21). The total daily doses should be given as four divided oral doses after meals and at bedtime. Compliance to this regimen in a small group of patients with relapsed ovarian cancer has been documented to be over 95% (22). There is no pharmacokinetic information on this dosing regimen and the effect of food on altretamine bioavailability in humans. In combination regimens, altretamine is typically used at a dose of 150 mg/m²/day for 7 to 14 days of monthly cycles (23).

Altretamine should be temporarily discontinued for 14 days or longer and subsequently restarted with a 20% to 25% dose reduction for any of the following side effects: gastrointestinal intolerance unresponsive to symptomatic measures; leukocyte count less than 2,000/mm³ or granulocyte count less than 1,000/mm³; platelet count less than 75,000/mm³; or progressive neurotoxicity. If neurologic symptoms fail to stabilize on the reduced-dose schedule, altretamine should be discontinued.

Side Effects and Toxicities. Altretamine is administered at a dose of 260 mg/m² (single agent) or 150 mg/m² (in combination) on an intermittent schedule and is relatively well tolerated. Single-agent data for this drug are available for 1,014 patients (24). With high, continuous daily dosing, nausea and vomiting were the dose-limiting toxic effects, and a form of reversible peripheral neurotoxicity occurred occasionally. Myelosuppression was mild to moderate. Leukocyte and platelet counts usually recovered within 1 week of therapy discontinuation.

In a study of 395 patients with advanced ovarian cancer treated with altretamine-containing combination regimens with or without cisplatin, no additional effect of altretamine on the incidence or severity of neurotoxicity could be demonstrated (25). Peripheral neuropathy and central nervous system symptoms are more likely to occur in patients receiving continuous, high-dose daily altretamine administered on an intermittent schedule than in those receiving moderate doses. Neurologic toxicity reverses after the drug is discontinued. Pyridoxine should not be used concomitantly with altretamine to reduce neurotoxicity because clinical trials data suggest it may inhibit cytotoxic activity. Concurrent administration of altretamine and antidepressants of the monoamine oxidase (MAO) inhibitor class may cause severe orthostatic hypotension. Cimetidine, an inhibitor of microsomal drug metabolism, increased altretamine's half-life and toxicity in a rat model.

In two phase 2 studies of single-agent altretamine, at a dose of 260 mg/m² for 14 to 21 days of each monthly cycle, the most common toxicity was grade 2 to 3 nausea (23%) (26,27). In a consolidation therapy phase 2 trial, only three

patients (4%) experienced any grade 4 toxicity: granulocytopenia (two patients) and anxiety/depression (one patient). The most common grade 3 toxicities were malaise, fatigue, or lethargy in seven patients (7%) and nausea in six patients (6%). Aside from these, there were no other grade 3 or 4 toxicities that occurred in more than 5% of patients (27).

With continuous high-dose daily drug administration, nausea and vomiting of gradual onset occur frequently. Although in most instances these symptoms are controllable with antiemetics, the severity sometimes requires altretamine dose reduction or, rarely, discontinuation.

Data from three large clinical trials demonstrated that altretamine can be added to full therapeutic doses of cyclophosphamide, doxorubicin, and cisplatin (CHAP) without evidence of increased hematologic toxicity (28–30). Leukopenia below 3,000 cells/mm³ occurred in fewer than 15% of the patients on a variety of intermittent- or continuous-dose altretamine regimens. Fewer than 1% had leukopenia below 1,000 cells/mm³. When given in high doses over a 21-day course, nadirs of leukocyte and platelet counts were reached by 3 to 4 weeks, and normal counts were observed by 6 weeks. With continuous administration, nadirs are reached in 6 to 8 weeks.

Bleomycin

Chemistry. Bleomycin (Blenoxane), an antineoplastic, is a mixture of complex glycopeptides originally isolated from a strain of the fungus *Streptomyces verticillus*. The primary components are bleomycins A₂ and B₂. The family of bleomycin glycopeptides has a relatively high molecular weight and is quantitated in units of cytotoxic activity (i.e., roughly 1 U/1 mg of polypeptide protein). Bleomycin is used as palliative treatment in patients with advanced cervical (31) and vulvar cancers. Other clinical indications include squamous cell carcinomas of the head and neck, lymphomas, and testicular carcinoma. The molecular formula of bleomycin A₂ is C₅₅H₈₄N₁₇O₂₁S₃ (molecular weight = 1,414) and the molecular formula of bleomycin B₂ is C₅₅H₈₄N₂₀O₂₁S₂ (molecular weight = 1,425).

Mechanism of Action. Although the exact mechanism of action is unknown, a key to its activity is the isolation of native compounds from *S. verticillus* as coordinated Cu(II) complexes, which are inactive as antitumor agents. When complexed with ferrous iron, bleomycin becomes a potent oxidase, producing DNA strand breaks by oxygen free radicals. Its unique mechanism of action is schedule dependent and cell cycle dependent for the G₂ phase.

The oxygen radicals produced by the bleomycin-iron complex bound to DNA primarily cause single-strand breaks and a lesser degree of double-strand breaks. There is a subsequent release of base propenals of all four DNA bases: guanine, thymine, adenine, and cytosine. These modified free bases result from cleavage of the deoxyribose sugar at the 3'-4' bond. There is an apparent specificity for the release of thymine and for DNA binding at guanine-rich sequences in actively transcribed genes (32). The linker regions of DNA between nucleosomes comprise an important site for specific strand cleavage by bleomycin (33). Several mechanisms have been theorized to explain the development of resistance to bleomycin. Less important mechanisms appear to include DNA repair, membrane alterations, and decreased drug accumulation. The primary mechanism probably involves metabolic inactivation of bleomycin by a cytosolic hydrolase, which is in the cysteine proteinase family. The enzyme inactivates bleomycin by replacing a terminal amine with a hydroxyl group. The distribution of bleomycin hydrolase appears to explain some of the relative resistance and sensitivity to bleomycin in normal tissues. Normal tissues with high

intrinsic hydrolase activities, such as the liver, spleen, intestine, and bone marrow, are not targets for bleomycin's toxic effects. In contrast, lung tissues and skin have low levels of hydrolase activity and are particularly susceptible to bleomycin-induced toxicity. However, there appears to be no direct correlation between hydroxylase levels in tumor cells and bleomycin-induced cytotoxicity (33). The development of other methods of bleomycin metabolism by tumor cells may be responsible for the emergence of drug resistance (34).

Drug Disposition. Bleomycin is eliminated predominantly by urinary excretion. This accounts for 45% to 62% of a dose after 24 hours. In the blood, the drug is rapidly cleared, and two phases of elimination are apparent. As a practical point, this means that over 95% of a dose has been completely eliminated by 24 hours (about six half-lives) (35). If administered by an intracavitary route, a large percentage of a bleomycin dose is absorbed, and the fractional systemic bioavailability is about 45% for intrapleural or intraperitoneal injections. The drug appears to efflux more slowly from the peritoneal cavity. This suggests that there is significantly greater local drug retention in the intraperitoneal space. This may explain some of the drug's unique efficacy by intracavitary administration (36). An increased exposure to drug in these local compartments is also reflected by the tenfold higher drug levels achieved with intraperitoneal or intrapleural therapy than with equivalent intravenous dosing.

Renal insufficiency markedly alters bleomycin elimination (37). This effect becomes most pronounced in patients with creatinine clearance values less than 25 to 35 mL/min (37). In these patients, the volume of distribution is unaltered at about 20 L, but the half-life varies as the inverse exponent of creatinine clearance. Thus, significant bleomycin dose reductions are required in all patients with reduced renal function.

Dosage. Bleomycin (in combination with cisplatin and etoposide or vinblastine) is used most commonly by bolus intravenous administration at dosages of as high as 30 mg/week for up to 12 weeks in the treatment of patients with germ cell tumors of the ovary. These 30-mg doses often are associated with delayed febrile episodes that can be inhibited successfully with a morning dose of dexamethasone or prednisone.

Bleomycin continues to be used commonly by continuous intravenous infusion at dosages of 10 mg/m²/day for 4 consecutive days, with courses repeated every 4 weeks. This schedule has been proven to be successful in the treatment of women with metastatic cervical cancer. Total bleomycin doses should usually not exceed 400 mg to avoid serious pulmonary toxicity.

Bleomycin can also be administered by the intramuscular route in doses of 15 to 30 mg. Absorption appears to be complete, and because of its lack of vesicant activity, the intramuscular route has been proven to be extremely safe (38).

Side Effects and Toxicities. Bleomycin's dose-limiting side effect is pulmonary toxicity, which occurs in approximately 10% of treated patients and in rare instances can result in death. The likelihood of lung damage increases with advanced age, chest irradiation (39), hyperoxia during surgical anesthesia (40), renal insufficiency, and cumulative doses greater than 400 U. However, pulmonary toxicity is variable and may occur in younger patients following low cumulative doses. Bleomycin-induced lung damage presents as pneumonitis with dry cough, dyspnea, and rales and may progress within weeks to pulmonary fibrosis. Bleomycin should be discontinued at the first clinical signs of lung toxicity. Acute pneumonitis is often responsive to corticosteroid therapy; however, there is no effective therapy for the chronic pulmonary fibrosis that may result from bleomycin therapy (41). Evidence from pre-clinical models of bleomycin-induced pulmonary thrombosis has documented that pretreatment with amifostine can abrogate this dose-limiting toxicity (42,43).

Bleomycin is nonmyelosuppressive (a factor that facilitates its use in combination chemotherapeutic regimens). Mucocutaneous toxicities, including mucositis, are the primary acute side effects of bleomycin. Manifestations of cutaneous reactions include hyperpigmentation, erythema, rash, striae, pruritus, thickening of the nail beds, and, in rare instances, scleroderma (44). Fever, chills, and alopecia are common. Mild nausea, vomiting, and anorexia may also occur, but are typically self-limiting. Infrequent side effects include headache, pain at tumor site, and anaphylactoid reactions. An idiosyncratic reaction consisting primarily of mucositis and skin rash has also been reported (45).

Special Precautions. Bleomycin should be used with extreme caution in patients with significant renal impairment or compromised pulmonary function; frequent radiographs are recommended. Because up to 70% of a bleomycin dose is eliminated by renal excretion, the bleomycin dose should be reduced for individuals with severe renal insufficiency. Unfortunately, there are no prospectively evaluated dosing nomograms for bleomycin dose adjustment. An empiric dose-adjustment formula has been described (37). The percentage dose reductions that are indicated by applying this formula to a "normal" creatinine clearance (CrCl) of 120 mL/min and a fractional urinary drug excretion of 0.45 are CrCl >35 mL/min, no dose reduction required; CrCl = 20 mL/min, 50% dose reduction; CrCl = 15 mL/min, 52% dose reduction; CrCl = 10 mL/min, 55% dose reduction; and CrCl = 5 mL/min, 60% dose reduction. This is only a general guide, and it has not been clinically validated in a prospective study or retrospective analysis. Patients over 65 years of age may be at increased risk of developing orthostatic hypotension, especially when the recommended rate of intravenous infusion is exceeded.

Drug Interactions. Nephrotoxic drugs may significantly reduce the rate of bleomycin clearance and thus increase toxicity. Yee et al. (46) observed markedly reduced bleomycin clearance in children who had received six courses of a regimen including cisplatin (cumulative dose 300 mg/m²). In another case report, fatal bleomycin pulmonary toxicity occurred in a patient with cisplatin-induced acute renal failure (47). Similar toxic interactions should be anticipated for combinations of bleomycin with other nephrotoxic drugs, such as aminoglycosides, amphotericin, or cyclosporine.

Special Applications. Because of its nonvesicant nature, bleomycin has been administered by a number of nonvascular routes, including intramuscular (38), subcutaneous (48), and, most significantly, intrapleurally for the management of malignant effusions. When compared with tetracycline, intrapleurally administered bleomycin, 60 to 120 U, had greater therapeutic benefit for the management of malignant pleural effusions (36). When compared with tetracycline, intrapleurally administered bleomycin 60 to 120 U had greater therapeutic benefit as evidenced by a longer time to effusion recurrence (46 vs. 32 days, $p = 0.037$) and a lower 3-month effusion recurrence rate (30% vs. 53%, $p = 0.047$). Because toxicities were similar for both therapies, bleomycin was selected as the preferred intrapleurally administered therapy for malignant pleural effusions.

Capecitabine

Chemistry. Capecitabine (Xeloda) is an orally administered antineoplastic agent. In patients with metastatic breast cancer, capecitabine in combination with docetaxel is indicated after failure of prior anthracycline-containing chemotherapy, and monotherapy is indicated for those who are resistant to paclitaxel and are resistant to anthracycline-containing chemotherapy (or further anthracycline-containing chemotherapy is not indicated). Capecitabine is a fluoropyrimidine carbamate

prodrug form of 5'-deoxy-5-fluorouridine (5'-DFUR) that is enzymatically converted to 5-fluorouracil (5-FU) *in vivo*. Its chemical name is 5'-deoxy-5-fluoro-N-[(pentylloxy) carbonyl]-cytidine and its molecular weight is 359.35.

Mechanism of Action. Capecitabine itself is inactive, but after absorption in the gastrointestinal tract is metabolized to 5-FU by three enzymes: carboxylesterase, which converts capecitabine to 5'-deoxy-5-fluorocytidine in the liver; cytidine deaminase in the liver and tumor tissue, which converts it to 5'-deoxy-5-fluorouridine; and thymidine phosphorylase, which in many cases is highly expressed in tumors, completes the final step of conversion to 5-FU. Theoretically, capecitabine therapy is likely to be most effective in patients with tumors that express high concentrations of thymidine phosphorylase (resulting in greater 5-FU being generated in the tumor) and low concentrations of dihydropyrimidine dehydrogenase (which rapidly breaks down 5-FU) (49). 5-FU acts as a false pyrimidine or antimetabolite ultimately to inhibit the formation of the DNA-specific nucleoside base thymidine. The metabolites of 5-FU, 5-fluoro-21-deoxyuridine-5'-monophosphate (FdUMP) and 5-fluorouridine triphosphate (FUTP), inhibit thymidylate synthase (FdUMP) and are incorporated into cellular RNA (FUTP). DNA synthesis and function are inhibited by the incorporation of FdUMP into cellular DNA (50).

Drug Disposition. After oral administration, capecitabine reaches peak blood levels in about 1.5 hours, and peak 5-FU levels are reached at about 2 hours. Food reduces the rate and extent of absorption for both capecitabine and 5-FU. Plasma protein binding is not dose dependent and is less than 60% for capecitabine and its metabolites. Capecitabine (95.5% of administered dose) and its metabolites are excreted in urine. Capecitabine has no effect on the pharmacokinetics of docetaxel or vice versa. The precise pharmacokinetics of capecitabine have been difficult to establish, which is thought to be due to the large interindividual and intraindividual variation in expression of the enzyme dihydropyrimidine dehydrogenase (44).

Administration and Dosage. Capecitabine is available as 150- and 500-mg tablets for oral use. The recommended dose is 2,500 mg/m² daily to be administered as two doses: 1,250 mg/m² in the morning and 1,250 mg/m² in the evening for 2 weeks followed by a 1-week rest (21-day cycle). Because of the high rate of grade 2 or greater capecitabine-induced palmar-plantar erythrodysesthesia (PPE), recommendations have been made to reduce the starting dose to 2,000 mg/m² daily. It should be taken with water within 30 minutes after a meal. The same dosage of capecitabine should be used when combined with docetaxel, which should be administered at 75 mg/m² as a 1-hour infusion on day 1 of the 21-day cycle. Premedication (per docetaxel labeling) should be started prior to docetaxel administration for patients receiving the combination therapy.

Side Effects and Toxicities. The only side effect that occurs more frequently with capecitabine than with intravenous 5-FU is PPE (15% to 20% of patients). The other more common side effects of capecitabine include diarrhea (40%) and nausea and vomiting (30% to 40%). Grade 3 hyperbilirubinemia occurred in 15.2% and grade 4 in 3.9% of patients in the clinical safety database of Xeloda. Of those patients experiencing grades 3 and 4 hyperbilirubinemia, many (64% and 71%, respectively) had liver metastases at baseline, and 57.5% and 35.5% had elevations in alkaline phosphatase or transaminases, respectively. Other less common side effects include myelosuppression (less frequent than with IV 5-FU), leukopenia, and cardiotoxicity. In general, capecitabine is relatively well tolerated.

Special Precautions. Because capecitabine is administered orally, patients should be informed how to monitor their toxicity symptoms and be instructed to maintain the prescribed dosing regimen. Capecitabine has been shown to

alter coagulation parameters in patients undergoing treatment concomitantly with coumarin-derivative anticoagulants (e.g., warfarin) (49). Therefore, patients taking oral coumarin-derivative anticoagulant therapy should be monitored regularly with regard to coagulation parameters (international normalized ratio or prothrombin time). Patients over the age of 80 years and those with mild to moderate liver dysfunction should also be closely monitored.

Carboplatin

Chemistry. Carboplatin (Paraplatin) is an alkylating agent that is approved by the FDA for the treatment of patients with advanced ovarian cancer of epithelial origin. It is also active against metastatic endometrial and cervical cancer. Carboplatin has a molecular formula of $C_6H_{12}N_2O_7Pt$ and a molecular weight of 371.25. Its chemical name is platinum, diammine[1,1-cyclobutane-dicarboxylato(2-),0'],-(SP-4-2). The water solubility of carboplatin (14 mg/mL) is approximately 10 times that of cisplatin.

Mechanism of Action. Carboplatin, like cisplatin, produces an equal number of predominantly interstrand DNA cross links rather than DNA-protein cross links, causing equivalent lesions and biologic effects. The differences in potencies appear to be related to the aquation rate, which is 14 mg/mL for carboplatin, as compared to 1 mg/mL for cisplatin. It covalently binds to DNA with preferential binding to the N-7 position of guanine and adenine (50). Like cisplatin, carboplatin must first undergo sequential losses of the nonamine carboxylato ligands. Although this process proceeds readily with the loss of the chlorides in cisplatin, the rate of leaving or “opening” of the carboxylato moieties in carboplatin is much slower (51). The molar potency of carboplatin in creating DNA lesions and cytotoxicity was observed to be roughly 2% of cisplatin *in vitro* and 25% to 33% of cisplatin *in vivo* (52,53). A more striking difference is the markedly delayed onset of peak cross linking for carboplatin compared with cisplatin. With carboplatin, maximal DNA cross linking occurs 18 hours after exposure compared with 6 to 12 hours for cisplatin (53). In addition, carboplatin-induced DNA cross links appear to have a slower rate of resolution than cisplatin-induced cross links. This slower onset and offset of carboplatin cross linking is believed to be a direct result of a slow rate of monofunctional adduct formation or a slower rate of conversion of monoadducts to cross links. Despite the pharmacokinetic differences between carboplatin and cisplatin, phase 3 studies and meta-analyses of clinical studies reveal equivalent activity between carboplatin and cisplatin in all prognostic subgroups of ovarian cancer patients (54,55).

Harrap (56) described nuclear protein phosphorylation after treatment with both cisplatin and carboplatin. These events appear to correlate with cell killing (57). Carboplatin reacts with two sites on DNA to produce cross links, as has been observed with cisplatin (58). The formation of DNA adducts results in the inhibition of DNA synthesis and function and inhibits transcription (50). These lesions involve a bifunctional platinum adduct to a single-strand DNA. This may produce transcriptional miscoding and an inhibition of DNA synthesis. It is possible that the cytotoxic effects of carboplatin are the result of binding to nuclear and cytoplasmic proteins. Carboplatin-induced cytotoxicity is not cell cycle phase specific, but it can be maximized by exposing cells in S phase to the drug.

Drug Disposition. The pharmacokinetics of carboplatin differ significantly from those of cisplatin. Table 16.1 shows that the plasma clearance of carboplatin is biphasic and slower than that of cisplatin, with a much higher percentage of drug being excreted in the urine. Unlike cisplatin, relatively

TABLE 16.1

CARBOPLATIN PHARMACOKINETICS

Cumulative 24-hour urinary excretion	65% (if creatinine clearance >60 mL/min)
<i>In vitro</i> half-life (H ₂ O)	~24 hours
Plasma half-life	
β-phase (free drug)	180 minutes
Protein-bound drug	>5 days
Volume of distribution	1,620 L
Protein binding	30% (slow equilibration)

little carboplatin is bound to plasma proteins. The major route of elimination of carboplatin is glomerular filtration and tubular secretion. There is little or no true metabolism of the drug. The carboxylato bonds in carboplatin are slowly hydrolyzed to yield transient aquated intermediates. These activated platinum species are believed to lead directly to irreversible adducts to DNA or protein. Overall, the rate of hydrolysis of carboplatin is significantly slower than that of cisplatin, leading to much slower reactivity with DNA (59). Because as much as 65% of a carboplatin dose is excreted in the urine, significant dose adjustments are recommended for patients with creatinine clearance values less than 60 mL/min.

Carboplatin is widely distributed in body fluids and achieves good penetration into pleural effusions and ascites fluid (60). Pharmacokinetic studies in patients receiving continuous carboplatin infusions show that, although total platinum levels increase over the course of the infusion, free or active platinum levels can decrease from 78% on day 1 to 38% on day 4 of a 4-day infusion.

Administration and Dosage. Carboplatin is usually administered as a brief infusion over 15 minutes or longer in a solution of 0.9% sodium chloride or 5% dextrose in water. The drug is typically diluted in 500 mL of fluid and infused IV over 15 to 30 minutes to 1 hour without further hydration (61). Carboplatin has also been administered as a continuous 24-hour IV infusion for 1, 4, or 5 days, or as a continuous IV infusion for 21 days.

The Calvert equation is the most frequently used formula for carboplatin dosing, inasmuch as it requires minimal calculations, results in predictable levels of myelosuppression, and prevents underdosing or overdosing in patients with excellent or poor renal function, respectively (62). The Calvert formula appears below along with general guidelines for selecting the specific carboplatin AUC.

$$\text{Carboplatin total dose (mg)} = \text{AUC (mg/mL} \cdot \text{min)} \\ \times [\text{GFR (mL/min)} + 25]$$

AUC = 7, when carboplatin is used as a single agent in patients with good bone marrow reserve; 6, when carboplatin is used in combination regimens in patients with good bone marrow reserve or when used as a single agent in patients who have had prior moderate chemotherapy; and 4, when carboplatin is used as a single agent in patients with prior heavy chemotherapy exposure.

Glomerular filtration rate (GFR) can be determined by measuring creatinine clearance (i.e., [⁵¹Cr]-ethylenediaminetetraacetic acid) for all patients or estimated creatinine clearance for patients who have had no prior cisplatin exposure or have not had cisplatin for at least 2 months prior to carboplatin dose determination. As an example, if the desired carboplatin AUC is 6 for a patient with an estimated creatinine

clearance (CrCl) of 75 mL/min, the total carboplatin dose would equal $6 \times (75 + 25)$, or 600 mg.

As noted above, the Calvert formula uses the following estimate of carboplatin clearance: $Cl = GFR + 25$. Although the method may be optimal (63), isotopic determination of the GFR as measured by [^{51}Cr]-ethylenediamine-tetraacetic acid (^{51}Cr -EDTA) is a costly, invasive procedure and the estimated creatinine clearance is often substituted for the GFR. A commonly used method for estimating creatinine clearance is the Cockcroft-Gault equation (64):

$$\text{CrCl} = [0.85 \times (140 - \text{age}) \times \text{Wt}(\text{kg})] / [72 \times \text{Scr}(\text{mg/dL})]$$

(CrCl as calculated by the above equation is reduced by 15% for women; Scr = serum creatinine.)

Both the Cockcroft-Gault calculation of creatinine clearance and creatinine clearance based on a 24-hour urine collection result in a systematic underestimation of the carboplatin AUC by approximately 10% (65–67). This level of bias may be deemed to be acceptable in view of the clinical utility of substituting creatinine clearance for GFR.

The Calvert formula has been prospectively evaluated by Sorenson et al. (68) in 24 previously untreated ovarian cancer patients and was found to more accurately predict carboplatin exposure than calculation of dose based on body surface area. The AUC of carboplatin as calculated by the Calvert formula accurately predicted the level of myelosuppression as determined by the relative decrease in the platelet count (68).

The recommendation dosage for single-agent carboplatin in ovarian cancer patients with good bone marrow reserve, based on body surface area, is 360 mg/m² given intravenously every 4 weeks. Because renal excretion is the primary route of carboplatin elimination, the carboplatin dose must be reduced for patients with compromised kidney function. The drug manufacturer's package insert recommends carboplatin doses of 250 and 200 mg/m² for patients with creatinine clearances of 41 to 59 and 16 to 40 mL/min, respectively.

The most frequently used primary chemotherapeutic regimen for advanced ovarian cancer is a combination of paclitaxel (175 mg/m² by 3-hour IV infusion) followed by carboplatin (at a targeted AUC of 5 or 6 by 30- to 60-minute IV infusion) every 21 days (if blood counts are adequate) for six cycles (69).

Side Effects and Toxicities. Although the activity is comparable to cisplatin, carboplatin is better tolerated, as measured by toxicity (e.g., low incidence of alopecia [70]) and quality of life analysis (55). The usual dose-limiting toxicity of carboplatin is bone marrow suppression, particularly thrombocytopenia (71). Leukopenia and anemia also occur but are less severe.

The platelet nadir is achieved 3 weeks after an IV bolus injection, and recovery is generally complete 4 to 5 weeks after dosing. However, patients with poor bone marrow reserve from previous chemotherapy or radiation therapy can have more profound thrombocytopenia and leukopenia with carboplatin treatment. Cell depletion may persist for several weeks after dosing.

Nausea and vomiting induced by carboplatin is much less severe than with cisplatin and rarely lasts beyond 24 hours. In a study of 943 ovarian cancer patients randomized to carboplatin, only 9% experienced greater than grade 2 nausea and/or vomiting (70). Emesis can usually be blocked entirely with aggressive therapy using antiemetic drug combinations (72). Diarrhea has been reported in only 6% of patients and constipation in 3% of carboplatin-treated patients (73).

Nephrotoxicity has been reported with carboplatin, but it is much less common and less severe than with cisplatin. In a large review, transient elevations in serum creatinine and blood urea nitrogen were described in 7% and 16% of patients, respectively (73). Measured creatinine clearances dropped in

25% of patients, and a slight increase in uric acid was described in the same percentage of patients. However, there can be a significant loss of serum electrolytes, including potassium (16% of patients) and magnesium (37%). Serum calcium is only rarely decreased after carboplatin (73).

A few cases of carboplatin-induced hematuria have been described. Hepatic enzyme elevations occasionally occur with carboplatin (73). Alkaline phosphatase was transiently increased in 36% of patients and serum glutamic oxaloacetic transaminase (SGOT) or serum glutamic pyruvic transaminase (SGPT) in about 15% of patients. Serum bilirubin levels are rarely elevated (4%) (73).

Neurotoxicity is uncommon after carboplatin and was described in only 2.5 of 428 (6%) patients treated on a variety of schedules for different tumor types (73). Mild paresthesias have been reported in a few patients receiving cumulative carboplatin doses of more than 1.6 g/m² (71). Unlike cisplatin, these peripheral nerve toxicities rarely produce any disabling symptoms. In most cases, no neurotoxicity was attributed to the drug.

Ototoxicity does not appear to be problematic with carboplatin, and only 8 of 710 (1.1%) patients have described clinical hearing deficits, mainly tinnitus (73). However, if pretreatment and serial audiometric tests are performed, as many as 15% of patients may have some decrease in audio acuity. Fortunately, ototoxicity from carboplatin sometimes improves after therapy is halted. Like cisplatin, greater ototoxicity from carboplatin can be expected in patients with pre-existing hearing loss or in those concurrently being given other ototoxic drugs, such as aminoglycosides.

Other rare carboplatin toxicities include alopecia (2% of patients), mucositis (2%), skin rash (1.7%), injection-site irritation without extravasation necrosis (0.4%), and a flu-like syndrome (1.3%) (73). The same study described alterations in taste sensation. Skin disorders from carboplatin treatment may appear as an erythematous rash in exposed areas and do not occur in all patients who had developed similar rashes on cisplatin (71).

Although carboplatin-associated hypersensitivity reactions rarely occur when the drug is administered as part of an initial chemotherapeutic regimen, subsequent administration of carboplatin in the setting of second-line or salvage therapy is associated with an increased risk of hypersensitivity. It has been estimated that over 25% of patients who receive more than six courses of platinum-based (i.e., cisplatin or carboplatin) chemotherapy develop sensitivity to carboplatin (74). The onset of symptoms may occur during the carboplatin infusion or up to 3 days after drug administration. Mild reactions consist of localized itching and erythema, primarily of the palms and soles, and/or facial flushing, whereas severe reactions can cause diffuse erythema, tachycardia, wheezing, facial edema, chills, rigors, throat and chest tightness, dyspnea, vomiting, alterations in blood pressure (both hypotension and hypertension), and, in extreme cases, respiratory arrest. Mild cases may respond to IV diphenhydramine (50 mg) or oral diphenhydramine (25 to 50 mg every 4 to 6 hours) and additional courses of carboplatin can be administered. Severe hypersensitivity reactions typically necessitate the discontinuance of carboplatin; however, some patients are able to receive additional courses of carboplatin with administration of corticosteroids for several days prior to carboplatin administration. Hypersensitivity reactions may also occur when carboplatin is administered by the intraperitoneal route (75).

Platinum-based chemotherapy (either cisplatin or carboplatin) has been shown to increase the risk of leukemia in ovarian cancer patients (76). Following carboplatin-based chemotherapy, the estimated relative risk of leukemia is 6.5 (95% confidence interval, 1.1 to 9.4). The relative risk increases

as a function of both cumulative dose and duration of treatment. Patients who receive 4,000 mg or greater of carboplatin have a relative risk of 7.6 of developing leukemia, whereas patients who receive more than 12 months of carboplatin-based chemotherapy have a relative risk of 7.0. Although radiation therapy alone does not increase the risk of leukemia, radiation therapy administered in combination with platinum-based chemotherapy is associated with a significantly higher risk of leukemia than platinum-based chemotherapy without radiation ($p = 0.006$). The average time to onset of secondary leukemia is 4 years after the diagnosis of ovarian cancer. Although the potential benefits of platinum-based chemotherapy for ovarian cancer far outweigh the risk of secondary leukemia, the dose-dependent leukemogenic potential of platinum-based chemotherapy should be considered during its administration to patients with early-stage disease.

With the high doses of carboplatin used in autologous bone marrow transplantation programs, other severe toxicities may occur. These include hepatotoxicity (both hepatitis and cholestasis) and severe renal dysfunction (60,77). Nausea, vomiting, and electrolyte wasting are also more profound with high-dose carboplatin treatments. In addition, other unusual toxic effects may occur. These include hemorrhagic colitis, optic neuritis, and interstitial pneumonitis.

As noted below (see Drug Interactions), paclitaxel ameliorates carboplatin-induced thrombocytopenia.

Drug Interactions. Although the pharmacokinetics of carboplatin are not altered by coadministration of paclitaxel, patients who receive combination chemotherapy with carboplatin plus paclitaxel experience less thrombocytopenia than would be predicted if carboplatin was administered as a single agent (65,78). The relationship between free platinum exposure and thrombocytopenia following carboplatin/paclitaxel chemotherapy can be described by a sigmoid maximum effect model (65). In that the degree of neutropenia appears to be unaffected by coadministration of paclitaxel and carboplatin, this pharmacodynamic interaction is believed to occur at the megakaryocyte level (78).

The cytoprotective agent amifostine reduces carboplatin-induced thrombocytopenia (79) but also extends the plasma half-life of carboplatin (80). In a randomized trial of carboplatin with or without amifostine, the median platelet nadir of patients treated with carboplatin 500 mg/m² was 88,000/ μ L, whereas the nadir in patients who received amifostine 910 mg/m² was 127,000/ μ L ($p = 0.023$) (79). Pharmacokinetic studies have shown that amifostine administered just before the carboplatin infusion and 2 to 4 hours thereafter is associated with a significant increase in the terminal half-life of the ultrafiltrable platinum species (e.g., in patients with a creatinine clearance less than 80 mL/min the platinum half-life increased from 4.2 to 5.6 hours with the addition of amifostine). In patients with good renal function, the impact of the increase in terminal half-life was associated with a minimal effect on the AUC. However, patients with impaired renal function experienced significant increases in the AUC of the ultrafiltrable platinum species (80).

Special Applications. Patients with advanced ovarian cancer have been treated with intraperitoneal carboplatin in doses ranging from 200 to 650 mg/m² (81). Pharmacologic studies have demonstrated that serum concentrations are equivalent between intravenous and intraperitoneal carboplatin regimens, but IP administration results in more than ten times the concentration in the peritoneal cavity as compared to IV administration (82). However, cisplatin may be a better choice for intraperitoneal delivery in that it appears to have significantly better penetration into tumor masses than carboplatin (83). Several early phase trials show potentially promising results (15,84); however, there is a need for phase 3 research

to determine the possible efficacy of IP carboplatin and trials to determine the optimal dosing schedule.

Because of its relative lack of nonhematologic side effects, carboplatin has become the platinum analog of choice for bone marrow transplantation regimens. A regimen developed at Loyola University that consists of high-dose carboplatin combined with cyclophosphamide, mitoxantrone, and autologous bone marrow support was selected for an intergroup phase 3 study of high-dose versus standard-dose chemotherapy for ovarian cancer patients with low-volume, persistent disease following primary chemotherapy (GOG-164). Although this study was closed in May 1999 because of inadequate patient accrual, the high-dose regimen was well tolerated among the 24 patients entered to the trial. With adequate hydration and mannitol diuresis to prevent nephrotoxicity, nonhematologic side effects were predominantly mucositis, ototoxicity, and diarrhea (77).

Cisplatin

Chemistry. Cisplatin (Platinol, *cis*-diamminedichloroplatinum) is a primary drug in the treatment of advanced cancer of the ovary, cervix, and endometrium. It has the molecular formula PtCl₂H₂N₂ (molecular weight = 300.1). It is a planar inorganic heavy metal complex containing a central atom of platinum surrounded by two chloride atoms and two ammonia molecules in the *cis* position. It is soluble in water at a concentration of 1 mg/mL. Only the *cis*-isomer is therapeutically active.

Mechanism of Action. Cisplatin's interaction with DNA is probably its primary mode of action. The antitumor effect of cisplatin has been correlated with binding to DNA and the production of intrastructural cross links and formation of DNA adducts, similar to carboplatin (58,85). Intrastrand cisplatin adducts can cause changes in DNA conformation that may affect DNA replication (86). Platinum DNA adduct levels have been measured in patients' leukocytes and correlated with clinical response (85).

Mechanisms of cisplatin drug resistance is an area of concentrated research. Methods by which tumor cells may develop resistance to platinum agents include decreased drug accumulation, increased glutathione levels, enhanced DNA repair, and increased capacity to tolerate DNA damage (86). Platinum resistance is related to expression of excision repair proteins, one of which (ERCC-1) has been identified as playing a critical role in the synergy of gemcitabine and cisplatin. Phase 2 data suggest that gemcitabine may reverse cisplatin resistance, as gemcitabine-cisplatin combination therapy was active in platinum-resistant ovarian cancer patients (87). Mechanisms of resistance also include the increased inactivation of thiol-containing proteins such as glutathione and glutathione-related enzymes, a deficiency in mismatch repair enzymes (e.g., hMHL1, hMSH2), and decreased drug accumulation due to alterations in cellular transport (50).

Drug Disposition. Cisplatin demonstrates a triphasic disappearance curve with a $t_{1/2\alpha}$ of 20 minutes, a $t_{1/2\beta}$ of 48 to 70 minutes, and a terminal-phase half-life of 24 hours (88). The first two phases of disappearance represent clearance of free drug from the plasma, and the third phase is probably removal of drug from the plasma proteins. The ratio of cisplatin to total free platinum in plasma has a great deal of interpatient variability, from 0.5 to 1.1 after a dose of 100 mg/m². Three hours after a bolus injection and 2 hours after a 3-hour infusion, 90% of the plasma protein is bound to the platinum in cisplatin, not the cisplatin itself. The complexes between albumin and platinum are slowly eliminated with a minimum half-life of 5 days or more (89). Ninety percent of the drug is removed by renal mechanisms (i.e., glomerular filtration and

tubular secretion), and less than 10% is removed by biliary excretion. Fecal excretion appears to be insignificant. Platinum is present in tissues for as long as 180 days after the last administration. There is a potential for accumulation of ultrafilterable platinum plasma concentrations whenever cisplatin is administered on a daily basis, but not when dosed on an intermittent schedule.

Administration and Dosage. Cisplatin may be administered intravenously or intraperitoneally. Cisplatin should be mixed only in solutions containing 0.9% or more sodium chloride, because drug stability is directly related to the concentration of the salt. When admixed with dextrose-containing solutions, by chromatographic analysis, the drug appears to be relatively unstable, with decomposition evident by 2 hours (90). Platinum can also form significant, colored complexes if directly admixed with mannitol and stored for 2 to 3 days (91). Short-term (<24 hour) admixtures, however, have been successfully used. Needles or intravenous sets containing aluminum should not be used in the preparation or administration of cisplatin, because this drug rapidly reacts with aluminum, resulting in a loss of drug potency and the formation of a black precipitate (92).

To protect against nephrotoxicity, it is critical that a high urinary output be maintained during cisplatin therapy. Several methods of accomplishing this have been recommended; however, the most widely practiced method involves prehydration and mannitol diuresis (93). If cisplatin is administered in a hospital setting, patients should receive hydration with 1 to 2 L of fluid prior to cisplatin. Mannitol diuresis is accomplished by diluting the cisplatin in 2 L of normal saline containing 37.5 g of mannitol. The solution is then infused over 6 to 8 hours. Adequate hydration and urinary output should be maintained during the next 24 hours. A safe outpatient procedure using concurrent mannitol that appears to prevent serious nephrotoxicity has also been reported (94). The desired dose of cisplatin plus 50 g mannitol is diluted to 1 L with 5% dextrose plus 0.45% sodium chloride, USP. This solution may then be infused at a rate of no greater than 1 mg/min. For patients with known cardiac disease, the dose may be placed in 200 mL of a 10% mannitol solution and infused at a rate of no greater than 1 mg/min. This is followed by 200 mL of additional 10% mannitol. An alternative is to add the drug to 400 mL of 10% mannitol that is then brought up to a 1-L volume with normal saline containing 3 g of magnesium sulfate and administered intravenously over 1 hour (95).

IP cisplatin administration and nursing guidelines are described in detail elsewhere (96,97), using the GOG-172 regimen, adapted to a 3-hour paclitaxel infusion (IV paclitaxel 135 mg/m² over 3 hours day 1 + IP cisplatin 100 mg/m² day 2 + IV paclitaxel 60 mg/m² day 8). A totally implantable device (intravenous port, such as single-lumen venous-access catheter: 9.6F, Port-A-Cath or Bardport) is surgically placed in the intraperitoneal space at least 2 days before cisplatin administration. Placement can be done at the time of surgery or postoperatively (e.g., laparoscopically). It is important to note that peritoneal or fenestrated catheters can lead to fibrous sheath formation, small bowel obstruction, and perforation and should be avoided (98). Day 2 IP administration requires that cisplatin be mixed in 1 L of normal saline and then warmed to body temperature. The 1-L cisplatin solution is instilled as rapidly as possible into the intraperitoneal space via the catheter, and should be followed by up to 1 additional liter of saline to the point of mild abdominal discomfort. The cisplatin solution is allowed to remain in the intraperitoneal cavity (i.e., the fluid is not drained). Concurrently, at least 1 L normal saline must be administered IV along with 40 g mannitol to ensure a brisk diuresis to eliminate the cisplatin. Since cisplatin has the potential to be highly emetogenic, it is important to consider an aggressive antiemetic regimen (96,99).

Retrospective analysis by Levin and Hryniuk (100) strongly suggests that the cisplatin efficacy against ovarian cancer is directly correlated with cisplatin dose intensity (i.e., mg/m²/week). Typical high-dose regimens include 20 mg/m² daily for 5 days repeated every 3 weeks, 100 to 120 mg/m² IV every 3 to 4 weeks, or 100 mg/m² on day 1 and day 8 repeated every 20 days (101,102). Holleran and DeGregorio (103) prepared an excellent review of high-dose (200 mg/m²/course) cisplatin. Dose-limiting toxicities with the higher dose regimens include severe, relatively irreversible neurotoxicity and myelosuppression. Responses have been seen in conventional-dose cisplatin-refractory patients, but they generally are of relatively short duration.

Side Effects and Toxicities. Dose-related nephrotoxicity is the major dose-limiting toxicity of cisplatin. It is manifested by renal tubular damage resulting in an elevation of the BUN or serum creatinine. The peak detrimental effect on renal function usually occurs between the 10th and 20th days after treatment. The renal damage is usually reversible. Patients concomitantly receiving gentamicin and cephalothin have been shown to be at greater risk of developing acute renal failure (104).

Madias and Harrington (105) have characterized the renal damage of cisplatin as being similar to mercury nephrotoxicity. Pathologically, renal tubular necrosis, degeneration, and interstitial edema without glomerular changes are observed. Although clinically overt renal toxicity may be common, it is usually reversible. However, some degree of long-term damage is likely. The renal-protective effect of hydration and mannitol is well established in animals and humans, and renal impairment can be prevented (94).

Ototoxicity, manifested by high-frequency hearing loss (above the frequency of normal speech), may be seen in as many as 30% of patients treated with cisplatin (106). Hearing impairment may be dose related and can be unilateral or bilateral. Occasional tinnitus (but not vestibular dysfunction) has been reported. The ototoxicity may be partially reduced by adequate hydration and the use of mannitol diuresis. Patients with lower than average threshold before chemotherapy with cisplatin were more likely to experience greater threshold shifts (106).

Neurotoxicity can be a dose-limiting side effect of cisplatin, particularly with high-dose regimens (107). The range of cisplatin-induced neurologic deficits includes peripheral sensory neuropathy, ototoxicity, autonomic neuropathy manifested by orthostatic hypotension and gastric paresis, Lhermitte's syndrome, and rarely focal encephalopathy, often accompanied by cortical blindness. Peripheral neuropathy is by far the most common cisplatin-induced neurotoxicity. Neurotoxicity is dose dependent, with symptoms typically developing after cumulative doses of 300 mg/m² or greater. A review of published literature (108) found that neurotoxicity occurred in 85% of patients at cumulative doses of 300 mg/m² or greater, but occurred in only 15% of patients who had received a cumulative dose below this level. Initial symptoms are usually numbness and tingling in the distal fingers and toes. If cisplatin is continued, proximal extension of the peripheral neuropathy occurs, and the sense of joint position becomes impaired, resulting in more severe neurologic symptoms, including ataxia, gait disturbances, loss of manual dexterity, and wheelchair dependency. Symptoms may begin and progress up to 4 or more months after discontinuation of cisplatin. In 30% to 50% of patients, cisplatin neuropathy is irreversible.

Early clinical data suggest that a number of investigational agents may ameliorate cisplatin-induced neurotoxicity (107). Agents that have been associated with positive preclinical results include ORG2766 (109), an adrenocorticotropic hormone (ACTH) analog, and the sulfhydryl-based compounds amifostine and glutathione. Only amifostine has been associated with a significant reduction of grades 2 and 3 neurotoxicity in the setting of an adequately designed phase 3 trial

(110). Further development of a neuroprotective agent, such as amifostine, could significantly enhance the clinical effectiveness of cisplatin, enabling dose-intensive therapy and greater cumulative doses to be delivered to more patients with sensitive tumors. In 2003, the GOG initiated a phase 3 trial of low-dose, intravenous bolus amifostine three times weekly to reverse grade 2 or greater peripheral neuropathy (GOG-192).

Symptomatic hypomagnesemia frequently occurs with cisplatin. In a study to determine the effects of magnesium supplementation on cisplatin-induced hypomagnesemia, the administration of magnesium (oral and intravenous) with cisplatin to one group of patients produced less renal tubular damage and no compromise in efficacy than that seen in a group not supplemented with magnesium (111).

Without adequate antiemetic therapy, most patients who receive cisplatin experience nausea and vomiting. This reaction may be severe and usually starts within the first hour after treatment and may persist for 24 to 48 hours. Delayed nausea and vomiting, lasting from 3 to 5 days, also may occur. The combination of a 5-HT₃ inhibitor (e.g., ondansetron or granisetron) with dexamethasone (10 to 40 mg IV) has reduced the incidence of severe nausea and vomiting by as much as 75% (112). Delayed nausea and vomiting can be eradicated by continuation of oral low-dose dexamethasone (with or without a 5-HT₃ inhibitor) for the first 5 days after platinum treatment (113). Other less effective antiemetic regimens to prevent cisplatin-induced nausea and vomiting include prochlorperazine, dexamethasone, and lorazepam; metoclopramide and dexamethasone; metoclopramide and methylprednisolone; or metoclopramide and lorazepam (72,114).

Anaphylactic hypersensitivity reactions consisting of tachycardia, wheezing, hypotension, and facial edema occurring within a few minutes of IV administration have occurred occasionally after a dose of cisplatin given to previously treated patients (115). These hypersensitivity reactions have been controlled with corticosteroids, epinephrine, or antihistamines. Wiesenfeld et al. (116) reported successful retreatment with cisplatin after apparent allergic reactions in two patients. *In vivo* and *in vitro* tests in one patient could not demonstrate an immunologic basis for the initial reaction. Both patients were successfully rechallenged with cisplatin after only diphenhydramine pretreatment. This suggests a nonallergic cause of the acute hypersensitivity reactions occasionally seen with platinum.

Myelosuppression occurs in 25% to 30% of patients receiving the recommended dose, and is more pronounced at higher doses. Coombs-positive hemolytic anemia also occurs as a result of cisplatin treatment. Cisplatin-induced anemia has been shown to respond to recombinant erythropoietin (117).

Drug Interactions. When cisplatin is given in combination with other agents, the order of drug sequence can affect the severity of drug-induced myelosuppression. Rowinsky and Donehower (118) conducted a phase 1 study of sequential escalating doses of paclitaxel and cisplatin therapy and determined that myelosuppression was more severe when cisplatin administration preceded paclitaxel than when given after paclitaxel. Another phase 1 study was conducted to evaluate the effects of drug sequence of treatment with cisplatin in combination with topotecan (119). This study also found a significantly higher incidence of myelosuppression when cisplatin was administered first.

Cisplatin-induced nephrotoxicity should be considered whenever this agent is given prior to or in combination with other cytotoxic drugs that are cleared by renal elimination (e.g., bleomycin, ifosfamide, etoposide, methotrexate). Cisplatin reduces the renal clearance of these agents, resulting in an increased accumulation of these drugs. Yee et al. (46) observed markedly reduced bleomycin clearance in children

who had received six courses of a regimen including cisplatin (cumulative dose 300 mg/m²). In another case report, fatal bleomycin pulmonary toxicity occurred in a patient with cisplatin-induced acute renal failure (47).

Cisplatin is directly inactivated by mesna and amifostine (50). The FDA has approved amifostine to reduce the cumulative renal toxicity associated with repeated administration of cisplatin in patients with advanced ovarian cancer. In a phase 3 randomized study of ovarian cancer patients, amifostine treatment, prior to IV cisplatin plus cyclophosphamide, did not appear to reduce cisplatin's anticancer activity (120). However, there are only limited data in other chemotherapeutic settings, and the FDA recommends that amifostine should not be administered to patients in settings where chemotherapy could produce a significant survival advantage or cure except in a clinical trial (121).

Special Applications. The efficacy of cisplatin can be increased significantly in patients with stage III, optimal disease (i.e., <1 cm² residual tumor) epithelial ovarian cancer when it is administered by the IP route as part of a primary, combination chemotherapy regimen. A pivotal phase 3 trial (GOG-172) performed by members of the GOG determined that the IP administration of cisplatin 100 mg/m² (on day 2, preceded by IV paclitaxel 135 mg/m² over 24 hours on day 1 and followed by IP paclitaxel 60 mg/m² on day 8, every 3 weeks for six cycles) was associated with a highly significant 16-month increase in overall survival as compared with the standard treatment arm (IV cisplatin 75 mg/m² plus IV paclitaxel 135 mg/m² over 24 hours every 3 weeks for six cycles) in patients with advanced, optimal ovarian cancer (4). Despite the higher incidence of toxicity in the IP arm, these effects appear to be of short duration, as patients treated IP and IV reported equivalent quality of life 1 year post-treatment (8). As a result, the National Cancer Institute issued a Clinical Announcement on January 5, 2006, recommending IP therapy as the referred treatment for optimal, advanced ovarian cancer (122).

Intraperitoneal therapy is not recommended for patients who have suboptimal cytoreductive surgery (i.e., >1 cm in largest diameter of a tumor nodule), because IP cisplatin (as well as other cytotoxic agents) only penetrates a few millimeters into tumor plaques (16). Additional considerations regarding the appropriate patient selection for consideration of IP therapy are discussed in detail elsewhere (96,97,123).

Multiple phase 3 studies have shown that cisplatin-based chemotherapy as an adjunct to radiation therapy improves survival in cervical cancer patients (22,124,125).

Cyclophosphamide

Chemistry. Cyclophosphamide (Cytosan, Neosar, CTX, CPM, and Endoxan) is an alkylating agent that before the advent of paclitaxel was used in the primary chemotherapy of advanced, epithelial-type ovarian and endometrial cancer. At this time, it is uncommonly used in the treatment of gynecologic cancers because of the more effective agents currently available (e.g., paclitaxel). It is occasionally used in the third-line treatment of ovarian cancer and as a second-line agent in the treatment of choriocarcinoma. It is a cyclic phosphamide ester of nitrogen mustard and is referred to chemically as 2-[bis-(2-chloroethyl)amino]tetrahydro-2H-1,3,2-oxazaphosphorine 2-oxide monohydrate. Its molecular weight is 279.1. The monohydrate is unionized and lipid soluble; in normal saline or water, it is soluble to a maximum of 4% at room temperature.

Mechanism of Action. Cyclophosphamide, a bifunctional substituted nitrogen mustard, was synthesized in 1958 in an attempt to achieve greater selective toxicity for tumor tissue. The N-methyl moiety of nitrogen mustard is replaced with a cyclic phosphamide group, resulting in a stable, inactive

compound. The bis-(2-chloroethyl) group cannot ionize until the cyclic phosphamide is opened at the phosphorus-nitrogen linkage.

Activation of cyclophosphamide is a multistep process. The liver microsomal P450 mixed-function oxidase system converts the parent drug to 4-hydroxycyclophosphamide. This metabolite exists in equilibrium with the acyclic tautomer, aldophosphamide. These compounds may be further oxidized by hepatic aldehyde oxidase to the inactive metabolites of carboxyphosphamide and 4-ketocyclophosphamide. Nonenzymatic conversion to the cytotoxic compounds of phosphoramidate mustard and acrolein occurs in susceptible peripheral tissues.

Most of the alkylating agents, like cyclophosphamide, are bifunctional, which facilitates their reaction with two cellular molecules. Accordingly, they can cross link the two opposite strands of DNA to give an interstrand cross link, react with two sites on the same strand (intrastrand cross link), or cross link DNA to protein. The latter type of lesion is generally considered to be innocuous, but the relative significance of the other cross links is still in contention. DNA intrastrand cross links are more frequent than interstrand cross links and are more often considered to be the critical lesions.

These two classes can be differentiated by the structure of the cross links in DNA. Generally, the entire mustard is involved in the cross link, with the two mustard "arms" linked usually to the N7 position of guanine. Because these guanines can be separated by several bases in DNA, the linkages represent particularly bulky lesions.

Drug Disposition. After IV administration, approximately 15% of the drug is excreted unchanged in the urine and the remainder as metabolites. The plasma half-life of the parent compound after doses of 6 to 80 mg/kg appears to range from 4.0 to 6.5 hours (126). Approximately 50% of the alkylating metabolites (but not parent drug) is bound to plasma proteins.

Although cyclophosphamide is exclusively excreted by the kidneys, because of the unionized nature of the intact drug molecule, tubular reabsorption is avid. Hepatic inactivation appears to be the major mechanism of active drug elimination. The mean renal clearance of intact drug is approximately 11 mL/min, or 15% of creatinine clearance, but renal elimination remains the major route of disposition of the more polar, less lipid-soluble metabolites (127). There can be significantly prolonged retention of active (alkylating) metabolites in patients with severe renal failure, and doses should be adjusted accordingly.

Dosage. Cyclophosphamide is active in many different types of malignancies. The dosing schemes are numerous and depend on the particular disease. Two general categories of treatment schedules exist. In the method generally used to treat ovarian and endometrial cancers, an intermediate dose (600 to 1,000 mg/m²) is given all at once over a short period. This treatment approach usually involves other drugs, such as cisplatin, carboplatin, or doxorubicin, whose additive toxic effects must be considered in selecting the dose and frequency of cyclophosphamide administration. Adequate hydration for 72 hours before and following high-dose treatment with cyclophosphamide is recommended to reduce cyclophosphamide-induced hemorrhagic cystitis (128).

Side Effects and Toxicities. Myelosuppression consisting primarily of leukopenia is the usual dose-limiting toxic effect of cyclophosphamide. Both the nadir and time of bone marrow recovery are rapid at 8 to 14 and 18 to 21 days, respectively. Although this drug has long been considered to be "platelet sparing," significant thrombocytopenia can also occur at very high doses (>1.5 g/m²).

Acute, sterile hemorrhagic cystitis is an infrequent toxic manifestation but is occasionally dose limiting. It is understandably more common in poorly hydrated or renally com-

promised patients. The onset of this complication may be delayed from 24 hours to several weeks. It is detected by gross hematuria or a microscopic hematuria of greater than 20 erythrocytes per high-power field. The bleeding may persist but is usually transient. Prophylactic hydration with intake of at least 3 L/day appears to offer the best protection. With continued therapy, patients characteristically develop a fibrotic "small bladder," and urinary frequency may become a permanent problem. There is a definite increase in the risk of bladder cancer in these patients. The availability of the sulfhydryl mesna as a prophylactic treatment of patients at high risk for developing cyclophosphamide-induced cystitis has almost completely eliminated this side effect.

A syndrome of inappropriate antidiuretic hormone (SIADH), or "water intoxication," has been reported after cyclophosphamide treatment. This is more common with IV doses greater than 50 mg/kg and is both a limitation to and consequence of fluid loading (129). Alopecia occurs to some degree in all patients receiving cyclophosphamide and is significant in at least half of all patients treated. Regrowth of hair may occur even with continuing treatment. Gastrointestinal problems are more common with high doses given orally. Anorexia, nausea, and vomiting are all common reactions, but they are usually controlled with IV antiemetic regimens. A rare pulmonary toxic effect has been reported with a pneumonitis picture similar to "busulfan lung." The typical clinical presentation is that of an interstitial pneumonitis, usually occurring after long-term and continuous low-dose therapy (130). The onset of symptoms is insidious. Pathologically, there can be alveolitis with eventual fibrosis and atypical type II pneumocytes. Steroids may be beneficial. Other toxic effects include testicular atrophy, sometimes with reversible oligospermia and azoospermia. Amenorrhea also has been reported. As with all alkylating agents, drug-induced congenital abnormalities are possible. With high-dose therapy used for bone marrow transplant (120 to 180 mg/kg), cyclophosphamide-associated cardiac toxicity has been reported (131).

Special Precautions. It is important to keep the patient well hydrated during cyclophosphamide therapy to reduce the potential for hemorrhagic cystitis. It is advisable to administer at least 1 L of additional IV fluids (usually normal saline) to assure an adequate urine volume to excrete the cyclophosphamide metabolite acrolein, which can otherwise alkylate bladder mucosa and cause hemorrhagic cystitis. The patient should be instructed to drink at least eight glasses of fluid daily during the 2 days after cyclophosphamide administration. In patients prone to developing cystitis, consider administering prophylactic IV mesna, a sulfhydryl-containing compound that can neutralize acrolein.

Drug Interactions. Cyclophosphamide must be metabolized to be active. Although some cyclophosphamide may be activated by phosphatases and phosphamidases peripherally, most of the drug is metabolized by microsomal enzymes in the liver (132). These enzymes may be activated by drugs like phenobarbital or inhibited by drugs like proadifen (SKF 525A). Because active and toxic metabolites are generated by the reactions of these enzymes and cyclophosphamide, many potential drug interactions may exist.

Barbiturates and other inducers of hepatic microsomal enzymes, such as phenytoin and chloral hydrate, may increase the rate of hepatic conversion of cyclophosphamide to its toxic metabolites. Similarly, cyclophosphamide may block the metabolism of barbiturates, increasing sedative effects. Although the clinical significance of these reactions is not clear, cyclophosphamide toxicity may be increased by the H₂-histamine blocker cimetidine (133). Cimetidine, but not ranitidine, may increase cyclophosphamide's myelotoxicity through an increase in the concentration · time product of its active metabolites (e.g., 4-hydroxycyclophosphamide and phosphoramidate mustard) (134). Thus, H₂-blockers like ranitidine

may be safer to use than cimetidine when high doses of cyclophosphamide are administered.

Dactinomycin

Chemistry. Dactinomycin (actinomycin D, ACT-D, Cosmegen) has been shown to be active in the treatment of patients with germ cell tumors of the ovary and endometrium and of gestational trophoblastic disease (135,136). It has a molecular weight of 1,255 and an empiric formula of $C_{62}H_{86}N_{12}O_{16}$. The drug is an antitumor antibiotic isolated from *Streptomyces parvulus*. The molecular structure includes two peptide loops linked to a three-ring chromophoric phenoxazone ring system (actinomycin). The drug is highly soluble in water, forming an amber- to gold-colored solution.

Mechanism of Action. Dactinomycin becomes anchored into or around a purine-pyrimidine base pair in DNA by intercalation. DNA-dependent ribosomal RNA synthesis and new messenger RNA synthesis is inhibited. The peptide loops appear to allow tight drug binding to DNA because the actinomycin (phenoxazone) moiety alone is inactive. This can occur adjacent to any G-C pair in DNA.

Bound dactinomycin molecules dissociate very slowly from DNA owing to electrostatic interactions of the cyclic peptide rings with each strand of the DNA double helix. This process, which stabilizes the intercalative interaction, appears to be crucial for cytotoxicity.

Dactinomycin on a molar basis is one of the most potent antineoplastic agents available. The drug possesses some hypocalcemic activity, similar to mithramycin. Although maximal cell killing is observed in the G_1 phase, the cytotoxic action is thought to be primarily cell cycle nonspecific. Actively proliferating cells are more sensitive than quiescent cells to the lethal effects of the drug (137).

In that dactinomycin is a natural product, it is not surprising that the primary mode of tumor cell resistance to dactinomycin is mediated through overexpression of P-glycoprotein (138).

Drug Disposition. Tattersall et al. (139) studied the pharmacokinetics of radiolabeled [3H]dactinomycin in patients, and the drug appeared to be only minimally metabolized and was concentrated in nucleated cells. There was a greater drug uptake into bone marrow than in plasma. Drug penetration into the central nervous system was not observed. Urinary and fecal recovery totaled only 30% each after 9 days, and there was significant drug retention in lymphocytes and granulocytes. This may explain the prolonged terminal plasma half-life of 36 hours observed after single dactinomycin doses. There appears to be little metabolism because approximately 90% of excreted drug is collected as the intact molecule. Some monolactone forms of dactinomycin are recovered in the urine.

Using a more specific radioimmunoassay, a much shorter dactinomycin half-life is described ($t_{1/2\alpha} = 0.78$ minutes, $t_{1/2\beta} = 3.5$ hours) (140). The discrepancies between these and Tattersall's findings reflect the differences in the assays used.

Administration and Dosage. Dactinomycin is administered intravenously by slow IV push or, preferably, into the tubing of a freely running IV solution. A 5- to 10-mL flush of 5% dextrose in water (D_5W) or normal saline is recommended before and after IV push administration to ensure vein patency and to flush any remaining drug from the tubing.

Dactinomycin is commonly given intravenously in short "pulse" doses of 500 $\mu\text{g}/\text{m}^2$ daily for as long as 5 days in adults. The dose for each 2-week cycle should not exceed 15 $\mu\text{g}/\text{kg}/\text{day}$ or 400 to 600 $\mu\text{g}/\text{m}^2/\text{day}$ for 5 days.

A wide variety of dosing regimens have been employed. Several clinical studies have documented equal efficacy and toxicity for single-dose dactinomycin regimens (141,142). In nonmetastatic gestational trophoblastic cancer, a single IV dose of 1.25 mg/m^2 every 14 days produced a 99% remission

rate after four courses of therapy (142). Compared with five divided doses of 500 $\mu\text{g}/\text{m}^2/\text{day}$, the single-dose method produced slightly greater mild to moderate toxic effects.

Side Effects and Toxicities. Bone marrow depression is the usual dose-limiting toxic effect of dactinomycin. It is usually manifested 7 to 10 days after dosing. All blood elements are affected, but primarily the platelets and leukocytes are depressed. Combined with gastrointestinal reactions, myelosuppression appears to be dose limiting as well as dose dependent (143). Immunosuppression is another well-known effect of dactinomycin. Patients should not receive this drug during viral infection because of the risk of developing disseminated disease.

Occasional gastrointestinal consequences, such as vomiting, can severely represent the acute dose-limiting toxic effects of dactinomycin. Vomiting can persist for 4 to 20 hours, but it can be controlled by combination antiemetic regimens (144). Mucositis can also be severe. It is characterized by severe oral ulcerations and diarrhea in 30% of patients. Reversible alopecia may occur with dactinomycin. A variety of other skin manifestations have been reported, including acneiform changes, erythema, and hyperpigmentation.

Dactinomycin is toxicologically similar to the anthracyclines and characteristically interacts with radiation therapy, producing delayed "radiation recall" skin damage. Previously irradiated or even irritated skin may become reddened and inflamed after drug administration. Frank necrosis is sometimes reported. Oral ulcers may also develop after radiation therapy. These reactions may occur months after radiation therapy. Experimentally, radiation therapy given after dactinomycin does not produce this effect.

Dactinomycin potentiates pulmonary radiation and decreases radiation tolerance by at least 20%. Reintroduction of dactinomycin following pulmonary radiation has resulted in fatal pulmonary fibrosis (145). As noted in the Special Precautions section below, dactinomycin is highly ulcerogenic if extravasated.

Special Precautions. Dactinomycin is extremely damaging to soft tissue and every effort should be made to ensure vein patency during administration. Extravasations characteristically result in immediate pain and swelling followed by indolent, poorly healing necrotic ulcers (144).

Dactinomycin is highly potent and is typically dosed in micrograms per kilogram. Doses must be calculated and prepared carefully to prevent inadvertent overdosage of this drug. No specific antidote to overdosage is known, although granulocyte colony-stimulating factors may be useful.

Dactinomycin is a potent immunosuppressant and can inhibit the effectiveness of vaccinations given after drug administration. The drug also produces radiation recall skin and soft-tissue damage if given after ionizing radiation.

Docetaxel

Chemistry. Docetaxel (Taxotere) is a semisynthetic analog of paclitaxel and has an FDA-approved indication for locally advanced or metastatic breast cancer after failure of prior chemotherapy. It is also FDA approved for locally advanced or metastatic non-small cell lung cancer after failure of prior platinum-based chemotherapy. It has also shown marked antitumor activity against a variety of solid tumors, including both platinum-sensitive and platinum-refractory epithelial ovarian cancer (146,147). The natural component of docetaxel is 10-deacetyl baccatin III, which is extracted from the needles of the European yew tree (*Taxus baccata* L.) (147). Docetaxel has a molecular weight of 861.9 and the empirical formula $C_{43}H_{53}NO_{14} \cdot 3H_2O$. Unlike paclitaxel, which uses a polyoxyl compound (Cremophor) as a diluent, docetaxel is formulated in Tween 80 and alcohol.

Mechanism of Action. In a manner similar to paclitaxel, docetaxel promotes microtubule assembly and inhibits the depolymerization of tubulin. However, compared with paclitaxel, the microtubules formed by docetaxel are more slowly reversible and there are differential effects on tau binding sites and on microtubule-associated proteins. Docetaxel-induced stabilization of microtubules halts cellular division in M phase, thereby preventing cell replication.

Drug Disposition. The pharmacokinetics of docetaxel when administered as an IV infusion lasting from 1 to 24 hours have been investigated in a number of studies (148). When administered as a typical 1-hour infusion at doses of 70 to 100 mg/m², pharmacokinetics reveal triphasic elimination with a plasma AUC of 3.13 to 4.83 mg/mL/hour, a peak plasma concentration of 2.57 to 3.67 µg/mL, and a terminal-phase plasma half-life of 13.6 hours. There is very limited renal excretion of docetaxel; the 24-hour urinary excretion was 1.4% of the dose administered. Plasma drug clearance was determined to be 21.3 L/h (149).

Administration and Dosage. All patients receiving docetaxel should be premedicated with oral corticosteroids such as dexamethasone 16 mg/day (e.g., 8 mg bid) for 3 days beginning 1 day prior to docetaxel administration in order to reduce fluid retention and the risk of hypersensitivity reactions.

Docetaxel is commercially available in single-dose 20- and 80-mg vials with accompanying diluent vials. Both the docetaxel vials and the diluent vials should stand at room temperature for approximately 5 minutes prior to mixing. The entire contents of the diluent vial should be aseptically transferred to the docetaxel vial and the resulting contents should be gently rotated for 15 seconds to promote complete mixture. The resulting concentration of docetaxel is 10 mg/mL. Foam may be present owing to the Tween 80; however, it should largely dissipate within a few minutes. The infusion solution is prepared by aseptically withdrawing the proper amount of docetaxel with a calibrated syringe and adding it to a 250-mL infusion bag or bottle containing either 0.9% sodium chloride or 5% dextrose solution to produce a final concentration of 0.3 to 0.9 mg/mL. The infusion solution should be mixed by manual rotation and inspected for particulate formation and/or discoloration. Solutions that are cloudy or that contain particulate matter should be discarded.

The recommended dose of docetaxel for salvage chemotherapy of breast cancer is 60 to 100 mg/m² IV as a continuous 1-hour infusion every 3 weeks. For non-small cell lung cancer, the recommended dose is 75 mg/m² IV as a continuous 1-hour infusion every 3 weeks. The optimal dosing schedule for docetaxel in gynecologic cancers is presently undefined. A 100-mg/m² dose administered as a 1-hour infusion every 3 weeks has been used in phase 2 trials. Other tolerable docetaxel dose schedules that have been identified in phase 1 studies are 50 mg/m²/day on days 1 and 8 every 3 weeks; 70 to 90 mg/m² by 24-hour continuous IV infusion every 3 weeks; 80 to 100 mg/m² by 6-hour infusion every 3 weeks; 14 mg/m²/day for 5 days by 1-hour infusion every 21 days (150); and 30 to 35 mg/m² weekly (151). Docetaxel has been administered in combination with cisplatin using the following schedule: docetaxel 85 to 100 mg/m² as a 1-hour IV infusion followed (3 hours after completion) by cisplatin 75 mg/m² as a 3-hour IV infusion, with cycles being repeated every 3 weeks (152).

The docetaxel dose should be reduced for patients with moderate liver impairment (see Special Precautions section below).

Side Effects and Toxicities. The major dose-limiting toxicity of docetaxel is neutropenia, which is noncumulative and generally resolves within 7 to 8 days. The combined results of early phase 2 studies of docetaxel (without steroid premedication) in ovarian cancer revealed that at a dose level of 100 mg/m² every 3 weeks, over 90% of patients developed

grades 3 to 4 neutropenia, with febrile neutropenia occurring in 8% to 44% of patients (153). The incidence of other grade 3 to 4 toxicities were stomatitis 0% to 5%, diarrhea 6% to 20%, dermatitis 4% to 8%, acute hypersensitivity reactions 7% to 12%, and fluid retention 8% to 12%. Other docetaxel-induced side effects include alopecia, anemia, neurosensory effects (paresthesia, dysesthesia, pain), and asthenia (150).

In early phase 2 studies, slow-onset (i.e., after three to five courses) cumulative fluid retention leading to peripheral or generalized edema with possible development of pleural effusion and/or ascites was a common dose-limiting toxicity. However, a 5-day premedication regimen with corticosteroids, starting the day before docetaxel administration, significantly reduces this side effect. In a retrospective analysis, severe fluid retention occurred in 20% of patients who received no premedication compared with 5% of patients who received steroid prophylaxis. Additionally, the percentage of patients who discontinued treatment secondary to fluid retention was reduced from 32% to 2% ($p < 0.00001$) with the use of a 5-day corticosteroid regimen (150). Steroid prophylaxis also reduces the incidence and severity of dermatologic side effects and hypersensitivity reactions.

The spectrum of docetaxel-induced hypersensitivity reactions is less severe than that associated with paclitaxel. In the absence of prophylactic medication, mild hypersensitivity reaction as characterized by flushing, rash, and pruritus occurs in approximately 5% of docetaxel administrations. Moderate reactions with dyspnea and/or slight hypertension occur in 8% of treatments, and severe reactions (with bronchospasm, angioedema, and/or severe hypertension) occur in less than 2% of docetaxel administrations (154). Initial symptoms of hypersensitivity to docetaxel therapy generally occur within minutes of the start of the first or second course of docetaxel and resolve rapidly with interruption of the infusion. Patients can be successfully rechallenged with docetaxel therapy following medication with corticosteroids, antihistamines, and H₂-agonists.

Dermatologic toxicities typically appear as maculopapular eruptions and desquamation generally localized to the extremities. Nail changes, including onycholysis, may also occur. Skin changes are largely self-limiting and may be alleviated with glycerin/chlorhexidine ointment or oral pyridoxine. This side effect can often be prevented with prophylactic oral steroids and H₁- and H₂-agonists (155). Recurrent skin toxicity refractory to oral prophylactic medication and pyridoxine therapy may respond to local hypothermia during docetaxel administration (156).

Special Precautions. Patients with impaired liver function have a significant reduction in docetaxel clearance and an increased risk of life-threatening side effects. Analysis of the overall safety database revealed that patients with moderately impaired liver function (defined as transaminase levels more than 1.5 times the upper limit of normal and alkaline phosphatase more than 2.5 times the upper limit of normal) have a 27% reduction in docetaxel clearance and a 38% increase in the area under the concentration · time curve (150). When compared with patients with normal liver function, patients with at least moderately impaired liver function had a significantly greater incidence of febrile neutropenia (40% vs. 16%) and toxic death (20% vs. 1.4%). Grades 3 to 4 nausea/vomiting, stomatitis, and thrombocytopenia were also increased in patients with impaired liver function (150).

The recommended docetaxel dose level for a patient with moderate hepatic impairment (defined as transaminases between 1.5 and 3.5 times the upper limit of normal and an alkaline phosphatase between 2.5 and 6.0 times the upper limit of normal) is 75 mg/m² over 1 hour. No safe docetaxel dose can be recommended for patients with greater than moderate liver impairment (157).

Special Applications. Verschraegen et al. (158) have published preliminary evidence that patients with ovarian cancer may respond to docetaxel even though they have had progression of their disease on paclitaxel. They noted a partial response rate of 37.5% in eight eligible patients. A phase 2 study conducted by the GOG of 60 patients with paclitaxel-resistant ovarian and peritoneal carcinoma observed responses in 22.4% of patients, with 5.2% achieving complete response and 17.2% achieving partial response (at a dose of 100 mg/m² IV over 1 hour every 21 days) (159). However, the 75% incidence of grade 4 neutropenia in this study suggests that further study is needed to determine the appropriate dose and schedule.

Doxorubicin

Chemistry. Doxorubicin (Adriamycin), a primary agent in the treatment of metastatic endometrial cancer and advanced ovarian cancer, is an anthracycline antibiotic obtained from *Streptomyces peucetius* var. *caesius*. It has a molecular weight of 580. The doxorubicin structure includes a water-soluble basic reducing amino sugar, daunosamine, linked by a glycosidic bond to carbon atom number 7 on the D-ring of the water-insoluble chromophore aglycone, adrimycinone.

Structural changes in the side groups of doxorubicin alter antitumor potency and pharmacokinetic properties. The aglycone is inactive, and modifications in the amino sugar substituents can also alter antitumor or toxic potency (160).

In DNA, the amino sugar projects into the minor groove and can interact electrostatically with negatively charged phosphate groups in the DNA strand to stabilize the aglycone moiety. Doxorubicin can also form complexes with iron or copper by means of the hydroquinone moieties (161). Metal-iron doxorubicin complexes may contribute to cardiotoxicity by enhancing redox cycling of the quinone moiety to produce membrane-damaging oxygen free radicals (162). Doxorubicin hydrochloride is freely soluble in water, slightly soluble in normal saline, and very slightly soluble in alcohol.

Doxorubicin also is commercially available in a polyethylene glycol (PEG)-coated (pegylated, Stealth) liposomal form (see Liposomal Encapsulated Doxorubicin section below).

Mechanisms of Action

DNA Binding. The anthracyclines, including doxorubicin, probably have several modes of action. The anthracycline portion of the molecule appears to intercalate between stacked nucleotide pairs in the DNA helix by means of P-P-type bonds (163). The drug may also bind ionically around certain base pairs of DNA (adlineation). The overall effect of this is interference with nucleic acid synthesis, specifically an inhibition of DNA synthesis (164). However, preribosomal RNA synthesis is also affected by the drug binding to DNA, preventing DNA-directed RNA and DNA transcription (165).

Mechanisms other than intercalation may also contribute to the antitumor effect of the doxorubicin molecule. The contribution of alkylation to antitumor effects has not been established.

Free-Radical Formation. Oxygen free-radical intermediates containing an unpaired electron can be formed by doxorubicin. This can react rapidly with oxygen to form superperoxide, and with hydrogen peroxide, highly reactive hydroxyl radicals can form. These radicals damage membrane lipids by peroxidation, break DNA strands by attacking ribose-phosphate bonds, and directly oxidize purine or pyrimidine bases, thiols, and amines. Free-radical mechanisms have most often been associated with cardiotoxicity.

Doxorubicin appears to be active in all phases of the cell cycle, and although maximally cytotoxic in S phase, it is not phase specific (166). Cells exposed to lethal doxorubicin concentrations in G₁ can proceed through S phase but are then

blocked and die in G₂. Higher concentrations can also produce an S-phase blockade (167).

Inhibition of DNA Topoisomerase II. Topoisomerases are enzymes capable of covalent binding to DNA, forming transient breaks in one strand (TOPO-I) or two strands (TOPO-II). This activity is highly phase dependent for G₂, and in the case of TOPO-II, normally mediates strand passage to facilitate DNA condensation or decondensation (168). Doxorubicin and other DNA intercalators inhibit the strand-passing activity of TOPO-II by increasing and stabilizing the initial enzyme-DNA (cleavable) complexes. This leads to protein-linked DNA double-strand breaks that are roughly proportional to the cytotoxic potency of the drug *in vitro* (169).

Drug Disposition. Doxorubicin pharmacokinetics are usually described using a two-compartment or three-compartment open model. The drug is rapidly distributed in body tissues, and about 75% of the drug is bound to plasma proteins, principally albumin (170). In the blood, the free doxorubicin fraction depends on the hematocrit, with more free drug being available in patients with a reduced hematocrit (171). The avid binding to DNA is believed to explain the prolonged terminal elimination half-life of 30 to 40 hours, the large apparent volume of distribution of up to 28 L/kg, and the incomplete (50%) total recovery of drug in urine, bile, and feces (172). Human tissues with high drug concentrations (in descending order) include liver, lymph nodes, muscle, bone marrow, fat, and skin (173). The drug does not distribute into the central nervous system.

There is a significant distribution of doxorubicin into human breast milk (174). Doxorubicin levels of 0.24 μM and 0.2 μM of doxorubicinol have been measured in human milk. They produce cumulative AUCs in breast milk of 9.9 and 16.5 μM · hour, respectively. Both of these values were greater than concurrent plasma AUC values. However, doxorubicin does not appear consistently to pass the placenta. Except for one study reporting low drug levels in placental blood of 0.78 to 1.19 nmol/g and no drug in cord blood plasma, several other trials detected no drug in amniotic fluid after doxorubicin administration to pregnant patients (175,176).

Doxorubicin is extensively metabolized and eliminated primarily as glucuronide conjugates of the parent aglycone or its hydroxylated congener doxorubicinol. The conjugated metabolites are exclusively excreted in the bile and feces. Overall, biliary excretion accounts for about 40% of an administered dose (177). Approximately 42% of the biliary drug is parent doxorubicin, 22% is doxorubicinol, and 36% is other metabolites (177). Only 5% to 10% of the administered drug is excreted in the urine as doxorubicin (40%), doxorubicinol (29%), and other metabolites (31%).

In liver disease, patients with cholestasis have delayed doxorubicin clearance and experience exaggerated toxic reactions from standard doses (178). However, hepatoma patients with cirrhosis or simple hepatocellular enzyme elevation appear to have normal doxorubicin clearance and toxic effects from standard doses (179). Although obesity reduces clearance of doxorubicin in adult cancer patients (180), there were no differences in doxorubicin toxicity between normal, mildly obese, and obese patients.

There is some evidence that repeated doxorubicin dosing alters pharmacokinetics (181). In these reports, doxorubicin levels were lower after repeated dosing, which suggests increased drug clearance. However, because neither toxicity nor response rates are altered, the clinical significance of these observations has not been established. Age may also be a factor. In one trial, the highest clearances of doxorubicin were observed in younger patients (182). These observations suggest that higher peak doxorubicin levels may be achieved in older patients.

TABLE 16.2**INTRAVENOUS DOSING GUIDELINES FOR DOXORUBICIN**

Dose (mg/m ²) ^a	Intravenous method	Schedule	Average cumulative tolerable dose (mg/m ²) ^b
60 to 75 ^c	Bolus	Every 3 weeks	550
30	Bolus	3 successive days, every 3 weeks	550
20	Bolus	Weekly	750
60	96-h infusion	Every 3 to 4 weeks	1,000

^aLower doses should be administered to patients with hepatobiliary dysfunction and for poor bone marrow reserve or performance status.

^bRepresents average total cumulative dose tolerated without clinical evidence of doxorubicin cardiotoxicity.

^cAllows for greater dose intensity in breast cancer.

The hepatic extraction ratio for doxorubicin in humans is 0.45 to 0.50, and systemic drug levels are about 25% lower with intra-arterial administration compared with IV dosing (183). Several studies have shown that the pharmacokinetics of intra-arterial drug are similar to those after IV doses (173). The relatively low hepatic extraction rate and similar overall disposition patterns provide little pharmacokinetic rationale for intra-arterial administration as a means of localizing doxorubicin effects to the liver (184).

Administration and Dosage. Short IV push infusions and IV bolus injections have been used with doxorubicin. A slow IV push over several minutes with constant monitoring of the patient and blood return can help minimize the chance of serious tissue damage occurring because of extravasation. A 5- to 10-mL flush of normal saline or D₅W before and after administration is strongly recommended to test vein patency and flush any remaining drug from the tubing. Alternatively, injection into the side port of a running IV infusion has also been recommended. The patient should be asked to report immediately any change in sensation during the administration. Old venipuncture sites or infusion sites previously used for administering blood, antibiotics, or other medications should not be used to administer doxorubicin. Heparin locks (unless recently inserted) are not recommended because the drug is chemically incompatible with sodium heparin.

Prolonged infusions increase the incidence and severity of stomatitis and dermatologic reactions. Administration through tunneled central venous catheters or indwelling vascular access ports is mandatory for all prolonged infusions. Careful patient and site monitoring are required because doxorubicin extravasation from central vascular access devices can occur.

Numerous dosing schedules have been reported. The individual doxorubicin dose depends on clinical variables, including the cumulative dose administered to date and the potential for interaction with other drugs or radiation (Table 16.2). As a single agent, doses of 60 to 75 mg/m² as a single intravenous injection have been used and repeated no more often than every 3 weeks. An alternative scheme uses 20 to 30 mg/m² given daily for 3 consecutive days and repeated in 3 weeks (185). When used in combination therapy, the most commonly used dosage is 40 to 60 mg/m² given as a single intravenous injection every 21 to 28 days.

Both the dose and rate of dosing (dose intensity) can have therapeutic impacts for different agents and tumors (186). Clinical studies with doxorubicin show that greater dose intensity is associated with enhanced response rates in breast cancer (187). The doses compared in this trial were 70 mg/m² every 21 days for eight cycles versus 35 mg/m² every 21 days for 16 cycles.

Dose adjustments are required in a number of clinical settings (Table 16.3), specifically in the case of hyperbilirubinemia.

TABLE 16.3**MODIFICATIONS OF DOXORUBICIN DOSES^a**

Condition	Recommended dose modification
Prior doxorubicin	Limit total cumulative lifetime dose (by IV bolus) to 550 mg/m ² (188)
Prior chest radiation therapy	Reduce total dose limit to 300 to 350 mg/m ²
Obesity	Base dose on ideal body weight (180)
Hepatobiliary dysfunction	Reduce dose for elevated serum bilirubin (give 50% of dose for serum bilirubin of 1.2–1.9 µg/dL, and give 25% of dose for serum bilirubin ≥3.0 mg/dL) (178) Use indocyanine green disappearance rate as an indicator of doxorubicin clearance
Infusion method	Greater cumulative (total) dose may be afforded by weekly bolus doses or continuous (96-hr) infusions ^b (189)

^aAverage safe cumulative doxorubicin dose is 750 mg/m² using standard infusion schedules.

^bAverage safe cumulative doxorubicin dose is 1,000 mg/m² when administered with a 96-hr infusion schedule.

A 50% dose reduction is indicated if plasma bilirubin concentration is 1.2 to 3.0 mg/dL, and the dose must be reduced by 75% if plasma bilirubin concentration reaches 3.1 to 5.0 mg/dL.

Side Effects and Toxicities. The single acute dose-limiting toxicity for doxorubicin is bone marrow suppression. The most commonly seen dose-limiting toxicity is leukopenia, with a nadir at 10 to 14 days. Other hematologic toxicities, such as anemia and thrombocytopenia, have been reported, but they are rare and generally less severe. Recovery from myelosuppression is usually prompt, with resolution often within about 1 week after the nadir.

Doxorubicin is known to produce local skin and deep-tissue damage at the site of inadvertent extravasations (190). Ulcers may result after 33% of extravasations. The lesions undergo a slow, indolent expansion and occasionally involve tendons and other deep structures. They characteristically do not heal and are associated with prolonged local drug retention (191). Reilly et al. (190) recommend early surgical debridement, with skin grafting and tendon repair for serious infiltrations. Numerous pharmacologic antidotes have been evaluated, but few have demonstrated unequivocal clinical efficacy. The application of cold, topical dimethylsulfoxide is recommended (192).

Cardiac consequences from the drug have included acute effects, such as a rare pericarditis-myocarditis syndrome or electrophysiologic aberrations, and a total-dose-related cardiomyopathy (193). Nonspecific electrocardiographic changes during infusion or immediately afterward may be seen. These include T-wave flattening, ST depression, supraventricular tachyarrhythmias, and extra systolic contractions (194). These conduction abnormalities are generally transient, not associated with severe morbidity, and do not require dose modification.

Cardiomyopathy from doxorubicin is dose related. It presents initially as a clinical syndrome identical to classic congestive heart failure. It is usually irreversible, but symptoms can be managed with standard medical therapy involving digitalis, glycosides, and diuretics. Potential risk factors for doxorubicin cardiotoxicity include cumulative doses greater than 550 mg/m², prior mediastinal irradiation (≥ 20 Gy), age greater than 70 years, and preexisting cardiovascular diseases, such as prior myocardial infarction or long-standing hypertension (189). Anthracycline-induced cardiomyopathy can also occur 4 to 20 years after the drug is stopped at standard dose limits (195). The administration of anthracyclines incorporated into liposomes is one method that may significantly reduce the risk of cardiac toxicity (see the Liposomal Encapsulated Doxorubicin section below) (196).

At total doses under 500 mg/m², the incidence of cardiomyopathy is less than 1%; between 501 and 600 mg/m², 11% are affected; and the incidence is 30% for doses above 600 mg/m². In a retrospective cardiotoxicity study of 4,018 patient records, Von Hoff et al. (188) described an overall incidence of 2.2% for doxorubicin-induced congestive heart failure. In this analysis, there was no influence of performance status, sex, race, and tumor type on the incidence of cardiomyopathy. However, elderly patients were at greater risk even after adjustment for the normally decreased cardiac function in this group. The major determinants were the dose, the schedule of administration, and the age of the patient. A weekly doxorubicin dosing schedule was associated with significantly less congestive heart failure than an every-3-weeks dosing schedule. Continuous IV infusions over 96 hours also can significantly lessen doxorubicin cardiotoxicity (197).

Dexrazoxane (Zinecard) is a chemoprotective agent with an FDA-approved indication for reducing doxorubicin-associated cardiomyopathy in women with metastatic breast cancer who have received a cumulative doxorubicin dose of ≥ 300 mg/m² and who, in their physician's opinion, would benefit from

further doxorubicin therapy (see the Modulating Agents section below).

There is evidence that doxorubicin is a radiosensitizing or "radiomimetic" agent and can cause reactivation of tissue reactions in areas previously irradiated (198). Radiation recall reactions have also been reported in areas of previous drug infiltration. A particularly sensitive area for serious recall toxicity is the esophagus (199).

Other toxic effects are observed in rapidly proliferating normal tissues. These include marked alopecia in all hairy body areas. Stomatitis may occur at high doses and is more pronounced when the drug is given on consecutive days. It generally begins in the sublingual and lateral tongue regions as a burning sensation with noticeable erythema. The initial inflammation typically progresses to ulceration after a few days. Anal fissures or proctitis have been rarely reported. Nausea and vomiting are common but of moderate intensity. Diarrhea is rare with consecutive daily dosing, and the emetic effects are generally limited to the first day of treatment. Hyperpigmentation of the skin, especially the nail beds, may occur. Extravasations of doxorubicin are known to cause severe ulceration and soft tissue necrosis (190). Vein patency should be assured before injection and constantly monitored during administration.

As discussed later in this chapter, pegylated liposomal encapsulation dramatically alters the pharmacokinetic profile of doxorubicin and, hence, the drug's toxicity profile.

Drug Interactions. Doxorubicin is believed to interact with numerous other drugs. Most of these effects have been described only in experimental systems, and their clinical significance is, therefore, unknown. However, several potentially significant interactions have been described in cancer patients. Altered doxorubicin disposition is postulated with α -interferon, and substantial doxorubicin dose reductions are required (200). The combination of doxorubicin with H₂ antihistamines, such as ranitidine or cimetidine, may also increase toxicities significantly and necessitate drug dose reduction.

Special Applications. Doxorubicin has been investigational administered intrapleurally to patients with malignant pleural effusions (201). Doses of 30 mg were diluted in 20 mL of saline and administered by paracentesis needle as a bolus. Eight of 11 patients responded to doxorubicin, including one complete response. This response rate was superior to nitrogen mustard or tetracycline. Toxicity included pain or fever in 20% of patients and nausea or vomiting in 45% of patients. No alopecia or hematologic toxicity was reported. Markman et al. (202) combined doxorubicin (3 mg) with cytarabine (61 mg) and cisplatin (100 mg/m²) in the treatment of seven cancer patients with malignant pleural effusions. Two ovarian cancer patients responded, and no significant systemic toxicities were reported. All injections were given in 250 mL of saline, and aggressive hydration was given to counteract cisplatin nephrotoxicity.

Etoposide

Chemistry. Intravenous etoposide (VP-16) is used commonly in combination chemotherapy regimens for the treatment of patients with germ cell tumors of the ovary (136). Oral etoposide has activity as a salvage agent for refractory or recurrent ovarian cancer (203). It is a semisynthetic epipodophyllotoxin derived from the root of *Podophyllum* (the May apple plant, or mandrake). The chemical name is demethylepipodophyllotoxin 9-[4,6-O-(R)-ethylidene- β -D-glucopyranoside]. Etoposide has the molecular formula of C₂₉H₃₂O₁₃ and a molecular weight of 588.58. It is highly soluble in methanol and chloroform, slightly soluble in ethanol, and sparingly soluble in water. Because of poor water solubility, the commercial drug is dissolved in an ethanol-based cosolvent system.

Etoposide was originally synthesized from *Podophyllum embodi* (204). Structure-activity studies show that the hydroxyl group at the C-4' position is required for activity and that alterations at this site can dramatically affect activity.

Mechanism of Action. There is marked schedule dependence for etoposide cell killing, and cytotoxic effects are maximal in G₂ phase (205). There is also some activity against cells in late S phase, and the drug can halt cell cycle traverse at the S-G₂ interphase (206).

Etoposide produces protein-linked DNA strand breaks by inhibiting DNA TOPO-II enzymes (207). This normal mammalian enzyme mediates double-strand-passing activities in G₂ phase to condense or decondense supercoiled DNA (208). Drug-induced inhibition of TOPO-II is an energy-dependent process that is influenced by dose and duration of exposure.

Etoposide does not bind directly to DNA, but rather stabilizes a transition form of the DNA-TOPO-II complex (207). The number of single and double DNA strand breaks reflects the cytotoxic dose-response curve (209). Etoposide and intercalative drugs such as doxorubicin "poison" TOPO-II enzymes by stabilizing an otherwise transient form of TOPO-II covalently linked with DNA (169). Normal TOPO-II strand-passing activity is thereby blocked, and cell progression out of G₂ phase is halted (168). The production of cytotoxicity by etoposide may ultimately involve chromosomal breaks characterized as sister chromatid exchanges (210).

Another postulated etoposide mechanism involves microsomal activation to reactive intermediates capable of generating oxygen free radicals (209). Nucleoside transport is also inhibited at high drug concentrations, but whether this makes a major contribution to the antitumor effect is unknown (211).

Drug Disposition. A two-compartment open pharmacokinetic model appears to adequately describe etoposide disposition in cancer patients (212). The terminal half-life of the drug appears to be about 7 hours and is independent of the dose, route, or method of administration (213). Renal excretion appears to account for about 30% of overall drug elimination. Forty-two to 66% of radiolabeled drug is recovered in the urine, of which less than half is parent etoposide.

With standard doses of etoposide, no drug is detectable in the cerebrospinal fluid (CSF), and even after doses of 400 to 800 mg/m², CSF levels were less than 2% of concurrent plasma levels (214). Despite the low distribution of drug into the CSF, mean levels of 1.4 µg/g (range undetectable to 5.9 µg/g) have been measured in brain tumor tissue (215). The drug also distributes into myometrial carcinoma and normal myometrium, achieving levels 50% of those in the blood (216).

Biliary secretion of parent drug accounts for 2% or less of the dose, although fecal recovery of drug and metabolites is variable, ranging from 1.5% to 16.3% (217). However, patients with obstructive jaundice excrete a larger fraction of the dose in urine (46%) than do unaffected patients (35%), which suggests that there is a slight decrease in hepatic drug metabolism with a commensurate increase in renal clearance (214).

The plasma protein binding of etoposide is normally high, averaging 95% in typical patients (218). The free (unbound) fraction of etoposide can vary from 6% to 37% among patients. Patients with increased bilirubin or decreased albumin may have an increase in the free fraction even though systemic clearance is unaltered (218). Myelosuppression may also be commensurately increased in these patients. Other conditions that may decrease etoposide clearance include prior cisplatin therapy, obesity, and elevated alkaline phosphatase levels (219).

The absolute oral bioavailability of etoposide gelatin capsules ranges from 25% to 74%, with a mean of 48% (220). Some patients experience a 30% change in overall bioavailability (both increased and decreased) with repeat dosing. Neither food nor other chemotherapeutic agents appear to alter

etoposide absorption (221). Wide variations in peak levels and AUC values were also described in this trial.

Administration and Dosage. Etoposide must be diluted prior to use with either 0.5% dextrose or 0.9% sodium chloride to give a final concentration of 0.2 to 0.4 mg/mL. Etoposide should be given by IV infusion over a 30- to 60-minute period. Severe hypotension may occur if the drug is given too rapidly. Although not a vesicant, extravasation of the drug should be avoided (222). Examine all solutions for fine precipitates; mix before use. Precipitation may occur if the solution is prepared 0.4 mg/mL. Continuous infusions of etoposide have been used as a means of enhancing efficacy because of its phase-specific mode of antitumor action. Most infusions have used 5-day courses, although 72-hour infusions have also been employed (223).

Oral administration of etoposide capsules may be useful if patient compliance is high and low-emetogenic drug regimens are used. The capsules may be taken all at once to achieve the desired dose. Neither food nor other chemotherapeutic drugs appear to alter oral absorption of the drug (221). The GOG has investigated multiple trials of oral etoposide at various dosing regimens. Based on a cumulative review of these trials and schedules, it was found to be active in platinum-resistant ovarian cancer patients (overall response rate 26.8%; 7.3% clinical complete remission rate) and in platinum-sensitive patients (overall response rate 34.1%; 14.6% clinical complete remission rate) (223). One of these trials that demonstrated activity used an oral etoposide dosing schedule of 50 mg/m²/day for 21 days every 28 days with dose escalation to 60 mg/m²/day when feasible (224). Studies using similar oral etoposide dosing schedules in patients with cervical cancer and endometrial cancer failed to show significant activity in these tumor types (225,226).

The variety of doses and schedules that have been used with etoposide are presented in Table 16.4. General principles of dosing include more frequent administration to take advantage of cell cycle-dependent cytotoxicity, an approximate doubling of oral doses due to 50% bioavailability for the gelatin capsules, and significant dose reductions for combinations of etoposide with other myelosuppressive drugs or for patients with poor bone marrow reserve or poor performance status. In general, etoposide doses can be repeated every 3 to 4 weeks depending on the leukocyte count. A pharmacokinetic study in patients with obstructive jaundice showed that no significant dose reductions are needed if renal function is normal (229).

Side Effects and Toxicities. Side effects and toxicities for oral and intravenous administration of etoposide as a single agent are similar. The principal toxicity of etoposide is dose-related and dose-limiting bone marrow suppression. Leukopenia and thrombocytopenia occur, but leukopenia consistently predominates, with a nadir at approximately 16 days and with recovery usually beginning by days 20 to 22.

Gastrointestinal complaints of nausea, vomiting, or anorexia are usually minor and are more frequent with the oral preparations (230). Other adverse effects include alopecia in 20% to 90% of patients, headache, fever, and hypotension (231). Severe hypotension can occur if the drug is infused too rapidly (<30 minutes) (217). Stomatitis has been infrequently reported. Rare instances of generalized allergic reactions and anaphylaxis have occurred (232). A few episodes of cardiotoxicity, including myocardial infarction and congestive heart failure, have been described (233). Immune suppression appears to be minimal with this drug (231). Bronchospasm with severe wheezing has been rarely observed and has usually been responsive to antihistamines and glucocorticosteroids. Chemical phlebitis also has been associated with etoposide, although the reaction is most likely related to solubilizers in the diluent. Diluted solutions of etoposide are not vesicants.

TABLE 16.4

INTRAVENOUS AND ORAL DOSING SCHEDULES FOR ETOPOSIDE

Administration method	Dose		Repeat dosing interval (wk)	Clinical application
	mg/m ² /day	Days		
Short single-dose IV infusion	200–250	1	7	Single agent, small cell lung cancer
Short multiple-dose IV infusion	100	1–5	3–4	Testicular cancer
	100	1,3,5	3–4	With other drugs
Continuous IV infusion	45	1–7	3	Phase 1
	125	1–5	4	Phase 1, single agent
	30	1–5	4	With cisplatin in advanced cancer
	80	1–5	4	Phase 1, good-risk patients
	50	1–5	4	Poor-risk patients
	125	1–3	4	Adult patients with advanced cancer (227)
Oral	500	1 (24-hr)	3	Small cell lung cancer
	160	1–5	3–4	Small cell lung cancer
	50	1–21	4	Ovarian cancer (228)

For inadvertent extravasations of highly concentrated etoposide solution, hyaluronidase may be effective (234).

Neurotoxicity has been rarely reported with etoposide. This has consisted of somnolence and fatigue in 3% of patients and peripheral neuropathy in less than 1% of patients. However, the drug may exacerbate preexisting neuropathy caused by vincristine (235). Predisposing factors included advanced age, impaired nutritional status, and poor performance status. Degradation of myelin lamellae has been observed in affected nerves.

Special Applications. Despite preclinical data showing peritonitis with intraperitoneal injections, combinations of etoposide and cisplatin have been administered safely by the intraperitoneal route. Barakat et al. (236) performed a phase 2 study of three courses of intraperitoneal cisplatin 100 mg/m² plus etoposide 200 mg/m² as consolidation therapy in patients with stages II to IV epithelial ovarian cancer with negative second-look surgeries. When compared with a similar group of contemporaneous patients who did not receive consolidation therapy, the disease-free survival distribution between the two groups (using the log-rank test) was found to be significant ($p = 0.03$) in favor of consolidation therapy (236). European researchers have used a combination of etoposide 350 mg/m² IP, followed by cisplatin 200 mg/m² IP with IV sodium thiosulfate (4 g/m² bolus, followed by 12 g/m² over 6 hours) protection every 4 weeks for four to six cycles in ovarian cancer patients with either no residual disease or minimal residual disease at second-look surgery. The regimen was fairly well tolerated, although there was one study-related patient death from a bowel perforation and resulting complications. Other major clinical complications were nausea, vomiting, and the formation of intraabdominal adhesions. Grade 3 to 4 leukopenia and thrombocytopenia occurred in 30% and 6% of cycles, respectively (237).

Etoposide in combination with other chemotherapeutic agents and autologous stem cell rescue is often used in salvage therapy for germ cell tumors or metastatic trophoblastic disease. Two commonly used regimens are bleomycin, etoposide, and cisplatin (BEP) and ifosfamide, carboplatin, and etoposide (ICE) (238).

5-Fluorouracil and Floxuridine

Chemistry. 5-Fluorouracil (5-FU) is a fluorinated pyrimidine differing from the normal DNA substrate, uracil, by a fluorinated number 5 carbon (chemically, 5-fluoro-2,4(1H,3H)-pyrimidinedione). 5-FU has activity as a second-line agent in advanced ovarian and cervical cancers and, in combination with cisplatin, is used as an adjunct to radiation therapy in women with locally advanced cervical cancer. Floxuridine (FUDR) is highly similar to its prodrug, 5-FU. The discussion of FUDR in this chapter will be limited to its special application as an intraperitoneally administered agent for salvage therapy for ovarian cancer. 5-FU is light sensitive and precipitates at low temperatures or, occasionally, with prolonged standing at room temperature. It has the molecular formula of C₄H₃FN₂O₂ and a molecular weight of 130.08.

Mechanism of Action. 5-FU acts as a false pyrimidine or antimetabolite ultimately to inhibit the formation of the DNA-specific nucleoside base thymidine. There are at least three mechanisms of action: inhibition of thymidylate synthase by 5-fluoro-21-deoxyuridine-5'-monophosphate (FdUMP), the active metabolite of 5-FU; incorporation of 5-fluorouridine triphosphate (FUTP) into cellular RNA; and incorporation of FUTP into cellular DNA (239). 5-FU is a cell cycle phase-specific agent with cytotoxic effects seen maximally in S phase.

Drug Disposition. There is disagreement over whether 5-FU is eliminated by a two-compartment or three-compartment model (2,240). Fraile et al. (241) demonstrated that plasma levels of 5-FU after oral administration are quite erratic. Schaaf et al. (227) documented that the pharmacokinetic characteristics of 5-FU are nonlinear. Doubling of the dose was accompanied by a decrease in nonrenal clearance. The half-life from the high dose was twice as long as that for the low dose of 5-FU. Their data were compatible with a product-inhibition model. Yoshida et al. (242) found positive correlations between the dose and serum steady-state levels (C_{SS}) and areas under the concentration · time curves (AUCs). Patients who developed toxic reactions had greater C_{SS}s and AUCs. However, there were no correlations between serum levels and patient response to therapy.

5-FU and FUDR are extensively metabolized in the liver (hepatic metabolism can detoxify up to 80% of the total dose). However, there is no absolute documentation that patients with impaired liver function require dose reductions of 5-FU (243); however, patients should be monitored as they may be at increased risk of toxicity. As much as 15% of a dose may be found intact in the urine by 6 hours, with 90% of this excreted in the first hour. Depressed renal function does not generally require dosage adjustment for 5-FU.

5-FU distributes to all areas of body water by simple diffusion. Significant quantities of the drug may enter the central nervous system, and after 15 mg/kg given IV, CSF levels of 6 to 8×10^{-6} M are obtained after 30 minutes. These levels persist for several hours and slowly subside. Although distribution to brain tissue is less rapid, abnormal areas, such as those with neoplasms, may more readily take up drug.

5-FU achieves high and persistent levels in effusions after IV administration. Hepatic administration through the portal vein or artery also achieves high concentrations in the liver parenchyma and produces relatively low systemic levels.

Santini et al. (228) showed that therapeutic monitoring of 5-FU levels in patients with head and neck cancer can be used to improve the therapeutic index of the drug (i.e., less toxicity with maximal efficacy).

Administration and Dosage. Doses of 5-FU to be given by the IV push route do not require further dilution from the commercial solution. Vein patency should be assured before giving a dose, with a 5- to 10-mL flush of normal saline or D₅W and another flush after the dose to rinse the remaining drug from the tubing. For short infusion (less than 24 hours), the rate of administration is not critical, and the dose should be given at a rate compatible with the particular vein selected. The patient should be continuously monitored to guard against extravasation. Most doses can be conveniently given over 1 to 2 minutes in this fashion.

Continuous infusions (over 4 to 5 days) may maximize efficacy of this cycle-specific drug and lessen hematologic toxicity (244). Infusions of the drug may be added to a convenient volume of D₅W or normal saline, and each reconstituted daily dose can be administered over 24 hours. Commonly, the daily dose of the drug is added to 1 L, although volume is not critical.

Regimens reported for the use of 5-FU include the use of a loading dose, weekly IV bolus, continuous infusions over 4 to 5 days or over 6 weeks, and oral dosing. 5-FU may be administered intravenously as a bolus, rapid injection on a monthly (425 to 450 mg/m² IV on days 1 to 5 every 28 days) or a weekly schedule (500 to 600 mg/m² every week for 6 weeks every 8 weeks), or continuous IV infusion (24-hour infusion 2,400 to 2,600 mg/m² every week; 96-hour infusion 800 to 1,000 mg/m²/day; or 120-hour infusion 1,000 mg/m²/day on days 1 to 5 every 21 to 28 days) (50). Oral doses of up to 15 to 20 mg/kg/day for 5 to 8 days have been used (245). However, the efficacy of oral 5-FU has not been confirmed at this time (see the Capecitabine section above for a discussion of the oral prodrug of 5-FU).

The loading dose scheme calls for one course of 400 to 500 mg/m² (12 mg/kg; maximum of 800 mg) daily for 5 days every 28 days given as a single daily bolus injection or as a 4-day continuous infusion. This is followed by a weekly maintenance regimen. Horton et al. (246) and Jacobs et al. (247), however, strongly associated the use of the loading dose with significant morbidity and occasional fatalities, and suggested that it offers no greater antitumor efficacy over a weekly bolus injection of 15 mg/kg given IV.

Maintenance 5-FU dosing regimens include the following: 200 to 250 mg/m² (6 mg/kg) every other day for 4 days, repeated in 4 weeks (if toxicity has resolved); or 500 to 600 mg/m² (15 mg/kg), given IV weekly as a continuous infusion or bolus injection (with and without the loading dose).

By continuous infusion, higher daily doses have been successfully used, and many investigators have reported lessened hematologic toxicity and enhanced efficacy. Most of a dose is eliminated by the liver and the remainder by the kidney. Therefore, marked dysfunction in either system probably requires a dose reduction.

There are two commonly used dosing regimens for 5-FU combined with leucovorin: 370 mg/m²/day of 5-FU for 5 days plus leucovorin given as a continuous infusion of 500 mg/m²/day, beginning 24 hours before the first dose of 5-FU and continuing for 12 hours after completion of therapy; or 5-FU given at doses of 500 to 1,000 mg/m² every 2 weeks, preceded by calcium leucovorin at a dose of 20 mg/m² given as a 10-minute infusion (248).

Phase 3 studies performed by the GOG, SWOG, and Radiation Therapy Oncology Group have documented the efficacy of cisplatin/5-FU chemotherapy as an adjunct to radiation therapy in women with high-risk cervical cancer (22,124,249). The regimen used in the SWOG study was cisplatin 70 mg/m² by 2-hour IV infusion on day 1 of radiation followed by 5-FU 1,000 mg/m²/day by 96-hour continuous infusion on days 1 to 4 every 3 weeks for four cycles, with the first and second cycles given concurrently with radiation therapy (124). The addition of concurrent cisplatin-based therapy to radiation therapy significantly improved progression-free and overall survival in this study; however, no definitive study has compared cisplatin versus cisplatin/5-FU as an adjunct to radiation therapy for cervical cancer, and the relative importance of 5-FU remains to be addressed.

Side Effects and Toxicities. The most pronounced and dose-limiting toxic effects of 5-FU are on the normal, rapidly proliferating tissues of the bone marrow and the lining of the gastrointestinal tract. Some nausea and vomiting can be expected. These adverse effects may respond relatively well to antiemetic treatment. Stomatitis, however, is usually an early sign of impending severe toxicity that may become evident after 5 to 8 days of therapy. Symptoms include soreness, erythema, or ulceration of the oral cavity or dysphagia. Other reported gastrointestinal symptoms are diarrhea, proctitis, and esophagitis.

Leukopenia, primarily granulocytopenia, and thrombocytopenia occur with a nadir at 9 to 14 days for the granulocytes and 7 to 14 days for platelets. Patients who are poor candidates for 5-FU therapy are those with a total leukocyte count of 2,000/mm³ or less or platelet count of 100,000/mm³ or less or those with poor nutritional status at the outset of therapy.

Some degree of alopecia is expected, although hair regrowth has occurred even when successive doses are given. Partial loss of nails and hyperpigmentation of the nail beds and other body areas (e.g., face, hands) have been reported. These may resemble the hyperpigmentation seen in Addison's disease. A maculopapular rash may occur on the extremities and sometimes the trunk. The rash is usually reversible. Sunlight may heighten or initiate many dermatologic reactions to 5-FU.

Palmar-plantar erythrodysesthesia (PPE) or hand-foot syndrome PPEs have been reported with very long continuous infusion 5-FU (over several weeks). This has been reported in 42% to 82% of patients in various series. The syndrome is progressive and disrupts treatment (250). This has encouraged the development of prodrugs of 5-FU, such as 5'-deoxy-5-fluorouridine, capecitabine, BOF-A2, ftorafur, UFT, and S-1 (251,252). Although there is no indicated treatment for PPE, the incidence has been reduced to a few percentage points by limiting 5-FU continuous infusion durations to 21 days with at least 1 additional week off drug. Possible therapies that have yet to be evaluated in clinical trials include DMSO, systemic corticosteroids, and pyridoxine (vitamin B₆) (251,253).

Hyperpigmentation over the veins used for 5-FU administration has been observed (254). In one the veins remained patent, but there was marked darkening of the skin immediately over the vein.

5-FU may also cause an acute cerebellar syndrome that can persist beyond the period of actual treatment (255). Neurotoxicity may be evidenced by headache, minor visual disturbances, cerebellar ataxia, or all three. This is a rare complication. The neurotoxic metabolite is probably fluorocitrate.

Cardiotoxicity is a rare but potentially serious toxicity attributable to 5-FU. The incidence of cardiotoxicity may vary from 1.2% to 18.0% of patients (256), and includes cases of myocardial infarction, angina, dysrhythmias, cardiogenic shock, sudden death, and electrocardiographic changes. The mechanism producing 5-FU-induced cardiotoxicity is unknown.

Special Precautions. 5-FU should never be given to pregnant women. 5-FU may increase the cortisone requirement in patients who have had an adrenalectomy (e.g., for breast cancer), and consideration should be given to increased doses of cortisone for patients receiving 5-FU.

Because dihydropyrimidine dehydrogenase is the rate-limiting enzyme in the metabolism of 5-FU, patients with a familial deficiency of dihydropyrimidine dehydrogenase (familial pyrimidinemia) should not receive 5-FU. The administration of 5-FU to patients with this enzyme deficiency has led to severe toxicity and even death (257, 258).

Accidental splashing of 5-FU on the skin or eyes of personnel should be treated with immediate irrigation with saline solution or water. There have been no long-term sequelae of these accidents (259).

Because of the alkaline nature of the drug, admixture with any acidic agents (amino acids, penicillin, multivitamins, insulin, tetracycline) represents a theoretic incompatibility.

Special Applications. FUDR, a closely related analog of 5-FU, has efficacy as a salvage agent when administered as an intraperitoneal agent to stage III ovarian cancer patients with minimal residual disease (i.e., <1 cm) following second-look surgery. A SWOG study utilized intraperitoneal FUDR (3 g/day for 3 days every 3 weeks for six courses) as a salvage regimen in this patient population and documented a median overall survival of 38 months (260). Additionally, 69% of study patients had not progressed 12 months after receiving intraperitoneal FUDR. Because the majority of the intraperitoneal FUDR dose is extracted during "first pass," it is relatively well tolerated, although grade 4, uncomplicated neutropenia was observed in 14% of patients (260). Because of the favorable 1-year progression-free survival in this study, a subsequent phase 1-2 trial was conducted by the SWOG (261). The researchers recommend that the regimen of IP FUDR + IP cisplatin (or IP FUDR with both platinum) be tested in a phase 3 trial in comparison to IP cisplatin (261).

Speyer et al. (262) investigated intraperitoneal 5-FU in patients with ovarian and colon carcinomas. Using a Tenckhoff catheter, patients received repeated 36-hour courses of eight 2-L exchanges, each 4 hours long, or a 3- to 5-day course of single, daily 2-L instillations. 5-FU concentrations ranged from 10^{-6} M (130 μ g/L) to 8×10^{-3} M (1×10^{-3} M \times 1 g/L).

The procedure was relatively well tolerated locally, although there were two instances of catheter-related bacterial peritonitis that were easily managed. Concentrations of 4×10^{-3} M for 36 hours caused mucositis, pancytopenia, and alopecia. The systemic toxicities were quite severe with the highest dose tested (8×10^{-3} M). Pharmacokinetic studies revealed first-order drug elimination, with an intraperitoneal half-life of 72 to 112 minutes. Intraperitoneal drug levels were 300-fold greater than simultaneous plasma levels. Intraperitoneal 5-FU administration appears to produce high drug concentrations with minimal systemic toxicity. Objective responses were documented in two of seven patients studied in this phase 1 investigation. The investigators recommended further intraperitoneal 5-FU investigation at initial drug concentrations of 4×10^{-3} M (500 μ g/L) for 36 hours (262).

Suhrland and Weisberger (263) used intracavitary 5-FU to manage malignant pleural effusions from carcinoma of the breast and lung tumors and to control malignant ascites from ovarian carcinoma. Approximately 38% of the patients responded to a single intracavitary dose of 2 to 3 g. For pericardial effusions, doses of 500 to 1,000 mg were used. Repeat dosing was not necessary. Patients with pleural effusions also tended to respond better than those with ascites. Although side effects were minimal in this study, some systemic toxicity was consistently produced.

Gemcitabine

Chemistry. Gemcitabine (Gemzar) is a relatively new chemotherapeutic agent that was approved by the FDA in 1995 for treatment of patients with advanced pancreatic cancer based on an increase in survival and clinical benefit (improvement in pain and performance status). The combination of gemcitabine plus cisplatin also is FDA approved and is considered standard therapy for patients with advanced non-small cell lung cancer. Gemcitabine has demonstrated significant activity in advanced ovarian cancer patients and is active against refractory ovarian cancer and cervical cancer, as well as other solid tumors (264–266). Gemcitabine is a synthetic nucleoside analog with a structure that is highly similar to deoxycytidine and cytosine arabinoside (ara-C). Gemcitabine HCl is 2'-deoxy-2',2'-difluorocytidine monohydrochloride (β isomer). The empiric formula for gemcitabine is $C_9H_{11}F_2N_3O_4 \cdot HCl$ and the agent has a molecular weight of 299.66.

Mechanism of Action. Gemcitabine is a prodrug and undergoes multiple phosphorylations by deoxycytidine kinase at the intracellular level to form the active diphosphate and triphosphate metabolites. The triphosphate is incorporated into DNA as a fraudulent base pair. Following the insertion of gemcitabine, one additional deoxynucleotide is added to the end of the DNA chain before replication is terminated. This process is known as "masked chain termination" and prevents exonucleases from excising off the fraudulent base pair (267,268). The diphosphate inhibits ribonucleotide reductase and thereby depletes the deoxynucleotide pools that are necessary for DNA synthesis and repair (269). Inactivation of gemcitabine occurs when the drug is metabolized by cytidine deaminase (both intracellularly and extracellularly) to form difluorodeoxyuridine (dFdU) (270).

Drug Disposition. Following administration of gemcitabine 1,000 mg/m² by 30-minute IV infusion, the parent compound undergoes rapid clearance in a biphasic manner. The plasma half-life and clearance are dose, age, and gender dependent. Gemcitabine pharmacokinetics were evaluated in 353 patients with varied solid tumors using short infusions (<70 minutes) and long infusions (70 to 285 minutes) at various total doses (500 to 3,600 mg/m²) (271). There is a three- to fourfold interpatient variability in pharmacokinetics. As noted above, gemcitabine is metabolized intracellularly by deoxycytidine kinase to form the active diphosphate and triphosphate metabolites. The drug is inactivated both intracellularly and extracellularly by cytidine deaminase to form dFdU. Of the administered gemcitabine dose, 99% is excreted in the urine either as the parent compound (<10%) or as dFdU (272).

Dutch researchers have performed a pharmacokinetic schedule-finding study of gemcitabine plus cisplatin. Gemcitabine 800 mg/m² was administered as a 30-minute infusion either 4 hours before, 24 hours before, 4 hours after, or 24 hours after administration of cisplatin 50 mg/m² by 1-hour IV infusion. Neither of the dosing schedules that used a 4-hour interval between drug administrations resulted in significant pharmacokinetic or pharmacologic differences. However, when gemcitabine was administered 24 hours before cisplatin, there was a twofold decrease in the plasma AUC of platinum.

Furthermore, when the order of the drugs was reversed (i.e., cisplatin was administered 24 hours before gemcitabine), there was a 1.5-fold increase in the concentration · time product of the active triphosphate metabolite of gemcitabine within white blood cells. On the basis of these results, the investigators are conducting a phase 2 study of the cisplatin/gemcitabine combination wherein cisplatin is administered 24 hours prior to gemcitabine (273).

Administration and Dosage. Gemcitabine should be diluted in 0.9% sodium chloride to a concentration of no greater than 40 mg/mL (higher drug concentrations may result in incomplete dissolution). Gemcitabine is generally administered as a 30-minute IV infusion at a dose of 1,000 mg/m²; infusion durations of greater than 60 minutes are associated with dose-limiting flu-like symptoms (274).

The standard dosing schedule used for treatment of pancreatic cancer is 1,000 mg/m² by 30-minute IV infusion once weekly for 7 weeks for cycle 1 followed by a 1-week rest and then 1,000 mg/m² once weekly for 3 weeks followed by a 1-week rest for subsequent cycles (275).

Multiple phase 2 studies of single-agent gemcitabine in refractory/recurrent ovarian cancer have used a dosing schedule of 800 to 1,250 mg/m² once weekly for 3 weeks followed by a week of rest; however, doses above 1,000 mg/m² may be associated with higher toxicity (266).

In vitro studies have shown synergism between gemcitabine and cisplatin in a variety of human cancer cell lines (276). It is believed that this synergism is primarily the result of increased platinum-DNA adduct formation (276). As noted (see the Drug Disposition section above), the interval between cisplatin and gemcitabine administration can affect both pharmacokinetic and pharmacologic parameters (273). This combination appears to be especially promising for patients with advanced ovarian cancer. Several phase 2 studies have been conducted in previously untreated ovarian cancer patients using a dosing schedule of cisplatin (75 to 100 mg/m²) on day 1 followed by gemcitabine 1,250 mg/m² days 1 and 8 (264,277). Others have performed phase 2 studies of gemcitabine plus cisplatin for patients with relapsed ovarian cancer after prior platinum-based chemotherapy and have determined that cisplatin 30 mg/m² plus gemcitabine 600 to 750 mg/m² on days 1 and 8 every 21 days is an active and tolerable regimen that demonstrated activity in platinum-resistant patients (87,278).

Side Effects and Toxicities. Gemcitabine-induced toxicity is highly schedule dependent; small daily doses are associated with greater toxicity than large doses administered on a weekly basis (279). The dose, schedule, and duration of infusion of gemcitabine directly affects the toxicity profile (279). Infusion durations of greater than 60 minutes are associated with increased myelosuppression and hepatic toxicity, whereas the administration of small daily doses results in dose-limiting flu-like symptoms (270,274). When gemcitabine is administered using the standard weekly dosing schedule, therapy is generally well tolerated and bone marrow suppression is the major dose-limiting toxicity.

Analysis of safety data from 22 completed clinical trials in which gemcitabine was administered on a weekly basis to 979 patients revealed that neutropenia was the most significant hematologic side effect. Six percent of patients experienced grade 4 neutropenia and an additional 20% experienced grade 3 neutropenia. Grade 4 leukopenia was experienced by less than 1% of patients. Decreases in white blood cell counts were noncumulative, short-lived, and rarely resulted in complications. Only 6 of 979 patients (1.1%) developed severe infections, and no patient developed a life-threatening infection. Grades 3 and 4 anemia were experienced by 6.8% and 1.3% of patients, respectively, and only 2 of the 979 patients discontinued gemcitabine secondary to anemia. Grades 3 and 4 thrombocytopenia occurred in 4.1% and 1.1% of patients,

respectively. Less than 1% of patients received platelet transfusions and only four patients (0.4%) discontinued therapy on account of thrombocytopenia (279).

Gemcitabine is associated with a low incidence of hepatic toxicity. Grade 3 elevations in alkaline phosphatase, alanine aminotransferase (ALT), or aspartate aminotransferase (AST) occurred in less than 8% of patients. Grade 4 elevations in these liver enzymes occurred in 2% or fewer of patients. Grade 3 or 4 increases in bilirubin occurred in 1.8% and 0.8% of patients, respectively. It is noteworthy that one third of patients in this study population had documented liver metastases (279).

Clinically significant renal toxicity rarely occurs with gemcitabine therapy. However, rare cases of hemolytic uremic syndrome have been reported with gemcitabine therapy. The incidence is believed to be approximately 0.6% (279).

Other nonhematologic toxicities that were reported in more than 5% of patients were nausea/vomiting (64.3% overall, 17.1% grade 3, 1.2% grade 4), fever (37.3% overall, 0.7% severe), edema (greater than 20% of patients), flu-like symptoms (18.9%, 0.9% severe), cutaneous reactions (24.8%, 0.2% severe), alopecia (14.1%, 0.4% severe), diarrhea (12.1%, 0.7% severe), somnolence (9.1%, 0.9% severe), infection (8.7%, 1.1% severe), mucositis (8.4%, 0.2% severe), constipation (7.8%, 0.7% severe), and dyspnea (7.7%, 1.2% severe). Nausea and vomiting rarely were dose limiting and only two (0.2%) patients discontinued gemcitabine therapy because of nausea. Fever was a fairly frequent toxicity and sometimes occurred in the absence of flu-like symptoms or infection. Subcutaneous edema, including peripheral edema and facial edema, occurred in a significant number of patients. Edema was generally mild to moderate in nature; few patients (0.6%) discontinued gemcitabine because of this side effect, and the edema resolved after drug discontinuation. Flu-like symptoms consisted of headache, back pain, chills, myalgia, asthenia, and anorexia and were generally short lived. Paracetamol was reported to provide relief to some patients. Cutaneous reactions consisted of erythema in mild cases (15.5%) and dry desquamation, vesiculation, and/or pruritus in moderate cases (9.1%). Only one patient developed severe cutaneous toxicity that was characterized as moist desquamation and ulceration. Dyspnea (with or without bronchospasm) occurs in less than 10% of patients following gemcitabine administration. This toxicity generally occurs within a few hours of treatment and resolves within 6 hours (279).

Fatal pulmonary toxicity (acute respiratory distress syndrome) has been reported as a rare side effect of gemcitabine therapy (280). Symptoms include progressive dyspnea, tachypnea, marked hypoxemia, and bilateral interstitial infiltrates consistent with pulmonary edema. Some patients have responded to the termination of gemcitabine therapy and treatment with corticosteroids and diuretics. Prior radiation therapy to the mediastinum may be a risk factor for gemcitabine-induced pulmonary edema (280,281).

Possible incompatibilities between gemcitabine solutions and other drug solutions have not been studied.

Ifosfamide

Chemistry. In combination with cisplatin, ifosfamide (IFEX, Holoxan) is a commonly used drug for the first-line treatment of patients with advanced cancer of the cervix, and in combination chemotherapy, it is a second-line treatment for patients with advanced cancer of the ovary (282,283). It also has activity in advanced or recurrent endometrial cancer (284). Chemically, ifosfamide is 3-(2-chloroethyl)-2-[(2-chloroethyl)amino]-tetrahydro-2H-1,3,2-oxazaphosphorine-2-oxide, and is chemically related to the nitrogen mustards and a structural analog of cyclophosphamide. It differs only in the position of one of the two chloroethyl groups, which is

transposed to the endocyclic (ring) nitrogen in ifosfamide. The molecular formula is $C_7H_{15}Cl_2N_2O_2P$, and the compound has a molecular weight of 261.1.

Mechanism of Action. Ifosfamide is a metabolically activated alkylating agent. Like cyclophosphamide, it must first undergo hydroxylation by microsomal (mixed-function oxidase) enzyme systems (285). The activation of ifosfamide occurs more slowly than that of cyclophosphamide, and there is quantitatively greater oxidation of the chloroethyl side chains with ifosfamide. This leads to a greater production of chloroacetaldehyde, a possible neurotoxin.

The activation process generates highly reactive metabolites, particularly 4-hydroxyifosfamide, which are capable of cellular uptake and, ultimately, covalent binding to protein and to DNA (286). Metabolites can spontaneously break down to yield the bladder irritant acrolein and the active alkylating moiety ifosforamide mustard. Cross linking of DNA strands proceeds from ifosforamide mustard, but acrolein binds nonspecifically and covalently to bladder epithelium. The DNA-cross-link distance is greater for ifosfamide (seven atoms) compared with cyclophosphamide (five atoms). Furthermore, the aziridine forms more slowly and is less reactive since it lacks a positive charge (287). Chain scission of DNA and inhibition of thymidine uptake also occur with ifosfamide. The primary mechanism of alkylation is not cell cycle specific.

Drug Disposition. The pharmacokinetics of ifosfamide appear to be qualitatively similar to those of cyclophosphamide. Creaven et al. (288) found a plasma half-life of radiolabeled ifosfamide ($5,000 \text{ mg/m}^2$) of 13.8 hours, with 82% urinary (radioactivity) recovery.

The plasma decay pattern appears to be biexponential (two-compartment model) for large bolus doses and monoexponential (one-compartment model) with fractionated doses. In contrast to single-dose pharmacokinetics studies, Allen et al. (289) found that with sequential daily administration of $2,400 \text{ mg/m}^2/\text{day}$ for 3 days, there is monoexponential plasma decay with a half-life of 6.9 hours and a metabolized urinary recovery fraction of 72.8%, in contrast to the biexponential decay (plasma half-life 15.2 hours) of a single-bolus dose of ifosfamide ($5,000 \text{ mg/m}^2$). This finding suggests that the metabolic disposition of the drug may be dose dependent. These half-lives are approximately twice those reported for cyclophosphamide. Of note, a longer ifosfamide half-life may be seen in obese patients who are more than 20% over ideal body weight. The renal clearance rate of ifosfamide is about twice that for cyclophosphamide: 21.3 versus 10.7 mL/min in bolus dosing and 18.7 versus 10.7 mL/min with fractionated doses. Only about half of an ifosfamide dose is metabolized compared with about 90% for cyclophosphamide. This reflects a substantial difference in the metabolic clearance capacity for the two analogs. Although more intact (inactive) ifosfamide than cyclophosphamide is renally excreted, urinary alkylating activity persists longer with ifosfamide.

Creaven et al. (288) demonstrated that because unchanged ifosfamide, but not metabolites, penetrates the blood-brain barrier, alkylating activity in the CSF may occur but is probably negligible.

Administration and Dosage. Ifosfamide is reconstituted by the addition of sterile water to the vial, which should be shaken to dissolve. Ifosfamide may be further diluted to a concentration of 0.6 to 29.0 mg/mL in 5% dextrose or 0.9% sodium chloride. It is administered intravenously, usually by a short infusion. Ifosfamide may also be administered by slow IV push in a 75-mL minimal volume of sterile saline solution but not water and infused over at least 30 minutes or by continuous infusion over 5 days. Large single doses of ifosfamide produce much more toxicity than fractionated schedules, which are therefore preferred in solid-tumor treatment regimens. Adequate hydration of the patient before and for 72 hours after

ifosfamide therapy is recommended to reduce the incidence of drug-induced hemorrhagic cystitis. The use of a concurrent prophylactic agent for hemorrhagic cystitis, such as mesna (Mesnex), is required to prevent severe hematuria from high-dose ifosfamide. At least 2 L of fluid each day is recommended to produce a copious urine output.

Continuous infusions of ifosfamide over 24 hours have also been given every 3 weeks (290). Mesna can be given concurrently in the same infusion container or as a 4-hour intermittent IV bolus (291). However, renal toxicities may be increased with the single, large infusions. Extravasation of the drug should not cause tissue necrosis, but one case report has been described (292).

The FDA-approved dose for testicular cancer is $1,200 \text{ mg/m}^2/\text{day}$ for 5 consecutive days every 21 days. Other dosage schedules include $2,000 \text{ mg/m}^2$ IV continuous infusion on days 1 to 3 every 21 days as part of the MAID regimen (mesna, Adriamycin, ifosfamide, dacarbazine) for soft-tissue sarcoma; $1,000 \text{ mg/m}^2$ on days 1 and 2 every 28 days as part of the ICE regimen (ifosfamide, carboplatin, etoposide) for non-Hodgkin's lymphoma; and $1,000 \text{ mg/m}^2$ on days 1 to 3 every 21 to 28 days as part of the TIC regimen (paclitaxel, ifosfamide, carboplatin) for head and neck cancer (50).

A phase 2 study evaluated ifosfamide ($1,500 \text{ mg/m}^2$ IV over 1 hour, days 1 to 3) with mesna in combination with paclitaxel (175 mg/m^2 IV over 3 hours on day 1) and cisplatin (75 mg/m^2 IV over 2 hours on day 2) as first-line therapy in advanced, suboptimally debulked epithelial ovarian cancer patients (293). This regimen was associated with an 85% objective response rate and a median overall survival of 52.8 months in 22 patients with stage III or IV disease. A regimen of paclitaxel (175 mg/m^2), ifosfamide ($5,000 \text{ mg/m}^2$), and cisplatin (75 mg/m^2 or 50 mg/m^2 in irradiated patients) every 21 days in 45 recurrent or persistent cervical cancer patients was associated with a 67% objective response rate (294).

Morgan et al. (295) evaluated several IV push and infusion dose schedules in non-small cell lung cancer: 700 to $900 \text{ mg/m}^2/\text{day}$ by IV push for 5 days repeated every 3 weeks; 700 to $1,000 \text{ mg/m}^2/\text{day}$ for 5 days repeated every 3 weeks plus 1 g/day of oral ascorbic acid; 4 g/m^2 slow infusion repeated every 3 weeks; and 900 mg/m^2 by IV push weekly. There appeared to be less hematuria produced with the sequential 5-day schedule with concomitant ascorbic acid.

Rodriguez et al. (296) described a 47% response rate in leukemia patients with continuous infusions of ifosfamide at $1,200 \text{ mg/m}^2/\text{day}$ given for 5 days. Significant genitourinary toxicity was not encountered, and myelosuppression predominated as the dose-limiting toxicity. In combination with other cytotoxic drugs, such as doxorubicin or lomustine (CCNU), a single IV push dose of $1,000 \text{ mg/m}^2$ (not to exceed $12,500$ total) has been recommended.

Side Effects and Toxicities. Creaven et al. (288) reviewed the clinical toxicity of ifosfamide given as a large bolus injection (200 to $10,000 \text{ mg/m}^2$) and in a fractionated 3-day ($2,400 \text{ mg/m}^2/\text{day}$) schedule. Urinary tract toxicity is the dose-limiting factor with both schedules. The clinical hallmark is hemorrhagic cystitis, which is caused by excretion of active alkylating metabolites into the urinary bladder. Vigorous hydration with oral and intravenous fluids and concomitant mesna are needed to prevent serious ifosfamide-induced bladder damage. Hydration may also overcome the antidiuretic effects of this drug. Nelson et al. (291) used IV furosemide (20 to 40 mg) to maintain adequate urine flow in a phase 1 study of ifosfamide. Diuretic responses usually occurred within 1 hour.

Symptoms of dysuria and urinary frequency appear to parallel those of hematuria. The onset of symptoms is 1 to 2 days after injection, with an average duration of 9 days (range 1 to 41 days) (297). Dose-related ifosfamide-induced nephrotoxicity was detected by elevation of the BUN, producing a subsequent

dose-related uremia in 66% of patients receiving 150 mg/kg. Other lesions seen at autopsy (four of seven patients) included evidence of acute tubular necrosis and pyelonephritis. At low daily doses, granular cylindruria was seen in all patients, denoting marked tubular damage. The cylindruria cleared within 10 days of drug discontinuance (298). DeFronzo et al. (298) also described glomerular dysfunction and a Fanconi-type picture in a patient treated with ifosfamide. Prior cisplatin therapy may also increase ifosfamide-induced nephrotoxicity (299,300).

Nausea and vomiting appear to be common and are more severe after a rapid injection of large ifosfamide doses. Emesis typically begins within a few hours of administration and persists an average of 3 days (range 1 to 28 days) (297).

Hematologic toxicity from ifosfamide usually involves only a mild to moderate degree of leukopenia in most patients. In a review by Creaven et al. (288), significant thrombocytopenia was not encountered for any of the dose schedules used.

Lethargy and confusion are seen with high doses of ifosfamide and may be caused by the chloroacetaldehyde metabolite. Nelson et al. (291) observed that this lasted from 1 to 8 hours, was spontaneously reversible, and was related to the passage of intact drug into the central nervous system (CNS). Seizures, ataxia, stupor, and weakness have been reported after ifosfamide. These effects may be increased by concomitant neurotoxic drugs, such as certain antiemetics, tranquilizers, narcotics, and antihistamines. There is a single case report of nonconvulsive status epilepticus associated with ifosfamide therapy. The patient responded to discontinuation of the ifosfamide and phenytoin therapy (301). Although alkylating metabolites appear to penetrate the blood-brain barrier, the levels achieved are too low to be useful in the treatment of CNS tumors (288).

Alopecia is usually seen with ifosfamide, especially when large bolus doses are used. In a study by Van Dyk et al. (297), the average onset of maximal hair loss was 19 days (range 11 to 32 days) after the start of treatment.

Hepatic enzyme elevations have been described in some patients. The elevations in alkaline phosphatase and serum transaminase are transient and typically resolve rapidly without sequelae.

Special Precautions. The patient must be kept well hydrated during ifosfamide therapy to reduce the potential for hemorrhagic cystitis. The use of mesna given intravenously or orally is required to prevent hemorrhagic cystitis. Table 16.5 outlines the recommended mesna schedule for ifosfamide uroprotection.

TABLE 16.5

DOSING SCHEDULES FOR MESNA COMBINED WITH IFOSFAMIDE

Route of mesna administration	Dose (mg/kg) as a percentage of ifosfamide dose at times before and after ifosfamide		
	15 minutes before	4 hours after	8 hours after
Intravenous	20%	20%	20%
Oral ^a	Not recommended, use IV route	40% ^a	40% ^a

^aFor highly reliable patients with total emetic control, mesna solution can be diluted 1:1 to 1:10 in carbonated cola drinks or in chilled fruit juices (e.g., apple, grape, tomato, and orange juice) and administered orally.

Patients who have received previous or concurrent therapy with radiation or cytotoxic drugs may require significant ifosfamide dosage reductions. Dose reductions should also be considered for patients with impaired renal function and/or serum albumin concentrations below 3.5 g/dL.

Drug Interactions. Several drug interactions are possible with ifosfamide. Because the compound undergoes hepatic activation by microsomal enzymes, induction is potentially possible by pretreatment with various enzyme-inducing drugs, such as phenobarbital, phenytoin, and chloral hydrate.

Nephrotoxic drugs like cisplatin may significantly increase ifosfamide renal damage (300). Other drug interactions reported for cyclophosphamide that may also occur with ifosfamide include reactions with metabolic alteration of H₂ antihistamines, such as cimetidine.

Irinotecan

Chemistry. Irinotecan (CPT-11, Camptosar), a TOPO-I inhibitor, is a water-soluble semisynthetic derivative of camptothecin, a natural product extracted from the stem wood of the *Camptotheca acuminata* tree that has significant antitumor activity. It was approved by the FDA in 1998 for treatment of patients with progressive metastatic colon or rectal cancer following 5-FU therapy. Early clinical development of camptothecin was halted because of severe, unpredictable hemorrhagic cystitis, vomiting, and myelosuppression. Subsequently, irinotecan was formulated as a prodrug to have greater water solubility, increased antitumor activity, and less toxicity than the parent compound. Its chemical name is (4S)-4,11-diethyl-4-hydroxy-9-[(4-piperidino-piperidino)carbonyloxy]-1Hpyrano[3',4':6,7]indolizino[1,2-b]quinoline-3,14 (4H,12H) dione hydrochloride trihydrate. This drug has a molecular weight of 677.19 and the empirical formula is C₃₃H₃₈N₄O₆ · HCl · 3H₂O.

Mechanism of Action. Irinotecan's cytotoxicity is believed to be related to the inhibition of TOPO-I, an enzyme necessary for DNA replication (208). Irinotecan is activated to the active metabolite, SN-38, by the liver (302). Irinotecan and SN-38 bind to the transient TOPO-I-DNA complex, stabilize the complex, and thereby promote DNA single-strand breaks. These strand breaks prevent DNA replication and result in cell death (208,302). Current research suggests that the cytotoxicity of irinotecan is due to DNA damage produced during DNA synthesis. Mammalian cells cannot repair these double-strand breaks.

Drug Disposition. Pharmacokinetic studies performed by Rothenberg et al. (303) have determined that when irinotecan is administered as a 90-minute IV infusion at dose ranges of 50 to 180 mg/m², the plasma terminal-phase half-life for irinotecan (total) was 7.9 ± 2.8 hours, 6.3 ± 2.2 hours for irinotecan (lactone), and 11.5 ± 3.8 hours for SN-38 (the active metabolite). The time of peak plasma concentration for irinotecan was at infusion end, whereas the time of peak concentration for total SN-38 varied from 30 to 90 minutes after completion of the infusion. Plasma clearance was unrelated to dose, with a mean clearance of 15.3 ± 3.5 L/h/m² for the total and 45.6 ± 10.8 L/h/m² for the lactone. At the 150-mg/m² dose, the following pharmacokinetic parameters were observed: peak plasma concentration—1.97 µg/mL for total irinotecan, 0.83 µg/mL for the lactone form, and 36.7 ng/mL for total SN-38; and concentration · time product (AUC) 8.44 µg · h/mL for total irinotecan, 2.81 µg · h/mL for the lactone form, and 409.8 ng · h/mL for total SN-38. Renal excretion was not a major route of drug elimination.

Abigeres et al. (304) determined in their pharmacokinetic study of irinotecan (100 to 700 mg/m² by 30-minute IV infusion) that the plasma disposition of irinotecan was biphasic or triphasic. The mean plasma terminal-phase half-life, volume of

distribution, and total body clearance of irinotecan were 14.2 ± 0.9 hours, 157 ± 8 L/m², and 15 ± 1 L/m²/h, respectively. Both the irinotecan and SN-38 concentration · time product (AUC) increased linearly with dose. At the 350-mg/m² dose level, the irinotecan and SN-38 AUCs were 34.0 ± 4.1 µg · h/mL and 451 ± 100 ng · h/mL, respectively. The plasma terminal-phase half-life of SN-38 was 13.8 ± 1.4 hours.

Administration and Dosage. The appropriate dose of irinotecan should be diluted with 500 mL of dextrose (5%) to a final concentration of 0.12 to 1.1 mg/mL and administered IV over 90 minutes (303). Alternatively, French investigators have administered irinotecan by diluting the appropriate amount of drug in 250 mL of 0.9% sodium chloride solution and delivering the drug IV over 30 minutes (304).

In the United States, the recommended dose for irinotecan therapy in colon cancer patients is 125 mg/m² weekly by 90-minute infusion for 4 weeks followed by a 2-week rest. In Europe, the recommended dose is 300 to 350 mg/m² by 90-minute infusion every 21 days. The U.S. schedule has been used in three phase 2 clinical trials, wherein irinotecan displayed modest activity in cervical cancer patients (305–307). When administered as a single dose every 3 weeks, a 240-mg/m² dose is recommended (303,308). French investigators have determined that a 600-mg/m² 30-minute IV infusion every 3 weeks can be administered if drug-induced diarrhea is aggressively managed by high-dose loperamide (e.g., up to 16 mg/day); however, these investigators recommended a dose level of 350 mg/m² every 3 weeks until further experience is gained with higher dose levels (304).

Side Effects and Toxicities. Diarrhea and neutropenia are the major dose-limiting toxicities associated with irinotecan (303,304,308). Other moderate to severe toxicities associated with irinotecan therapy include anemia, dehydration (secondary to diarrhea), nausea, vomiting, anorexia, abdominal cramping, cumulative asthenia, thrombocytopenia, renal insufficiency, elevations in liver transaminases, and alopecia.

The diarrhea associated with irinotecan appears to be due to two separate mechanisms. The diarrhea that may occur during irinotecan infusion is highly responsive to atropine therapy and, therefore, appears to be related to cholinergic activity. However, the subacute diarrhea that develops 2 to 3 weeks after irinotecan therapy is refractory to anticholinergic agents. The most effective treatment for the subacute diarrhea is institution of therapy with antimotility agents (i.e., loperamide or diphenoxylate hydrochloride with atropine sulfate) at the first signs of increased intestinal motility (e.g., loose bowels). If left untreated, subacute diarrhea can rapidly progress to grade 4 toxicity. This life-threatening diarrhea is refractory to antidiarrheal therapy and generally lasts for 5 to 7 days. Patients with grade 4 diarrhea should be hospitalized and receive supportive care with IV fluids and electrolyte replacement (303).

Special Precautions. As described above (see the Side Effects and Toxicities section), irinotecan can induce grade 4 diarrhea that is refractory to antidiarrheal medication. Patients who are receiving irinotecan must be monitored carefully for early symptoms of increased intestinal motility and should receive antimotility therapy (e.g., up to 16 mg/day loperamide) as soon as initial symptoms of diarrhea appear. A low level of glucuronidation in the biliary system has been associated with the development of severe diarrhea in some patients (309).

Special Applications. The TOPO-I inhibitor irinotecan also has been shown to have activity against advanced cervical cancer. Cottu et al. (310) reported response rates in patients with relapsed cervical cancer ranging from 20% to 22%. The GOG reported a response rate of 13.3% (6 of 45) in patients with advanced cervical cancer with no prior chemotherapy (306). No responses were reported in second-line (after resistance to cisplatin) treatment in a phase 2 study of 16 patients (305).

However, Verschraegen et al. (307) reported a 21% response rate in the same patient population ($n = 42$). Reviews by Eisenhauer and Vermorken (311) and Verschraegen (312) have reported response rates ranging from 13% to 24%. The combination of irinotecan (60 mg/m² 90-min IV on days 1, 8, and 15) followed by cisplatin (60 mg/m² on day 8) administered every 3 weeks has demonstrated activity in a phase 2 trial of first-line treatment of cervical cancer, with a 1-year disease-free and overall survival of 26.7 and 65.1%, respectively (313).

Liposomal Encapsulated Doxorubicin

Chemistry. Liposomal doxorubicin (Doxil, Caelyx) is FDA approved for the treatment of patients with metastatic, refractory ovarian cancer and AIDS-related Kaposi's sarcoma. Doxorubicin HCl, which is the established name for (8S,10S)-10-[(3-amino-2,3,6-trideoxy- α -L-lyxo-hexopyranosyl)oxy]-8-glycolyl-7,8,9,10-tetrahydro-6,8,11-trihydroxy-1-methoxy-5,12-naphthacenedione hydrochloride, has a molecular weight of 579.99 and the molecular formula C₂₇H₂₉NO₁₁ · HCl. The liposomal carriers are composed of N-(carbonyl-methoxy-polyethylene glycol 2000)-1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine sodium salt (MPEG-DSPE), 3.19 mg/mL; fully hydrogenated soy phosphatidylcholine (HSPC), 9.58 mg/mL; and cholesterol, 3.19 mg/mL. Greater than 90% of the drug is encapsulated in the liposomes. The liposomal encapsulation of doxorubicin dramatically alters the pharmacokinetic and toxicity profiles of the drug.

Mechanism of Action. The mechanism of action of doxorubicin was discussed previously (see the Doxorubicin section). Liposomes are microscopic vesicles composed of a phospholipid bilayer that are capable of encapsulating active drugs. The liposomes of the encapsulated form of doxorubicin are formulated with surface-bound methoxypolyethylene glycol (MPEG), a process often referred to as pegylation, to protect liposomes from detection by the mononuclear phagocyte system (MPS) and to increase blood circulation time (314).

Drug Disposition. Liposomal doxorubicin is associated with a much longer plasma half-life, slower plasma clearance, and reduced volume of distribution than free doxorubicin. In a pharmacokinetics study performed in six patients with solid tumors, the area under the plasma disappearance curve was 1.0 mg/L · hour versus 609 mg/L · hour when 25 mg/m² of doxorubicin was administered as free drug or as a pegylated liposomal form, respectively. The initial half-life was 0.07 versus 3.2 hours, and the terminal half-life was 8.7 versus 45.2 hours for the free and liposomal forms of doxorubicin, respectively. Additionally, the steady-state volume of distribution was 254 L versus 4.1 L for the free and liposomal forms, respectively (315). Liposomal encapsulation of doxorubicin has also been shown to result in fourfold to 16-fold increases in tumor-tissue drug concentrations relative to that achieved following administration of the free form.

Administration and Dosage. Liposomal doxorubicin must be diluted in 250 mL of 5% dextrose prior to administration. Because liposomal doxorubicin contains no preservative or bacteriostatic agent, aseptic technique must be strictly observed. Liposomal doxorubicin may be administered as an IV infusion over 30 to 60 minutes. In that liposomal doxorubicin is not a vesicant, extravasation of the drug is not a critical concern. For ovarian cancer patients, liposomal doxorubicin should be administered at a dose of 50 mg/m² (every 4 weeks) at an initial rate of 1 mg/min to reduce the risk of infusion reactions. The rate may be increased to a 60-minute infusion if no adverse events are noted. The recommended dose in AIDS-related Kaposi's sarcoma patients is 20 mg/m² over 30 minutes, once every 3 weeks, for as long as patients respond and tolerate treatment.

Side Effects and Toxicities. Unlike the parent drug, liposomal doxorubicin is not a vesicant and is associated with minimal cardiotoxicity, alopecia, and nausea/vomiting. However, the liposomal encapsulation results in acute infusion reactions, and an increased rate of PPE and stomatitis (316). PPE is a dose-limiting toxicity that can occur in 26% of patients who receive 50 mg/m² every 4 weeks (317). Stomatitis is a second dose-limiting toxicity associated with liposomal doxorubicin. Current methods to prevent PPE and stomatitis include dose reduction and discontinuation. (Grade 1—redose; if patient has experienced previous grade 3 or 4 toxicity, delay the treatment by 2 weeks until resolution to grades 0 to 1 and reduce dose by 25% before returning to original dose level. Grades 2 to 4—delay up to 2 weeks until resolved; if no resolution to grades 0 to 1, discontinue. Grades 3 to 4—after delay and resolution to grades 0 to 1, decrease dose by 25%; if no resolution, discontinue.) To help relieve pain from PPE, topical wound care, elevation, and cold compresses may be used as supportive care (253). Topical DMSO has been used to treat skin extravasations (99% DMSO four times daily up to 14 days), but has yet to be evaluated in a randomized trial (251). Other possible therapies that have yet to be evaluated in clinical trials include systemic corticosteroids and pyridoxine (vitamin B₆) (253).

Infusion-related reactions occur in fewer than 10% of patients treated with liposomal doxorubicin and are most common during the first course of treatment. Symptoms may include flushing, shortness of breath, facial swelling, headache, chills, back pain, tightness in the chest and throat, and hypotension. Alopecia has been observed in only 15% of ovarian cancer patients treated with liposomal doxorubicin.

Melphalan

Chemistry. Melphalan (Alkeran, L-phenylalanine mustard, L-PAM) is a phenylalanine derivative of nitrogen mustard that acts as a bifunctional alkylating agent. Melphalan is FDA approved for the chemotherapy of patients with multiple myeloma. The agent's molecular formula is C₁₃H₁₈Cl₂N₂O₂ and its molecular weight is 305.2. It is known chemically as 4-[bis(2-chloroethyl)amino]-L-phenylalanine. Melphalan is water insoluble and previously was only commercially available in a 2-mg tablet form. However, a parenteral formulation was approved by the FDA in 1993. Melphalan for injection is supplied as a freeze-dried powder in single-use vials containing 50 mg melphalan and 20 mg povidone. A vial of sterile diluent (10 mL) is also supplied.

Mechanism of Action. Melphalan is an alkylating agent of the bischloroethylamine type. Its cytotoxicity appears to be related to the extent of its interstrand cross linking with tumor-cell DNA, probably by binding at the N⁷ position of guanine (318). The cross-helical base pairing causes strain and possible rupture of the double-stranded DNA backbone.

Melphalan is relatively stable in media containing high concentrations of chloride ions and at acid pH (318). It has a relatively short *in vitro* half-life in plasma of approximately two hours owing to the rapid hydroxylation of the chloroethyl groups of the molecule. Melphalan may form a reactive immonium ion that can alkylate or hydroxylate the monohydroxy and dihydroxy metabolites. Monohydroxy melphalan possesses only 2% of the cytotoxicity of the parent compound, and the dihydroxy derivative is inactive (319).

Melphalan is usually transported into cells by two amino acid-transporting systems: the sodium-independent system that transfers leucine and a monovalent cation-dependent system similar to that which transfers alanine, serine, or cysteine (320). Melphalan efflux from cells appears to be sodium independent, to be stimulated by amino acids in the extracellular medium, and to occur by a simple diffusion mechanism.

Drug Disposition. Melphalan has extremely variable systemic availability after oral administration. In the average patient, approximately one third of an administered dose of melphalan can be recovered from plasma after a bolus oral dose. The range of systemic availability after oral dosing varies from none to over 90%. The terminal-phase plasma half-life of orally administered melphalan is approximately 90 minutes, and the 24-hour urinary excretion rate averages 11% (321). Melphalan penetration into cerebrospinal fluid is low. Plasma protein binding ranges from 60% to 90%, and approximately 30% is irreversibly bound to plasma proteins.

Studies of melphalan metabolism, using an isolated perfused rat liver model and *in vitro* rat microsomal enzyme preparations, have documented insignificant hepatic biotransformation (322).

Two groups of investigators have reported that the systemic availability of melphalan is increased if the drug is administered in the fasting state. The presence of a large meal appears to enhance melphalan degradation at the alkaline pH found in the upper small bowel before systemic absorption (323).

Patients with multiple myeloma receiving intravenously administered melphalan achieved longer durations of survival than those receiving the oral formulation. Furthermore, a significantly lower dose of intravenously administered drug was associated with life-threatening leukopenia and infectious complications compared with the oral formulation (323).

Administration and Dosage. The usual IV dose is 16 mg/m² (15- to 20-minute infusion) administered at 2-week intervals for four doses, then at 4-week intervals. The oral agent dose is 6 mg/day for 2 to 3 weeks, followed by up to 4 weeks without treatment. As a single agent, one-time IV doses of 1 mg/kg repeated at 4- to 6-week intervals are generally well tolerated. Although the manufacturer reports equal effects from intravenous or oral doses, bioavailability differences and the potential for lessened hepatic clearance of IV doses suggest IV dosing at reduced levels. In a surgical adjuvant setting for ovarian carcinoma, melphalan has been used in large cyclic doses of 1 mg/kg given IV over 8 hours and repeated in 4 weeks (324). The apparently equivalent therapeutic results with intravenous and oral dosing are surprising in light of the reported poor oral absorption of the compound.

Side Effects and Toxicities. Compared with other standard alkylating agents, melphalan is relatively well tolerated after oral administration. Except for dose-limiting bone marrow suppression (i.e., neutropenia, thrombocytopenia, anemia), other acute side effects are uncommon and include infrequent nausea and vomiting and, rarely, skin rash and pulmonary toxicity (325). Melphalan is characterized by its potential to cause cumulative bone marrow damage, as expressed by profound and prolonged depression of neutrophils and platelets. There is a slow reduction in peripheral leukocyte and platelet counts to their nadirs at 28 to 35 days after drug administration followed by a 14- to 21-day recovery period.

Acute nonlymphocytic leukemia has been reported in patients with multiple myeloma and ovarian cancer after prolonged melphalan therapy. In one Swedish study of 474 patients with ovarian carcinoma, there were four cases of acute nonlymphocytic leukemia among 12 patients who received 800 mg or more of melphalan (326). An evaluation of the relationship between alkylating agents and leukemic disorders in 3,363 one-year survivors of ovarian cancer revealed that the 10-year cumulative risk of acquiring leukemia was 11.2% after treatment with melphalan and 5.4% after cyclophosphamide treatment (327). The risk of developing leukemia after melphalan and cyclophosphamide treatment was significantly higher than in matched patient groups who received no chemotherapy. These data suggest that, to reduce the leukemia risk, the total dose of melphalan should not exceed 600 mg.

Special Applications. One major impediment to the success of cancer chemotherapy is the rapid development of drug resistance as manifested clinically by short objective responses and subsequent, progressive tumor growth despite aggressive chemotherapy. Several mechanisms have been postulated to explain this relatively universal phenomenon.

Melphalan therapy has been used in autologous bone marrow transplantation. A series of studies has been reported for high-dose (120 to 225 mg/m²) IV administered melphalan against adult melanoma, breast, and colon cancers (328). Although the resulting high response rates appear to be promising, most have been partial, and survival advantages have not yet been established. In general, these high doses of melphalan have been tolerated relatively well, with diarrhea and stomatitis becoming severe and dose-limiting at doses greater than 200 mg/m².

Because ovarian cancer remains confined to the intraperitoneal space for most of its natural history, there has been increasing interest in the intraperitoneal administration of cytotoxic drugs to patients with minimal residual intraperitoneal disease (i.e., plaques <1 cm in diameter) after aggressive cytoreductive surgery or primary chemotherapy. Melphalan exhibits a high degree of *in vitro* cytotoxicity as compared with other standard chemotherapeutic agents when tested against fresh human ovarian cancer tumors at drug concentrations achievable by intraperitoneal administration (329). In addition to its high degree of cytotoxicity, melphalan's high molecular weight ensures a relatively low clearance from the peritoneal space.

In a phase 1 dose-finding study, Howell et al. (330) showed that an intraperitoneal melphalan dose of 70 mg/kg was tolerated, with only moderate leukopenia (median nadir 2,000 cells/ μ L) and thrombocytopenia (median nadir 69,000 platelets/ μ L) and no evidence of peritoneal irritation. The peak peritoneal concentration averaged 93-fold greater than the plasma concentration, and total drug exposure for the peritoneal cavity averaged 63-fold greater than that for the plasma.

Methotrexate

Chemistry. Methotrexate is an active drug in the first-line treatment of gestational choriocarcinoma, chorioadenoma destruens, and hydatidiform mole. It is used in the prophylaxis and treatment of meningeal leukemia, and is used in combination with other agents for the treatment of breast cancer, epidermoid cancers of the head and neck, advanced mycosis fungoides, advanced non-Hodgkin's lymphoma, lung cancer, and metastatic squamous cell cancer of the cervix. Methotrexate is a cell cycle-specific antifolate analog, which differs from folic acid in two substitutions: an amino group for a hydroxyl in the pteridine portion of the molecule and a methyl group on the amino nitrogen between the pteridine nucleus and the benzoyl group of 4-amino-10-methyl folic acid. Chemically, methotrexate is N-[4-[(2,4-diamino-6-pteridinyl)methyl]benzoyl]-L-glutamic acid. It is a weak acid with a molecular weight of 454.45 and a molecular formula of C₂₀H₂₂N₈O₅. It is only slightly soluble in water and alcohol. Sodium methotrexate is water soluble and is used in injectable preparations.

Mechanism of Action. Free intracellular methotrexate tightly binds to dihydrofolate reductase, blocking the reduction of dihydrofolate to tetrahydrofolic acid, the active form of folic acid. As a result, thymidylate synthetase and various steps in *de novo* purine synthesis that require 1-carbon transfer reactions are halted. This in turn arrests DNA, RNA, and protein synthesis.

Amino acid syntheses blocked by methotrexate include those requiring 1-carbon transfer, such as the conversion of glycine to

serine and homocysteine to methionine. Experimental studies have shown that thymidylate synthetase is inhibited at methotrexate concentrations of 10⁻⁸ M or less, but inhibition of purine synthesis requires concentrations of 10⁻⁷ M or greater (331).

Methotrexate undergoes a variable degree of polyglutamation intracellularly. The polyglutamated forms of the drug are positively charged and do not readily pass through cell membranes. Methotrexate polyglutamates form an intracellular pool of active drug that is retained for long periods, sometimes months, after a single dose (332). The ability of tumor cells to add t-glutamyl residues to methotrexate may be a key determinant of antitumor activity.

The effects of methotrexate are rapidly reversible as free methotrexate leaves the cells. The normal intracellular levels of dihydrofolate are very low (10⁻⁸ M) but increase greatly after methotrexate administration.

Resistance to methotrexate may develop as a result of elevated dihydrofolate reductase activity or defective transport of methotrexate into malignant cells. Increased dihydrofolate reductase enzyme levels may also result from amplification of the dihydrofolate reductase gene, a process associated with homogeneously staining regions of chromosomes and an unstable inheritance mediated by double minutes or extra chromosomal DNA fragments (333). Certain quinazolines have been shown to be effective inhibitors of thymidylate synthetase and may be useful clinically in overcoming this type of resistance (334). *In vitro* studies and clinical experimentation with high-dose therapy indicate that a major mechanism of resistance is probably secondary to decreased cellular uptake.

Methotrexate is classified as a cell cycle phase-specific antimetabolite with activity mostly in S phase. Experimentally, methotrexate synchronizes tumor cells in S phase about 36 to 72 hours after administration (335).

The enhanced toxic effect on tumors compared with normal tissue from high-dose methotrexate with leucovorin rescue may be a result of bypassing normal carrier-mediated cell membrane transport of methotrexate. Leucovorin and its metabolite, 5-methyltetrahydrofolate, share a common influx transport site with methotrexate. There appear to be at least two active transport carrier systems involved in the influx and efflux of methotrexate and folates (336). If normal cells are rescued with calcium leucovorin, methotrexate can then exert a relatively greater toxic effect on the tumor cells. Selective rescue of normal cells may be mediated by a slower rate of DNA synthesis relative to the tumor cell or to tissue-specific differences in transmembrane transport.

Drug Disposition. Orally administered methotrexate is rapidly but incompletely absorbed from the gastrointestinal tract. It reaches peak blood levels in approximately 1 hour. Approximately 50% to 60% of the drug in the blood is bound to plasma proteins. Methotrexate is widely distributed to body tissues. In conventional doses, methotrexate is excreted unchanged in the urine. In high doses, it is partially metabolized to 7-hydromethotrexate, which is only slightly soluble in acidic solutions. About 1% to 11% of a dose is excreted as the 7-hydroxy metabolite, and this may comprise as much as 35% of the drug level in the terminal elimination phase. Only about one third of an oral dose is absorbed, but intramuscular absorption is almost 100% (337).

The hepatic extraction coefficient for methotrexate appears to be very low and intra-arterial hepatic doses show metabolism and pharmacokinetics similar to IV doses (338). Methotrexate is both filtered at the glomerulus and actively secreted by the renal tubule. Drugs that interfere with renal excretion of weak acids, such as probenecid, sulfapyrazone, and salicylates, may be expected to reduce the rate of methotrexate excretion. Probenecid has been used successfully in one study to produce a prolonged elevation of plasma methotrexate levels from otherwise low doses of methotrexate (339).

Plasma decay of methotrexate levels has been reported to be biphasic and possibly triphasic. Huffman et al. (340) reported half-lives after a 30 mg/m² dose to be triphasic: 0.750 ± 0.11, 3.49 ± 0.55, and 26.99 ± 4.44 hours, respectively. Stoller et al. (341) reported a biphasic plasma decay for high-dose therapy of 2.06 ± 0.16 and 10.4 ± 1.8 hours. Wang et al. (342) reported age-dependent biphasic elimination of high-dose methotrexate.

Patients with pleural effusions may accumulate methotrexate that slowly distributes from this compartment back into the plasma to increase systemic exposure and the risk of toxicity (343). Effusions should be drained before administration of methotrexate.

Administration and Dosage. Methotrexate may be given by the oral, intramuscular, intravenous (intravenous infusion or push), intra-arterial, or intrathecal routes. For treatment of neoplastic disease, oral administration of low-dose methotrexate is preferred owing to the rapid absorption of the tablet form of the agent. Methotrexate has been given by numerous dosing schedules. The usual starting doses are adjusted based on clinical response and hematologic monitoring. In general, methotrexate is administered orally or intramuscularly in doses of 15 to 30 mg daily for a 5-day course. Courses are usually repeated for three to five times as required, with rest periods of 1 or more weeks between courses until toxicities subside (344). Leucovorin is indicated following treatment with higher doses of methotrexate to diminish toxicity.

If the IV formulation is administered, the dose should be reduced by 50% for patients with renal insufficiency (BUN ≥ 30 mg/L). Similar dose reductions should be made for the oral form, although no specific guidelines are available. Methotrexate administration is contraindicated in patients with a creatinine clearance less than 40 mL/min and/or a serum creatinine greater than 2 mg/dL.

Side Effects and Toxicities. Hematologic effects of methotrexate include leukopenia, thrombocytopenia, and anemia. They occur rapidly and depend on the dose and schedule used. The nadir of hemoglobin depression occurs after 6 to 13 days and of reticulocyte at 2 to 7 days, with rebound between 9 and 19 days. Leukocyte nadir occurs within 4 to 7 days, followed by partial recovery and then, in rare instances, a second decrease in the leukocyte counts occurs during days 12 to 21. The platelet nadir is reached in 5 to 12 days. Hypogammaglobulinemia may also occur after methotrexate administration.

Nausea, vomiting, and anorexia are usually the earliest gastrointestinal symptoms. Gingivitis, glossitis, pharyngitis, stomatitis, and ulcerations with bleeding of the mucosal membranes of the mouth or other portions of the gastrointestinal tract may occur. If ulcerative stomatitis or diarrhea occurs, methotrexate therapy must be interrupted to prevent severe hemorrhagic enteritis or intestinal perforation.

Hepatotoxicity is more common in patients receiving high-dose therapy and in those receiving frequent small doses. Hepatocellular injury is indicated in liver function tests by a rise in serum glutamic oxaloacetic transaminase (SGOT) and serum glutamic pyruvic transaminase (SGPT), usually within the first 12 hours. Prothrombin times may rise with a decrease in plasma factor VII activity, and indirect hyperbilirubinemia may develop. All of these usually return to normal within 1 week. Hepatocytes appear to be protected by fractionated high-dose methotrexate treatments with leucovorin rescue if treatments are administered at intervals of less than 1 week. This may be due to leucovorin activity remaining from prior doses. Various pathologic hepatic changes can occur, including atrophy, necrosis, fatty changes, fibrosis, and cirrhosis. Liver biopsy is the only reliable means of assessing the degree of methotrexate hepatotoxicity.

Dermatologic side effects include erythematous rashes, pruritus, urticaria, folliculitis, vasculitis, photosensitivity,

depigmentation, or hyperpigmentation. Alopecia may occur, with several months being required for regrowth. CNS effects include dizziness, malaise, and blurred vision. Encephalopathy also has been reported. Intrathecal administration has been followed by increased CSF pressure, convulsions, paresis, and a syndrome resembling the Guillain-Barré syndrome (342). Deaths have been reported after intrathecal therapy. Renal failure may occur in patients receiving methotrexate, especially in high doses. This risk may be decreased by alkalinization of the urine to increase methotrexate solubility and by giving large quantities of fluid. Other reactions rarely reported include chills and fever, osteoporosis, and pulmonary reactions, mainly fibrosis (345).

Drug Interactions. Potential drug interactions have been postulated to occur with other protein-bound drugs, such as salicylates, sulfonamides, phenytoin, and *p*-aminobenzoic acid. These drugs displace methotrexate from its protein-binding site in the blood, causing an increase in the levels of the free drug. However, the overall degree of binding is probably not high enough for major displacement interactions.

Antibiotics used in gut sterilization may also alter methotrexate pharmacokinetics in humans, eliminating the slow phase of excretion (346). Salicylates and probenecid may also compete with methotrexate for renal tubular secretion and increase its serum half-life.

Ethyl alcohol may increase the possibility of methotrexate-induced hepatotoxicity. Oral anticoagulants, such as warfarin, may be greatly potentiated by methotrexate. Methotrexate may alter the liver metabolism of these drugs.

There are several drug interactions described for methotrexate with other chemotherapeutic agents. For example, a clinically significant interaction between methotrexate and L-asparaginase involves the administration of methotrexate 3 to 24 hours before L-asparaginase. The methotrexate treatment is believed to block protein synthesis and reduce asparaginase toxicities, allowing larger doses to be given. Some sequential methotrexate combinations may produce enhanced therapeutic activity. For example, methotrexate given 4 to 9 hours before 5-FU may produce enhanced antitumor activity in breast cancer, but with a commensurate increase in toxic effects (132,347). The mechanism of this interaction involves a significant increase in 5-FU for at least 3 hours (347). The reverse sequence decreases therapeutic activity (348).

Methotrexate activity is enhanced, and thus toxicity increased, when it is used with aspirin, penicillins, nonsteroidal anti-inflammatory agents, cephalosporins, or phenytoin. These agents inhibit the renal excretion of methotrexate (50).

Special Applications. Very high doses of methotrexate have been administered for a variety of tumors. Although leucovorin rescue reduces toxicity, it is still not certain that high-dose therapy is superior to more conventional dosing without rescue. Specific dosing schemes vary, but a high dose of methotrexate is usually administered intravenously and followed by calcium leucovorin 24 to 36 hours after initiation of therapy to prevent toxicity. Table 16.6 presents specific dosing recommendations.

The dose range of methotrexate with leucovorin rescue is 100 mg/m² to 10 g/m² given every 1 to 3 weeks. The lower end of this dosing spectrum has been administered in four divided oral doses over a 24-hour period. Most frequently, the dose is given by IV infusion in 1 to 2 L of fluid as a rapid infusion or over 6 to 24 hours. Higher peak methotrexate levels occur with more rapid IV infusions, and this may be theoretically more efficacious. There does not appear to be a clinical difference in toxicity between rapid and prolonged infusions. Only the 500- and 1,000-mg vials with no preservative should be used for this purpose. Further dilution of methotrexate is necessary and can be accomplished with normal saline or D₅W.

High-dose methotrexate has been associated with reversible nephrotoxicity. At high concentrations, methotrexate may

TABLE 16.6

DETERMINATION OF LEUCOVORIN DOSE FOR HIGH-DOSE METHOTREXATE (50 TO 250 MG/KG OVER 6 HOURS) REGIMENS^a

Plasma methotrexate concentration at 48 hours (M)	Leucovorin administration	
	mg/m ² of leucovorin every 8 hours	No. of doses of leucovorin
$<5 \times 10^{-7}$	15	7
5×10^{-7}	15	8
1×10^{-6}	100	8
2×10^{-6}	200	8

^aPlasma methotrexate concentration at 96 hours should be determined also. If the plasma concentration at 96 hours is $\geq 5 \times 10^{-6}$ M, the previously used leucovorin regimen should be continued until the plasma methotrexate concentration is $\leq 5 \times 10^{-7}$ M. All patients should also be prehydrated for 12 hours to establish an alkaline diuresis using 1.5 L/m² of fluid containing 10 mEq of bicarbonate and 20 mEq of KCl (pH of urine should be 7.0).

precipitate in the renal tubule, causing tubular dilatation and damage. The pK_a of methotrexate is 5.4. When the urine pH is near this value, methotrexate exists predominantly in its insoluble form and is likely to precipitate. Renal toxicity may be prevented by increasing urine alkalinity and flow. Sodium bicarbonate (3 g every 3 hours for 12 hours before therapy) is usually sufficient to induce an alkaline urine in adults. The sodium bicarbonate should be continued with frequent urine pH checks during the therapy and for 48 hours after the dose has been delivered. Methotrexate serum levels are useful in predicting toxic reactions and appropriately adjusting rescue doses of leucovorin (349). High-dose methotrexate with rescue is complicated and potentially extremely toxic. Only experienced teams using carefully designed protocols should attempt this treatment. Immediate methotrexate levels should be readily available. Fatal renal or hematologic reactions have occurred at major treatment centers despite the prophylactic precautions described (350).

Mitomycin

Chemistry. Mitomycin (Mutamycin, mitomycin C) is a purple antibiotic isolated from *Streptomyces caespitosus* that is indicated for disseminated adenocarcinoma of the stomach or pancreas in combination with other agents and as palliative treatment. It has also been proven to be useful in combination chemotherapy as a third-line agent in the treatment of advanced cervical cancer. Its chemical name is [1aR]6-amino-8-[[[(aminocarbonyl)oxy]methyl]-1,1a,2,8,8a,8b-hexahydro-8a-methoxy-5-methylazirino[2',3':3,4]-pyrrolo[1,2-a]indole-4,7-dione, and it has a molecular weight of 334. Mitomycin is heat stable, is soluble in water and other organic solvents, and has a unique absorption peak at 365 nm (351). In solution, it is slowly inactivated by visible but not ultraviolet light. It is very unstable in acidic and highly basic conditions. The aziridine and carbamate groups on mitomycin are necessary for alkylating activity but not for antibacterial activity. The compound is activated by reduction of the quinone moiety, which releases a methanol residue from the molecule. This allows the aziridine ring to open, exposing an electrophilic carbon at C₁ (alkylating site). The second (cross-linking) site for alkylation is exposed at C₁₀ after an enzymatic or chemically mediated loss of the carbamate side chain.

Mechanism of Action. Mitomycin is activated *in vivo* to an alkylating agent that cross links complementary DNA strands, halting DNA synthesis. DNA is the major site of mitomycin activity, although at extremely high concentrations, RNA synthesis may also be affected. The active metabolites of mitomycin resulting from reduction of the quinone moiety yield an opened aziridine ring exposing the primary alkylating site at C₁. A second alkylating site at C₁₀ is exposed with the enzymatic loss of the carbamate side chain (352). The molecular site of DNA binding has been identified at the N₂ and O₆ positions of adjacent guanines in the minor groove of DNA (353).

Activation of the drug can be mediated by chemical reducing agents, by microsomal enzymes, or even by brief exposure to an acidic pH. The extent of DNA binding appears to be related to the guanine and cytosine content of the particular DNA. Cytotoxicity probably results directly from DNA synthesis inhibition secondary to alkylation.

Oxygen free radicals may also contribute to the cytotoxicity of mitomycin by producing DNA strand breaks (354). Oxygen free radicals are produced by cyclic redox reactions of the quinone moiety. Mitomycin's cytotoxic action is not cell cycle phase-specific, but cytotoxic effects are maximized if cells are treated in late G₁ and early S phase. In addition to the direct cytotoxic effects of the drug, mitomycin also causes chromosomal aberrations (mutagenic activity), and in experimental systems, it is a potent carcinogen and teratogen.

Kennedy et al. (355) described selective activation of mitomycin by hypoxic cells, suggesting some drug selectivity for hypoxic tumors. Resistance to mitomycin involves an increase in specific cytosolic proteins (possibly a glutathione transferase) and collateral resistance with anthracyclines and dactinomycin (356). The latter type of multidrug resistance is mediated by P-glycoprotein expression, with resultant enhanced drug efflux, as observed in mitomycin C-resistant L-1210 cells (357).

Drug Disposition. Mitomycin is cleared rapidly from the vascular compartment. Peak serum concentrations of about 1 µg/mL are typically achieved after IV bolus doses of 10 mg/m². Less than 10% of the dose is excreted into the urine, and this is complete within a few hours after administration. Mitomycin also has been detected in the bile and feces, although animal studies demonstrate that the highest drug levels occur in the kidneys. Detectable levels were also found in muscle, lung, intestine, stomach, and eye, but not in the brain, spleen, or liver (351).

The primary means of mitomycin elimination is by liver metabolism, but the specific enzymes responsible are unknown. However, the enzymes responsible for metabolism do not appear to involve the P450 mixed-function oxide family. *In vitro* studies demonstrate drug inactivation on contact with tissue preparations from the spleen, liver, kidney, brain, and heart. This inactivation is further augmented by anaerobic conditions (357).

There is no detectable change in mitomycin pharmacokinetics in patients with altered hepatic function nor when other drugs, including furosemide, are given concurrently (358). Schilcher et al. (359) showed that the pharmacokinetics of mitomycin do not change after the administration of high doses.

Mitomycin distribution into bile and ascites fluids has been quantitated in patients receiving standard IV doses. The maximum biliary level of 0.5 µg/mL was achieved after 2 hours and was five- to eightfold higher than simultaneous plasma levels during the elimination phase (360). Mitomycin also rapidly penetrates into ascites fluid and reaches maximal concentrations of 0.05 µg/mL 1 hour after administration. This distribution represents about 40% of the total plasma exposure. The drug also appears to slightly concentrate in cervical tissues after IV administration (361).

With intra-arterial administration, the hepatic extraction of mitomycin averages only 23% (362). The calculated relative

advantage for hepatic arterial infusions is only 2.5- to 3.6-fold greater than for other methods.

Administration and Dosage. Sterile water (10 mL) should be added to each 5-mg vial of mitomycin and shaken gently to dissolve. Mitomycin should be administered intravenously to avoid extravasation of the drug. If extravasation occurs, severe local tissue necrosis may occur (363). The drug is usually given by a slow IV push, with continuous patient monitoring to lessen the chance of extravasation. Short infusions in 100 to 150 mL of D₅W or normal saline have also been used. Vein patency should be checked before the administration of any dose, using 5 to 10 mL of fluid that does not contain the drug. The same procedure should follow the dose. This flushes any remaining drug from the tubing and the venipuncture site.

The recommended dose of mitomycin used as a single agent is 20 mg/m² given IV every 6 to 8 weeks. In combination with other myelosuppressive drugs, mitomycin doses are typically limited to 10 mg/m² every 6 to 8 weeks. Bolus doses greater than 20 mg/m² produce severe toxicity without greatly enhancing efficacy.

Repeat dosing of mitomycin should be based on adequate marrow recovery, including leukocytes, platelets, and erythrocytes. Leukocyte count should return to 4,000/mm³ and platelet count to 100,000/mm³.

An ambulatory continuous infusion of mitomycin has been administered at 0.75 mg/m²/day for consecutive 50-day dosing (364). A dosing regimen of 3 mg/m²/day for 5 days every 4 to 6 weeks has also been used (364). These regimens are believed to deliver greater dose intensity by reducing myelosuppression. Intra-arterial perfusion doses of 20 mg/m² have been given every 6 to 8 weeks (365).

Side Effects and Toxicities. Bone marrow suppression involving platelets, leukocytes, and erythrocytes is the most serious toxicity, and it can continue for 3 to 8 weeks after drug administration is halted (351). Myelosuppression, particularly anemia, can be cumulative. This has been minimized by keeping total lifetime doses under 50 to 60 mg/m².

Gastrointestinal disturbances in the form of nausea, vomiting, and anorexia occasionally develop. These reactions are usually not severe and have an onset within 1 to 2 hours after administration. They may persist for several hours. Stomatitis may also occur, but it is generally not severe.

Renal toxicity detected by increasing serum BUN and creatinine levels with glomerular dysfunction is occasionally seen. This does not appear to be dose- or treatment-duration related, and it is usually not severe. However, mitomycin can also induce a microangiopathic hemolytic anemia with progressive renal failure (hemolytic-uremic syndrome) and cardiopulmonary decompensation. This disease is fatal within 3 to 4 weeks of diagnosis, although the onset is typically delayed for months after mitomycin administration (366). The incidence of this toxic effect may approach 10% among patients given large cumulative doses (366). In one series, renal complications from mitomycin developed in 1.6% of 63 patients receiving a total dose of 50 mg/m² or less, 11% of 37 patients receiving 50 to 69 mg/m², and 28% of 18 patients receiving total doses greater than 70 mg/m² (367). This suggests that a threshold for inducing microangiopathic hemolytic anemia may be a cumulative dose of about 50 mg/m² of mitomycin. Signs of the disease include thrombocytopenia, circulating schistocytes, and acute renal failure. Histopathologic examinations of the kidneys reveal fibrin thrombi in arterioles, tubular atrophy, and widespread glomerular necrosis.

Veno-occlusive disease of the liver has been reported after high-dose mitomycin therapy and autologous bone marrow transplantation (368). Signs include progressive hepatic dysfunction, abdominal pain, and ascites. Although this rarely has been observed with low-dose therapy, it appears to be much more frequent after high-dose regimens.

Alopecia may occur after mitomycin therapy, but it is usually not severe. Rarely, purple bands in the nail beds correspond to sequential doses of the drug. Lethargy or weakness may occur and can last from several days to 3 weeks. Fatigue and some drowsiness or confusion have also been observed. Dose-related skin reactions and fever with drug administration are occasionally seen.

Severe soft-tissue ulcers may also be expected if the drug escapes the vein during administration. Mitomycin extravasation injuries can result in chronic ulcers that can expand over months (363). Particularly distressing aspects of some mitomycin extravasations include the delayed (3 to 4 months) and sometimes distal occurrence of soft-tissue ulceration after uneventful injections in a peripheral vein (369). In animals, the only effective antidote to mitomycin skin reactions was topical DMSO (99% DMSO). Mitomycin extravasations may be empirically treated with topical application of 1.5 mL of DMSO every 6 hours for 14 days (370).

Interstitial pneumonia thought to be secondary to mitomycin has been reported for a small number of patients. These patients showed rapid improvement after treatment with corticosteroids (371).

Special Precautions. Myelosuppression may be cumulative with successive doses of mitomycin and may necessitate dose reductions. Careful monitoring of blood counts is critical. Serious local ulceration may occur if the drug is delivered outside the vein. Extravasation of mitomycin must be avoided.

Clinically significant antitumor drug synergy in humans has yet to be described for mitomycin, although it is probably at least additive in several drug combinations, including the FAM regimen (5-FU, doxorubicin, mitomycin) used in gastrointestinal cancer, the MOB regimen (mitomycin, vincristine [Oncovin], bleomycin) used in carcinoma of the uterine cervix, and megestrol acetate in patients with advanced breast cancer.

Special Applications. Mitomycin and intraperitoneal hyperthermia were combined to prophylactically treat patients with gastric cancer (372). Mitomycin (8 to 100 µg/mL) was administered continuously in bags containing 2,000 mL of heated (40°C to 45°C) saline solution. The total perfusion was 8 to 12 L over 50 to 60 minutes, comprising a mitomycin C dose of 64 to 100 mg. Low peak plasma levels (0.1 µg/mL) were produced, and approximately 39% of the administered dose was retained intraperitoneally. The half-lives of mitomycin C in the perfusate are 10 to 17 minutes (α) and 70 to 120 minutes (β) (373). Serum protein levels decreased significantly during and after the procedure, indicating that serum protein reaccumulates in the peritoneal space.

Mitomycin (5 to 10 mg) has also been given every 28 days combined with cisplatin (100 mg/m²) using the intraperitoneal route. Mitomycin was always given 1 week after cisplatin, and the dose was diluted in 2 L of normal saline. In 11 patients with malignant peritoneal mesothelioma, five of eight previously untreated patients had reduced fluid reaccumulation lasting from 2 to 32 months (median 5 months) (202). The major toxic reaction was pain, and catheter failure was related to the intraperitoneal mitomycin.

Oxaliplatin

Chemistry. Oxaliplatin (Eloxatin, diaminocyclohexane platinum, DACH platinum) is a third-generation platinum with the molecular formula C₈H₁₄N₂O₄Pt and the chemical name of *cis*-[(1R,2R)-1,2-cyclohexanediamine-N,N']][oxalato(2-)O, O']platinum, and it has a molecular weight of 397.3. Oxaliplatin is an organoplatinum complex in which the platinum atom is complexed with 1,2-diaminocyclohexane (DACH) and with an oxalate ligand as a leaving group. Oxaliplatin is slightly soluble in water (6 mg/mL), slightly soluble in

methanol, and practically insoluble in ethanol and acetone. It is FDA approved for second-line treatment in metastatic colorectal cancer in combination with fluoropyrimidines.

Mechanism of Action. Oxaliplatin binds to DNA in a manner similar to cisplatin, in that it binds to repeating deoxyguanosines d(GpG) in a single DNA strand. It reacts with DNA to produce intrastrand cross links (>90%) at adenine-guanine d(ApC) sites and to produce intrastrand cross links (<5%) with guanosines of opposing DNA strands (dG)₂ (50,128). This results in inhibition of DNA synthesis, function, and transcription. Oxaliplatin reacts more rapidly with DNA to form these interlinks and intralinks (e.g., within 15 minutes) than the other platinum agents (12 hours for cisplatin and over 24 hours for carboplatin) (128). Furthermore, unlike the other platinum-DNA adducts, mismatch repair enzymes are unable to recognize the adducts formed by oxaliplatin because of their bulkier size (50).

Drug Disposition. In a summary of pharmacokinetic studies, plasma platinum C_{max} values have been shown to be in the range of 2.59 to 3.22 µg/mL, and mean AUC_{0-48h} in the range of 50.4 to 71.5 µg/mL · hour after an oxaliplatin dose of 130 mg/m² (2-hour infusion) (373). Inpatient and outpatient variability was moderate to low (23% and 6%, respectively) (374). In 1-hour infusion studies, mean plasma platinum C_{max} and AUC_{0-24h} increased in a dose-dependent fashion up to 180 mg/m². The pharmacokinetics of platinum in ultrafiltrate after administration of oxaliplatin are triphasic and characterized by short α (0.28 hour) and β (16.3 hours) distribution phases, which are followed by a long terminal γ phase (273 hours) (375). Oxaliplatin is primarily cleared from plasma by renal excretion (53.8%) and covalent tissue binding. Clearance is not affected by age, gender, or hepatic impairment (375).

Administration and Dosage. Reconstitute oxaliplatin by adding 10 mL sterile water for each 50-mg vial, or dextrose (5%). The solution must be further diluted in 250 to 500 mL of 5% dextrose prior to administration. The infusion line should be flushed with D₅W prior to administration of any concomitant medication (375). Premedication with antiemetics is recommended.

The recommended dose for metastatic colorectal cancer is as follows: on day 1 of every 2-week cycle, oxaliplatin (85 mg/m²) is generally administered intravenously with leucovorin (200 mg/m²) over 120 minutes at the same time in two separate bags using a Y-line, followed by 5-FU (400 mg/m² IV bolus), followed by 5-FU (600 mg/m²) in 500 mL D₅W as a 22-hour continuous infusion. On day 2, the patient should receive leucovorin (200 mg/m²) over 120 minutes at the same time in two separate bags using a Y-line, followed by 5-FU (400 mg/m² IV bolus), followed by 5-FU (600 mg/m²) in 500 mL D₅W as a 22-hour continuous infusion.

In phase 2 trials for gynecologic cancers, the recommended dose of oxaliplatin is 130 mg/m² intravenously over 2 hours every 21 days (376,377).

Side Effects and Toxicities. Oxaliplatin produces dose-limiting peripheral neuropathy and gastrointestinal and hematologic adverse events. Neurotoxic symptoms usually resolve within a week of stopping therapy; however, symptom intensity is cumulative with repeated courses of oxaliplatin (28,374,378). Other common adverse events include mild leukopenia and mild to moderate thrombocytopenia. Nausea and vomiting are common, and antiemetic prophylaxis is required with oxaliplatin therapy.

Unlike other platinum-containing agents, oxaliplatin is not associated with nephrotoxicity. Alopecia has not been reported with oxaliplatin.

Special Applications. Oxaliplatin is an agent with substantial activity in platinum-sensitive ovarian cancer patients previously treated with cisplatin. Bougnoux et al. (379) noted two complete and eight partial responses in 24 patients who

were platinum sensitive (41.7% response rate). Similar findings were seen in a phase 2 study, which also saw a 42% response rate in platinum-sensitive patients. Chollet et al. (380) studied similar populations of patients and noted six responses in 13 platinum-sensitive patients (46%) and a 17% response rate (3 of 18 patients) in platinum-resistant patients. Phase 2 studies have seen only minimal activity in platinum-resistant patients (less than 6% response rate) (377).

Paclitaxel

Chemistry. Paclitaxel (Taxol) is one of the most commonly used drugs in oncology, with FDA approval for primary or salvage therapy for epithelial ovarian cancer, as salvage therapy for metastatic breast cancer, in second-line treatment of AIDS-related Kaposi's sarcoma, and in the treatment of non-small cell lung cancer. It is also active against a variety of other solid tumors, including cervical and endometrial cancer (380,381). It is a diterpene plant product derived from the bark of the Pacific yew, *Taxus baccata*. It has a molecular weight of 853.9, is insoluble in water, and has an empiric formula of C₄₇H₅₁NO₁₄. Its chemical name is 5β,20-epoxy-1,2α,4,7β,10β,13α-hexahydroxytax-11-en-9-one-4,10-diacetate 2-benzoate 13-ester with (2R,3S)-N-benzoyl-3-phenylisoserine.

Mechanism of Action. Paclitaxel acts as a mitotic spindle poison. In a manner contrary to known mitotic spindle inhibitors, such as colchicine and podophyllotoxin, paclitaxel promotes assembly of microtubules and stabilizes them, preventing depolymerization. This inability to depolymerize microtubules prevents cellular replication (118).

Drug Disposition. Early pharmacokinetic studies using standard doses and a 24-hour infusion suggested that paclitaxel pharmacokinetics were linear; however, with short infusions and/or high dose levels, paclitaxel's nonlinear pharmacokinetics become readily apparent (157). The nonlinearity is due to saturable distribution, metabolism, and elimination. Terminal elimination half-life is largely dependent on the dose and administration schedule. At a dose level of 175 mg/m² with a 3-hour infusion, mean pharmacokinetic parameters of paclitaxel include the following: plasma t_{1/2α}, 16 minutes; plasma t_{1/2β}, 140 minutes; plasma t_{1/2γ}, 18.75 hours; plasma clearance, 12.69 L/h/m²; plasma AUC, 16.81 µmol/L · hour; 48-hour urinary excretion, <10% of dose; and 48-hour fecal excretion, 70% of dose (157).

Clearance is rapid and not due to urinary excretion; the major route of paclitaxel elimination is believed to be via hepatic metabolism and subsequent biliary excretion (381). About 70% to 80% of the drug is eliminated by fecal excretion.

Administration and Dosage. All patients undergoing paclitaxel therapy should receive premedication to prevent severe hypersensitivity reactions. A recommended regimen is dexamethasone (either 20 mg orally the night before treatment and the morning of treatment or 20 mg IV 30 minutes before paclitaxel delivery) plus diphenhydramine (50 mg) and famotidine (20 mg) IV 30 minutes before chemotherapy (382). For the majority of patients, administration of dexamethasone 20 mg IV 30 to 60 minutes before paclitaxel is sufficient and has been proven to be effective in preventing hypersensitivity reactions.

Paclitaxel is commercially available as an injection concentrate in 30-mg (5 mL), 100-mg (16.7 mL), and 300-mg (50 mL) multidose vials. Before infusion, paclitaxel must be diluted with 0.9% sodium chloride, 5% dextrose, 5% dextrose and 0.9% sodium chloride injection, or 5% dextrose in Ringer's injection to a final concentration of 0.3 to 1.2 mg/mL. The solution is stable for up to 27 hours at room temperature. Paclitaxel should be administered through an in-line filter with a microporous membrane not greater than 0.22 µ to remove particulates that are present in paclitaxel solutions. Although particulate formation does not indicate loss of drug

potency, solutions exhibiting excess particulate matter formation should be discarded. Because of the possibility of leaching of phthalate plasticizers with paclitaxel solutions, only non-polyvinylchloride (such as polyethylene or polyolefin) IV administration sets should be used.

As a result of an unacceptable level of severe hypersensitivity reactions in early phase 1 studies (most likely related to the Cremophor EL vehicle), a 24-hour infusion schedule and a premedication regimen with corticosteroids and histamine H₁- and H₂-antagonists were used in all phase 2 and 3 clinical trials conducted in the United States from 1987 to 1992. Later clinical studies established that a 3-hour paclitaxel infusion schedule can be administered safely without a significant increase in major hypersensitivity reactions and that the shortened infusion schedule is associated with significantly less grade 4 neutropenia than the 24-hour infusion (i.e., 71% vs. 18% for the 24- and 3-hour infusions, respectively) (383). Follow-up studies have determined that a 1-hour infusion schedule also is feasible; however, infusion durations less than 1 hour are associated with a prohibitively high rate of hypersensitivity reactions (384).

There were early concerns that the shorter infusion schedules might be associated with a decline in efficacy. However, results from GOG-158, a phase 3, randomized study in women with optimal disease, advanced ovarian cancer, revealed that paclitaxel 175 mg/m² by 3-hour infusion combined with carboplatin (targeted AUC of 7.5) (arm II) had similar activity with less toxicity than paclitaxel 135 mg/m² by 24-hour infusion plus cisplatin 75 mg/m² (arm I) (385). Median progression-free survival and overall survival were 19.4 and 48.7 months, respectively, for arm I (paclitaxel-cisplatin) compared with 20.7 and 57.4 months, respectively, for arm II (paclitaxel-carboplatin). Because of its ease of administration and lower toxicity profile (cisplatin plus short-infusion paclitaxel is associated with dose-limiting neurotoxicity), the recommended primary chemotherapy regimen for advanced ovarian cancer is paclitaxel 175 mg/m² by 3-hour infusion plus carboplatin (targeted AUC of 6.0 to 7.5) every 21 days for six cycles (385). Although this generally is a well-tolerated regimen, neurosensory toxicity and prolonged thrombocytopenia can prove to be dose limiting. The FDA-approved regimen for first-line treatment of ovarian cancer is paclitaxel 135 mg/m² over 24 hours plus cisplatin 75 mg/m² every 21 days for six cycles or paclitaxel 175 mg/m² over 3 hours plus cisplatin 75 mg/m².

The FDA-approved recommended regimen for salvage therapy for patients with platinum-refractory ovarian cancer is paclitaxel 135 or 175 mg/m² administered IV over 3 hours every 3 weeks, but the optimal regimen has not been clearly established. Paclitaxel has been administered by various other schedules during investigational studies in patients with solid tumors, including 135 to 250 mg/m² as a 24-hour continuous infusion every 3 weeks; 212 to 225 mg/m² as a 6-hour infusion every 3 weeks; 30 mg/m² as a 1-hour infusion daily for 5 days every 3 weeks; 30 mg/m² as a 6-hour infusion daily for 5 days every 3 weeks; 120 to 140 mg/m² as a 96-hour infusion every 3 weeks; and 150 mg/m² as a 120-hour infusion every 3 weeks (118). Most recently, IP therapy for optimally debulked advanced ovarian cancer has demonstrated a significant survival advantage with a regimen of intravenous paclitaxel on day 1, intraperitoneal cisplatin on day 2, and intraperitoneal paclitaxel on day 8 (see the Intraperitoneal Drug Pharmacokinetics and Cisplatin sections of this chapter for more details on this IP regimen) (4,96,97).

Special Precautions. Before the institution of standard prophylactic medications, the incidence of major hypersensitivity reactions associated with paclitaxel therapy approached 25% to 30%. With premedication, the incidence of severe hypersensitivity reactions has decreased to less than 2%. The majority of

paclitaxel-induced hypersensitivity reactions can be categorized as grade 1, with symptoms of dyspnea with bronchospasm, urticaria, and hypotension. Major sensitivity reactions usually occur within the first 10 minutes after the first or second dose of paclitaxel (118). Minor symptoms of flushing and rashes are not predictive of the future development of severe manifestations (118,383). According to National Cancer Institute guidelines for paclitaxel administration, emergency equipment must be available and medical personnel should be in attendance during paclitaxel infusion, especially during the first 15 minutes of the first and second courses. Vital signs should be periodically monitored during the first several hours of drug infusion. The paclitaxel infusion should be discontinued immediately if symptoms of a major hypersensitivity reaction occur (including respiratory distress, hypotension, generalized urticaria, and angioedema). Severe hypersensitivity reactions may be treated with IV epinephrine, IV diphenhydramine, IV fluids, and nebulized beta-agonists. Steroid therapy may be helpful in the resolution of recurrent symptoms (386). There is strong evidence that patients who develop major hypersensitivity reactions may be successfully retreated with slow, low-dose infusions of paclitaxel after premedication with multiple high doses of corticosteroids and antihistamines (387).

Drug Interactions. Paclitaxel therapy appears to modify the hematologic toxicity associated with platinum agents. Rowinsky et al. (388) conducted a phase 1 study of sequential escalating doses of paclitaxel and cisplatin therapy and determined that myelosuppression was more severe when paclitaxel was administered immediately after cisplatin therapy than when given prior to cisplatin.

Concomitant medications that contain substrates or inhibitors of hepatic enzymes, principally cytochrome P450 isoenzymes CYP₂C₈ and CYP₃A₄, may increase paclitaxel clearance, and caution should be exercised when administering paclitaxel. In a study by Chang et al. (389), the pharmacokinetics of paclitaxel were significantly altered by the concomitant use of anticonvulsants (i.e., phenytoin, carbamazepine, and phenobarbital), and the maximum tolerated doses of paclitaxel in malignant glioma patients were 360 mg/m² for those on anticonvulsant therapy versus 240 mg/m² for those not receiving anticonvulsants. There was also a significant difference in paclitaxel metabolite and toxicity profiles between the two groups. Central neurotoxicity, rather than neutropenia, was the dose-limiting toxicity in patients on anticonvulsant therapy who received paclitaxel at a dose greater than 350 mg/m².

Special Applications. Paclitaxel is a particularly promising agent for intraperitoneal administration, in that this route of drug delivery results in a more than 3-log increased exposure of the peritoneal cavity relative to systemic circulation. Additionally, potentially cytotoxic levels of paclitaxel remain in the peritoneal cavity for 5 to 7 days following intraperitoneal (IP) administration, and thus weekly intraperitoneal treatment results in continuous drug exposure (390). A phase 2 study in women with ovarian, fallopian, or peritoneal cancer and small-volume residual disease following primary chemotherapy has shown that IP paclitaxel has significant activity as evidenced by a 61% surgically defined complete response rate (391). Three large phase 3 trials in the GOG and the Southwest Oncology Group (GOG-104/SWOG-8501, GOG-114, and GOG-172) comparing various combination chemotherapeutic regimens administered IV or IP have documented significant survival advantages for the intraperitoneal treatment arms (3–5). Most recently, in GOG-172, an intraperitoneal regimen (intravenous paclitaxel, 135 mg/m² over 24 hours on day 1, intraperitoneal cisplatin 100 mg/m² on day 2, and intraperitoneal paclitaxel 60 mg/m² on day 8, every 21 days) was associated with a 25% reduction in the risk of death as compared to the intravenously administered regimen (intravenous paclitaxel plus cisplatin) ($p = 0.03$) (4). The day 1

paclitaxel may alternatively be given over 3 hours to reduce the myelosuppressive activity of paclitaxel and to eliminate the need for a hospital stay (96).

Paclitaxel has demonstrated activity against both endometrial and cervical cancers (392). Woo et al. (393) reported a 43% response rate to paclitaxel (95% CI, 6% to 80%) in seven patients with advanced, progressive, or recurrent endometrial cancer following platinum analog treatment. A GOG study noted a 14.3% complete and 21.4% partial response rate in 28 evaluable patients with endometrial cancer not previously treated with chemotherapy (394). Leukopenia was the most prominent side effect noted. A response rate of 37% (95% CI, 16% to 62%) was reported in 19 patients pretreated with cisplatin, doxorubicin, and cyclophosphamide (395). A GOG phase 2 trial of paclitaxel (3-hour infusion of 200 mg/m² every 21 days or 175 mg/m² for patients with prior pelvic radiation therapy) found a 27.3% response rate (95% CI, 15% to 42.8%) in 44 persistent or recurrent endometrial cancer patients who failed prior chemotherapy (396).

A GOG phase 2 trial of single-agent paclitaxel in advanced cervix cancer has demonstrated a response rate of 31% (380). Trials of combination cisplatin-paclitaxel (IV paclitaxel 175 mg/m² by 3-hour infusion followed by cisplatin 75 mg/m²) in metastatic and recurrent cervical cancer show moderate activity (47% response rate; 95% CI, 30% to 65%) (397). A similar response rate (45%) was seen in another phase 2 trial of first-line therapy of advanced cervical cancer (IV paclitaxel 135 mg/m² by 24-hour infusion followed by cisplatin 75 mg/m² every 28 days) (398).

Pemetrexed

Chemistry. Pemetrexed (Alimta) is an antifolate antineoplastic agent with the chemical name of L-glutamic acid, N-[4-[2-(2-amino-4,7-dihydro-4-oxo-1H-pyrrolo[2,3-d]pyrimidin-5-yl)ethyl]benzoyl]-, disodium salt, heptahydrate. It has a molecular weight of 597.49 and the molecular formula C₂₀H₁₉N₅Na₂O₆ · 7H₂O. Pemetrexed is FDA approved for combination therapy with cisplatin for malignant pleural mesothelioma, and for single-agent therapy for non-small cell lung cancer.

Mechanism of Action. Pemetrexed inhibits the folate-dependent enzymes thymidylate synthase (TS), dihydrofolate reductase (DHFR), and glycinamide ribonucleotide formyltransferase (GARFT). The inhibition of GARFT, for example, is directly associated with a decrease in the rate of tumor cells (399). Although methotrexate was an early but potent inhibitor of DHFR, the antifolate activity of pemetrexed is quite different. The K_m for pemetrexed is one hundredth that of methotrexate for folylpolyglutamate synthetase (FPGS), making it possible to rapidly and completely block TS activity, whereas methotrexate acts in a more gradual and cumulative process, only impacting cellular proliferation at the point where more than 95% of the enzyme is inhibited (399). Additional details regarding the unique mechanism of action of pemetrexed, including features of membrane transport, its maintained activity in loss of transport activity, and its comparison with other antifolates (e.g., 5-FU, methotrexate, raltitrexed) are discussed in more detail elsewhere (399).

Drug Disposition. Pemetrexed is primarily excreted in the urine and is only minimally metabolized. The elimination half-life is approximately 3.5 hours among patients with normal renal function. Pemetrexed exposure increases with decreasing renal function. Pemetrexed is 81% bound to plasma proteins, and binding is not affected by renal function.

Administration and Dosage. Pemetrexed is administered IV at 500 mg/m² over 10 minutes on day 1 of every 21-day cycle. When used in combination therapy, cisplatin (75 mg/m² over 2 hours) should begin 30 minutes after the pemetrexed

administration. The premedication regimen with pemetrexed includes corticosteroids (dexamethasone) to reduce skin rash reactions, and folate-containing vitamin supplementation (daily for at least 7 days prior to pemetrexed administration) to reduce some toxicities.

Side Effects and Toxicities. The most commonly occurring side effects associated with pemetrexed treatment include hematologic toxicity, fever and infection, stomatitis, pharyngitis, and rash. Although many toxicities appeared significantly lower among patients receiving folate supplementation (e.g., neutropenia, nausea, vomiting, fever, infection), hypertension (11% vs. 3%), chest pain (8%, vs. 6%), and thrombosis/embolism (6% vs. 3%) were higher among those receiving supplementation. Rare cases of colitis have been reported in post-marketing studies.

Topotecan

Chemistry. Topotecan (Hycamtin, topotecan hydrochloride) was approved by the FDA in 1996 for treatment of ovarian cancer patients after failure of primary chemotherapy. It is also indicated in the treatment of small cell lung cancer after failure of first-line chemotherapy. Topotecan is a semisynthetic analog of camptothecin. The parent compound is derived from the bark of an ornamental tree native to Asia, *Camptotheca acuminata*. Sodium camptothecin was studied in clinical trials in the late 1960s through the early 1970s. However, clinical development of this agent was halted despite evidence of a variety of tumor responses because of severe and unpredictable toxicities (e.g., myelosuppression and hemorrhagic cystitis) (400). Topotecan and other camptothecin analogs (e.g., irinotecan) have been formulated in an effort to overcome unacceptable toxicities and to increase cytotoxicity and water solubility. Topotecan incorporates a stable basic side chain at the 9-position of the A-ring of 10-hydroxycamptothecin, which increases aqueous solubility. The molecular weight is 457.9 (the HCl salt) and the formula is C₂₃H₂₃N₃O₅ · HCl (the free base has a molecular weight of 421.5). The chemical name of topotecan is (S)-10-[(dimethylamino)methyl]-4-ethyl-4,9-dihydroxy-1H-pyrano[3',4':6,7]indolizino [1,2-b]quinoline-3,14-(4H,12H)-dione monohydrochloride.

Mechanism of Action. In a manner similar to camptothecin, topotecan's cytotoxicity results from the inhibition of TOPO-I, an enzyme that induces reversible single-strand breaks during DNA replication. Camptothecin analogs bind with and stabilize the transient TOPO-I-DNA complex, preventing religation of the single-strand breakage. The interaction of the ternary topotecan-TOPO-I-DNA complex with replication enzymes results in double-strand DNA breaks and cellular death. Topotecan exists in a pH-dependent equilibrium as both a closed lactone ring and a hydroxy acid; the hydroxy acid is formed by hydrolysis of the lactone ring. The active lactone form predominates at a pH below 7.0, and at a pH of 6.0, over 80% of topotecan exists in the lactone form. Slow reaction kinetics studies have shown that the hydroxy acid is inactive and only the closed lactone bonds with the TOPO-I-DNA complex (302).

Drug Disposition. After IV administration, plasma pharmacokinetics show that the lactone form, which is active as an inhibitor of TOPO-I, is rapidly converted to the hydroxy acid form. At the end of a brief infusion, approximately half of the dose administered exits as hydroxy acid (308). One hour after administration, less than 30% of the dose remains in the lactone form. Topotecan does not inhibit TOPO-II.

Both forms of topotecan are subject to rapid biphasic elimination. In a summary of pharmacokinetics studies, the mean half-life of topotecan lactone was only 3.0 hours (range 1.2 to 4.9 hours) (302). Binding to plasma proteins is approximately 35%. Renal excretion appears to account for 40% to 70% of drug clearance (50,128).

When topotecan was administered as a weekly 24-hour IV infusion of 1 to 2 mg/m², the plasma steady-state concentration and the AUC increased linearly with dose. The lactone to total-drug-concentration ratio was constant, which suggests that the total drug concentration may be used as a measure of active lactone exposure with weekly, long infusions (401). Additionally, comparison of day 1 pharmacokinetics values with blood counts showed that both the topotecan AUC and lactone AUC were predictive of the level of neutrophil reduction on days 15, 22, and 29 using the sigmoid E_{max} model (401). This led the investigators to suggest that topotecan-induced myelosuppression is noncumulative and that elimination probably remains unchanged with repeat dosing in individual patients. Other studies have also found a correlation between the topotecan AUC and level of neutropenia (308,402).

Limited sampling models for topotecan pharmacokinetics have been proposed that may facilitate tailoring of topotecan drug doses in individual patients and large pharmacodynamic studies of topotecan (403). Plasma concentrations of the lactone and hydroxy acid forms of topotecan at 2 hours, after a 30-minute infusion, reliably predicted the lactone form AUC, the hydroxy acid AUC, the total topotecan AUC, and the clearance rate.

Administration and Dosage. Each 4-mg vial of topotecan should be reconstituted with 4 mL of sterile water. The resulting solution can be further diluted with either 0.9% sodium chloride or 5% dextrose. Because the active lactone form of topotecan is subject to a pH-dependent hydrolysis to the inactive hydroxy acid, consideration should be given to maintenance of an acidic pH during drug infusion. When the topotecan lactone is dissolved in 5% dextrose, only approximately 10% is converted to the hydroxy acid (308). Because the product does not contain an antibacterial preservative, it should be used immediately once constituted.

Parenteral topotecan has been administered by IV infusions varying in length from 30 minutes to 21 days (302). As discussed below, the dosing schedule has a profound effect on the maximum tolerated dose (MTD).

An oral formulation has been evaluated in murine tumor models and in phase 1-2 trials. It has been associated with excellent bioavailability and similar efficacy as compared with parenteral topotecan in four of the five murine tumor models tested (404). In early-phase human trials, oral topotecan is well tolerated and active in second-line therapy of ovarian cancer and small cell lung cancer, and is associated with less neutropenia than the intravenous formulation (405,406).

The standard FDA-approved dosing regimen is 1.5 mg/m²/day × 5 days by 30-minute IV infusion every 21 days, for a minimum of four courses owing to delayed tumor response, as tolerated (in the absence of tumor progression). However, this dosing schedule is associated with a more than 80% incidence of grade IV neutropenia. Many oncologists, therefore, use a dose of 1.25 mg/m²/day for 5 days and/or administer prophylactic granulocyte colony-stimulating factor (G-CSF).

In phase 1 studies, the MTD of topotecan was highly dependent on the length of infusion schedules; longer infusions were generally associated with lower MTDs. The estimated MTD of topotecan when administered as a 30-minute, 72-hour, and 120-hour continuous infusion is 22.5 mg/m², 1.6 mg/m²/day (4.8 mg/m² total), and 0.68 mg/m²/day (3.4 mg/m² total), respectively. As a continuous 21-day infusion administered every 28 days, the MTD of topotecan appears to be 0.5 mg/m²/day (10.5 mg/m²/cycle) (302,407). A weekly dosing schedule has been developed that appears to maintain antitumor activity without causing severe myelosuppression (408,409).

Side Effects and Toxicities. Toxicity data are available from a phase 3, randomized study of topotecan 1.5 mg/m²/day for 5 days every 21 days versus paclitaxel 175 mg/m² IV over 3 hours every 21 days in ovarian cancer patients with progressive

or recurrent disease following primary platinum-based chemotherapy (410). Neutropenia was the predominant toxicity in this study: 79% of patients experienced grade 4 neutropenia, 25% of patients experienced febrile neutropenia, and 5% of patients developed sepsis (two patients [2%] died of sepsis). The onset of grade 4 neutropenia was on days 9 through 15 of a chemotherapy cycle and it did respond to G-CSF therapy. Thrombocytopenia also occurred frequently: 50% of patients experienced grades 3 to 4 thrombocytopenia (25% experienced grade 4). Grade 4 anemia occurred in 3.6% of patients.

The most common nonhematologic toxicities were cumulative, dose-related alopecia (76%) and nausea/vomiting (10%, grades 3 to 4), which was amenable to antiemetic therapy. Other frequent toxicities were fatigue (41%), constipation (43%), diarrhea (40%), abdominal pain (27%), fever in the absence of neutropenia (29%), stomatitis (24%), dyspnea (24%), and asthenia (22%) (410).

Although the results of the study described in the above paragraphs led to an FDA approval of topotecan as salvage therapy for patients with ovarian cancer with a recommended dose level of 1.5 mg/m²/day for 5 days, it is important to note that the patients in this European study had only received one prior platinum-based chemotherapeutic regimen, and that most had received cisplatin (not carboplatin) and none had received prior paclitaxel. In general, topotecan-induced myelosuppression is more severe in patients who have previously received carboplatin and/or multiple prior chemotherapeutic regimens. For this reason, many clinicians use an initial topotecan dose of 1.25 mg/m²/day and/or administer prophylactic G-CSF.

Special Precautions. Because topotecan has a high rate of renal excretion and a modest hepatic clearance, a clinical study was conducted to evaluate the impact of renal and hepatic dysfunction on toxicity in patients undergoing treatment with topotecan on a daily × 5 dosing schedule (411). Pharmacokinetic analyses showed clear correlations between creatinine clearance and plasma clearance of both topotecan and topotecan lactone ($r^2 = 0.65$, $p < 0.0001$). Although the standard dose for patients with good renal function is 1.5 mg/m²/day × 5 days, this study determined that the recommended starting dose for patients with moderate hepatic dysfunction (creatinine clearance of 20 to 39 mL/min) was 0.75 mg/m². The investigators urged extreme caution with topotecan administration in patients with more profound renal insufficiency and recommend further dose reductions for heavily pretreated patients (411). Hepatic insufficiency did not appear to exacerbate hematologic toxicity (411). Nonhematologic toxicity appeared to be unaffected by either renal or hepatic insufficiency.

Drug Interactions. Drug sequence of the paclitaxel/topotecan combination had no apparent impact on hematologic toxicities or pharmacologic behavior (412). However, drug sequence of the cisplatin/topotecan combination did have a significant impact on toxicity and topotecan pharmacokinetics. Prior administration of cisplatin significantly reduced the clearance of topotecan (possibly as a result of subclinical nephrotoxicity) and increased hematologic toxicity (388). In GOG-182, carboplatin was administered on day 3 of a daily × 3 topotecan administration schedule, because administration of carboplatin on day 1 was associated with excessive neutropenia and thrombocytopenia (413).

There has been interest in sequential administration of topotecan (TOPO-I inhibitor) with TOPO-II inhibitors (e.g., doxorubicin, etoposide). The rationale is that administration of a TOPO-I inhibitor would induce up-regulation of TOPO-II in tumor cells and thus enhance cytotoxicity. One clinical/translational study of topotecan (0.17 to 1.05 mg/m²/day as a 72-hour continuous infusion on days 1 to 3) followed by etoposide (75 or 100 mg/m²/day as a 2-hour infusion daily on days 8 to 10)

failed to show reliable down-regulation of TOPO-I and up-regulation of TOPO-II following administration of topotecan (414). Although significant clinical activity was observed in this phase 1 study in patients with various solid tumors, the investigators concluded that the toxicity and translational research results did not support a significant synergistic advantage of this combination. Another study of the TOPO-I and TOPO-II inhibitor combination therapy (IV topotecan 0.5 mg/m²/day for 5 days and oral etoposide 50 mg twice daily for 7 days of every 21-day cycle, with dose escalation of topotecan 0.75 and 1.0 mg/m²) found the combination to be safe and effective in small cell lung cancer patients; however, the incidence of grades 3 to 4 neutropenia was 25%, and two patients died from neutropenic sepsis (415).

TOPO-I is a biochemical mediator of radiosensitization in cultured mammalian cells by camptothecin derivatives (416). There are *in vitro* and *in vivo* data suggesting that topotecan may have activity as a radiation-sensitizing agent (417). However, this apparent synergistic relationship remains to be explored in clinical trials.

Special Applications. Phase 1 trials of IP topotecan have demonstrated the feasibility of IP administration and the favorable toxicity profile (418,419). Pharmacokinetic studies revealed that the pharmacologic advantage associated with IP administration of topotecan (expressed as the ratio of the peritoneal to plasma AUC) was 31.2 (419). In a Netherlands study, patients were treated with escalating doses (5 to 30 mg/m² every 21 days). The dose-limiting toxicity was acute hypotension, chills, and fever at the 30 mg/m² dose level (418). The University of California, San Diego, study treated patients with escalating doses from 2 to 4 mg/m² every 21 days. The MTD of IP topotecan was determined to be 4 mg/m² every 21 days and the recommended dose for further phase 2 study was 3 mg/m². The dose-limiting toxicity was neutropenia. Other toxicities included anemia, vomiting, fever, and abdominal pain (419).

Vinblastine Sulfate

Chemistry. Vinblastine (Velban) is used in the treatment of germ cell tumors of the ovary (420) and has demonstrated activity in early clinical trials of cervical, endometrial, and ovarian cancers (420). In combination with other agents, it has also demonstrated activity in early trials of ovarian cancer (421). Vinblastine is the sulfate salt of an alkaloid isolated from *Vinca rosea* (periwinkle). It is structurally related to vincristine, another alkaloid isolated from the same plant. Vinblastine sulfate is a white to off-white crystalline powder that is freely soluble in water, soluble in methane, and slightly soluble in ethanol. Its empiric formula is C₄₆H₅₈N₄O₉ · H₂SO₄, and it has a molecular weight of 909.07.

Mechanism of Action. Vinblastine binds to tubulin and inhibits microtubule assembly. This inhibition prevents mitotic spindle formation and results in an accumulation of cells in metaphase (422).

Vinblastine is considered cell cycle phase specific for mitosis; however, the cytotoxic effect probably occurs in S phase and is expressed only in M phase. At high doses, direct effects may be expressed in S and G₁ phases. Vinblastine may be assumed to have stathmokinetic (cell cycle arrest) effects similar to vincristine.

Drug Disposition. After IV administration, vinblastine is rapidly cleared from the plasma and concentrated in various tissues. The apparent volume of distribution for the central compartment is quite large (three to four times the blood volume). Vincristine and vindesine approximate total body water in their distributions. There is a triphasic vinblastine elimination pattern, with average half-lives of 3.7 minutes, 1.6 hours, and 24.8 hours, respectively (423). The drug also localizes in platelet and

leukocyte fractions of whole blood (424). A radiolabeled drug study has shown that urinary elimination accounts for approximately 33% of the total vinblastine radioactivity, with 21% appearing in the stool, both after 72 hours (424). A large portion of the radiolabel was retained in the body: 73% remained at 6 days after dosing. Apparently, insufficient amounts of the drug pass the blood-brain barrier to produce an effective concentration in the central nervous system. Vinblastine is partially metabolized in the liver. Most of the drug is, therefore, ultimately excreted intact in the bile or the urine. Toxicity may be increased if there is obstructive liver disease, and doses should be greatly reduced.

Administration and Dosage. The solution for administration is usually prepared by adding 10 mL of sodium chloride solution (which may be preserved with phenols or benzyl alcohol) to the 10-mg vial. The use of other solutions is not generally recommended. The resultant solution has a concentration of 1 mg/mL and a pH of 3.5 to 5.0. Solutions prepared with preserved sodium chloride injection may be stored in the refrigerator (protected from light) for 28 days without significant loss of potency.

Vinblastine is usually given by the IV push technique, with the total dose being delivered over approximately 1 minute. This is usually accomplished by slowly pushing the dose through the injection site of a running IV infusion. Alternatively, the drug may be given directly into the vein. If this method is followed, the double-needle technique should be used: Do not use the same needle to withdraw the dose from the vial that is used for the direct injection into the vein. Vinblastine is very irritating and should not be given intramuscularly or subcutaneously. Vein patency should be checked before drug administration by flushing with a small quantity of normal saline or D₅W. After the dose has been given, the site should be flushed again to ensure that all of the drug has been delivered into the vein.

Vinblastine has been given by several dosing schemes. The dose depends on the protocol being followed, condition of the patient, other drugs or irradiation being used, and individual patient response. Usually, the drug is given no more frequently than once every week. In general, the dosage range is 3.8 to 18.5 mg/m² when used in combination with other agents. Patients are customarily started at a low dose and worked up in 1.8- to 1.9-mg/m² increments, depending on the degree of resulting leukopenia (e.g., the dose should not be increased beyond the dose at which the white cell count reaches 3,000 cells/mm³) (423). The dosage ranges for the indicated use of vinblastine are 6 mg/m² IV on days 1 and 15 as part of the doxorubicin-bleomycin-vinblastine-dacarbazine regimen (Hodgkin's disease) and 0.15 mg/kg IV on days 1 and 2 as part of the cisplatin-vinblastine-bleomycin regimen (testicular cancer) (50). In gynecologic malignancies, vinblastine is only rarely used for ovarian and trophoblastic disease.

Side Effects and Toxicities. The major toxic effect of vinblastine is a dose-related bone marrow depression. This is more frequent and severe than with the close structural analog, vincristine. Dose-related leukopenia occurs with a nadir of 4 to 10 days and with recovery occurring over another 7 to 14 days. Because of the relatively predictable nadir, it may be possible to administer vinblastine cautiously as often as every 7 to 10 days. Thrombocytopenia typically occurs; however, with standard dosing regimens, serious platelet depressions are infrequent. Erythrocytes are usually only slightly depressed.

Nausea and vomiting occur rarely with vinblastine therapy and are at least partially responsive to antiemetics. Severe stomatitis is occasionally observed. Gastrointestinal symptoms, which may be related to neurotoxicity, include constipation, adynamic ileus, and abdominal pain, especially if high doses (>20 mg) are used. These side effects are rarely seen with doses of less than 10 mg. Prophylactic stool softeners

may prevent constipation. Generalized muscle and tumor pain are commonly experienced by patients receiving vinblastine, especially in high doses (425).

Neurotoxicity associated with vinblastine occurs less frequently than with vincristine and usually occurs in patients on prolonged therapy or in those receiving high individual doses. Symptoms include paresthesias, peripheral neuropathy, depression, headache, malaise, jaw pain, urinary retention, tachycardia, orthostatic hypotension, or convulsions. Extravasations of vinblastine may result in local soft-tissue necrosis. Treatment with subcutaneously administered hyaluronidase is recommended (192). Other side effects include a reversible and mild alopecia, rashes, and photosensitivity reactions. Transient hepatitis has also been reported on the continuous-infusion regimen.

There have been several reports of a Raynaud's phenomenon associated with vinblastine or bleomycin in treating testicular cancer. The reaction consists of a delayed presentation of a cold feeling in the hands with physical evidence of cyanosis (426). Ginsberg et al. (427) demonstrated a case of vinblastine-associated syndrome of inappropriate antidiuretic hormone (ADH) secretion, which was previously thought to occur only with vincristine.

The drug is well documented as a teratogen in humans, and as with most anticancer drugs, usage in pregnancy is strongly contraindicated (428).

Special Precautions. Avoid extravasation of vinblastine. If extravasation occurs, stop the administration of the remaining drug immediately. Dorr and Alberts (429) favor injection of a corticosteroid into the infiltration site with sodium chloride to dilute the drug. Only minor tissue damage has occurred when vinblastine extravasation was treated with 50 to 500 mg of hydrocortisone sodium succinate. This is followed by cold compresses to minimize spread of the reaction.

Liver disease may alter the elimination of vinblastine and necessitate a dosage reduction. Neurotoxicity may be more frequent in patients with underlying neurologic problems or those who are weak or cachectic at the start of treatment.

Vinblastine solution is topically irritating and has caused corneal irritation when inadvertently splashed in the eyes. Protective precautions should be used by all persons working with the drug.

Vinorelbine

Chemistry. Vinorelbine (Navelbine) is a third-generation semisynthetic Vinca alkaloid that has been commercially available in the United States since 1994 for treatment of non-small cell lung cancer. Vinorelbine also appears to have significant activity in breast cancer patients (430) and moderate activity in patients with cervical or ovarian cancer (431,432), as well as other tumor types (433). It has a molecular formula of $C_{43}H_{54}N_4O_8 \cdot 2C_4H_6O_6$ and a molecular weight of 1079.12. Vinorelbine's structure differs from that of the parent compounds, vincristine and vinblastine, in that it contains a nine-member (rather than eight-member) catharanthine ring (434). Its chemical name is 3',4'-didehydro-4'-deoxy-*C'*-norvincaleukoblastine[*R*-(*R**,*R**)-2,3-dihydroxybutanedioate-(1:2)(salt)].

Mechanism of Action. Like other Vinca alkaloids, vinorelbine is classified as a "spindle poison" since it interacts with tubulin with resulting inhibition of microtubule assembly and cellular division during mitosis (435). Vinorelbine blocks cell cycle progression specifically in G₂ and M phases (128).

Drug Disposition. The pharmacokinetics of vinorelbine show large interpatient variability and are best described by a triphasic model. Following IV administration of a 30-mg/m²

dose, a peak plasma level of 1,000 ng/mL is achieved, but the plasma level declines to 100 ng/mL within 2 hours. Vinorelbine rapidly binds to platelets (78% of total dose) and plasma proteins (13.5%), and only 1.7% is available as free drug (435). The drug readily diffuses into other tissues, and has a large volume of distribution (75.61 L/kg). The terminal half-life is approximately 45 hours (436).

The primary means of vinorelbine clearance appears to be hepatic metabolism. Approximately 18% and 46% is recovered in the urine and feces, respectively; however, recovery was incomplete in pharmacokinetic studies (437).

Administration and Dosage. Vinorelbine is a vesicant and requires careful administration. The drug should be diluted in a syringe or IV bag to a concentration of 1.5 to 3.0 mg/mL (syringe) or 0.5 to 2 mg/mL (IV bag). When using a syringe or IV bag, vinorelbine should be diluted with dextrose (5%) or sodium chloride (0.9%). When using an IV bag, it may also be diluted with sodium chloride (0.45%), Ringer's injection, or lactated Ringer's injection. Diluted vinorelbine should be administered over 6 to 10 minutes into a side port of a free-flowing IV line closest to the IV bag. Following vinorelbine administration, the vein should be flushed with at least 75 to 125 mL of IV solution. Longer IV infusions (e.g., 20 minutes) are associated with a higher incidence of phlebitis (438).

Vinorelbine solution is incompatible with fluorouracil, mitomycin, and thiotepa. It is also incompatible with several antibiotics (including a number of cephalosporins, amphotericin B, ampicillin, piperacillin, and trimethoprim-sulfamethoxazole), acyclovir, furosemide, ganciclovir, methylprednisolone, and sodium bicarbonate (439).

Vinorelbine is generally administered at a dose of 30 mg/m² every week. This dosing schedule has been used in combination chemotherapeutic regimens; however, the recommended dosing schedule in combination with cisplatin (100 mg/m² every 4 weeks) is weekly administration of vinorelbine at a dose of 25 mg/m². Attempts to increase vinorelbine dose intensity using a daily × 3 every 21 days dosing schedule with or without G-CSF have not been successful (440). However, Weiss et al. (441) have reported that continuous infusion of vinorelbine at doses of 8 to 10 mg/m²/day with concurrent administration of G-CSF results in a twofold increase in vinorelbine dose intensity without increasing toxicity.

Side Effects and Toxicities. The primary dose-limiting toxicity of vinorelbine is myelosuppression, chiefly granulocytopenia (36% of patients, <500 cells/mm³). A safety summary of data from North American clinical trials reported that when vinorelbine was administered at a dose of 30 mg/m²/week to patients with breast cancer and non-small cell lung cancer, 64% of patients experienced grades 3 to 4 granulocytopenia, 50% experienced grades 3 to 4 leukopenia, and 9% developed grades 3 to 4 anemia. Despite the high incidence of granulocytopenia, most events were uncomplicated and only 7% of patients required hospitalization for fever and/or infection. The death rate due to sepsis was 1% to 2%. Myelosuppression was noncumulative, and the incidence of grades 3 and 4 granulocytopenia declined during later cycles of vinorelbine therapy. The granulocyte nadir typically occurred on day 14 of treatment, with recovery of the granulocyte count within 7 days (442).

Vinorelbine therapy is frequently associated with transient increases in liver enzymes, especially alkaline phosphatase. Virtually all patients experience a rise in alkaline phosphatase, with approximately 25% developing grade 3 toxicity and an additional 2% experiencing grade 4 elevations. Increases in AST and ALT also occur in more than half of all patients. However, most patients with liver enzyme increases remain asymptomatic and do not require dose modification of vinorelbine. Total bilirubin also can be elevated: 10% of

patients experience some degree of increased bilirubin, with 2% experiencing grade 4 elevation. Because of the high incidence of liver and bone metastases in the study population (breast cancer and non-small cell lung cancer patients), the proportion of these toxicities that is directly attributable to vinorelbine therapy is unknown (442).

Other common toxicities associated with vinorelbine when administered as a single agent at a dose of 30 mg/m²/week by a 20-minute IV infusion include nausea (38% overall, 2% severe), vomiting (17% overall, 2% severe), constipation (31%, 3% severe), asthenia (29%, 5% severe), injection-site reactions (26%, 2% severe), anorexia (15%, 1% severe), diarrhea (15%, 1% severe), stomatitis (14%, 0% severe), pain (13%, 2% severe), paresthesia (13%, <1% severe), fever (11%, 1% severe), and alopecia (10%, <1% severe) (442). Vinorelbine-induced nausea and vomiting are generally mild and are readily controlled with standard antiemetic medication (442). Injection-site reactions include erythema, warmth, pain, and phlebitis. Repeated administration of vinorelbine can result in discoloration of the vein. As discussed above, shortening the injection duration to 6 to 10 minutes significantly reduces the incidence of injection-site reactions (438).

Injection-site pain and pain of unspecified etiology have been reported with administration of vinorelbine as a single agent (442). Additionally, acute tumor pain has been reported in several cancer patients who received treatment with vinorelbine plus a platinum-containing agent (either carboplatin or cisplatin) (443).

Pulmonary toxicity is an infrequent side effect of vinorelbine. Approximately 5% of patients experience dyspnea. Some cases of dyspnea are characterized by rapid onset during administration and resolve with bronchodilator therapy. Other cases occur usually within 1 hour of vinorelbine infusion and are characterized by life-threatening progressive dyspnea and the development of interstitial infiltrates (442,444). The coadministration of mitomycin may increase the pulmonary toxicity of vinorelbine (444).

Rare side effects of vinorelbine include pancreatitis, PPE (with prolonged infusions), paralytic ileus, and syndrome of inappropriate ADH secretion (445–448).

Special Precautions. Vinorelbine extravasation can result in severe local irritation, tissue necrosis, and phlebitis. If extravasation occurs, the injection should be halted immediately and any remaining portion of the dose should be injected into a different vein. Specific antidotes for vinorelbine extravasation have not been studied; however, vinblastine extravasation reactions may be ameliorated with the use of corticosteroid injections followed by cold compresses (429).

Drug Interactions. In that Vinca alkaloids are metabolized by the cytochrome P450 3A system, coadministration of strong P450 inhibitors, such as erythromycin and ketoconazole, could potentially reduce vinorelbine clearance and increase toxicity (449). Doxorubicin and etoposide also are metabolized by the P450 system, and coadministration of these drugs with vinorelbine could potentially affect vinorelbine metabolism (449).

Mitomycin is known to exacerbate Vinca alkaloid-induced pulmonary toxicity (450), and the combination of high-dose vinorelbine (50 mg/m² on days 1 and 21) plus mitomycin (15 mg/m² on day 1) has been associated with life-threatening acute pulmonary toxicity characterized by rapid onset of severe, progressive dyspnea and the development of bilateral interstitial infiltrates (444).

The combination of paclitaxel and vinorelbine has been associated with severe neurotoxicity including grade 4 motor neuropathy, irreversible ototoxicity, and vocal cord paresis (451). In one report of clinical experience in five patients with preexisting, mild to moderate, paclitaxel-induced sensory neuropathy, the combination of vinorelbine 25 to 30 mg/m²

followed by paclitaxel 150 mg/m² by 3-hour infusion every 2 weeks resulted in severe, slowly reversing motor neuropathy in all five patients. Four of the five patients required the use of a wheelchair (451).

Special Applications. On a well-tolerated weekly dose schedule for vinorelbine, Bajetta et al. (452) noted four partial responses and one complete response in 31 patients (24 platinum resistant, 4 platinum sensitive, 5 with undetermined sensitivity) for an overall response rate of 15% (95% CI of 5.1, 37.9%). A phase 2 trial (vinorelbine 30 mg/m² weekly infusion) in persistent or recurrent ovarian cancer found a 29% objective response rate; granulocytopenia was a dose-limiting but manageable toxicity (431). This is consistent with previous findings of a 21% response rate in the population of heavily pretreated and platinum-resistant ovarian cancer patients (452).

Molecularly Targeted Agents

Erlotinib

Chemistry. Erlotinib (OSI-774, Tarceva) is an oral tyrosine kinase inhibitor (specifically, HER1/EGFR) that has the potential for inhibiting tumor-cell growth of a variety of tumors. Erlotinib has the molecular formula C₂₂H₂₃N₃O₄ · HCl and a molecular weight of 429.90. Erlotinib is FDA approved for the treatment of advanced or metastatic non-small cell lung cancer after failure or prior chemotherapy, and is approved for use in combination with gemcitabine for the first-line treatment of unresectable or metastatic pancreatic cancer. Phase 1 and 2 studies have demonstrated some activity in ovarian cancer and head and neck squamous cell cancer (453,454). There is also ongoing exploration of the use of erlotinib for maintenance of patients with ovarian cancer following front-line treatment (455).

Drug Disposition. Erlotinib is rapidly absorbed after administration, with peak plasma levels occurring at 4 hours. Plasma levels increase with dose, but daily administration does not cause unexpected drug accumulation (456). More than 90% of erlotinib is bound to plasma proteins. It is primarily metabolized by CYP3A4, which suggests that concomitant treatment with potent CYP3A4 inhibitors (e.g., ketoconazole, systemic antifungals, clarithromycin) may affect the metabolism of erlotinib (456).

Administration and Dosage. Erlotinib is administered orally. As a single agent, erlotinib is to be administered at 150 mg/day. Dosage should be reduced to 100 mg/day in combination therapy regimens. Food substantially increases the bioavailability of erlotinib; therefore, it should be taken at least 1 to 2 hours prior to the ingestion of food. When administered at 200 mg/day, diarrhea is dose limiting.

Side Effects and Toxicities. The dose-limiting toxicities associated with erlotinib include diarrhea and rash; however, at a dose of 150 mg/day, diarrhea can be effectively managed with loperamide. Other less common toxicities include headache, nausea and vomiting, and mucositis (453). It can be administered as a single agent, and has an additive effect on antitumor activity when combined with cisplatin, doxorubicin, gemcitabine, or low-dose paclitaxel without an associated increase in toxicity (457).

Sunitinib

Chemistry. Sunitinib (SU11248, Sutent), a multi-kinase inhibitor (e.g., VEGFR, PDGFR, FLT3, KIT, and RET inhibitor), was granted accelerated approval by the FDA in 2006 for the treatment of advanced renal cell carcinoma and

for the treatment of gastrointestinal stromal tumor (GIST) after disease progression on or intolerance to imatinib (Gleevec) (458). Clinical trials are planned and ongoing to evaluate the efficacy of sunitinib in the treatment of uterine and ovarian cancers and sunitinib is also being evaluated for potential efficacy against hematologic malignancies (459). Chemically, it is a butanedioic acid, hydroxy-, (2S)-, compound with *N*-[2-(diethylamino)ethyl]-5-[(*Z*)-(5-fluoro-1,2-dihydro-2-oxo-3*H*-indol-3-ylidene)methyl]-2,4-dimethyl-1*H*-pyrrole-3-carboxamide (1:1). The molecular formula of sunitinib is $C_{22}H_{27}FN_4O_2 \cdot C_4H_6O_5$ and the molecular weight is 532.6.

Drug Disposition. Maximum plasma concentration occurs within 6 to 12 hours following administration (458). The terminal half-life of sunitinib is approximately 40 to 60 hours, and the terminal half-life of its primary metabolite is 80 to 110 hours. Steady-state concentrations are achieved within 10 to 14 days. Concomitant treatment with CYP3A4 inducers (e.g., rifampin, St. John's Wort, dexamethasone) may decrease the concentration of sunitinib, whereas concomitant treatment with CYP3A4 inhibitors (e.g., ketoconazole, systemic antifungals) and grapefruit may increase the plasma concentration of sunitinib (458).

Administration and Dosage. Sunitinib is administered 50 mg/day for 4 weeks, followed by 2 weeks off medication. Sunitinib may be taken with or without food, as the pharmacokinetics are unaffected by food intake (460).

Side Effects and Toxicities. The most common side effects of sunitinib monotherapy include gastrointestinal (e.g., AST/ALT, lipase, amylase, bilirubin), rare cardiac (decreased left ventricular ejection fraction), renal/metabolic (e.g., creatinine, hypokalemia, hypernatremia, uric acid) and hematologic (e.g., neutrophils, platelets, hemoglobin) toxicities (458).

Lapatinib

Chemistry. The dual kinase inhibitor lapatinib (Tykerb) is FDA approved for combination therapy with capecitabine for the treatment of HER2-overexpressing breast cancers, as a post-first-line regimen. Lapatinib inhibits both HER2 and epidermal growth factor receptor (EGFR) kinases (461). It has the chemical name *N*-(3-chloro-4-[(3-fluorophenyl)methyl]oxyphenyl)-6-[5-[[2-(methylsulfonyl)ethyl]amino)methyl]-2-furanyl]-4-quinazolinamine bis(4-methylbenzenesulfonate) monohydrate, the molecular formula $C_{29}H_{26}ClFN_4O_4S$ ($C_7H_8O_3S$)₂·H₂O, and a molecular weight of 943.5.

Drug Disposition. Peak plasma concentration occurs approximately 4 hours after administration. The half-life of lapatinib is estimated to be between 7 and 24 hours, and steady-state concentrations are achieved within 6 to 7 days (462). Divided dosing (versus the same dose given once per day) results in nearly double the exposure (steady-state serum AUC). Systemic exposure is also increased with food (three- to fourfold higher AUC). Similar to other kinase inhibitors, concomitant treatment with CYP3A4 inducers may decrease the concentration of lapatinib, whereas concomitant treatment with CYP3A4 inhibitors may increase the plasma concentration of lapatinib.

Administration and Dosage. The FDA-approved dosage of lapatinib is 1,250 mg given orally daily (days 1 to 21), 1 hour before or at least 1 hour after a meal, in combination with capecitabine 2,000 mg/m²/day (administered orally in two doses approximately 12 hours apart) which is given on days 1 to 14 of the 21-day cycle.

Side Effects and Toxicities. Rash, nausea, and vomiting (grades 1 to 2) are the most common side effects associated with lapatinib (462). Lapatinib may decrease left ventricular ejection fraction. Serious adverse events have been rarely reported in clinical trials (462).

Estrogen Receptor/Progesterone Receptor-Targeted Agents

Anastrozole

Chemistry. Anastrozole (Arimidex) is FDA approved for the adjuvant treatment of postmenopausal patients with estrogen receptor positive (ER+) breast cancers following tamoxifen therapy, and is also indicated for postmenopausal women for the first-line treatment of ER+/ER-unknown breast cancer that is locally advanced or metastatic. Anastrozole is rarely associated with response in ER-negative disease. Anastrozole has been shown to have fewer side effects and a significant survival advantage as compared to megestrol acetate in the treatment of postmenopausal patients with breast cancer (463). Chemically, it is 1,3-benzenediacetonitrile, α,α,α' -tetramethyl-5-(1*H*-1,2,4-triazol-1-ylmethyl). It has a molecular formula of $C_{17}H_{19}N_5$ and a molecular weight of 293.4.

Mechanism of Action. Anastrozole is a nonsteroidal aromatase inhibitor that prevents the peripheral conversion of androgens (androstenedione and testosterone) to estrogens (estrone, estrone sulfate, and estradiol) (50). Anastrozole has a significant effect on serum estradiol; as low as 1 mg/day has caused estradiol levels to be undetectable (464). In patients receiving 5 and 10 mg of anastrozole, there was no effect on adrenal corticosteroids or aldosterone.

Drug Disposition. Following oral administration, anastrozole is well absorbed into the systemic circulation and not affected by food ingestion. Pharmacokinetics are linear and not affected by repeated dosing. Steady-state concentration levels are achieved after approximately 7 days of treatment.

Administration and Dosage. Anastrozole is administered orally at a dose of 1 mg/day. For advanced disease, treatment should continue until disease progression.

Side Effects and Toxicities. When compared in a controlled clinical study to megestrol acetate, the principal side effect of anastrozole was diarrhea (occurred in 8.4% vs. 2.8% of patients treated with megestrol acetate). In general, it is very well tolerated, with the most frequent side effects (any grade) being asthenia (18%), nausea (18%), headache (14%), hot flushes (13.2%), and pain (10%).

Special Applications. It is hypothesized that anastrozole may play a role on a molecular level in the endometrium. Most endometrial carcinomas are associated with endometrial hyperplasia and are estrogen receptor (ER) and progesterone receptor (PR) positive. In addition to ER/PR status, there is a progressive increase in the expression of the protein pS2 from normal to hyperplastic to well-differentiated carcinoma (465). Aromatase inhibition may be able to alter the course of disease by preventing the endometrium from being exposed to estrogen. This may in turn alter the expression of the pS2 protein as there is a strong association between ER/PR expression and expression of pS2 protein (465). Aromatase activity has been demonstrated in both ER/PR-positive and ER/PR-negative endometrial carcinomas (466). Although much research has yet to be done, phase 1 and 2 trials have demonstrated safety and minimal activity in an unselected population of recurrent endometrial carcinoma patients (467). There is some evidence that it may have benefit in the treatment of endometrial hyperplasia (468).

Letrozole

Chemistry. Letrozole (Femara) is a nonsteroidal aromatase inhibitor that is FDA approved for the first-line treatment of postmenopausal women with locally advanced or metastatic breast cancer (hormone receptor positive or hormone receptor unknown). Letrozole is also used for the treatment of advanced

breast cancer in postmenopausal women whose disease has progressed following antiestrogen therapy. Letrozole has also demonstrated some activity in palliative care for recurrent ovarian cancer (469,470). The chemical name of letrozole is 4,4'-(1H-9,1,2,4-Triazol-1-ylmethylene) dibenzonitrile, and the empirical formula is $C_{17}H_{11}N_5$.

Mechanism of Action. Similar to other aromatase inhibitors, letrozole inhibits the conversion of androgens to estrogens via the aromatase enzyme. Letrozole treatment does not increase serum follicle stimulating hormone (FSH), and as a selective gonadal steroidogenesis inhibitor, does not impact adrenal mineralocorticoid or glucocorticoid synthesis.

Drug Disposition. Letrozole is not affected by food intake, and is rapidly and completely absorbed through the gastrointestinal tract. The terminal elimination half-life is 2 days. The major excretion route is via the kidneys. Steady-state plasma concentration is reached in 2 to 6 weeks of daily 2.5-mg dosing. These concentrations are up to two times higher than after a single dose. Steady-state levels can be maintained for long periods of time without continuous accumulation of letrozole.

Administration and Dosage. Letrozole is administered orally, at 2.5 mg per day. Letrozole can be taken at any time during the day regardless of food intake. Treatment is indicated until disease progression.

Side Effects and Toxicities. Letrozole has a more favorable toxicity profile as compared to tamoxifen, with greater or equivalent efficacy in breast cancer patients (471). The most common side effects include bone pain, hot flashes, back pain, nausea, arthralgia, and dyspnea, each occurring in no more than 20% of patients.

Medroxyprogesterone

Chemistry. The chemical name of the progestational agent medroxyprogesterone acetate (Provera) is pregn-4-ene-3,20-dione,17-(acetyloxy)-6-methyl-,(6 α)-. Its empirical formula is $C_{24}H_{34}O_4$, with a molecular weight of 386.53. Medroxyprogesterone acetate (MPA) therapy is indicated with estrogen therapy for therapeutic use in women to reduce the incidence of atypical endometrial hyperplasia. There is some evidence that MPA may be used for endometrial hyperplasia or stage 1 endometrial cancer as an alternative to surgery to preserve fertility with some success (472,473). MPA has demonstrated activity when used with other agents in advanced or recurrent endometrial cancer (474).

Drug Disposition. MPA is absorbed through the gastrointestinal tract, and is primarily metabolized by the liver. Maximum concentrations are reached within 2 to 4 hours after oral administration. Food intake enhances the bioavailability of MPA (C_{max} by up to 70% and AUC up to 33% increase), but does not affect its half-life (12 to 16 hours).

Administration and Dosage. MPA is administered at 5 or 10 mg/day for endometrial hyperplasia for 12 to 14 consecutive days every month. For abnormal uterine bleeding or amenorrhea, MPA is generally administered for a shorter duration (e.g., 5 to 10 consecutive days). Patients experience withdrawal bleeding for 3 to 5 days following the treatment cycle. MPA is recommended to be used with 0.625 mg conjugated estrogens in women with a uterus to avoid the risk of endometrial cancer. Women without a uterus may receive estrogen without a progestin. In addition to the tablet form for oral intake, there is an intramuscular (IM) depot formulation that may permit alternative treatment regimens. The IM formulation of MPA was compared to oral megestrol acetate for the treatment of menopausal symptoms in breast cancer patients. In this short-term study, the IM formulation provided superior benefit to patients and may be an alternative to long-term oral progestin therapy (475).

Side Effects and Toxicities. MPA, similar to other progestins (e.g., megestrol acetate), may cause abnormal uterine bleeding, breast tenderness, or nausea. A Women's Health Initiative (WHI) study found that estrogen plus progesterone was associated with an increased risk of myocardial infarction, stroke, invasive breast cancer, pulmonary emboli, and deep vein thrombosis in postmenopausal women (476). A memory study embedded within the WHI study found that this combination may also be associated with an increased risk of developing dementia in women over the age of 65 (477). A black box warning now included on the MPA package insert recommends that estrogen/progesterone be used at the lowest possible dose for the shortest duration possible for the specific treatment goals of the patient.

Megestrol

Chemistry. The chemical name of megestrol acetate (Megace) is 17 β -acetyloxy-6-methylpregna-4,6-diene-3,20-dione. Similar to MPA, it has the empirical formula $C_{24}H_{34}O_4$, and has a molecular weight of 384.51. Megestrol acetate is an FDA-approved progestin that is used for the palliative treatment of advanced carcinoma of the breast or endometrium (i.e., recurrent, inoperable, or metastatic disease). In general, progestational agents are currently used in the treatment of endometrial hyperplasia at a variety of doses and schedules. The GOG is currently investigating megestrol acetate in trial GOG-0224 (A Randomized, Controlled Phase II Evaluation Of Megestrol [Megace®] in Different Dose and Sequence in the Treatment of Endometrial Intraepithelial Neoplasia [EIN] from a Referred Cohort of Atypical Endometrial Hyperplasia [AEH] or EIN). GOG-0224 is designed to provide objective data toward a standard treatment regimen for the care of women with EIN or AEH in addition to understanding the actual mechanism of action of progestational agents in the endometrium.

Drug Disposition. Megestrol acetate is primarily excreted in the urine, and oral absorption rates are variable. Time to peak concentration ranges from 1.0 to 3.0 hours, and the plasma elimination half-life ranges from 13.0 to 104.9 hours. Steady-state plasma concentrations have not yet been established.

Administration and Dosage. Megestrol acetate is supplied in 20- and 40-mg tablets for oral intake. Although the recommended dosage for breast cancer is 160 mg/day (40 mg qid), and for endometrial carcinoma it is 40 to 320 mg/day in divided doses, there are a wide variety of dose and schedules implemented therapeutically for precancerous conditions (e.g., AEH).

Side Effects and Toxicities. The side effect profile of the progestational agents megestrol acetate and MPA is similar. However, weight gain is a common side effect with megestrol acetate. Thrombophlebitis and pulmonary embolism have been reported with megestrol acetate. Other toxicities include nausea and vomiting, edema, breakthrough menstrual bleeding, and dyspnea. In general, there are only rare severe toxicities reported with progestational agents.

Tamoxifen

Chemistry. Tamoxifen citrate (Nolvadex) is a non-steroidal agent with antiestrogenic properties. It is indicated for the treatment of metastatic breast cancer and as adjuvant treatment in node-positive breast cancer in postmenopausal patients. Tamoxifen competes with estrogen for binding sites, which explains its increased effectiveness in ER+ tumors. Chemically, tamoxifen is (Z)-[4-(1,2-diphenyl-1-butenyl) phenoxy]-N,N-dimethylethanamine 2-hydroxy-1,2,3-propanetricarboxylate (1:1), and has a molecular weight of 563.62.

Mechanism of Action. Tamoxifen is a nonsteroidal agent that has antiestrogenic properties in the breast and ovary, but acts like an estrogen agonist in the endometrium and bone (478). It may exert its antitumor effects by binding the estrogen receptors. Because of this mechanism, it is most beneficial in the treatment of ER+ tumors.

Drug Disposition. Peak plasma concentrations (average 40 ng/mL) take place approximately 5 hours after dosing. The decline in plasma concentrations is biphasic with a terminal elimination half-life of about 6 days. Steady-state concentrations for tamoxifen are achieved in about 4 weeks after initiation of therapy. Tamoxifen is extensively metabolized, with N-desmethyl tamoxifen being the major metabolite. Approximately 65% of the administered dose is eliminated in the feces within 2 weeks (479).

Administration and Dosage. Tamoxifen is available in 10- and 20-mg tablets for oral administration. The recommended dosage is 20 to 40 mg/day; when the higher daily dose is prescribed, it should be divided into two doses of 20 mg (morning and evening).

Side Effects and Toxicities. Tamoxifen causes estrogenic changes of the vaginal and cervical squamous epithelium and increases the incidence of cervical and endometrial polyps (480). It is associated with an increased risk of uterine malignancies (endometrial adenocarcinoma and uterine sarcoma). Other serious adverse events associated with tamoxifen treatment include stroke, deep vein thrombosis, and pulmonary embolism. A discussion weighing the benefits versus the risks should take place prior to treatment with tamoxifen; however, the benefits have been determined to outweigh the risks in women who take tamoxifen to reduce the risk of breast cancer recurrence. The National Adjuvant Breast and Bowel Project (NSABP P-1) found a higher incidence of the following side effects for tamoxifen versus placebo, respectively: vaginal discharge (54.7% vs. 34%); cold sweats (21.4% vs. 14.8%); hot flashes (77.7% vs. 65.1%); night sweats (66.8% vs. 54.9%); and genital itching (47.1% vs. 38.3%) (481). Serious adverse events reported more frequently among women taking tamoxifen as compared to placebo in the NSABP P-1 trial included uterine malignancy, uterine sarcoma, stroke, and pulmonary embolism.

Special Applications. Some ovarian cancers express hormonal receptors, a factor supporting the investigation of tamoxifen in the treatment of ovarian malignancies (482). It has demonstrated activity in patients with platinum-refractory ovarian cancer, with response rates ranging from 13% to 17% (with some complete responses), and with durations ranging from 4.4 months to more than 5 years (482–484). In the series by Hatch et al. (482), patients with ovarian cancer who had complete or partial responses on tamoxifen were more likely to have an ER+ tumor (89% ER+) than those who had stable disease or progression on tamoxifen (59% had elevated ER). The favorable toxicity profile of tamoxifen makes it an ideal agent to consider in patients with refractory ovarian cancer.

Antiangiogenesis Agents

Angiogenesis is the process by which new blood vessels are sprouted from preexisting ones. Endothelial cells must migrate, proliferate, and assemble into tubes during this process. In normal tissues, blood vessel growth is tightly controlled by numerous angiogenesis-stimulating factors and angiogenesis-inhibiting factors. Vascular endothelial growth factor (VEGF) and platelet-derived endothelial-cell growth factor (PD-ECGF) are two of the most extensively studied growth factors that appear to function primarily as angiogenesis-stimulating factors. Other growth factors and cytokines, such as basic fibroblast growth factor (bFGF), have multiple

functions in addition to angiogenesis stimulation (485). Naturally occurring factors that suppress angiogenesis include angiostatin, endostatin, interferon- α , interferon- β , interferon- γ , interleukin-1, interleukin-12, platelet factor-4, thrombospondin-1, 1,2-methoxyestradiol, tissue inhibitor metalloproteinases (TIMPs), and, at high concentrations, tumor necrosis factor- α (486).

In the early 1970s, Folkman (487) pioneered the study of tumor angiogenesis with his observation that the growth of tumor nodules to a diameter of greater than 1 to 2 mm required neovascularization of the tumor. He hypothesized that pharmacologic suppression of tumor angiogenesis could induce tumor dormancy. Further research has shown that formation of new blood vessels within tumor nodules results in an exponential increase in tumor cell growth; the transition from hyperplasia to malignancy parallels the induction of neovascularization; and tumor angiogenesis is a prerequisite for metastatic spread (485,488). Additionally, blood vessel density of tumors has been shown to be a potentially important prognostic factor in multiple human neoplasms, including cancers of the ovary, cervix, and endometrium (489,490).

Obviously, this is a very brief discussion of tumor angiogenesis. The reader is referred to several reviews on angiogenesis inhibition and its potential for cancer treatment (486,491). Several angiogenic agents that have FDA approval for various indications that may have potential for the treatment of gynecologic cancers are briefly discussed below.

Bevacizumab

Chemistry. Bevacizumab (Avastin) is recombinant humanized monoclonal IgG1 antibody that is designed to inhibit angiogenesis through targeting the human VEGF. Bevacizumab is FDA approved for treatment for first-line metastatic colorectal cancer in combination with 5-FU-based chemotherapy. Ovarian, endometrial, and cervical cancers have been shown to express VEGF-A (492). Early trials show promising results in refractory ovarian cancer and heavily pretreated cervical cancer patients (494–496); however, larger randomized trials are needed to demonstrate efficacy in gynecologic cancer populations.

Administration and Dosage. Bevacizumab is administered 5 mg/kg IV once every 14 days until disease progression.

Side Effects and Toxicities. The most common serious (grade 3 to 4) side effects of bevacizumab treatment include asthenia, pain, hypertension, diarrhea, and leukopenia. Bevacizumab has been associated with gastrointestinal perforation, wound healing complications, and hemorrhage. Hemorrhage was specifically pronounced among patients with recent hemoptysis; therefore, these patients should not receive bevacizumab. Patients receiving bevacizumab therapy have also demonstrated an increase in hypertension, proteinuria, and congestive heart failure. It is recommended that bevacizumab therapy be delayed at least 28 days following any major surgical procedure. The safety of bevacizumab in patients with cardiovascular disease is unknown.

Thalidomide

Chemistry. Thalidomide (Thalomid) is an antiangiogenic agent that is indicated for the treatment of cutaneous manifestations of erythema nodosum leprosum (ENL). However, thalidomide has been used in the treatment of various advanced malignancies and has demonstrated possible activity in ovarian and papillary-serous peritoneal carcinoma (497). Thalidomide has the chemical name α -(N-phthalimido)glutarimide. The molecular structure is $C_{13}H_{10}N_2O_4$, and it has a molecular weight of 258.2.

Mechanism of Action. Although the exact mechanism of action is not fully characterized, the immunologic effects of

thalidomide may be related to suppression of excessive tumor necrosis factor- α (TNF- α) production and down-modulation of selected cell surface adhesion molecules involved in leukocyte migration (498).

Dosage and Administration. Thalidomide is an oral agent, which is supplied in 50-, 100-, and 200-mg gelatin capsules. When used in chemotherapeutic regimens, the dose of thalidomide is generally titrated up to 400 mg/day as an evening dose (50). When used in a pilot study of ovarian and peritoneal carcinoma, daily thalidomide was initiated at 200 mg, with doses increasing by 100 mg per day every 2 weeks until response or tolerance (493).

Side Effects and Toxicities. Thalidomide is teratogenic and should not be used at any time during pregnancy. Latex condoms should be used by sexually active males using the drug because thalidomide is present in semen. The most common side effects include somnolence, peripheral neuropathy, dizziness, neutropenia, rash, and HIV viral load increase.

MODULATING AGENTS/ SUPPORTIVE CARE DRUGS USED IN THE TREATMENT OF GYNECOLOGIC CANCERS

Defining approaches to improve the therapeutic index of cancer chemotherapy, such that tumor-cell kill is enhanced while toxicity to normal cells is minimized, remains a fundamental goal of cancer treatment. A major limiting factor in successful cancer therapy is the ability of the tumor to develop resistance to the drugs used for treatment. A second fundamental problem faced by the oncologist treating patients with chemotherapy is the acute and chronic toxic effects of the drugs to the normal tissues. One approach that holds promise for the improvement of the therapeutic index is the concept of modulation, or the use of drugs with little or no cytotoxic activity to modulate the efficacy of standard anticancer drugs. Modulating agents can be divided into three main classes based on their ability to (a) protect host tissue from the toxic effects of the cancer drugs; (b) potentiate anticancer drugs; and (c) reverse acquired drug resistance. In this section, we discuss agents with chemoprotective abilities used with chemotherapy in the treatment of gynecologic cancers. The drugs outlined are not meant to be fully inclusive and the reader is referred to Tew et al. (499) for a complete review on the subject of modulation of anticancer drug activities.

Chemoprotective Agents

Amifostine

Chemistry. Amifostine (Ethyol) is, to date, the most extensively developed broad-spectrum cytoprotective agent. Originally developed as a radioprotective compound, amifostine was selected from a series of over 4,400 synthetic thiol derivatives developed by the U.S. Army as having the most effective radioprotective effects and best safety profile (500). Subsequently, an extensive number of studies have demonstrated that amifostine selectively protects normal, but not tumor, tissue from the toxicities induced by radiation therapy and chemotherapy (499,501). Amifostine is FDA approved and indicated to reduce the cumulative renal toxicity associated with repeat cisplatin administration in patients with advanced ovarian cancer or non-small cell lung cancer. It is also approved for chronic, three times weekly dosing, 15 to 20 minutes prior to daily radiation therapy in patients with head and neck cancer. Chemically, it is 2-[(3-aminopropyl) amino]ethanethiol dihydrogen phosphate

(ester), its empiric formula is $C_5H_{15}N_2O_3PS$, and it has a molecular weight of 214.22.

Mechanism of Action. Amifostine is an inactive prodrug that is dephosphorylated to the active, free thiol species, WR1065, at the tissue site by cell membrane-bound and capillary alkaline phosphatase. The higher specific activity of the membrane-bound enzyme in normal tissue versus tumor tissue promotes rapid transport of the active thiol metabolite into the normal cell, with negligible transport into the cancer cells. The higher pH and higher activity of capillary alkaline phosphatase in normal tissue also contribute to the preferential uptake of WR1065 by normal cells (502). A number of mechanisms of protection by WR1065 have been reported, including scavenging of oxygen free radicals, direct intracellular binding to and subsequent detoxification of the active species of alkylating and platinum compounds, prevention or reversal of cisplatin-DNA adduct formation, induction of hypoxia, and alterations in intracellular glutathione and polyamine levels.

In addition to protecting normal cells from the cytotoxic effects of chemotherapy, amifostine has been shown to stimulate bone marrow progenitor cells (503) and sensitize tumor cells both *in vitro* and *in vivo* to the cytotoxic effects of anticancer agents, including nitrogen mustard, paclitaxel, melphalan, and carboplatin (80,504,505). Thus, amifostine is unique in that it is the only known modulating agent that may improve the therapeutic index for antitumor agents by dual mechanisms, that is, decreasing toxicity to normal tissue and potentiating tumor-specific cytotoxicity.

Drug Disposition. Pharmacokinetic studies in humans have shown that following IV administration at a dose of 740 or 910 mg/m², amifostine is rapidly cleared from the plasma and taken up into normal tissues with an α half-life of less than 1 minute and a β half-life of less than 10 minutes (506). Within 5 to 10 minutes after completion of a 15-minute infusion, greater than 90% of the parent drug is cleared from the plasma. A terminal elimination phase with a half-life of 48 minutes has also been reported (507). However, the plasma levels were very low during the elimination phase, and repeat dosing with amifostine at 2-hour intervals did not lead to increasing peak values at the end of each infusion.

Analyses of the human pharmacokinetics of WR1065 and the symmetric disulfide WR33278 following a single dose or three doses of amifostine (740 or 910 mg/m²) 15 minutes before and 2 and 4 hours after chemotherapy have also been reported (507). WR1065 is rapidly cleared from the plasma by fast uptake into the tissues and conversion to disulfides. The initial half-life of 0.18 hour is followed by a slower, second phase with a half-life of 7.3 hours, where only low plasma levels are present. The final half-life of the disulfides ranged from 8.4 to 13.4 hours, and these metabolites were detectable 24 hours after treatment. As such, the disulfides may serve as an exchangeable pool of WR1065. After repeat dosing with amifostine, peak levels of WR1065 were increased, but peak levels of the disulfides were slightly decreased. This may suggest a change in the uptake or elimination of WR1065 or a saturation of the disulfide formation.

Amifostine changes the pharmacokinetics of carboplatin in humans, resulting in a longer, final half-life of ultrafiltrable platinum species in patients with a normal creatinine clearance, and a small increase in the AUC value (80). One can speculate that amifostine's effect on carboplatin pharmacokinetics may increase the efficacy of carboplatin in patients, similar to what has been observed in tumor-bearing mice. The effect of amifostine on the pharmacokinetics of cisplatin is minor, resulting in an increase of the final half-life of ultrafiltrable platinum but not unchanged cisplatin (508).

Administration and Dosage. The originally recommended schedule of amifostine was as a 15-minute IV infusion administered 15 to 30 minutes before chemotherapy; however, a

markedly lower incidence of both hypotension and emesis has been documented when amifostine is administered by rapid IV bolus (509). Although an optimal dose has not been defined, amifostine is generally given at the MTD ranging from 740 to 910 mg/m². The rapid IV bolus administration of these amifostine doses can be achieved in increments of 500 mg with 5 minutes separating each dose, up to three IV injections, markedly minimizing nausea and hypotension.

Special Applications. Amifostine has been shown in a number of clinical trials to protect against cisplatin-induced nephrotoxicity and neurotoxicity and cyclophosphamide-induced hematotoxicity (501). Results of a randomized, multicenter phase 3 trial of cyclophosphamide (1,000 mg/m²) and cisplatin (100 mg/m²) with or without amifostine (910 mg/m²) every 3 weeks for six cycles in advanced epithelial ovarian cancer patients confirmed that pretreatment with amifostine reduces the cumulative renal, hematologic, and neurologic toxicities of the chemotherapy regimen (120). Final analysis of 242 patients (122 received amifostine) revealed that amifostine pretreatment yielded significant protection against the toxic effects of cisplatin. Twenty-six percent of patients (31 of 120) on the chemotherapy-alone arm compared with 10% of patients (12 of 122) pretreated with amifostine had treatment-limiting renal, neurologic, or ototoxicity requiring discontinuation of cisplatin treatment ($p = 0.001$). No patients on the amifostine arm discontinued therapy because of nephrotoxicity compared with seven patients on the chemotherapy-alone arm ($p = 0.008$). Significant hematoprotection also was observed, including a 53% reduction in the percentage of patients experiencing neutropenia-associated events ($p = 0.019$) and a 62% reduction in the total incidence of neutropenia-associated events ($p = 0.005$). The latter resulted in a 61% reduction in the number of days in the hospital ($p = 0.019$) and a 61% reduction in days on antibiotics ($p = 0.031$). No difference in survival was observed at a 41-month median follow-up period between patients on either arm of the study, suggesting that amifostine does not reduce the antitumor efficacy of chemotherapeutic treatment.

Results from a study in breast cancer patients receiving high-dose chemotherapy with autologous bone marrow support showed that amifostine treatment of bone marrow cells prior to *ex vivo* purging with 4-hydroxycyclophosphamide (4-HC) resulted in a significant decrease in time to leukocyte engraftment from 36 days (4-HC alone) to 26 days ($p = 0.032$) (510). Additionally, those patients treated with amifostine required significantly fewer platelet transfusions and days of antibiotic therapy. Results of a randomized phase 2 trial of carboplatin plus amifostine versus carboplatin alone in patients with advanced solid tumors indicated that amifostine can reduce the cumulative thrombocytopenia resulting from carboplatin treatment (79).

There have been several small, randomized studies of amifostine in combination with carboplatin plus paclitaxel in the

management of advanced ovarian cancer (511–513). In each of these trials, amifostine demonstrated some activity against the development of grade 2 and/or grade 3 neurotoxicity. Within the randomized trial publication, De Vos et al. present a pooled analysis of three selected trials of amifostine with similar dosing schedules of carboplatin plus paclitaxel (511). There was statistically significant evidence in this analysis that IV amifostine pretreatment reduced the risk of grade 2/3 neurotoxicity.

Side Effects and Toxicities. The dose-limiting toxicities of amifostine include nausea, vomiting, and arterial hypotension. However, the emesis and hypotension can be reduced to relatively mild toxicities through rapid IV bolus administration together with the preadministration of IV fluids, dexamethasone (20 mg IV in adults), and ondansetron (0.15 mg/kg IV) within 1 hour prior to chemotherapy (514). Amifostine administered on a daily $\times 5$ schedule at 825 mg/m², with cisplatin and radiation therapy, can result in hypocalcemic effects; however, these doses are no longer used in clinical trials. Wadler et al. (515) reported that amifostine in extremely high doses can lead to a cumulative effect on decreased serum ionized calcium levels, which is mediated by direct inhibition of parathyroid hormone (PTH) activity. Administration of oral calcium with vitamin D supplements and frequent monitoring of serum ionized calcium levels are recommended for patients treated with the higher doses of amifostine, cisplatin, and radiation therapy.

Special Applications. The complications associated with IV administration have led to the ongoing development of amifostine for subcutaneous (SC) administration at 200 mg/m² three times weekly. The SC administration of amifostine has been evaluated in a number of preclinical and clinical studies; safety and efficacy studies have been conducted and are ongoing (516). Amifostine by either the IV bolus or SC routes in low (i.e., 200 to 340 mg/m²) daily to three times weekly dosing schedules reduces both the acute and chronic cystitis and enteritis associated with pelvic irradiation in gastrointestinal, gynecologic, and urologic cancers, as shown in Table 16.7.

Dexrazoxane

Dexrazoxane (Zinecard), a metal-chelating agent, belongs to the bis-dioxopiperazine family, and was originally designed as a potential antitumor agent. Although early clinical trials failed to provide significant evidence of cytotoxic activity (517), an observation was made that the drug caused a marked increase in the urine clearance of iron and zinc (518). These findings, coupled with preclinical studies that showed that dexrazoxane and other chelating agents could prevent the acute myocardial damage induced by anthracyclines (519) without reducing the antitumor effect of the drugs (520), led to the use of dexrazoxane as a cardioprotective agent. Animal studies have shown that dexrazoxane can offer significant protection against anthracycline-induced cardiotoxicity, and dexrazoxane was most effective when given from 30 minutes

TABLE 16.7

AMIFOSTINE EFFICACY IN COLORECTAL/PELVIC CANCERS: PHASE 2/3 TRIALS

Study	Phase; study population	Treatment outcomes
Anthanassiou, 2003 (537)	Phase 3; pelvic carcinomas with radiation therapy	Amifostine reduced radiation-induced bladder and lower gastrointestinal toxicity
Koukourakis, 2000 (516)	Phase 2 subcutaneous amifostine; pelvic carcinomas with radiation therapy	Subcutaneous amifostine reduced radiation-induced mucosal toxicity and treatment interruptions
Antonadau, 2004 (538)	Phase 3; advanced colorectal cancer radiation plus chemotherapy	Amifostine reduced grade 2 gastrointestinal toxicity

before to 15 minutes after doxorubicin (521). Subsequent studies demonstrated that the degree of cardioprotection elicited by dexrazoxane is dependent on the dose of the anthracycline and the severity of the cardiomyopathy (522). Results from the initial clinical study of dexrazoxane in patients with metastatic breast cancer were encouraging and confirmed those of the preclinical studies. Speyer et al. (523) conducted a randomized trial of FAC (fluorouracil 500 mg/m², doxorubicin 50 mg/m², cyclophosphamide 500 mg/m²) versus FAC plus dexrazoxane 1,000 mg/m², administered as an IV bolus injection 30 minutes before FAC therapy. Pretreatment with dexrazoxane offered significant protection against doxorubicin-induced cardiotoxicity as assessed by clinical examination, radionuclide scan of left ventricular ejection fraction, and endomyocardial biopsy. Patients receiving dexrazoxane received higher cumulative doses of doxorubicin, and significantly fewer of these patients were removed from the study because of cardiotoxicity.

Chemistry. Dexrazoxane is an FDA-approved chemoprotective agent that reduces the severity and incidence of cardiomyopathy in women with metastatic breast cancer undergoing doxorubicin therapy. It is chemically known as (S)-4,4'-(1-methyl-1,2-ethanediy)bis-2,6-piperazinedione, has the molecular formula C₁₁H₁₆N₄O₄, and has a molecular weight of 268.28.

Mechanism of Action. The proposed mechanism by which dexrazoxane reduces cardiotoxicity is through chelation of free or loosely bound iron by the hydrolyzed form of the drug (524). This prevents the binding of anthracyclines to intracellular iron and subsequent formation of toxic free radicals.

Administration and Dosage. Dexrazoxane is specifically indicated for women who have received a cumulative dose of 300 mg/m² or greater of doxorubicin and who, in the physician's opinion, would benefit from further doxorubicin therapy. Dexrazoxane must be reconstituted with 0.167 molar (M/6) sodium lactate to give a concentration of 10 mg dexrazoxane for each milliliter of sodium lactate. It may be further diluted with either 0.9% sodium chloride or 5.0% dextrose to a concentration range of 1.3 to 5.0 mg/mL in intravenous infusion bags. It should be given slow IV push or rapid drip IV infusion. Dexrazoxane should be administered no less than 30 minutes before doxorubicin, and the recommended dose ratio of dexrazoxane to doxorubicin is 10:1 (i.e., dexrazoxane 500 mg/m²:doxorubicin 50 mg/m²).

Side Effects and Toxicities. Although randomized studies have shown that myelosuppression was slightly greater in patients pretreated with dexrazoxane, this does not appear to be clinically significant. In addition to dose-limiting granulocytopenia, other toxicities associated with the drug include mild nausea/vomiting and alopecia.

A number of studies in patients with advanced breast cancer have confirmed the protective effects of dexrazoxane against anthracycline-induced cardiotoxicity (525). Additionally, dexrazoxane was shown to have a significant cardioprotective effect in pediatric patients treated up to a cumulative doxorubicin dose of 410 mg/m² (526).

Special Applications. In addition to the cardioprotection indication for dexrazoxane, there are a number of other potential applications for this agent (527). Of particular interest, relative to the treatment of gynecologic malignancies, is the finding that dexrazoxane can enhance the effects of cisplatin in both drug-sensitive and drug-resistant human ovarian cancer cell lines.

Leucovorin

Leucovorin, a chemically reduced derivative of folic acid, is also known as citrovorum factor or folinic acid and was the original chemoprotective agent employed to overcome

high-dose methotrexate-induced bone marrow toxicity (528). Leucovorin can serve as a substitute for the endogenous reduced-folate cofactor (N⁵,N¹⁰-methylene tetrahydrofolate) that is diminished by methotrexate. Thus, leucovorin can "rescue" cells by replenishing intracellular reduced-folate pools and preventing methotrexate toxicity via blockade of thymidine synthesis. Leucovorin acts in a dose- and time-dependent fashion and must be given within 48 hours of methotrexate in order to elicit its rescue effects.

Leucovorin is also a successful modulatory agent used clinically to potentiate the antitumor activity of 5-FU (499). Leucovorin can enhance the DNA toxicity induced by 5-FU through the formation of a stable tertiary complex of 5, 10-methylene tetrahydrofolate, thymidylate synthase, and fluorodeoxyuridine monophosphate. Compared with 5-FU alone, this combination has been shown to produce higher response rates and, in some cases, longer survival for patients with metastatic gastrointestinal malignancies (529). The combination of 5-FU and leucovorin currently is being tested extensively in other malignancies, including metastatic breast cancer (530). A complete review of leucovorin as a modulating agent is beyond the scope of this chapter and the reader is referred to a number of excellent reviews on this topic (499,531).

Mesna

Mesna (Mesnex) is used clinically as a specific chemoprotective agent against bladder toxicity resulting from oxazophosphorine-based alkylating agents, such as cyclophosphamide and ifosfamide. It is sodium-2-mercaptoethane sulfonate, with the molecular formula C₂H₃NaO₃S₂ and a molecular weight of 164.18.

Mechanism of Action. Mesna inactivates the protein-reactive aldehyde, acrolein metabolite of ifosfamide and cyclophosphamide, which accumulates in the urinary bladder and results in dose-limiting urotoxicity (234). Plasma conversion of mesna to its inactive disulfide metabolite, dimesna, allows for the pretreatment and simultaneous administration of mesna as a urinary protector for ifosfamide and cyclophosphamide (high dose). Following renal filtration and secretion, dimesna is converted back to the active parent compound by glutathione reductase, which is subsequently delivered to the bladder. The mesna-free sulfhydryl groups in the urinary bladder can directly complex to and thus neutralize acrolein, in addition to potentially blocking acrolein formation in the urinary tract (532). The metabolic characteristic of mesna should preclude any potential protection to tumors. Indeed, there is no clinical evidence that mesna coadministration with ifosfamide results in decreased antitumor activity. However, mesna has been shown to prevent the cytotoxicity of platinum agents when given simultaneously with them in *in vitro* models. As such, careful scheduling of mesna is warranted for clinical trials using ifosfamide in combination with platinum compounds. Additionally, mesna should not be given simultaneously with cisplatin.

Drug Disposition. Proper scheduling of mesna has been based on pharmacokinetic analysis, which showed that mesna and dimesna have relatively short half-lives of approximately 1 hour and that peak urinary thiol accumulation following IV or oral mesna occurs at 1 and 3 hours, respectively (533). Because the half-life of mesna is much shorter than that of acrolein, it must be administered beyond the completion of ifosfamide.

Administration and Dosage. Mesna is available for IV bolus injection (100 mg/mL) or for oral use, available as 400-mg tablets. For IV administration, it should be diluted to obtain a final concentration of 20 mg/mL. The diluted solution is stable for 24 hours at room temperature. The approved schedule for IV administration of mesna is as a bolus dose (20% of the

ifosfamide dose) prior to ifosfamide and two additional doses 4 and 8 hours after ifosfamide treatment (283). A combination of IV and oral mesna has been used to simplify outpatient ifosfamide therapy. The oral dose of mesna is given equal to 40% of the ifosfamide dosage in two doses at 2 and 6 hours after ifosfamide administration, based on a 50% urinary bioavailability of oral mesna. Oral doses of 3 g/m² have been well tolerated in patients; however, nausea was observed in healthy volunteers receiving oral doses greater than 2 g/m². Goren et al. (534) reviewed the dosing schedules and incidence of hematuria in 47 clinical studies in which oral mesna was administered to 1,986 patients who received greater than 6,475 courses of ifosfamide. Compilation of the data showed that a variety of doses and schedules of oral and IV mesna were effective at preventing hemorrhagic cystitis in patients treated with a number of different ifosfamide regimens. Although an optimal dose and schedule of mesna has not been established, adequate protection against ifosfamide-induced cystitis can be achieved using an initial IV dose of mesna that is equal to 20% of the ifosfamide dose, followed by two oral doses of mesna, each equal to 40% of the ifosfamide dose.

Side Effects and Toxicities. The most common side effects of mesna include headache, injection site reactions, flushing, dizziness, nausea, vomiting, flu-like symptoms, and coughing. Patients may develop hematuria (up to 6%) when administered ifosfamide plus mesna; a urine sample should be evaluated for hematuria each day prior to ifosfamide therapy.

Special Applications. The superiority of mesna as a chemoprotectant against ifosfamide- and cyclophosphamide-induced bladder toxicity has been demonstrated in a number of clinical trials (283). In a comparative study of patients treated with ifosfamide at a dose of 2 g/m²/day for 5 days, only 20% of the patients treated with mesna (400 mg/m²) exhibited hematuria compared with 60% of those treated with N-acetylcysteine (NAC, 1.5 g/m²) (534). Similar results were reported by Munshi et al. (535), wherein 4.2% of patients treated with mesna developed hematuria compared with 27.9% of NAC patients. In a phase 2 trial of ifosfamide and mesna in patients with platinum/paclitaxel-refractory ovarian cancer, there were no documented episodes of hemorrhagic cystitis, but one patient experienced treatment-related microscopic hematuria (282).

Subcutaneous administration of mesna is also being explored as an alternative to IV and oral dosing (536). Patients with gynecologic cancers receiving ifosfamide were treated with an initial IV dose of mesna at 20% of the ifosfamide dose. A subcutaneous infusion of mesna was given approximately 30 minutes after the completion of the ifosfamide infusion. A total dose of mesna equal to 40% of the ifosfamide dose was infused at a rate of 4 mL/hr over 8 hours. The subcutaneous infusion of mesna was well tolerated, and no episodes of gross hematuria were observed.

Oprelvekin

Chemistry. Oprelvekin (Neumega) is FDA approved for the prevention of severe thrombocytopenia and to reduce the need for platelet transfusions in patients with nonmyeloid malignancies. The active ingredient is produced *Escherichia coli* by recombinant DNA technology. This protein has a molecular mass of 19,000 daltons and is similar to native interleukin 11 (IL-11) with the exception of its lack of the amino-terminal praline residue.

Mechanism of Action. IL-11 is a thrombopoietic growth factor that induces megakaryocyte maturation resulting in increased platelet production. Platelets that develop as a result of oprelvekin therapy are morphologically and functionally similar to those produced normally.

Dosage and Administration. Oprelvekin is administered subcutaneously (to the abdomen, thigh, hip, or upper arm) at

a dose of 50 µg/kg daily. Patients with renal impairment (creatinine clearance less than 30 mL/min) should receive half the normal dose (e.g., 25 µg/kg daily). Oprelvekin should be initiated within 24 hours of the completion of chemotherapy until the patient's platelet count is at least 50,000/µL. Treatment generally lasts between 10 and 21 days, and is not recommended beyond 21 days.

Side Effects and Toxicities. Allergic reactions may occur with oprelvekin, and patients should be counseled to be aware of potential allergic symptoms. Treatment with oprelvekin may also cause severe fluid retention. Fluid balance should be monitored during treatment. Other serious adverse effects associated with oprelvekin treatment include cardiovascular events and anemia.

Palifermin

Chemistry. Palifermin (Kepivance) is a human keratinocyte growth factor (KGF) that is FDA approved to reduce the incidence and duration of severe oral mucositis in patients with hematologic malignancies who are receiving myelotoxic therapy requiring hematopoietic stem cell support. The active ingredient is produced in *E. coli* by recombinant DNA technology.

Mechanism of Action. The KGF receptor is present on many epithelial cells in the digestive system (e.g., tongue, buccal mucosa, stomach, esophagus, intestine, salivary glands), and other organs (e.g., lung, liver, pancreas, bladder, skin, and eye). Palifermin enhances the proliferation of KGF-expressing epithelial cells, and has demonstrated the ability to thicken the tongue, buccal mucosa, and gastrointestinal tract.

Administration and Dosage. Palifermin is administered as an IV bolus at a dose of 60 mcg/kg/day for 3 days prior (with dose three to be administered within 24 to 48 hours of therapy) to and 3 days following myelotoxic therapy (with the fourth dose to be administered following but on the same day as hematopoietic stem cell infusion), for a total of six doses. Additional palifermin therapy should not be initiated within 4 days since the most recent administration of palifermin. Palifermin should be reconstituted in 1.2 mL of sterile water for a final concentration of 5 mg/mL. Reconstitution should be performed aseptically and contents should be gently swirled during dissolution. Palifermin should be used immediately; the reconstituted solution should be discarded if left for over 1 hour. Reconstituted medication may be refrigerated for up to 24 hours and must be protected from light.

Side Effects and Toxicities. The most common toxicity reported with palifermin is skin rash. Severe toxicities reported with palifermin include fever, gastrointestinal events, and respiratory events, although these were reported at a similar rate as patients receiving placebo.

CHAPTER 17 ■ HORMONES AND HUMAN MALIGNANCIES

G. LARRY MAXWELL, AMIR A. JAZAERI, AND LAUREL W. RICE

INTRODUCTION

Hormones have been linked to several of the most commonly occurring human malignancies, including breast, endometrium, ovary, and colon. The ability of hormones to stimulate cellular proliferation, leading to random genetic errors, is postulated as the basis by which these peptides promote the development of human neoplasia. The laboratory investigation of the pathways and mechanisms by which hormones affect their biologic responses is an exploding area of research, largely as a result of the tremendous potential for translational research and improved patient care. This chapter reviews the relationship between hormones and human malignancies, specifically as they relate to risk, prevention, and treatment.

HORMONE RECEPTOR PATHWAYS AND MECHANISMS

Overview

Steroid hormones are involved in a variety of growth and developmental processes and exert their physiologic effects by binding to their respective receptors. Steroid hormone receptors are part of the ligand-activated nuclear transcription factor superfamily whose members also include glucocorticoid, mineralocorticoid, androgen, thyroid, retinoid, progesterone (PR), and estrogen (ER) receptors (1). In the inactive state these receptors are bound to repressor/chaperone complexes within the cytoplasm. Upon binding to their respective ligands, the receptor-ligand complex undergoes dimerization followed by nuclear localization (leading to the name “nuclear receptor”). Inside the nucleus the steroid hormone-receptor complex binds to specific DNA sequences called response elements (2). Also participating in this interaction are nuclear receptor coactivators and corepressors, as well as the general transcription machinery (3). The net result of these interactions is the transcriptional activation or repression of hormone responsive genes. More recently, nongenomic actions of ER and other nuclear receptors have been documented. These effects result from protein-protein interactions and membrane-associated nuclear receptor action (4).

Steroid Hormone Biosynthesis

Although a detailed description of steroid biosynthesis is beyond the scope of this chapter, a brief overview is presented

(Fig. 17.1) to highlight targets of therapeutic intervention. The rate-limiting and irreversible reaction in steroid synthesis is the conversion of cholesterol to pregnenolone by the P450-linked side chain-cleaving enzyme (P450_{ssc}) (5). In the ovary this reaction is regulated by follicle-stimulating hormone (FSH) and luteinizing hormone (LH) via cAMP and protein kinase A (PKA) signaling (6). This leads to increased production of androgen intermediates, androstenedione and testosterone, that are then converted by the P450-aromatase enzyme to estrone and estradiol (E₂), respectively. The expression of P450-aromatase enzyme is not limited to the ovaries; its expression and action in a variety of tissues lead to local E₂ production in these tissues (7). This local E₂ biosynthesis may be especially significant in men and postmenopausal women, where ovarian hormone production is lacking. Furthermore, high levels of locally synthesized E₂ have been implicated in breast carcinogenesis (8).

Examination of the transcription patterns of the gene encoding aromatase *CYP19* has revealed tissue-specific promoter usage. Promoter I.1 is used in the placenta; I.4 in adipose tissue, bone, and skin; and promoter II in breast cancer (CA), endometriosis, and ovary (9). The transcripts generated from these promoters are translated into the same protein. However, the presence of tissue-specific promoters has raised the possibility of developing tissue-selective aromatase inhibitors. Such agents would be able to block E₂ in breast CA, for example, without affecting estrogenic pathways in bones (7,10).

Steroid Hormone Receptor Structure

Steroid receptors are comprised of six functional domains (Fig. 17.2) (11). The A/B domain is highly variable among the different members of this family and contains within it the hormone-independent activating 1, or AF-1, domain. The C region consists of the DNA-binding domain (DBD) and is relatively conserved. Within the central DBD two zinc fingers target the receptors to their corresponding hormone response elements. The DBD binds as a dimer with each monomer recognizing half of the palindromic DNA sequence of the response element. The D domain is a peptide linker that connects the DBD to the ligand-binding domain (LBD). The E region is a multifunctional domain and contains amino acids involved in ligand binding, receptor dimerization, nuclear localization, coactivator/corepressor interaction, and ligand-dependent activating function (AF-2). The F region is a variable extension of the E region.

FIGURE 17.1. Steroid hormone biosynthesis. Notice the important role of aromatase in the conversion of androgens to E2s.

Estrogen Receptors

The two main isoforms of the human ER are ER- α and ER- β . ER- α is encoded by the *ESR1* gene, which maps to the 6q25.1 locus. This isoform was the only known ER until 1996 when a second isoform, now known as ER- β , was discovered. Estrogen receptor- β is encoded by the *ESR2* gene located on chromosome 14q23 (12). The human ERs exhibit 96% and 58% homology in their DBD and LBD, respectively, while the other domains show relatively little similarity. These structural differences result in distinct ligand affinities and physiological properties. For example, raloxifene has a significantly higher affinity for ER- α and genistein, a naturally occurring phyto-E2 that has a 30-fold higher affinity for ER- β compared to ER- α *in vitro*. Furthermore, tamoxifen and raloxifene exhibit partial agonist activities after binding to ER- α , while they act as pure antagonists when bound to ER- β (13). This is thought to result from distinct conformational changes induced by ligand binding in the two receptors (14).

ER- α is the predominant ER isoform in some tissues including breast, uterus, and pituitary gland, while ER- β has notably higher expression in ovarian granulosa cells, prostate gland, gastrointestinal tract, endothelial cells, and parts of the nervous system (15,16). However, in many tissues some expression of both receptors is observed. As noted above, ER- α and ER- β have

been shown to have unique physiologic properties. In addition, they are capable of forming ER- α /ER- β heterodimers and thus influencing each other's function (17). In this context, ER- β has been shown to function as a dominant inhibitor of ER- α (18). Therefore, it is likely that normal physiologic function in E2 responsive tissues relies on the relative expression ratio of ER- α and ER- β in those tissues. There is evidence to suggest that perturbations of the normal ER- α -to-ER- β ratio correlate with neoplastic states. Cancers of the ovary, colon, and endometrium are all characterized by a relative loss of the normally predominant ER subtype when compared to normal tissue (19–22). Whether these changes predispose to or are a result of carcinogenesis remains to be elucidated. The development of ER- α , ER- β , and double knockout mice (ERKO, β ERKO, and $\alpha\beta$ ERKO, respectively) has helped with the identification of each receptor's physiologic role in their target organs (23). These findings are summarized in Table 17.1.

Both ER- α and ER- β have several isoforms resulting from exon deletions due to alternative splicing (24,25). Several of these ER- α and ER- β "splice variants" have been demonstrated to possess altered hormone binding and/or transcriptional properties. Some can act in a dominant negative fashion by dimerizing with the wild-type receptors and interfering with their function *in vitro* (26). The *in vivo* physiologic or pathophysiologic significance of these variants awaits further clarification.

FIGURE 17.2. Functional domains common to steroid receptors. The A/B domain is highly variable among the different members of this family and contains the hormone-independent activating 1, or AF-1, domain. The C region consists of the DNA-binding domain (DBD). The D domain is a peptide linker that connects the DBD to the ligand-binding domain (LBD). The E region is a multifunctional domain and contains the LBD as well as amino acids involved in receptor dimerization, nuclear localization, coactivator/corepressor interaction, and ligand-dependent activating function (AF-2). The F region is a variable extension of the E region.

TABLE 17.1**SUMMARY OF FINDINGS FROM ESTROGEN-RECEPTOR KNOCKOUT MICE EXPERIMENTS**

Organ	Phenotype		
	α ERKO	β ERKO	$\alpha\beta$ ERKO
Pituitary gland	High LH	None	High LH
Ovary	Hemorrhagic cysts, high estrogen and testosterone due to high LH, anovulatory	Reduced ovulation	Anovulatory, “sex-reversed” follicles with Sertoli-like cells
Endometrium	Estrogen insensitive, no growth or induction of estrogen-responsive genes	Normal growth and response to estrogen	Estrogen insensitive, no growth or induction of estrogen-responsive genes
Breast	No pubertal development	Normal development and lactation	No pubertal development

LH, luteinizing hormone.

As mentioned above, ER- α and ER- β have been shown to regulate transcription by interacting with other transcription factors and signal mediators (27–29). This mechanism involves protein-protein interaction and does not require DNA binding. One example of this type of interaction is the influence of ERs on the transcriptional activity mediated by the components of the activating protein 1 (AP-1) pathway *jun* and *fos* (30). In the presence of ER- α , E2 stimulates, while tamoxifen and raloxifene inhibit AP-1–dependent transcription. In contrast ER- β produces the opposite effect, with estradiol inhibiting, and tamoxifen and raloxifene stimulating AP-1–mediated transcription. An additional mechanism of ER action involves “cross talk” with growth factors including insulin-like growth factor 1 (IGF-1), epidermal growth factor (EGF), and transforming growth factor β (TGF- β) (31,32). Epidermal growth factor can mimic the effects of E2 on the reproductive tract. This effect is dependent on ER- α since it can be blocked by ER antagonists and is absent in ERKO mice despite an intact EGF signaling cascade (32). Mechanisms for this cross talk involve signal transduction from growth factor receptors via the *ras/raf/MAPK*, as well as the *AKT/PI3K* cascade intermediaries culminating in the phosphorylation and activation of ER’s AF-1 domain (33). AKT activation results in cell survival and inhibition of apoptosis. In normal tissue this pathway is kept in check by a phosphatase called PTEN. PTEN is a tumor suppressor that negatively regulates the *PI3K/AKT* pathway by dephosphorylating PIP3. The activation of the *PI3K/AKT* pathway is particularly relevant in endometrial adenocarcinoma where up to 80% of malignancies and 55% of premalignant lesions have been shown to harbor PTEN mutations (34,35). Most investigations of the growth factor–ER cross talk have involved ER- α . However, recently positive regulation of AKT over ER- β was reported via phosphorylation of glucocorticoid receptor-interacting protein 1 (GRIP1) transcriptional coactivator (36).

Finally, for decades it has been observed that exposure to estrogens can lead to immediate physiologic sequelae independent of transcriptional effects. These observations supported the presence of ERs outside the nucleus as the mediators of these nongenomic steroid hormone effects (37). While the details of this nongenomic effect of estrogens are still under investigation, there appear to be at least two major mechanisms involved. The first consists of interactions of ER- α and its splice variants with components of the growth factor signaling cascades including *MAPK* and *PI3K* pathways (38,39).

The second mechanism involves a G protein coupled receptor, GPR30, an intracellular transmembrane receptor that localizes mainly to the endoplasmic reticulum. In this pathway estrogens diffuse through the plasma membrane and bind GPR30 at the endoplasmic reticulum. This results in intracellular calcium mobilization and synthesis of phosphatidylinositol 3,4,5-trisphosphate in the nucleus. Activation of this pathway has been demonstrated in cells that lack ER- α and ER- β expression (40).

Progesterone Receptors

The effects of progesterone are mediated by two PR proteins, PRA and PRB. The two PR proteins are products of the same gene, *PGR*, which has been mapped to chromosome 11q22–q23. These isoforms result from transcription from alternative promoters (41). The two PR forms are identical except that PRB has an additional 164 amino acids contained at its N-terminus compared to PRA. This unique region of PRB contains a transcription-activating functional domain, AF-3, in addition to AF-1 and AF-2, which are common to PRA (42). The two PRs exhibit differences in function that are cell context and promoter dependent. For example, PRB uniformly exhibits progestin-dependent transactivation in various cell types examined. However, PRA’s transcriptional activity is cell and response element specific. When tested on simple progestin response elements (PRE), PRA and PRB display similar transactivational activity. However, PRA’s activity is reduced or abolished on more complex response elements (43). In addition, PRA has been shown to act in a dominant negative fashion, antagonizing the transcriptional activity of not only PRB, but also other nuclear receptors such as the glucocorticoid, mineralocorticoid, androgen, and estrogen receptors (44).

In general, most tissues express equal levels of the two PR isoforms. However, differential expression can be observed as each promoter is regulated independently. For example, in the endometrium, stromal cells express predominantly PRA throughout the menstrual cycle, whereas the epithelial cells switch from PRA to PRB during the early secretory phase (45). It has been hypothesized that dysregulation of the normal PRA-to-PRB ratio may lead to disordered proliferation or neoplasia. In support of this hypothesis, PRA knockout mice (PRAKO) exhibit endometrial hyperplasia mediated by PRB following exposure to progestins (46). Similar studies using

PRB knockout mice (PRBKO) have shown that PRA is sufficient for eliciting progesterone's reproductive responses in the ovary and the uterus. In contrast, PRB is required to elicit normal proliferative responses of the mammary gland to progesterone (46). Finally, changes in PR isoform relative or overall expression have been described in endometrial, ovarian, and breast cancers (21,22,47). The significance of these alterations awaits further investigation.

Like estrogen receptors, progesterone receptors also possess nongenomic functions that are mediated through two general mechanisms. The first involves interaction with the Src/Ras/MAPK pathway (48), while the second pathway is mediated by plasma membrane-associated G protein-coupled receptors distinct from the classical PRs (49). Clinical significance and potential therapeutic implications of the two different pathways are active areas of steroid hormone research at this time.

HORMONES AS RISK FACTORS FOR HUMAN MALIGNANCIES

Endogenous Hormones and Modulation of CA Risk

Obesity

The prevalence of obesity, defined as a body mass index (BMI) >30, has become an epidemic health care issue, affecting 20% of Americans and approximately 35% of eastern Europeans. When overweight patients (BMI >25) are included, the prevalence of this problem in the United States approaches 56% (50). In women with endometrial CA, obesity is a comorbid condition in up to 40% of cases (50,51). Obesity has been associated with a two- to fivefold increase in endometrial CA risk in both pre- and postmenopausal women (50,52). A recent case-control study performed by the American Cancer Society reported that the cancer death rates were 62% higher for morbidly obese women compared to normal sized women. Specifically, the relative risk of CA-related mortality was significantly increased among obese women with breast CA (relative risk [RR] 1.63; 95% CI, 1.44 to 1.85) and colon CA (RR 1.33; 95% CI, 1.17 to 1.51). In patients with cervix and ovarian CA, a moderate (RR <2) yet significantly increased risk was observed. Uterine CA was most strongly associated with death: women with BMI >40 had an RR of CA-related mortality of 6.25 (95% CI, 3.75 to 10.42) (50,53). The results of recent epidemiologic studies have prompted the International Agency for Research on Cancer (IARC) to recommend avoidance of weight gain in order to minimize the risk of cancers of the colon, breast, and endometrium (50,54).

The relationship between obesity and endometrial carcinoma has been the most clearly elucidated. Progesterone deficiency, related to oligo- or anovulation, is one of the major risk factors for endometrial cancer in obese premenopausal women. The endometrium is chronically stimulated by unopposed E2, inducing neoplastic changes.

In both pre- and postmenopausal women, excess weight frequently results in increased androgen production, which decreases hepatic production of sex hormone binding protein (SHBG). Reducing SHBG increases bioavailable estrogens, including estrane. Obesity is also associated with greater bioavailability of estradiol (E2), but this effect is noted only among postmenopausal women. In premenopausal women, negative feedback of estradiol on FSH, a stimulator of ovarian estradiol synthesis and aromatase activity, helps maintain constant estradiol levels throughout the menstrual cycle. Peripheral conversion of androgens in premenopausal women is subsequently limited by decreased FSH and aromatase activity.

Endometrial CA risk, therefore, does not appear to be directly related to plasma E2 levels prior to menopause.

Obesity may also induce insulin resistance, which can lead to elevated levels of IGF-1. Progesterin deficiency, frequently accompanying obesity, can also lower levels of IGF binding protein (IGF-BP1), resulting in increased levels of IGF-1. The unregulated increase in serum IGF-1 provides a stimulus for continuous growth of the endometrium. Hyperinsulinemia can also lead to a reduction in SHBG. Hyperinsulinemia induces LH-mediated hypersecretion of ovarian androgens leading to oligoovulation and the polycystic ovary syndrome (PCOS), a disease process highly correlated with risk of endometrial cancer.

In postmenopausal obese women, peripheral conversion of androgens is an important source of serum estrogens. Elevated FSH levels typically present in postmenopausal women also contribute to the estrogenic state by the stimulation of aromatase activity. The increase in endogenous unopposed estrogens among obese postmenopausal women leads to the observed increased risk of developing endometrial carcinoma (50,55).

Perinatal E2 Levels

An association between perinatal exogenous estrogen exposure and an increased risk of CA in the offspring suggests that CA risk may be modulated *in utero*. The synthetic nonsteroidal estrogen diethylstilbestrol (DES) was administered during pregnancy to over two million women in the 1940s through the 1960s. Subsequently, DES was banned by the Food and Drug Administration (FDA) due to its teratogenic effects on limb bud development. Epidemiologic studies later revealed that there was a higher incidence of clear cell adenocarcinoma of the vagina and cervix in seemingly normal offspring of mothers who ingested DES prenatally (50,56,57). In a laboratory setting, DES has been found to induce gynecologic carcinomas in developmentally exposed rodents (50,58). Mice treated neonatally with DES on days 1 to 5 have a 90% to 95% incidence of endometrial carcinoma at 18 months of life (59). These data strongly implicate a direct role of estrogen exposure, even early in development, in gynecologic carcinogenesis.

The increased incidence of gynecologic CA associated with antenatal DES exposure would suggest that the developing fetus or neonate is particularly susceptible to the epigenetic effects of estrogen. Investigators recently evaluated the carcinogenic potential of neonatal exposure for another E2 compound, genistein, a naturally occurring phytoestrogen found in many soy products. In this study, treated mice received equivalent estrogenic doses of DES, genistein, or placebo on days 1 to 5. At 18 months, the incidence of uterine adenocarcinomas was 31% for DES and 35% for genistein, suggesting that estrogenic compounds other than DES may be carcinogenic if exposure occurs early during development (50,60).

A growing body of evidence suggests that elevated perinatal levels of endogenous estrogen also may lead to an increased risk of CA in the offspring (50,61). High birth weight, which is an indirect measurement of perinatal endogenous estrogen (50), is associated with an increased risk of breast CA in the newborn's adulthood (62). This increased breast CA risk is even more dramatic in twins, where the levels of perinatal estrogen are more pronounced compared to singleton pregnancies (50,63). Neonatal conditions, such as neonatal jaundice or prematurity, which are associated with increased estrogen, are also associated with a significantly increased risk of breast CA. In contrast, preeclampsia, a condition characterized by low E2 levels during pregnancy, is associated with a decreased risk of breast CA in the newborn's adulthood. Similar studies have been undertaken in evaluating possible associations between perinatal exposures and endometrial cancer later in adulthood. Using a Swedish population cohort of 11,000 singletons with obstetric and long-term medical follow-up, investigators found

that women with higher birth weight had a 24% lower rate of endometrial cancer (64). Other investigators using similar Swedish cohorts and the data from the Nurses' Health Study have not found similar associations (65). Other studies have been undertaken in evaluating possible associations between perinatal exposures and endometrial cancer later in adulthood.

Exogenous Hormones and Modulation of CA Risk

Breast

Hormone Replacement Therapy

Women With No History of Breast CA. Multiple epidemiologic investigations have evaluated the relationship between hormone replacement therapy (HRT) and breast CA. In a meta-analysis of 51 studies of 52,705 women with breast CA and 108,411 women without breast CA, the Collaborative Group on Hormonal Factors in Breast Cancer (CGHFBC) determined that the risk of developing breast CA is increased in women using HRT, especially among women with >5 years of use (RR 1.3; 95% CI, 1.21 to 1.49). The cumulative incidence of breast CA was 45 per 1,000 women between the ages of 50 and 70, and use of HRT for >5 years was associated with an estimated cumulative excess of two breast CAs for every 1,000 users. The increased risk of breast CA risk associated with prolonged HRT was greater for women with low weight or BMI. Breast CAs diagnosed in women who had a history of HRT tended to be less advanced clinically compared to women with a negative history of use (66). The Breast Cancer Detection Demonstration Project, a cohort study with 46,355 postmenopausal women, 2,082 of whom were diagnosed with incident cases of breast CA, reported that women who had taken unopposed E2 had a 1.2-fold (95% CI, 1.0 to 1.4) increase in breast CA risk, while women taking combination E2 and progestin regimens had a 1.4-fold (95% CI, 1.1 to 1.8) increased risk. Breast CA risk was significantly elevated only in recent users with a BMI less than 24 (67). Finally, a recently reported case-control study involving 1,897 women with breast CA revealed that women using combination HRT had a statistically higher risk of breast CA (odds ratio [OR] 1.24; 95% CI, 1.07 to 1.45) than women taking unopposed E2 (OR 1.06; 95% CI, 0.97 to 1.15) (68).

The Women's Health Initiative (WHI), a randomized, double-blind, placebo-controlled trial, recently reported the interim analysis of 8,506 women who received continuous combination HRT (0.625 mg of conjugated equine estrogen plus 2.5 mg of medroxyprogesterone acetate) versus 8,102 women prescribed placebo. The Data and Safety Monitoring Board for the trial recommended early cessation of this trial arm secondary to the observed adverse effects. Interim results from the WHI study revealed that the risk of coronary heart disease (hazard ratio [HR] 1.29; 95% CI, 1.02 to 1.63), stroke (HR 1.41; 95% CI, 1.07 to 1.85), and pulmonary embolism (HR 2.13; 95% CI, 1.39 to 3.25) were all significantly elevated in patients receiving continuous combination HRT. The observed increased risk of breast CA (HR 1.26; 95% CI, 1.0 to 1.59) was similar to results from the aforementioned observational studies (69). A more detailed evaluation of the WHI data used a weighted Cox proportion hazards analysis in an effort to account for the lag in time required to achieve the full effects of the hormone on breast CA incidence. In this analysis, the rate of invasive breast CA was increased in patients receiving progestin plus estrogen (HR 1.24, weighted $p < 0.003$). In addition, patients on HRT were diagnosed with larger tumors and at a more advanced stage when compared to patients who received placebo (70).

In the WHI trial, 10,739 postmenopausal women with prior hysterectomy were randomized to received 0.625 mg of conjugated equine estrogen ($n = 5,310$) versus placebo ($n = 5,429$). In the initial manuscript the WHI investigators reported that there was a possible reduction in breast CA incidence but the results did not reach statistical significance (HR 0.77; 95% CI, 0.59 to 1.01) (71). Further analysis of the data revealed that treatment with conjugated equine estrogen for 7 years does not appear to increase the incidence of breast CA (72).

Women With a History of Breast CA. There is apprehension among physicians to prescribe HRT to women with a positive personal history of breast CA. The *theoretical* concern has been that exogenous hormones may stimulate the growth of dormant microscopic disease and ultimately lead to a decreased disease-free interval and survival.

Several case-control studies have reported that the rates of breast CA recurrence among survivors taking HRT vary from 3% to 7% (73–75) and don't appear to significantly diverge from stage-specific population rates of recurrence. In a case-control study by DiSaia et al. (76), 41 sporadic breast CA patients taking HRT were matched to controls according to age, stage, and socioeconomic status. A majority of the patients had early-stage disease. Recurrences were detected in 12 patients with stage I disease, one with stage II, and two with stage III. No evidence of increased disease recurrence was noted among the patients receiving HRT. In a subsequent analysis by the same authors, 125 sporadic breast CA survivors receiving HRT were compared to 363 control subjects matched according to age at diagnosis, stage of breast CA, and year of diagnosis. The analysis revealed that the risk of death was lower among the breast CA patients receiving HRT (OR 0.28; 95% CI, 0.11 to 0.71) According to the American College of Obstetricians and Gynecologists, the projected absolute lifetime risk for non-HRT users is approximately 10 cases of breast CA per 100 women. This risk would increase to 12 cases per 100 women using unopposed E2 and 14 cases per 100 women using combined E2 and progestin (77). Data from a prospective, randomized trial is not available to answer this question.

Oral Contraceptives. Since their introduction in the 1960s, over 200 million women throughout the world have taken oral contraceptives (OCPs). The CGHFBC performed a meta-analysis of 54 epidemiologic studies on 53,297 women with breast CA and 100,239 women without breast CA. Women who were current users or had used OCPs in the previous 10 years were at an increased risk of breast CA (RR 1.24; 95% CI, 1.15 to 1.33). In women taking OCPs, the breast CAs that developed were less advanced than those diagnosed in women with no history of OCP use (78). Because the results from this meta-analysis reflected data from studies completed over the prior 25 years, the Women's Contraceptive and Reproductive Experiences (Women's CARE) study was initiated in an effort to provide a more contemporary analysis of the relationship between OCPs and breast CA risk (79). In this case-control study, a total of 4,574 women with breast CA and 4,682 controls were compared. The RR was 1.0 (95% CI, 0.8 to 1.3) for current OCP use and 0.9 (95% CI, 0.8 to 1.0) for previous use, suggesting that among women aged 35 to 64 years of age, current or former OCP use is not associated with a significantly increased risk of breast CA.

Women With BRCA Mutations. In the meta-analysis by the CGHFBC, the increased risk of breast CA associated with OCP use was *not* influenced by a family history of breast CA (78). However, a threefold increased risk of breast CA was observed among women taking OCPs who had a positive family history of breast CA. This increased risk was observed only in women using high estrogen potency formulations before 1975 (80). A subsequent matched case-control study by Narod et al. revealed that among *BRCA1* carriers, an increased risk of early-onset breast CA was evident in women who used OCPs

prior to 1975 (OR 1.42; 95% CI, 1.17 to 1.75), used OCPs prior to age 30 (OR 1.29; 95% CI, 1.09 to 1.52), or who used OCPs for 5 or more years. Despite the increased risk associated with OCP usage among *BRCA1* carriers, an increased risk of breast CA was not observed among women with a *BRCA2* carrier status (81). In *BRCA1* carriers, the protective effects of OCPs against ovarian CA must be weighed against the possible increased risk of OCP use and breast CA.

Ovary

HRT

Women With No History of Ovarian CA. Recently, several well-designed case-control and cohort studies have evaluated the relationship between HRT and ovarian carcinoma. The American Cancer Society's Cancer Prevention Study II found that after accounting for OCP use and parity, postmenopausal women using HRT had higher rates of ovarian CA-related deaths compared to nonusers (RR 1.51; 95% CI, 1.16 to 1.96). The increased mortality risk was most notable for women using HRT for 10 or more years and persisted for up to 29 years after HRT cessation (82). This study is limited by the lack of information regarding estrogen and progestin potency. Another cohort study of 44,241 former participants in the Breast Cancer Detection Demonstration Project identified 329 women who developed ovarian CA during follow-up. Multivariate analysis revealed an increased association of estrogen-only HRT with ovarian CA (RR 1.6; 95% CI, 1.2 to 2.0) after accounting for age, menopause type, and OCP use (83). In contrast, an increased risk of ovarian CA was not noted among women who used estrogen and progestin. A Swedish case-controlled trial evaluated 655 case subjects with ovarian CA and 3,819 control subjects. An increased risk of ovarian CA was noted among women with a history of either estrogen (OR 1.43; 95% CI, 1.02 to 2.00) or estrogen with sequentially added progestins (OR 1.54; 95% CI, 1.15 to 2.05), particularly with hormone use exceeding 10 years. However, use of estrogen with continuously added progestin was *not* associated with an increased risk of ovarian CA when compared to nonusers (84). The latter two studies suggest that HRT regimens containing both E2 and progestin may not have the increased risk of ovarian CA observed with E2 therapy alone. However, the WHI recently identified, in women taking continuous combined HRT, an HR of 1.58 (95% CI, 0.77 to 3.24) for developing invasive ovarian carcinoma (85). The importance of the presence or absence of progesterone in HRT, as well as the type and potency, remains to be clearly elucidated.

Women With a History of Ovarian CA. Only one randomized, controlled clinical trial exists evaluating the risk of ovarian CA recurrence in patients receiving HRT. This study was designed to detect a 20% difference in survival between the two treatment groups. In this study, 130 patients less than 59 years of age with invasive ovarian CA were randomized to continuous E2 HRT or no supplementation. The median disease-free interval for women receiving HRT versus not was 34 months and 27 months, respectively, not reaching statistical significance (86).

OCPs. Multiple epidemiologic studies have revealed that OCPs are *not* a risk factor for ovarian CA, but rather a means of prevention. See below.

Endometrium

HRT

Women With No History of Endometrial CA. Multiple case-control and cohort studies also have suggested that the risk of endometrial CA is elevated among patients receiving unopposed estrogen. A meta-analysis of 30 studies indicated that the summary RR of endometrial CA was 2.7 for patients

receiving unopposed estrogen (87). The use of unopposed estrogen has also been shown to be associated with the development of endometrial hyperplasia. In the Postmenopausal E2/Progestin Intervention (PEPI) trial, 875 patients were randomized to receive one of five regimens: (a) placebo; (b) conjugated equine E2 (CEE), 0.625 mg/day; (c) CEE, 0.625 mg/day plus continuous medroxyprogesterone (MPA), 2.5 mg/day; (d) CEE, 0.625 mg/day plus MPA, 10 mg for 12 days each month; or (e) CEE, 0.625 mg/day plus micronized progesterone (MP), 200 mg/day for 12 days per month. Patients receiving unopposed estrogen had a significantly increased risk of atypical adenomatous endometrial hyperplasia (34% vs 1%) (88).

The addition of progestin to HRT has been shown to eliminate the increased risk of hyperplasia associated with unopposed E2. Although progestins have been associated with the effective treatment of endometrial hyperplasia, the data supporting the protective effects of progestins in HRT are limited. Many of the initial HRT regimens combining progestin and estrogens utilized the progestin for 7 days a month (89). Subsequent studies have recommended prolongation of the progestin component to at least 10 days each month. A case-control study of 832 endometrial CA patients and 1,114 controls in Washington State revealed that patients using a combined regimen of estrogen combined with progestin (0.625 mg/day CEE, 2.5 mg/day MPA) had a significantly lower relative risk (RR 1.4; 95% CI, 1.0 to 1.9) of endometrial CA compared to patients who had taken unopposed estrogen (RR 4.0; 95% CI, 3.2 to 5.1). However, patients receiving less than 10 days of cyclic progestin had an RR that was much higher (RR 3.1; 95% CI, 1.7 to 5.7) than patients receiving 10 to 21 days of cyclic progestin (RR 1.3; 95% CI, 0.8 to 2.2). Patients using either regimen of cyclic combination HRT had an increased risk of endometrial CA when these regimens were taken for a duration exceeding 5 years (cyclic progestin <10 days per month; RR 3.7; 95% CI, 1.7 to 8.2; cyclic progestin 10 to 21 days each month, RR 2.5; 95% CI, 1.1 to 5.5) (90). Subsequent data from the same investigators suggested that use of a continuous progestin HRT regimen may actually be protective against endometrial CA (91). The largest case-control study of continuous HRT involved 79 case subjects and 88 control subjects and revealed that the relative risk of patients receiving continuous HRT was 1.07 (95% CI, 0.80 to 1.43) (92). Data from the WHI indicated that the HR for endometrioid endometrial cancer (EEC) was 0.81 (95% CI, 0.48 to 1.36) in patients receiving continuous HRT with average follow-up of 5.6 years (85).

There has recently been some suggestion that the degree of endometrial CA risk reduction may be dependent on the type of progestin used in the continuous HRT regimen. A Swedish case-control study found that patients with a continuous HRT involving testosterone-derived progestins (i.e., norethisterone, norethisterone acetate, levonorgestrel, lynestrenol) were associated with a lower RR of endometrial CA than those patients whose regimens involved progesterone-derived progestins (i.e., medroxyprogesterone) (93). Data from the Continuous Hormones as Replacement Therapy (CHART) study found no evidence of endometrial hyperplasia in participants who received norethindrone acetate (a testosterone derived progestin). In this clinical trial, 1,265 patients were randomized to placebo versus one of eight treatment groups involving either various doses of unopposed ethinyl estradiol or various combinations of ethinyl estradiol plus norethindrone. Approximately 1,134 endometrial biopsies were performed over a 2-year follow-up period among women who received the combination HRT regimen; 1,232 biopsies were performed in the women given unopposed E2. As the dose of unopposed ethinyl estradiol was increased, there were increased percentages of subjects with endometrial hyperplasia. There were no cases of hyperplasia noted among the subjects who received different doses of the

testosterone-derived progestin norethindrone. The protective effect was noted even among patients randomized to receive doses of norethindrone as low as 0.2 mg (88). In contrast, the PEPI trial identified hyperplasia on a surveillance endometrial biopsy in 3 out of 339 patients who received E2 with a progesterone-derived progestin. Further studies are needed to determine the degree of endometrial CA risk influenced by the progestational activity of the progestin.

Women With a History of Endometrial CA. The use of E2 among patients with endometrial CA is controversial. *In vitro* treatment of Ishikawa endometrial CA cells with estrogen up-regulates ER expression and augments growth in endometrial CA cells (94,95). However, *in vivo* growth of residual microscopic endometrial CA in patients has not been proven to date. Four retrospective cohort studies have evaluated patients with early-stage endometrial CA receiving E2 postoperatively. Creasman et al. evaluated 221 patients with stage I disease, of whom 47 received postoperative HRT and 174 did not (96). Patients receiving HRT were followed for a median of 26 months. Regression analysis revealed that there was no increased risk of recurrent disease associated with HRT use, even when adjusting for age, tumor grade, myometrial lymph node status, and peritoneal cytology. A subsequent study by Lee et al. (97) compared the outcomes of 44 low-risk endometrial CA patients (stage IA/IB G1/G2 disease) who received HRT following treatment to 62 patients who received no HRT. There were no recurrences observed among the endometrial CA patients receiving HRT for a median duration of 64 months. Investigators from the University of California, Irvine, have also failed to demonstrate an increased risk of recurrent disease associated with postoperative HRT (98). In the first study, investigators evaluated 123 women with surgical stage I and II endometrial CA. Sixty-one women received postoperative estrogen and the mean duration of follow-up was 40 months. The disease-free interval was not significantly shortened among the patients receiving E2 (98). The second study was a retrospective cohort study that involved 75 patients with stage I-III disease who received HRT (51% E2 only, 49% E2 with added progestin) postoperatively. This group of patients was then matched according to decade of age at diagnosis and stage of disease to a group of endometrial CA patients in the study cohort not receiving HRT. Both groups were comparable in terms of parity, tumor grade, depth of myometrial invasion, histology, lymph node status, surgical treatment, concurrent morbidities, and postoperative radiation. The patients receiving HRT were followed for a mean interval of 83 months and patients not receiving HRT were followed for a comparable interval of 69 months. Patients using HRT had a longer disease-free interval compared to non-hormone users. Among the 150 patients, only 8 patients had stage III disease (99).

In a Committee Opinion by the American College of Obstetricians and Gynecologists Committee of Gynecologic Practice, the members announced that “the decision to use HRT in these women [endometrial CA patients] should be individualized on the basis of potential benefit and risk to the patient” (100). The Gynecologic Oncology Group (GOG) initiated a multicenter randomized, controlled trial aimed at an enrollment of 2,100 patients with stage I and II endometrial CA. The study was closed after enrollment of 1,200 patients because the majority of the patients were low-risk with stage IA and G1 disease. In the absence of adequate enrollment of more intermediate-high risk early-stage endometrial CA patients, the number of recurrences used in the ad hoc sample size determination would be underestimated leading to suboptimal power for the clinical trial. With the closure of this GOG protocol, the safety of exogenous estrogen use in women who have undergone surgical management of endometrial CA may never be fully ascertained.

OCPs. Multiple epidemiologic studies have revealed that OCPs are *not* a risk factor for endometrial CA, but rather a means of prevention. See below.

Selective Estrogen Receptor Modulators. The anti-estrogen tamoxifen has been used in the adjuvant therapy of advanced breast CA for years and has recently been evaluated as a chemopreventive agent in patients at a high risk for developing this malignancy. Tamoxifen increases the risk of second primary malignancies at other sites. A randomized, controlled trial involving 2,729 women performed by the Stockholm Breast Cancer Study Group revealed that patients given tamoxifen (40 mg/d) had a nearly sixfold increased risk of endometrial CA and a threefold increased risk of gastrointestinal CA (50,101). These findings were confirmed in the National Surgical Adjuvant Breast and Bowel Project (NSABP). In this study, 2,843 patients with node negative invasive breast CA were randomized to receive tamoxifen (40 mg/d) or placebo. The RR of endometrial CA in patients receiving tamoxifen was 7.5 (CI, 1.7 to 32.7) (102) compared to placebo (50). When the population-based rates of endometrial CA from another NSABP trial (B-06), and data from the Surveillance, Epidemiology, and End Results (SEER) Program were used in the calculation of risk, the RR of endometrial CA associated with tamoxifen use was 2.3 and 2.2, respectively. In addition, the average annual HR during follow-up was only 1.6 out of 1,000 in the group receiving tamoxifen (50,102), suggesting that routine screening would not be cost-effective.

Other selective estrogen receptor modulators (SERMs) are being evaluated as adjuvant treatment for breast CA in an attempt to avoid the increased risk of secondary malignancies, while maintaining the same or greater effectiveness. Results from the Multiple Outcomes of Raloxifene Evaluation (MORE) study indicate that patients receiving raloxifene had a lower incidence of breast CA without any increase in endometrial CA risk (50,103). However, the primary endpoint in this investigation was risk reduction of fracture in postmenopausal women with osteoporosis. In the National Surgical Adjuvant Breast and Bowel Project Study of Tamoxifen and Raloxifene (STAR) P-2 trial, investigators found that raloxifene is as effective as tamoxifen in reducing the risk of invasive breast cancer. Although the overall risk of developing endometrial cancer was similar in patients on raloxifene versus tamoxifen (RR 0.62; 95% CI, 0.35 to 1.08), the incidence of hyperplasia was less often found in the raloxifene group (RR 0.16; 95% CI, 0.09 to 0.29) (104).

Several other SERMs are under investigation. The results of ongoing clinical trials will confirm these preliminary findings and establish the applicability of this contemporary generation of SERMs.

Colon

HRT. Multiple epidemiologic studies have revealed that HRT is *not* a risk factor for colon CA, but rather protects against this malignancy. See below.

OCPs. Multiple epidemiologic studies have revealed that OCPs are *not* a risk factor for colon CA, but rather protect against this malignancy. See below.

SERMs. *In vitro* evidence has revealed that both tamoxifen and raloxifene are effective in reducing cell proliferation and viability of colon CA cell lines, suggesting a possible application in the prevention of colon CA (105). Unfortunately, the available epidemiologic evidence is limited and controversial regarding the issue of tamoxifen's effects on colorectal CA risk. A meta-analysis by the Stockholm Breast Cancer Study Group analyzed 4,914 postmenopausal women participating in one of three Scandinavian clinical trials evaluating adjuvant tamoxifen: the

Stockholm Trial, the Danish Breast Cancer Group Trial, and the South-Swedish Trial (101). The joint analysis of these three trials revealed that adjuvant tamoxifen therapy in breast CA patients increased the risk of colorectal CAs (RR 1.9; 95% CI, 1.1 to 1.3) (101). In contrast, findings from the NSABP B-14 and the SEER Program (106) have failed to confirm an increased risk of colorectal CA among patients receiving adjuvant tamoxifen therapy. Additional epidemiologic trials are needed to resolve the issue of adjuvant tamoxifen therapy and the risk of secondary sporadic colorectal CAs.

Although some epidemiologic evidence suggests that tamoxifen may be associated with an increased risk of sporadic colorectal CA, SERMs have been used in the treatment of desmoid tumors associated with hereditary colorectal CA. Colorectal CA includes two main mechanisms of inheritance: familial adenomatous polyposis (FAP) and hereditary non-polyposis colorectal CA (HNPCC). Desmoid tumors are fibroaponeurotic tumors that occur rarely in the general population but can be found in 12% to 17% of patients with FAP (107). Tamoxifen has been shown to have growth inhibition in desmoid tumor cell lines in an E2-independent mechanism (108). According to the practice guidelines of the Standard Task Force of Colon and Rectal Surgeons, high-dose tamoxifen (120 mg/day) and other SERMs may be used in the treatment of aggressive desmoid tumors. This recommendation is weak (level III) and based on limited descriptive European case series (109,110). The use of tamoxifen in the prevention or treatment of primary colorectal CA is not advocated.

Phytoestrogens. Increased rates of breast, colon, ovarian, and endometrial CA are found in Western societies. Phyto-E2s are possible dietary mediators of increased CA risk that are subdivided into two groups: isoflavonoids and lignans. Isoflavonoids are compounds with inherent E2-ic activity that can lead to low IGF expression and inhibition of aromatase and growth factors resulting in a possible chemoprotective effective in the breast. Lignans are compounds formed from plant lignan precursors by intestinal microflora. Both isoflavonoids and lignans are found in foods such as whole grain rye bread, soybeans, and red clover. Studies suggest that the development period during which the isoflavonoid is ingested is important in modulation of future CA risk. Ingestion of soy before or during adolescence may decrease the risk of future breast CA. However, there is no convincing evidence indicating that soy or other isoflavonoids are protective against breast CA or colon CA if ingested during adulthood (50,111). There is a paucity of data regarding the association between isoflavonoids and other CAs affecting women. A case-control study using a Hawaiian group revealed that the high consumption of soy products in adults significantly decreased the risk of endometrial CA even after accounting for confounding influences (50,112). Large, population-based studies are needed to determine the effects of isoflavonoids on specific CA risk, particularly since they are becoming a more common component of the American diet.

Consumption of whole grain products, berries, fruits, and vegetables can stimulate production of lignans, which can be indirectly measured via urinary enterolactone. Although women with breast CA have significantly lower levels of urinary enterolactone, it is unknown whether higher levels of enterolactone are protective against breast CA or whether they are a marker for an unknown chemoprotective compound associated with a healthier diet. High enterolactone production has been associated with inhibition of colon CA in animal models, but elevated levels have not been confirmed to be protective against colon CA in humans (50,111). In contrast, obesity as well as increased dietary fat intake is associated with decreased levels of urinary lignans, suggesting that the increased risk of CA associated with obesity may be in part related to lignan production.

HORMONES AND THE PREVENTION OF HUMAN CANCERS

Chemoprevention can be defined as the use of specific natural or synthetic chemical agents to reverse, suppress, or prevent the progression toward malignancies. Human carcinogenesis proceeds through multiple discernible stages of molecular and cellular alterations, thus providing the scientific rationale for clinical CA chemoprevention. The necessary requirements for evaluation of chemoprevention include (a) identification of high-risk individuals based on family history and/or genetic mutations; (b) identification of putative surrogate endpoints or biomarkers for CA; and (c) the possibility that relatively nontoxic agents may decrease the risk of a given malignancy. Prospective clinical trials are mandatory for evaluating potential strategies for preventing human malignancies.

Breast Cancer Chemoprevention

SERMs

Reducing the incidence of breast CA has the potential to provide a major impact on the morbidity of the disease and its treatment, cost to the individual and to society, and overall CA mortality. Epidemiologic studies indicate that E2-mediated events play a role in the development of breast CA. Tamoxifen, a SERM, has been utilized as a chemopreventive agent for breast CA in four randomized, prospective, placebo-controlled clinical trials. Raloxifene, a second-generation SERM, was investigated in the MORE trial, in which the primary endpoint was risk reduction of fracture in postmenopausal women with osteoporosis; the incidence of breast CA was a secondary endpoint. These five studies are reviewed and summarized below.

Breast Cancer Prevention Trial. In 1992, the National Cancer Institute in collaboration with the NSABP initiated the Breast Cancer Prevention Trial (BCPT, P-1) (113). The primary goal was to determine whether tamoxifen administered for 5 years prevented breast CA in women at high risk, including women 60 years or older, women 35 to 59 with a 5-year predicted risk of breast CA of at least 1.66%, or women who had a history of lobular carcinoma *in situ* (LCIS). Risk was estimated using the Gail model (114). Each of the 13,388 women enrolled was randomly assigned to receive tamoxifen 20 mg/day or placebo. The median follow-up time was 54.6 months, with 175 cases of invasive breast CA in the placebo group compared with 89 in the tamoxifen group (RR 0.51; 95% CI, 0.39 to 0.66; $P < 0.00001$). Tamoxifen reduced the incidence of ER+ tumors by 69%, but there was no difference in the incidence of ER- tumors.

Italian Tamoxifen Prevention Study. This double-blind, placebo-controlled, randomized trial began recruitment in October 1992 and ended in July 1997, and included healthy women aged 35 to 70 years of age (115). The trialist and data-monitoring committee ended recruitment because 26% of women dropped out of this study; 5,408 women were randomized to receive tamoxifen 20 mg/day or placebo for 5 years. Women were allowed to take HRT. The primary endpoints were reduction in the frequency and mortality of breast CA. At a median follow-up of 46 months, 19 CAs were diagnosed in the tamoxifen arm and 22 among women in the placebo arm ($P = 0.6$). An update was reported in 2002 (116). At 81.2 months of follow-up, 45 of 2,708 women receiving placebo and 34 of 2,700 women receiving tamoxifen developed breast CA (OR 0.76; 95% CI, 0.47 to 1.60). The difference was not statistically significant ($P = 0.215$). Among

women who used HRT either at baseline or during the study, breast CA was diagnosed in 17 of 791 receiving placebo and six of 793 receiving tamoxifen ($P = 0.022$).

Royal Marsden Hospital Chemoprevention Trial. This trial was initiated in 1986 as a preliminary pilot study for the International Breast Cancer Intervention Study (IBIS-I) (117). The aim of this study was to assess whether tamoxifen would prevent breast CA in healthy women at increased risk for the disease based on family history only. Each participant had at least one first-degree relative under the age of 50 with breast CA, one first-degree relative with bilateral breast CA, or one affected first-degree relative of any age and another affected first-degree or second-degree relative. Women were allowed to take HRT during this study. Randomization of 2,494 women between the ages of 30 and 70 to tamoxifen 20 mg/day or placebo occurred. The median follow-up was 70 months and 2,471 of the women were analyzed. The frequency of breast CA was the same for women receiving tamoxifen and placebo (tamoxifen = 34, placebo = 36; RR 1.06; 95% CI, 0.7 to 1.7), and there appeared to be no interaction between the use of HRT and the effect of tamoxifen on breast CA occurrence. An update of this trial reported 75 cases of breast CA in the placebo group compared with 62 in the tamoxifen group (OR 0.83; 95% CI, 0.58 to 1.16) (118,119).

International Breast Cancer Intervention Study. Randomization occurred to tamoxifen 20 mg/day or placebo for 7,152 women, aged 35 to 70 years and at high risk for breast CA (120). Eligible women had risk factors for breast CA indicating at least a twofold relative risk among those aged 45 to 70 years, a fourfold relative risk among those aged 40 to 44 years, and a tenfold relative risk among those aged 35 to 39 years. The women enrolled in this study were at moderately increased risk of developing breast CA, with 60% of the study cohort having a 10-year risk ranging from 5% to 10%. The IBIS-I investigators used a model to predict the absolute 10-year risk of developing breast CA, but the details of their model have not been published. Use of HRT was permitted, and approximately 40% of women used such therapy at some point during the trial. The primary endpoint was the incidence of breast CA, including ductal carcinoma *in situ* (DCIS). At a median follow-up of 50 months (7,139 women analyzed), 69 women in the tamoxifen group compared to 101 women in the placebo group developed breast CA (overall 32% reduction in breast CA rate; 95% CI, 8 to 50; $P = 0.01$). The risk of developing ER+ invasive tumors was reduced by 31%, but there was no reduction in the risk of ER- tumors. There was no difference in the incidence of breast carcinoma among women taking HRT during the study. However, among women who received HRT before the trial, 21 cases of breast CA developed in the placebo group and nine in the tamoxifen group (OR 0.43; 95% CI, 0.80 to 6.06).

Multiple Outcome of Raloxifene Evaluation. The MORE study was a multicenter, randomized, double-blind trial, raloxifene 60 or 120 mg/day or placebo for 3 years, with the primary endpoint of rate of fracture in postmenopausal women with osteoporosis (121). Breast CA incidence was a secondary endpoint. A total of 7,705 women, at least 2 years postmenopausal and no older than 80 years of age, were enrolled. Women who were taking E2 during the previous 6 months were excluded, and 12.3% of women reported a family history of breast CA. There were 27 cases of invasive breast CA in the placebo group compared to 13 in the raloxifene group (RR 0.24; 95% CI, 0.13 to 0.44; $P < 0.001$). There was no difference in breast CA incidence between the two doses of raloxifene. Raloxifene reduced the risk of invasive ER+ breast CA by 90% (RR 0.10; 95% CI, 0.04 to 0.24), but did not reduce the risk of ER- breast CA. Four-year results from this study have now been reported (122). These results, with extension to 4 years after initiation of the trial, are consistent with the

results based on the 3-year follow-up. The MORE trial was not designed to evaluate invasive breast CA as a primary endpoint. In addition, women in this trial were at lower risk of breast CA compared with women in the BCPT. Further study of raloxifene is indicated, and at this time this SERM cannot be recommended for chemoprevention outside of a clinical trial.

Summary of the Tamoxifen Chemoprevention Trials. The Royal Marsden and Italian studies failed to confirm the results of the BCPT, a reduction in the incidence of ER+ breast carcinoma in women taking tamoxifen. An updated report from the Italian Tamoxifen Prevention Study found a reduction in the incidence of ER+ breast CA among a subgroup of women. The results of the IBIS-I study confirmed that tamoxifen reduces the risk of breast CA. Numerous methodologic differences exist between the BCPT and European trials in trial design, trial implementation, and characteristics of the women studied. It is probable that both the Royal Marsden and Italian trials would fail to detect an overall effect for tamoxifen among the populations studied. Both of these trials were statistically less powerful and smaller than the BCPT, with fewer person-years of follow-up and fewer reported events. As well, the risk of breast CA among women in these trials was lower than the BCPT. The U.S. FDA approved the use of tamoxifen for breast CA risk reduction in women aged 35 years or older, with a 5-year risk of 1.66% or greater.

In January 2003, Cuzick et al. (119) published an overview of the above breast CA chemoprevention trials. The results are summarized in Figure 17.3. Tamoxifen reduced the incidence of ER+ breast CAs by 48% (95% CI, 36 to 58; $P < 0.0001$), with no reduction in the incidence of ER- breast CAs. Age had no effect on the degree of breast CA reduction. The rates of endometrial CA increased in all the tamoxifen prevention trials (consensus RR 2.4; 95% CI, 1.5 to 4; $P = 0.0005$); no increase in endometrial CA was observed with the use of raloxifene. Venous thromboembolic events were increased in all the tamoxifen prevention studies (RR 1.9; 95% CI, 1.4 to 2.6; $P < 0.0001$), with similar results seen in the MORE study. Overall, there was no effect on all-cause mortality in the tamoxifen prevention trials (HR 0.90; 95% CI, 0.70 to 1.17; $P = 0.44$). The authors concluded that the evidence clearly shows that tamoxifen can reduce the risk of ER+ breast CA.

The STAR trial (Study of Tamoxifen and Raloxifene), powered to demonstrate superior efficacy or equivalence of either tamoxifen (20 mg/day) or raloxifene (60 mg/day) in reducing the incidence of primary breast CA, was opened to accrual on July 1, 1999. The trial enrolled 19,747 women and data are available for 19,471 of them; 9,726 women in the tamoxifen arm and 9,745 women in the raloxifene arm. All women had a projected 5-year risk of developing breast CA of 1.66% or higher as determined by the Gail model. Eligible women included postmenopausal women 35 years or older with no prior history of invasive breast CA or DCIS. Postmenopausal women with a history of LCIS who are aged 35 years or older were also eligible. The number of invasive breast cancers was statistically equivalent (167 in the raloxifene group and 163 in the tamoxifen group). Both drugs reduced the risk of invasive breast cancer by around 50 percent.

Aromatase Inhibitors

Aromatase inhibitors (AIs) are being considered for use in breast CA chemoprevention. In contrast to SERMs, which are competitive inhibitors of E2 at its receptor, AIs suppress plasma E2 levels by inhibiting or inactivating aromatase, the enzyme responsible for the synthesis of E2s from androgenic substrates. This class of compounds has effectively challenged tamoxifen for use as adjuvant therapy in postmenopausal women with ER+ breast CAs, who constitute the majority of patients with breast CA. Evaluating women with early-stage

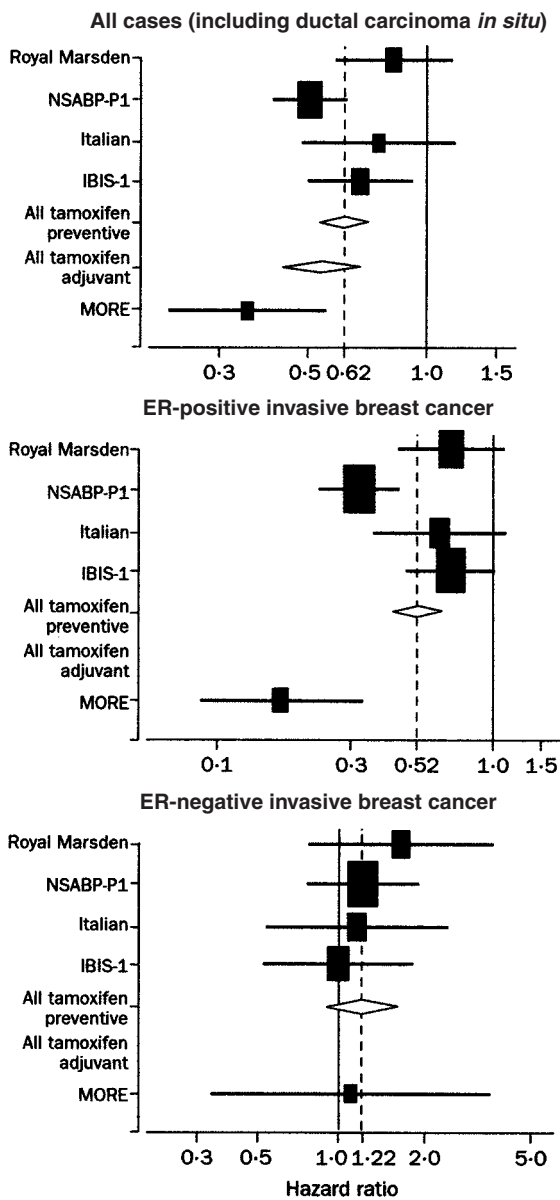

FIGURE 17.3. Incidence of breast CA. Note that the scale for the hazard ratio on the horizontal axis is different for each section of the figure. *Source:* Reprinted with permission from Cuzick J, Powles T, Veronesi U, et al. Overview of the main outcomes in breast-cancer prevention trials. *Lancet* 2003;361:296–300.

breast CA, the ATAC (Arimidex, Tamoxifen Alone or in Combination) Trialists' Group found that the incidence of contralateral invasive breast CA was lower in those receiving the third-generation AI (anastrozole [Arimidex]), when compared to tamoxifen, after a median of 33 months of follow-up (see below). By extrapolation, Arimidex might reduce the early incidence of breast CA to an even greater extent than tamoxifen and thus have potential in breast CA chemoprevention (116,123). The long-term effects of profound E2 suppression in postmenopausal women are unknown, and careful monitoring for bone demineralization and other potential problems is essential as the role of AIs evolves.

Prophylactic Oophorectomy

The potential role for oophorectomy as *chemoprevention* (decreased E2 levels) for breast CA in premenopausal women is an area of active investigation. In genetically uncharacterized

premenopausal women, oophorectomy is associated with a 50% reduction in breast CA incidence, but also incurs the associated negative effects of a surgically induced early menopause (124,125). In this patient population, where the overall incidence of breast CA is one in eight, it is not standard practice to offer oophorectomy for breast CA prevention. However, in premenopausal women with germ-line *BRCA1* and *BRCA2* mutations, the cumulative lifetime risk (to 70 years of age) of invasive breast CA is 60% to 85%, allowing for more serious consideration for prophylactic oophorectomy as a *chemoprevention*. The prevalence of germ-line *BRCA1* or *BRCA2* in the general population is 0.1% to 0.2%, contributing to a small fraction of all cases of breast CA, but as many as 10% of cases diagnosed in women younger than 40 years of age and approximately 75% of familial cases. Two recent publications support the practice of recommending prophylactic oophorectomy after the completion of childbearing in premenopausal women (126,127). Kauff et al., in a prospective study, reported on 170 carriers of *BRCA* mutations with a mean follow-up of 24.2 months, 98 of whom underwent prophylactic salpingo-oophorectomy (126). A 70% risk reduction in breast CA incidence was identified. Rebbeck et al., in a multicenter retrospective analysis, reported on 551 carriers of *BRCA* mutations with 11 years of follow-up, 259 of whom underwent a prophylactic salpingo-oophorectomy. A 53% risk reduction in breast CA incidence was identified (127). The reduced risk of a subsequent diagnosis of breast CA in women with *BRCA* mutations, after salpingo-oophorectomy, confirms an earlier report of a 47% reduction in this patient population (128).

Phytochemicals

Phytochemicals with potential anti-CA properties span a wide range of chemical types and activities. Their presence, concentration, and bioavailability in any of thousands of plant species used by humans is variably and incompletely documented. Several studies have specifically examined the effects of vegetable and fruit intake on breast CA risk. These studies suggest a protective effect of vegetable intake, particularly those rich in carotenoids. Beta-carotene intake has been associated with lower breast CA risk in several studies (129–131). High dietary fiber intake has also been associated with a lower risk of breast CA (132). The multiplicity of phytochemical actions at different sites in the process of tumorigenesis complicates the investigative effort needed for the development of chemopreventive agents from this class of compounds.

Endometrial Cancer Chemoprevention

Chemoprevention strategies for endometrial cancer (EEC) have been based on the observation that exposure to E2 with insufficient progestational stimulation predisposes women to EEC and its precursor lesion, atypical endometrial hyperplasia. While marked obesity, use of exogenous E2, early menarche, and diabetes have been identified as risk factors for the development of EEC, only early menarche has been associated with serous carcinoma, as well as its precursor lesion, endometrial intraepithelial carcinoma (EIC) (133). This observation, as well as other investigational work, supports the existence of a dualistic model for endometrial carcinogenesis, where atypical endometrial hyperplasia and EEC are E2 related and EIC and serous carcinoma are E2 unrelated. Further delineation of E2-independent pathways of endometrial carcinogenesis will be necessary to develop chemoprevention strategies for serous carcinoma, which accounts for a minority of endometrial carcinomas, but a disproportionate number of

endometrial CA deaths. Chemoprevention strategies for EEC, because of its clear association with E2, have been more easily identified, and are described below.

Continuous Combined HRT

Premature termination of one comparison (continuous combined HRT: daily conjugated equine E2 0.625 mg and medroxyprogesterone acetate 2.5 mg) in the WHI primary prevention trial occurred because cardiovascular disease and breast CA were increased, recognizing that colorectal CA, endometrial CA, and osteoporotic fractures were reduced (134). The reduction seen in the incidence of EEC with continuous HRT is in agreement with case-control studies that have documented a reduction in incidence of this malignancy in women taking continuous combined HRT (90,91,93).

OCPs

There is substantial evidence that ever-use of OCPs reduces the risk of EEC by approximately 50% (135). Numerous epidemiologic studies demonstrate that the reduced risk depends on the duration of OCP use. The risk is reduced by 20% with 1 year of use, 40% with 2 years of use, and 60% with 4 or more years of use (136).

A preliminary analysis of the Centers for Disease Control and Prevention (CDC) Cancer and Steroid Hormone (CASH) study attempted to characterize the protective effect of specific OCP formulations on EEC risk by comparing 187 endometrial CA cases with 1,320 controls (137). The CASH study determined that continuous OCP formulations provided protective effects (RR 0.4; 95% CI, 0.2 to 0.9) while sequential OCPs did not (RR 2.1; 95% CI, 0.8 to 5.8). Similarly, in the World Health Organization (WHO) Collaborative Study of Neoplasia and Steroid Contraceptives, 132 cases of EEC and 835 matched controls were evaluated to determine the protective effects of OCPs on endometrial CA. Investigators found that the risk of EEC was decreased among women who had a history of combination OCP use (OR 0.53; 95% CI, 0.29 to 0.97) (138). In both the CASH and the initial WHO study, combination OCP formulations were not categorized according to the potency of estrogen and progestin, thereby preventing an assessment of the effects on EEC risk according to the potency of the hormonal components.

In order to better understand the protective effects of combination OCPs, two case-control studies have attempted to evaluate progestin and estrogen potency of OCP formulations in relation to EEC risk. Following further enrollment of patients in the WHO Collaborative Study of Neoplasia and Steroid Contraceptives, investigators reported an analysis of 220 cases of EEC and 1,537 controls (139). In this study, a lower risk of EEC was observed with high progestin potency OCP formulations compared with low progestin potency. Although the number of patients using high potency progestin was very small in this study, the results suggested that high progestin potency OCP formulations could be more protective against EEC. A second case-control study evaluated 316 cases and 501 controls from women in the King or Pierce counties of Washington. Among these women, the relative risk for women who had used a high progestin potency OCP (RR 0.3; 95% CI, 0.1 to 0.9) was as low as the relative risk for women using a low potency progestin (RR 0.2; 95% CI, 0.1 to 0.8) (50). These results did not find a potency-dependent protective effect and suggested that the progestin potency was adequate to achieve a protective effect against endometrial CA in most combination OCP formulations. The methods of classifying progestin potency were the same in both the WHO study and the Washington State study, thereby eliminating differences in classification as a reason for the different findings from these two studies. Details regarding the specific OCPs

taken by case and control subjects were not reported in the Washington State study. The OCP formulations used in the second WHO study contained progestins that are no longer used in OCPs marketed in the United States. A third case-control study using data from the CASH study included 434 endometrial CA cases and 2,557 control subjects. Overall, high potency OCPs did not confer more protection than low potency OCPs. However, among women with a BMI >22.1 kg/m², those who used high potency progestin potency OCPs had a lower risk of endometrial cancer than those who used low potency OCPs (OR 0.31; 95% CI, 0.11 to 0.92) while those with a BMI <22.1 kg/m² did not (OR, 1.36; 95% CI, 0.39 to 4.70) (140). The small number of cases that were overweight (BMI >25 kg/m²) or obese (BMI >30 kg/m²) prevented an analysis with sufficient power to detect a statistically significant modifying effect of overweight status or obesity on the relationship between progestin potency and endometrial CA risk. However, these findings suggest that high potency OCPs may be associated with a greater protective effect than low potency OCPs among women with a larger BMI who are at the greatest risk of endometrial CA.

Intrauterine Devices

Seven studies have reported the relationship between previous copper or nonmedicated intrauterine device (IUD) use and endometrial CA (141–147). In all but one study, previous IUD use was associated with a decreased risk of EEC. The one study where this relationship was not validated was based on research in China, where the steel ring IUD was utilized, suggesting that this type of IUD is not protective against this malignancy (146). The landmark CASH study of the CDC was one of the studies to report significant protection against EEC (141). The majority of the articles reported subgroup analyses regarding factors such as type of IUD and duration/timing of use. In general, no consistent pattern emerged from the articles to suggest that length or timing of use, or type of IUD was associated with an increase or decrease in the risk of EEC (148).

The levonorgestrel-releasing IUD was investigated by Gardner et al. in women taking tamoxifen as adjuvant therapy for breast CA (149). This preliminary investigation, which included 122 women, randomized 64 patients to the IUD group and 58 patients to the no-IUD group. The authors did an outpatient hysteroscopic assessment with endometrial sampling at entry and after 12 months. A uniform decidual response was seen in all women with the IUD in place. Similar histologic patterns were identified in both groups at baseline and after 12 months. A statement on the effect of this device on the incidence of EEC in women taking tamoxifen cannot be made, but warrants further prospective evaluation.

Phytochemicals

The effect of dietary phytochemical consumption on endometrial CA risk is not clearly delineated. Levi et al. found a strong negative association between beta-carotene and vitamin C intake and endometrial carcinoma among Swiss women, but no clear effect was seen in similar studies in China and the United States (150–152). Barbone et al. demonstrated a protective effect of carotene intake on endometrial CA (153). Zheng et al. found a weak negative correlation between endometrial CA and plant food intake in the Iowa Women's Health Study (154). In an analysis of phytoestrogen (i.e., isoflavones, coumestans, and lignans) consumption and endometrial CA risk, investigators found that a lower risk was associated with increased intake. Obese postmenopausal women consuming relatively low amounts of phytoestrogens had the highest risk of endometrial cancer (OR 6.9; 95% CI, 3.3 to 14.5) compared with nonobese postmenopausal women

consuming high amounts of isoflavones (155). As is the case with breast CA, further investigative efforts are necessary to establish the role of phytochemicals in the prevention of endometrial CA.

Ovarian Cancer Chemoprevention

Although efforts to improve the survival of ovarian CA patients continue to focus on the development of more effective systemic therapies, the prevention of ovarian CA is an area of increasing interest. As is the case with breast CA, assessment of prevention efforts must be analyzed by genetic predisposition. In genetically uncharacterized U.S. women, the lifetime risk of developing ovarian CA is approximately 1.5%. *BRCA1* mutations increase the risk to 30% to 60%, while women who harbor a mutant *BRCA2* gene have an estimated risk of 10% to 30% (156). Precancerous lesions have not been well defined for ovarian CA, although phenotypic changes have recently been described (157). Future chemoprevention trials in ovarian CA have the potential to utilize biochemical markers of transformation, including cell cycle progression and apoptosis, as surrogate endpoint markers (158,159). Although hysterectomy alone, as well as tubal ligation, has been associated with a decreased risk of developing ovarian CA, this review will focus on *chemoprevention*.

OCPs

The ability of OCPs to reduce the risk of ovarian CA has been extensively studied and it is estimated that there is an overall reduction in risk approximating 40% (135). The adjusted odds ratio for *ever-use* of OCPs has consistently been shown to be between 0.6 and 0.7 (160–162). The degree of protection and the length of protection appear to be associated with the duration of OCP usage. Prolonged risk reduction has been reported when OCPs are used longer than 4 to 6 years, and minimal benefit has been observed if utilization is restricted to a period of 6 months to 2 years (163–166). One of the largest case-control studies to date is the CDC CASH study. In this study, 546 women with ovarian CA and 4,228 control subjects from eight population-based CA registries were compared. Women with a history of OCP use had a 40% reduced risk of epithelial ovarian CA (RR 0.6; 95% CI, 0.5 to 0.7) when compared to women with no history of OCP use. This protective effect was evident with as little as 3 months of OCP use and continued for up to 15 years following discontinuation of OCP use. OCP-mediated risk reduction was independent of the histologic type of ovarian CA (167).

It has been estimated that more than half of all ovarian CAs in the United States could be prevented by OCP usage for at least 4 to 5 years (161,162,168). The protective effect of OCPs appears to be consistent across races as John et al. demonstrated a reduction in risk of 0.6 in African American women with OCP use of 6 years or more (169). The estrogen/progestin content of any particular OCP and how it relates to protection against ovarian carcinoma needs further investigation. Ness et al. demonstrated identical risk reduction for OCPs with high-estrogen/high-progesterone content when compared with low-estrogen/low-progesterone content pills (170). Schildkraut et al., in an observational study, recently reported that low-progesterone OCP formulations were associated with a significantly higher risk of ovarian CA when compared with high-progesterone potency OCP formulations (171).

The lifetime risk of ovarian CA is approximately 45% in *BRCA1* carriers and 25% among *BRCA2* carriers (172). In women carrying *BRCA1* or -2 mutations, Modan et al. concluded that OCPs did not protect against ovarian CA in Israeli Jewish women. However, Narod et al. showed that the

use of OCPs in Jewish and non-Jewish women with *BRCA* mutations was strongly protective against this malignancy, with an odds ratio of 0.44 (95% CI, 0.28 to 0.68) (173,174). Important differences exist between the two studies, most notably that the controls in the Narod et al. study were all mutation carriers, while in the Modan et al. study only 1.7% of the controls carried the mutation. The use of OCP as a chemopreventive agent against ovarian CA should be considered in *BRCA* carriers.

Little is known about the mechanism of the protective effect of OCPs against ovarian CA, although it has been postulated that a major mechanism of OCP protection relates to a decrease in ovulatory cycles. There is data to suggest that an increased rate of apoptosis in aberrant epithelial cells secondary to the progestational component may also play an important role. Recently, Rodriguez et al. examined the effect on ovarian epithelium of levonorgestrel in 130 ovulatory macaque monkeys (175). These authors demonstrated significantly increased apoptotic cell counts in the ovarian epithelium of animals exposed to progesterone, leading to the hypothesis that progestin-induced apoptosis of the ovarian epithelium is responsible for the chemopreventive effect of OCPs.

Colon Cancer Chemoprevention

Colorectal CA is the fourth most common incident CA and the second most common cause of CA death in the United States. In 2000, there were an estimated 50,400 new cases of colon CA and 16,200 cases of rectal CA diagnosed in U.S. women; approximately 24,600 and 3,900 women died from these disorders, respectively (176).

HRT

Two recent meta-analyses have calculated an approximate one-third reduction in risk of *colon* CA among current or recent users of HRT, compared with about a 10% to 20% reduction among ever-users versus never-users of HRT (177,178). Although Nanda et al. determined that *rectal* CA was not related to HRT usage, Grodstein et al. determined a reduction in risk for ever-users versus never-users (RR 0.81; 95% CI, 0.72 to 0.92). Both meta-analyses are limited by lack of consistent and accurate reporting on type of HRT, as well as lack of control for potential confounders, such as diet, site of CA, family history, or screening. Adenomatous polyps precede colorectal CAs by a decade or more; thus any association between their presence and HRT is of obvious interest. Two case-control studies have found a protective effect of HRT on the development of adenomatous polyps (179,180). The prospective Nurses' Health Study reported a decreased risk of large adenomatous polyps for current users (RR 0.74; 95% CI, 0.55 to 0.99), whereas there was no association between small adenomatous polyps and HRT (181).

The WHI, a randomized, controlled primary prevention trial in which 16,608 postmenopausal women aged 50 to 79 years with an intact uterus at baseline were recruited by 40 U.S. clinical centers in 1993 to 1998, confirmed what other observational studies have suggested: a reduction in the incidence of colorectal CA in those women taking combined estrogen and progesterone therapy. In 8,506 women prescribed estrogen and progesterone, with a placebo control group of 8,102 women, a hazard ratio of 0.63 with a nominal 95% CI of 0.43 to 0.92 was observed. Colorectal CA rates were reduced by 37% (10 vs 16 per 10,000 person-years) (134,181).

There are several hypotheses regarding a protective effect of HRT on the risk of colorectal CA, including alteration of the predominant ER isoform, as well as E2's ability to decrease production of secondary bile acids.

OCPs

The relationship between OCPs and colorectal CA has not been clearly delineated. Recently, a large case-control study was conducted in northern Italy between the years 1985 and 1992, with 709 cases of colorectal CA and 992 control subjects (182). Ever-use of OCPs versus never-use through use of a multiple logistic regression was associated with a reduced risk of colorectal CA (RR 0.58; 95% CI, 0.36 to 0.92). Further, there was a suggestion that duration of use (i.e., more than 2 years) was associated with increased protection. More recently, the Nurses' Health Study cohort identified 502 cases of colorectal CA among participants between 1980 and 1992 (183). Among women using OCPs, use for 6 or greater years was associated with a 40% reduction in risk of colorectal CA (RR 0.60; 95% CI, 0.40 to 0.89). The trend for the duration effect was statistically significant ($P = 0.02$). Several smaller studies, all with serious limitations in study design and/or execution, have reported varying results regarding the relationship between OCPs and colorectal CA.

HORMONES AND THE TREATMENT OF HUMAN CANCERS

Whereas the role of hormones in the treatment of human malignancies has been most extensively examined in the management of breast carcinoma, the potential to exploit hormone-signaling pathways in the management of other malignancies, affecting both men and women, is rapidly becoming a reality. As our understanding both of the molecular biology of CA and of the human genome expands, targeted therapeutics, including hormonal manipulation, will undoubtedly assume a more critical role in the management of human malignancies.

Breast

Overview

When considering hormonal treatment (HT) of breast CA, it is important to distinguish between premenopausal women, in whom the primary source of estrogen is the ovaries, and postmenopausal women, in whom aromatization of androgens in the peripheral tissue is the major source of estrogen production. In premenopausal women, removal of the ovaries via surgical or radiologic ablation, or inhibition of ovarian estrogen production with a gonadotropin-releasing hormone (GnRH) analog, results in marked decrease in estrogen levels. SERMs, most notably tamoxifen, are a treatment option for

both premenopausal and postmenopausal women with ER-positive disease; they reduce tumor cell proliferation by binding to and blocking the activation of ERs. In premenopausal women, treatment with tamoxifen plus ovarian ablation may provide added benefit by decreasing estrogen levels through two complementary mechanisms (184). Aromatase inhibitors (AIs) interfere with estrogen production by targeting the peripheral aromatization of androgens. In postmenopausal women, in whom peripheral tissue production of estrogen is responsible for the majority of circulating estrogen, AIs are a likely choice in the selection of HT. The role of AIs in premenopausal women is less clear owing to the high level of ovarian estrogen in this patient population.

Adjuvant Hormonal Therapy for Early-Stage Breast Cancer—Postmenopausal Women

Tamoxifen prescribed for approximately 5 years after surgery to patients with early, ER-positive breast CA is the current standard of adjuvant therapy worldwide. The Early Breast Cancer Trialists' Collaborative Group (EBCTCG) conducted a meta-analysis to assess recurrence and mortality rates among randomized trials of women with primary breast CA who received adjuvant tamoxifen therapy or placebo. Table 17.2 details the reduction in recurrence and mortality, stratified by ER and PR status, revealing that women with hormone receptor-positive tumors experience a more significant improvement in both endpoints. Conversely, women with hormone receptor-negative tumors received little, if any, benefit from HT (184). Furthermore, the EBCTCG established that hormone receptor-positive women receiving tamoxifen demonstrated a 21%, 28%, and 50% reduction in recurrence and a 14%, 18%, and 28% reduction in mortality in the treatment groups of 1 year, 2 years, and approximately 5 years, respectively, with consistent benefits across various tamoxifen dosing regimens (20 to 40 mg/day) (184). Although the efficacy of tamoxifen in the adjuvant setting has been established, the toxicity profile of this agent, including an increased risk of EEC and thromboembolic events, has prompted investigative efforts into alternative therapies.

In 2002, anastrozole alone was approved as adjuvant treatment for early breast CA. The ATAC trial included 9,366 postmenopausal women with operable, early, invasive breast CA who had completed primary treatment and were candidates for adjuvant HT. The data demonstrated superior efficacy of anastrozole when compared to tamoxifen in improving disease-free survival in postmenopausal women with hormone receptor-positive or unknown early-stage breast CA. Disease-free survival was significantly longer for patients on anastrozole alone than for those who received tamoxifen alone (HR 0.83; 95% CI, 0.71 to 0.96; $P = 0.013$) or the combination of both (HR 0.81; 95% CI, 0.70 to 0.94; $P = 0.006$). The combination was not significantly different

TABLE 17.2

HORMONE RECEPTOR STATUS: EFFECT ON RESPONSE RATE IN EARLY-STAGE DISEASE

Receptor status	N	Reduction in recurrence % (95% CI)	Reduction in mortality % (95% CI)
ER ⁺ , PgR ⁺	7,000	37 (±6)	16 (±8)
ER ⁺ , PgR ⁻	2,000	32 (±12)	18 (±14)
ER ⁻ , PgR ⁺	602	23 (±24)	9 (±28)
ER ⁻ , PgR ⁻	2,000	1 (±14)	1 (±14)

Note: All patients were treated with tamoxifen.

Source: Early Breast Cancer Trialists' Collaborative Group. *Lancet* 1998;351:1451-1467.

from tamoxifen alone (HR 1.02; 95% CI, 0.89 to 1.18; $P = 0.8$) (123). The disease-free survival estimates at 3 years were 89.4%, 87.4%, and 87.2% on anastrozole, tamoxifen, and the combination, respectively. Incidence of contralateral breast CA was significantly lower with anastrozole than with tamoxifen (OR 0.42 [0.22–0.79]; $P = 0.007$). After publication of the ATAC data, the American Society of Clinical Oncology (ASCO) Health Services Research Committee suggested that a 5-year course of tamoxifen remain the standard adjuvant HT pending updated data from the ATAC trial and other trials of third-generation AIs in the adjuvant setting (185). The panel further suggested that it would be reasonable for a patient to be treated with anastrozole if there was a history of cardiovascular disease or thromboembolic events, or if the patient developed complications or intolerable side effects attributable to tamoxifen. The ATAC data was recently updated, with 68 months of follow-up, and the benefit of anastrozole over tamoxifen was maintained (186).

Goss et al. conducted a double-blind, placebo-controlled trial evaluating the effectiveness of 5 years of letrozole in 5,187 postmenopausal women with early-stage breast CA who had completed 5 years of tamoxifen therapy (187). The estimated 4-year disease-free survival rates were 93% for the letrozole group and 87% for the control group ($P < 0.001$), suggesting that in this subset of breast CA patients, AI therapy after tamoxifen provides a survival advantage. An analysis of the post-unblinding data was recently presented. Among the 2,594 women initially randomized to placebo, 1,655 women chose to receive open-label letrozole. At 54 months, a statistically significant benefit in disease-free survival favored the crossover patients (HR 0.31; $P < 0.0001$) (188). The Breast International Group (BIG) 1-98 study, a randomized, phase 3, double-blind trial, compared 5 years of treatment with various adjuvant endocrine therapy regimens in postmenopausal women with hormone receptor–positive breast CA: letrozole, letrozole followed by tamoxifen, tamoxifen, and tamoxifen followed by letrozole. A total of 8,010 women with data that could be assessed were enrolled: 4,003 in the letrozole group and 4,007 in the tamoxifen group. After a median follow-up of 25.8 months, 351 events had occurred in the letrozole group and 428 events in the tamoxifen group, with 5-year disease-free survival estimates of 84.0% and 81.4%, respectively. As compared with tamoxifen, letrozole significantly reduced the risk of an event ending a period of disease-free survival (HR 0.81; 95% CI, 0.70 to 0.93; $p = 0.003$), especially the risk of distant recurrence (HR 0.73; 95% CI, 0.60 to 0.88; $P = 0.001$). In postmenopausal women with endocrine-responsive breast CA, adjuvant treatment with letrozole, as compared with tamoxifen, reduced the risk of recurrent disease, especially at distant sites (189). Multiple other studies investigating the role of AIs in the adjuvant treatment of ER-positive breast CA, including the investigation of exemestane, have shown survival benefit (190). Many issues regarding the adjuvant use of AIs remain unsettled, including the optimal duration of treatment, the optimal sequencing with tamoxifen, and the optimal AI. The ASCO concluded in 2004 that optimal adjuvant endocrine therapy for postmenopausal women with hormone receptor–positive breast CA should include an AI either as initial therapy or after a period of treatment with tamoxifen (185).

Adjuvant Hormonal Therapy for Early-Stage Breast Cancer—Premenopausal Women

The EBCTCG overview analysis has confirmed that adjuvant tamoxifen confers a survival benefit for ER-positive patients regardless of menopausal status. Accumulated clinical trial data as well as the EBCTCG overview analyses have confirmed that ablation of functioning ovaries significantly improves

survival in breast CA patients younger than age 50, at least in the absence of chemotherapy (191). In premenopausal women with ER-positive, early-stage breast CA, significant investigation is ongoing regarding the role of AIs. Several investigations have suggested that young premenopausal women with hormone receptor–positive disease who fail to develop complete ovarian failure after chemotherapy may potentially benefit from ovarian suppression/ablation (OS/OA) (192). Several ongoing trials are expected to definitively address the various roles of combining chemotherapy, OS/OA, tamoxifen, and AIs in premenopausal patients with early-stage hormone receptor–positive breast CA. These trials include the Suppression of Ovarian Function Trial (SOFT), Tamoxifen and Exemestane Trial (TEXT), Premenopausal Endocrine Responsive Chemotherapy (PERCHE), and Austrian Breast and Colorectal Cancer Study Group (ABCSG).

Hormonal Therapy for Metastatic Breast Cancer

Regression of advanced breast CA as a result of prophylactic oophorectomy in premenopausal women was first described in 1896 (193). In unselected series of premenopausal women with metastatic breast CA, a 30% to 40% response with oophorectomy has been identified, whereas in ER-positive tumors, a 50% to 60% response has been noted.

Endocrine therapy for postmenopausal women with advanced hormonally responsive breast CA is based on the observation that greater than three fourths of these patients respond to HT, whereas only 11% of patients with hormone receptor–negative tumors show a response. Tamoxifen was the gold standard of first-line HT for metastatic breast CA until approximately 8 years ago. However, third-generation AIs have eclipsed tamoxifen in the treatment of postmenopausal women with metastatic estrogen-dependent breast cancer (194). Anastrozole and letrozole are both non-steroidal AIs that compete with the substrate for binding to the enzyme active site. Mouridsen et al. compared tamoxifen to letrozole in 907 women with a median follow-up of 18 months. Letrozole was associated with a longer time to disease progression than tamoxifen (9.4 vs. 6.0 months; $P = 0.0001$) (195). Two trials compared tamoxifen to anastrozole, with conflicting results. Nabholz et al. found that anastrozole provided longer time to disease progression compared to tamoxifen (11.1 vs 5.6 months; $P = 0.005$) (196). Bonnetterre et al., in a similarly designed study, failed to confirm these findings; anastrozole was as effective as tamoxifen, but not superior (197). Exemestane, another third-generation AI, is a mechanism-based steroidal inhibitor that mimics the substrate, resulting in inactivation of aromatase and has been proven to be effective in the treatment of metastatic breast cancer, particularly when used sequentially with anastrozole or letrozole (198). In summary, the third-generation–specific AIs, which include anastrozole (Arimidex), letrozole (Femara), and exemestane (Aromasin), are now available in the United States and are approved as first-line therapy for the treatment of metastatic breast CA.

Endometrium

Hormonal Treatment of Endometrioid Endometrial Cancer

The median survival of women with advanced or recurrent endometrioid endometrial CA (EEC) is less than 1 year. Utilizing the best chemotherapeutic regimen available, the complete response rate in those patients with advanced-stage EEC is only 22%. Histologic grade is known to be a predictor of stage and survival, with grade 3, poorly differentiated CAs

TABLE 17.3

ENDOMETRIOID ENDOMETRIAL CARCINOMA CLINICAL ESTIMATES

	Grade 1	Grade 2	Grade 3	Total
Estimated new cases, 2003 (SEER)	12,030	17,243	10,827	40,100
Estimated deaths, 2003	2,040	2,924	1,836	6,800
% of cases with deep myometrial invasion	10%	20%	42%	22%
Extrauterine spread at diagnosis	10.40%	26.00%	59.60%	21.80%
5-year survival (all stages)	87%	75%	58%	68%

Note: SEER, Surveillance, Epidemiology, and End Results.

portending a higher risk of extrauterine disease and thus poorer survival. Estimates from the SEER data registry for 2003 for both incidence and mortality are provided in Table 17.3. Carcangiu et al. evaluated 183 patients with EEC, establishing a correlation between the International Federation of Gynecology and Obstetrics (FIGO) grade and hormone receptor expression (199). The recognized association of higher grade with lower ER/PR expression carries implications for the use of HT in advanced EEC. A majority of advanced cases of EEC are grade 3 lesions, limiting the use of HT in this patient population.

Advanced or Recurrent Endometrioid Endometrial Cancer

Progestational Agents. The use of progestational agents in women with advanced or recurrent EEC has been under investigation for several decades. Several different types of progestational agents have been investigated, including hydroxyprogesterone caproate (Delalutin), medroxyprogesterone acetate (MPA, Provera), and megestrol acetate (Megace). A majority of studies evaluating this treatment modality have included small numbers of patients with no stratification for well-recognized predictors of response. In the last decade, several studies with larger patient sample size, clearer eligibility criteria, and clearer definition of response and toxicity have evaluated the effectiveness of progestational agents in the treatment of advanced or recurrent EEC. The GOG, in GOG protocol 48, evaluated unselected patients with advanced or recurrent EEC. An overall response rate (MPA 50 mg three times daily) of 18% (32 complete and 26 partial responses among 331 patients with measurable disease) and median progression-free and overall survival times of 4.0 and 10.5 months, respectively, were identified (200). In another GOG protocol, 299 eligible women with advanced or recurrent EEC were randomized to receive either oral MPA 200 mg/day or oral MPA 1,000 mg/day until unacceptable toxicity or disease progression (201). Among the 145 patients receiving the low-dose regimen, there were 25 (17%) complete responses and 11 (8%) partial responses; 109 patients (75%) demonstrated no response. Among the 154 patients receiving the high-dose regimen, there were 14 (9%) complete responses and 10 (6%) partial responses; 130 patients (84%) had no response. The overall response rates (complete plus partial; 25% and 16% for low- and high-dose regimens, respectively) favored the low-dose regimen. The median progression-free survival time was 3.2 months for the low-dose regimen and 2.5 months for the high-dose regimen. There was an association, including patients receiving both dosing regimens of MPA, between response and histologic grade, with well-differentiated tumors responding more frequently than poorly differentiated lesions. The response rates were 37% (22 of 59 patients), 23% (26 of 113 patients), and 9% (12 of 127 patients) for

those with grade 1, 2, or 3, respectively. As well, there was a noteworthy correlation between response and receptor content. The response rate was 8% (7 of 86 patients) for patients who were PR negative and 37% (17 of 46) for patients who were PR positive ($P < 0.001$). The response rate was 7% (4 of 55) for patients who were ER negative and 26% (20 of 77) for patients who were ER positive ($P = 0.005$). An association between receptor status and tumor grade was established as well. After tumor grade was adjusted for, PR concentration remained an important predictor of survival. In summary, the overall response rate for the progestational agents in women with advanced or recurrent EEC is relatively low. However, progestational agents remain a therapeutic alternative for this patient population, where significant comorbid conditions frequently exist, particularly in those women who can predictably expect a higher response based on grade and receptor content.

Combination Chemotherapy and Progestational Agents. Combining chemotherapy with hormonal therapy is an area of active research. Pinelli et al. prospectively treated 13 advanced EEC patients with carboplatinum 300 mg/mm² every 4 weeks for six cycles. Subsequently, Megace 80 mg/day for 3 weeks alternating with tamoxifen 40 mg/day for 3 weeks was prescribed. A complete response was obtained in 30% of patients, a partial response in 46%, stable disease in one patient, and disease progression in two patients (202). Work is ongoing investigating the role of combination cytotoxic chemotherapy and HT in the treatment of advanced or recurrent EEC.

Selective Estrogen Receptor Modulators. SERMs have been and continue to be investigated for HT of EEC. Tamoxifen was studied by the GOG in a phase 2 study of patients with advanced or recurrent EEC. At a dose of 20 mg twice daily, only 10% of 68 patients demonstrated objective response, but response occurred more commonly in grades 1 and 2 tumors (23% and 14%, respectively) compared to grade 3 tumors (3%) (203). From pooled reports of eight other studies including 257 patients, 22% of patients with advanced EEC responded to tamoxifen, but the range was wide in that it was from 0 to 53% (204). Tamoxifen can increase PgR content in endometrial CA tissues, which theoretically would enhance the activity of progestins, which frequently down-regulate PgR within the target tissue, prompting a relatively short duration of response. Clinical studies on alternating treatment with tamoxifen and progestin have provided conflicting results (Table 17.4) (201,203,205–208).

Other SERMs are also under investigation, including raloxifene and its metabolite, LY353381.HCl (arzoifene). First-generation SERMs, such as tamoxifen, have mixed estrogenic agonist and antagonist activity, whereas second-generation SERMs, such as raloxifene, have more selective E2 antagonism. Arzoifene (LY353381), a third-generation SERM, is a potent E2 antagonist in mammary and uterine tissues, with enhanced bioavailability and antiestrogenic activity compared

TABLE 17.4**HORMONAL THERAPY WITH PROGESTINS AND TAMOXIFEN IN ADVANCED OR RECURRENT ENDOMETRIAL CANCER**

Reference	Hormonal agent	Patients	CR (%)	PR (%)	OR (%)
(201)	MPA (200 mg/day)	145	17	8	25
	MPA (1,000 mg/day)	154	9	6	15

(205)	TAM/MA	56	21	5	26

Note: CR, complete response, MA, megestrol acetate; MPA, medroxyprogesterone acetate; OR, overall response; PR, partial response; TAM, tamoxifen.

with raloxifene. This SERM elicited a complete response in one and a partial response in eight of 29 patients with advanced EEC, with an overall response rate of 31%, a median duration of response of 13.9 months, and minimal toxicity. All responses occurred in progestin-sensitive patients. The relatively high response rate and the favorable toxicity profile make this agent worthy of further investigation (209,210).

Aromatase Inhibitors. Anastrozole and letrozole are active, highly selective nonsteroidal competitive inhibitors of the enzyme aromatase. It has been shown that significant amounts of aromatase are found in endometrial CA, with low amounts being present in the surrounding normal endometrial tissue. Rose et al. recently found in 23 patients that anastrozole at 1 mg a day for 28 days has minimal activity, with only a 9% partial response rate and a progression-free interval of 1 to 6 months in women with advanced EEC (211). The National Cancer Institute of Canada completed a multicenter phase 2 trial evaluating letrozole in postmenopausal women with recurrent or advanced endometrial carcinoma. Thirty-two eligible patients were treated with letrozole at 2.5 mg daily continuously. Of the 28 patients evaluated for response, one complete and two partial responses were noted; overall response was 9.4% (95% CI, 2 to 25). Eleven patients had stable disease for a median duration of 6.7 months (range 3.7 to 19.3 months). In conclusion, letrozole is well tolerated but has little overall activity in this cohort of women with endometrial cancer (212).

Antigonadotropins. Antigonadotropins, such as danazol, antagonize pituitary gonadotropin release and limit adrenal and estrogen production. Danazol has yet to be clinically tested in patients with endometrial CA. However, *in vitro* studies have shown it to inhibit endometrial tumor cell migration (similar to MPA) and inhibit invasive activity (not demonstrated by MPA) (213,214). The clinical effects of danazol on endometrial hyperplasia have been evaluated (215). Of 15 patients with pathologically proven hyperplasia, all were successfully converted to atrophic endometria by day 90 of danazol 400 mg/day. Given the perceived low toxicity of danazol in comparison to conventional chemotherapy, the lack of effective agents in this disease, and a theoretical rationale for its activity in endometrial CA, a phase 2 trial has been initiated by the GOG (GOG-0180).

Adjuvant Therapy for Endometrioid Endometrial Cancer

The use of progestational agents as adjuvant therapy for stages I and II EEC has been investigated by von Minckwitz et al. (216). They conducted a randomized trial of 388 patients with early-stage EEC who received either MPA (n = 133) or

tamoxifen (n = 121) orally for 2 years or were observed only (n = 134) after surgical therapy. After 56 months of follow-up, no benefit was observed from adjuvant progestin or tamoxifen therapy after surgical treatment in early-stage EEC. However, given the low frequency of recurrence in this patient population, larger randomized studies are needed to fully evaluate the role of progestational agents as adjuvant therapy in early EEC.

Progestational Agents as Primary Therapy for Endometrioid Endometrial Cancer

Several small series have retrospectively reported on the use of progestational agents alone, not preceded by hysterectomy, in the treatment of patients with EEC, either because of the desire to maintain fertility or because of comorbid conditions. No randomized, controlled studies exist evaluating progestational agents in either clinical scenario. Montz et al., in a prospective pilot study, reported on the use of the progesterone IUD in women with presumed stage IA, grade 1 EEC, who were at significant risk for perioperative morbidity (217). Follow-up endometrial biopsies were negative in 7 of 11 patients at 6 months and in 6 of 8 patients at 12 months. Recently, Ramirez et al. searched MEDLINE and other databases for English-language articles describing patients with grade 1 EEC who were treated with hormonal therapy. Ultimately, 81 patients in 27 articles were included in the study. Sixty-two patients (76%) responded to treatment. The median time to response was 12 weeks (range, 4 to 60 weeks). Fifteen patients (24%) who initially responded to treatment recurred. The median time to recurrence was 19 months (range, 6 to 44 months). Ten (67%) of the patients with recurrence ultimately underwent total abdominal hysterectomy. Residual endometrial carcinoma was found in six patients (60%). Nineteen patients never responded. Twenty patients were able to become pregnant at least once after completing treatment. The median follow-up was 36 weeks (range, 0 weeks to 30 years). No patients died of their disease. Further investigation is needed into this approach to the primary management of EEC (218).

Ovary

The ovary is an endocrine and end organ. Hormones and their receptors have been associated with ovarian CA and may be related to its causation. Some data suggest that hormonal therapies may have an effect on ovarian CA in palliative settings (219). Several investigators have established that hormone receptors are expressed in epithelial ovarian CA, and that significant alterations occur with malignant transformation (20).

Rao and Slotman reviewed 45 series, including 2,508 ovarian CA patients, and reported that 67% of tumors expressed ER and 47% expressed PR (220). Recently, one investigation found that the expression of the ERs and PRs correlated with long-term survival in invasive ovarian CA; the ER⁺PR⁺ phenotype predicted a more favorable tumor biology and long-term survival (221). Interestingly, many studies have demonstrated that ER- β is highly represented in normal epithelial cells or benign tumors (222), whereas ER- α is the main form expressed in malignant tumors. ER- β mRNA decreases in an inversely correlated way with tumor progression as compared with ER- α mRNA. The ER- α /ER- β mRNA ratio is markedly increased in ovarian CA (223). An increased ER- α /ER- β ratio has also been observed in different CAs, such as breast CA, prostatic CA, lung CA, and colorectal carcinoma. These data suggest that ER- β might play a protective role against ER- α mitogenic activity or that the loss of ER- β is a marker of cell dedifferentiation. However, multiple studies investigating the relationship between hormone receptor status in ovarian CA and prognostic factors, including disease-free interval and survival, have not produced consistent results. The ambiguous results in studies evaluating receptor status and survival in ovarian CA patients are due to several factors, including small numbers with heterogeneous groups of patients, different receptor assay methods,

and heterogeneity in the receptor content within one tumor population.

A large number of hormonal agents have been evaluated in the treatment of ovarian CA, including SERMs, E2, progestogens, androgens, AIs, and GnRH agonists. Progestin therapy in patients with advanced ovarian CA has a global response rate of 8% to 15% (220,224). One of the most widely studied compounds in this clinical setting is tamoxifen. Preclinical studies have confirmed that tamoxifen inhibits ovarian cell growth *in vitro*, providing rationale for the use of this agent in the treatment of ovarian CA. Several studies have evaluated the activity of single-agent tamoxifen in the treatment of advanced ovarian CA (Table 17.5) (225–242). Perez-Garcia and Carrasco reviewed the literature evaluating single-agent tamoxifen in the treatment of patients with advanced ovarian CA, most of whom were heavily pretreated and refractory to chemotherapy (243). A total of 648 patients were included with an overall response rate (ORR) of 13% (95% CI, 10.4 to 15.6, range 0 to 56), including a 4% complete response rate and a 9% partial response rate. In 38% of patients, stable disease was noted. These results are not entirely dissimilar from those seen with progestins. The role of GnRH agonists in the management of refractory ovarian CA has been evaluated in multiple studies and has been summarized by Paskeviciute et al. (244). In this study, GnRH

agonists induced an overall objective response in 8.5% of refractory ovarian CA patients with disease stabilization in 23% of these women.

Comparing chemotherapy alone to chemotherapy and hormonal therapy primarily in patients with advanced ovarian CA has been carried out by several investigators. However, these studies had small patient sample size and were not randomized, controlled studies. Schwartz et al. evaluated cisplatin and doxorubicin, with or without tamoxifen after initial surgery, without finding significant overall survival (OS) or progression-free survival (PFS) differences between both groups (237). Emons et al. randomized 135 patients with advanced ovarian CA to receive the GnRH triptorelin, or placebo, following surgery and chemotherapy, until the patient's death or termination of the trial. There were no significant differences in OS or PFS between the groups, with documented gonadotropin suppression (245). At least four randomized studies comparing chemotherapy and MPA or a GnRH versus chemotherapy alone in ovarian CA patients have been reported. These studies contain many of the same flaws as noted throughout this discussion, namely, small sample size and no stratification for optimal versus suboptimal surgical status, menopausal status, and histologic status.

Combining cytotoxic chemotherapy and tamoxifen or other hormonal agents as salvage therapy for patients with advanced ovarian CA is an area of investigation that warrants further study (246).

As previously stated, in patients with ovarian CA, receptor status does not reproducibly correlate with prognostic factors, including survival or disease-free interval. However, receptor status may be useful in predicting response to hormonal agents. Although several investigators have approached this question, results are not conclusive. The ascertainment of receptor status as a predictor of hormonal activity in ovarian CA will require a randomized clinical trial comparing hormonal activity in patients expressing hormone receptors versus those with no receptor expression, controlling for the many variables recognized as important prognosticators in ovarian CA.

Colon

The clinical data available evaluating the relationship between hormones and colon CA relate primarily to hormones as risk factors for the development of this common human malignancy. There is a plethora of data in colon CA cell lines regarding the effect of hormonal agents on cell growth, as well as cell death. To date, there are no clinical studies evaluating the treatment of colon CA, either in the adjuvant setting or otherwise, with hormonal agents.

CHAPTER 18 ■ INNOVATIVE 21st CENTURY THERAPIES

ERIC K. ROWINSKY, ARNO J. MUNDT, AND NADEEM R. ABU-RUSTUM

The convergence of a plethora of recently acquired information about specific molecular abnormalities that “drive” the malignant phenotype with profound advances in biomedical technology has ushered in a wide range of novel therapeutic options to treat patients with gynecologic malignancies. It has also brought about many challenges for clinical investigators. As novel anticancer therapeutics are developed, prioritization of these therapies for efficient allotment of clinical trial resources, identification of patients whose malignancies most likely express the molecular constituents resembling the true target, and derivation of relevant endpoints for both screening and assessment will be critical to their successful incorporation into our therapeutic armamentarium (1). In this chapter, many promising novel systemic therapeutics, as well as advances in the delivery of radiotherapy, particularly intensity-modulated radiation therapy (IMRT), that are likely to make incremental improvements in outcome and therapeutic indices for patients with gynecologic malignancies are discussed. The section on novel systemic therapeutics does not include information on agents targeting malignant angiogenesis, which are reviewed in Chapter 16.

SYSTEMIC THERAPIES: ADVANCES IN THE 21st CENTURY

The number of rationally designed, target-based systemic therapeutics undergoing development is unprecedented. The cellular processes that are specifically being targeted for therapeutic development are those that principally confer autonomy, which is the hallmark of the malignant phenotype. Novel targets, many of which are listed in Table 18.1, include those that are involved in aberrant growth signal transduction, cell cycle dysregulation, evasion of apoptosis, sustained angiogenesis, tissue invasion, metastasis, and immune tolerance (2–4). Based on the results of preclinical studies and early clinical trials to date, more selective therapeutics are likely to result in less cytotoxicity to normal tissues, and hence more “breathing room” to maximize the therapeutic indices of multiagent regimens. Therefore, it is expected that the development of therapeutics that differentially affect malignant and normal tissues will more readily achieve high therapeutic indices. However, most new targets for antiproliferative therapies have not yet been validated in clinical practice, and prioritizing the long list of rationally designed, target-based therapeutics entering clinical evaluations, so that those with a high potential for improving clinical outcome are accurately identified for further study, is a formidable challenge.

Proliferative Signal Transduction Elements as Therapeutic Targets

The broad term “signal transduction” refers to the means by which regulatory molecules, which govern the fundamental processes of cell growth, differentiation, and survival (e.g., extracellular hormones, growth factors, cytokines, specialized proteins), communicate and induce responses within cells, resulting in the coordination of proliferative and other essential processes among various tissues. Cell signaling is complex, with a wide array of components interacting through cascades of chemical signals arranged in overlapping networks (5,6). These networks, consisting of parallel tracks and intricate interconnections, enhance the robustness and diversity of signaling, and permit fine tuning, and amplification and diminution of outputs, which may not be accomplished as efficiently by simpler linear cascades. However, the inherent redundancy and complexity of networks also confer protection against toxins, thereby decreasing the likelihood that any therapeutic manipulation against a single element will be highly successful, unless the element significantly contributes to the tumor’s proliferative advantage.

Targeting aberrant and/or overactive proliferative cell signaling elements is perhaps the most important of ongoing developmental therapeutic endeavors against cancer, since aberrations in signal transduction processes enhance tumor cell proliferation, invasiveness, metastasis, and angiogenesis, and resist programmed cell death (apoptosis) despite insults caused by anticancer therapeutics (5–8). Furthermore, the development of therapeutics against such processes is projected to yield broadly generalizable results since most malignancies, including gynecologic cancers, possess at least one aberrant signaling element that confers a proliferative or survival advantage (5–7). The most common aberrations are those involving “loss of protein function,” but others result in “gain of function” or unchecked, autonomous, or constitutive activity of elements that normally regulate cell signaling (2,5,6,8). In contrast to the situations represented by chronic myelogenous leukemia, gastrointestinal stromal cell tumors, and a small proportion of breast and lung carcinomas, in which a single aberration, such as a *bcr-abl* translocation, and a mutation in *c-kit*, *ErbB1*, or *ErbB2*, respectively, is the principal driver of tumor proliferation, and successful targeting results in profound antitumor effects, most malignancies possess many aberrations, several of which confer proliferative advantages (2,9–12). However, targeting any one specific “driver” in a tumor that has multiple relevant aberrations may result in therapeutic efficacy, the magnitude of which relates to the importance of the driver itself and its contribution

TABLE 18.1**NOVEL TARGETS AND THERAPEUTICS UNDER DEVELOPMENT AS ANTICANCER APPROACHES**

General target	Specific target	Therapeutic
Growth signal transduction	Growth factor receptors ErbB family receptors Insulin growth factor–like receptor Platelet-derived growth factor receptor C-met family receptors	Anti-receptor antibodies Small-molecule inhibitors of receptor tyrosine kinases Anti-ligand antibodies
	Ras Raf MAPK Rapamycin-sensitive and PI3K/Akt/ <i>PTEN</i> pathways	Small molecule inhibitors of farnesyltransferase ASON (K-Ras, H-Ras, N-Ras) ASONS Small molecule inhibitors Small molecule inhibitors Rapamycin analogs Small molecule inhibitors against mTOR, PI3K, akt, p70s6k
Death-survival equilibrium	Bcl-2	ASONS Small-molecule inhibitors
	TRAIL and other death receptors Survival proteins	TRAIL agonist ligands TRAIL agonist antibodies Therapeutics targeting survivin, clusterin, others
Epigenetic mechanisms	Histone deacetylation Histone methylation	HDAC inhibitors Methyltransferase inhibitors and ASONS
Cell cycle control	Cyclin-dependent kinases (cdk) Checkpoint kinases 1 and 2	Small molecule kinase inhibitors
Protein degradation	Heat shock protein (Hsp-90)	Geldanamycin derivatives and other small molecules
	Ubiquitin-proteasome degradation pathway	Proteasome inhibitors Ubiquitin ligase inhibitors
Immune tolerance	Targeting CTLA4	Monoclonal antibodies

Note: ASONS, antisense oligonucleotides; CTLA4, cytotoxic T-lymphocyte-associated antigen 4; HDAC, histone deacetylase; MAPK, mitogen-activated protein kinase; mTOR, molecular target of rapamycin; PI3K, phosphatidylinositol 3-kinase; TRAIL, tumor necrosis factor–related apoptosis-inducing ligand.

to the tumor's proliferative and/or survival advantage. Nevertheless, even if the overall efficacy achieved by targeting only one of many drivers may be somewhat limited, the importance of many types of signaling elements, several of which are shown in Figure 18.1, as well as the selectivity of their cognate therapeutic, may impart minimal toxicity and favorable therapeutic indices, rendering the agent an attractive addition to our therapeutic armamentarium. Furthermore, the development of genomic profiling to assess aberrant expression of genes that govern signaling pathways or critical cellular elements, as well as pathway mapping, may facilitate achieving the aforementioned goals (13,14).

Rationale for Targeting the ErbB Receptor Family

Most current development efforts directed against signal transduction processes involve either membrane receptors or elements that comprise downstream signaling cascades. With regard to signal transduction receptors, development efforts are predominantly being directed against receptor tyrosine kinases (RTKs) and G-protein receptors (GPCRs), which have secondary relay systems that permit signal amplification, diversification, and cross talk (1,5–9). The complexity of signal transduction networks and the challenges related to the development of therapeutics against these intricate systems are

exemplified by the complex structural and functional aspects of the ErbB receptor family and related downstream processes, as well as the multifactorial determinants of each specific signal. The overexpression and/or constitutive activation of ErbB receptors favor cell proliferation, invasiveness, angiogenesis, and resistance to both chemotherapy and radiotherapy (3,5,6,8). Members of the ErbB receptor family include ErbB1 (also called EGFR or HER1), ErbB2 (HER2 or neu), ErbB3 (HER3), and ErbB4 (HER4), which are commonly overexpressed, overactive, or constitutively active in ovarian and other epithelial gynecologic malignancies (5,6,8,15–22). In addition to the extracellular domain of ErbB, which binds to growth factors and serves as a target for therapeutic antibodies, the ErbB receptor is comprised of a transmembrane domain and intracellular portions that consist of an RTK domain and a domain that regulates RTK activity (Fig. 18.2) (5,6,8,15,16). Ligand binding induces conformational changes in the receptor, which in turn activates the RTK, thereby facilitating dimerization with other ErbB receptors (5,6,8,15–21). Following dimerization, conformational changes result in phosphorylation or “activation” of specific tyrosine residues. Activated ErbB receptors, in turn, activate specific downstream signaling elements, thereby transducing mitogenic and other types of signals in the cell.

The specificity and potency and, in essence, the diversity of intracellular signals are determined, in part, by the effectors of ErbB, as well as by the identity of the ligand, dimer, and

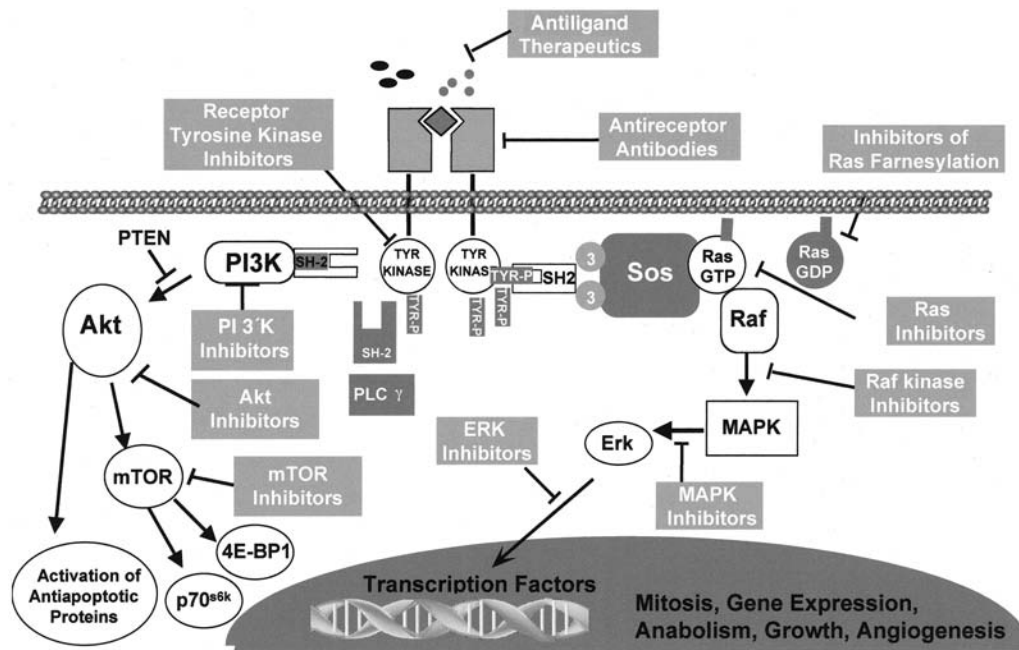

FIGURE 18.1. Schematic representation of critical signal transduction pathways and pathway elements that are being targeted with therapeutic strategies consisting of small molecules, antibodies, ASONs, and other novel approaches. The ErbB family of receptors, the insulin growth factor–like receptor (IGF-IR), the platelet-derived growth factor (PDGFR), and the c-met receptor family are examples of relevant upstream receptor targets for strategic therapeutic development.

specific structural determinants of the receptors. However, the principal determinant is the vast array of phosphotyrosine-binding (PTB) proteins that associate with the C-terminal “downstream docking” tail of each ErbB receptor after engagement into dimeric complexes (5,6,8,15–21). Whether a specific site is autophosphorylated, and hence which PTB signaling proteins are engaged, are determined by many factors, including the identity of the ligand and the specific heterodimer partner.

The diversity of signals generated through the ErbB receptor family is largely determined by the amino acid sequences of their C-terminal domains (8,16–21). These critical sequences, which contain tyrosine residues that undergo phosphorylation, represent docking sites for proteins that are involved in signal transduction. Docking sites are provided for proteins that recognize specific PTB residues in the context of their surrounding amino acids. Each ErbB receptor displays a distinct pattern of C-terminal autophosphorylation sites. At least for

FIGURE 18.2. Structures of ErbB family receptor tyrosine kinase receptors and their cognate ligands. The receptor consists of three domains: a ligand-binding extracellular domain containing two cysteine-rich regions (CR1 and CR2), a transmembrane domain, and an intracellular domain containing a tyrosine kinase region.

ErbB2, which does not have a direct activating ligand, PTB sites are essential for the transforming properties of the receptor. There is also a great deal of overlap in the signaling pathways activated by the four ErbB receptors. For example, the mitogen-activated protein kinase (MAPK) signaling pathway is an invariable activation target of all ErbB family members. There are also many examples of preferential modulation of specific pathways such as the presence of multiple binding sites for the regulatory subunit of phosphatidylinositol 3-kinase (PI3K) on ErbB3 and ErbB4 render these receptors the most efficient activators of the PI3K/Akt/*PTEN* “cell survival pathway” (8,17–19). Signals arising from the simultaneous activation of linear cascades, including the MAPK, stress-activated protein kinase cascade (SAPK), protein kinase C, and PI3K/Akt/*PTEN* pathways, are integrated in the nucleus into distinct transcriptional programs, the culmination of which is the net cellular response.

The principal process by which ErbB signaling is turned off is ligand-mediated receptor endocytosis, and the impact of the kinetics of this process on the overall magnitude of signaling is often understated (5,6,15,22). The kinetics of signal degradation are determined in part by the composition of the receptors. ErbB1 receptors are more likely to be degraded via endosome formation and lysosomal degradation, whereas the other ErbB receptors are relatively endocytosis impaired and are more often recycled (5,6,8,22). The rapid endocytosis and degradation of the activated ErbB receptor attenuate the signal generated at the cell surface in response to growth factor stimulation. The specific mode and site of degradation are also determined in part by the composition of the dimer. For example, ErbB1 homodimers are processed primarily by the lysosome; ErbB3 molecules are constitutively recycled; and heterodimerization with ErbB2 decreases the rate of endocytosis and increases recycling of its partners (5,6,8,22). ErbB2 homodimers, which are stable in the environment of the endosomal vacuole, are rapidly tagged with ubiquitin and processed for digestion, resulting in relatively weak signals, whereas ErbB2 heterodimers are unstable in the endosome, resulting in a lower rate of degradation and a higher rate of receptor recirculation. Networks also integrate heterologous signals from other networks and systems. In the case of ErbB, heterologous signals, including those induced by hormones, neurotransmitters, lymphokines, and stress inducers, are integrated into downstream messages (6,8). These interactions are mediated by protein kinases that directly phosphorylate the ErbB receptors, thereby affecting their kinase activity or endocytic transport. One type of *trans*-regulatory mechanism involves the activation of GPCRs, such as those for lysophosphatidic acid, thrombin, and endothelin. Agonists of GPCRs may result in a net increase of tyrosine phosphorylation of ErbB1 and ErbB2 by increasing the intrinsic kinase activity or inhibiting the phosphatase activity of the receptor. By a poorly defined mechanism, these agonists can also activate matrix metalloproteinases, which can then cleave membrane-tethered ErbB ligands (such as heparin-binding epidermal growth factor [EGF]), thereby freeing them to bind to the ErbBs. Activation of GPCRs may also activate Src family kinases, which leads to the phosphorylation of tyrosine residues on the intracellular domains of ErbB. These activities trigger events downstream of ErbB, contributing to the mitogenic potential of heterologous agonists. Interconnections between other signaling pathways help to integrate and coordinate cellular responses to extracellular stimuli.

The ErbB receptor family and related signaling networks provide enormous signaling diversity at many levels, including ligand specificity, receptor partnering, providing scaffolding sites for effector signaling proteins and substrate specificity for their kinase activities, receptor degradation, and integration of heterologous signals (5,6,8,16–24). Diversity between various

types of cells and tissues also exists, depending on the expression levels and the preferred stoichiometry for interactions of the receptors and ligands. Taken together, it is clear that ErbB receptors couple to specific downstream pathways with differing efficiencies, thus affording an astonishing range of signaling possibilities. The particular cellular response to ErbB stimulation is a function of the cellular context, as well as the specific ligand and ErbB dimer. This has been shown best for mitogenic and transforming responses; homodimeric receptor combinations are less mitogenic and transforming than the corresponding heterodimeric combinations, and ErbB2-containing heterodimers are the most potent. For example, neither ErbB2 nor ErbB3 alone can be activated by ligand; the ErbB2-ErbB3 heterodimer is the most transforming and mitogenic receptor complex.

Current Therapeutic Efforts Targeting the ErbB Receptor Family

Perhaps the best example of both the therapeutic implications and limitations of targeting signal transduction elements is the situation represented by trastuzumab (Genentech, South San Francisco, California, USA) in targeting ErbB2 (*HER2/neu*) in patients with breast cancer (6,11,23–25). Targeting ErbB2 with trastuzumab results in impressive clinical activity, albeit limited to women with breast cancer whose tumors have amplified ErbB2, which drives proliferation (6,11,23–25). In contrast to the situation in breast cancer, trastuzumab treatment results in negligible antitumor activity in patients with advanced ovarian carcinoma, which commonly expresses ErbB2 (25–29). The lack of relevant activity despite receptor expression is due to the fact that *HER2/neu* gene amplification, which is a prominent driver of proliferation in breast cancer, is uncommon in gynecologic and most other malignancies. The same can be said about the profound responsiveness of only a small proportion of non-small cell lung cancers with mutations of ErbB1 following treatment with small molecule RTK inhibitors and other therapeutics target ErbB1 (12). Although these signal transduction inhibitors confer clinical benefit in patients with various cancers that do not have ErbB1 RTK mutations, much less impressive activity is generally noted.

In addition to therapeutic antibody approaches designed to target ErbB2, several small-molecule RTK inhibitors of ErbB2 are undergoing clinical development. They encompass agents that specifically inhibit the ErbB2 RTK, including CP724,714 (Pfizer, Groton, Connecticut, USA) and ARRY-380 (Array, Boulder, Colorado, USA); agents that inhibit both ErbB1 and ErbB2 RTKs, including lapatinib (Glaxo SmithKline, Philadelphia, Pennsylvania, USA), ARRY-543 (Array); and pan-ErbB RTK inhibitors, including CI-1033 (Pfizer) and EKB-569 (Wyeth Ayerst, Collegeville, Pennsylvania, USA) (26–28). To date, these agents have not been thoroughly evaluated in patients with ovarian cancer and other gynecologic malignancies, but impressive antitumor activity has not been observed with single-agent treatment in early studies (29–33).

Pertuzumab (2C4; Genentech), a recombinant humanized monoclonal antibody that binds to the extracellular domain of ErbB2 and blocks its ability to dimerize with other ErbB family members, represents a new class of targeted therapeutics known as ErbB dimerization inhibitors (34,35). In a phase 2 trial of pertuzumab in patients with recurrent or refractory advanced ovarian cancer, proof of principle was demonstrated, with 5 (4.3%) of 117 patients experiencing partial responses; 8 (6.8%) additional patients had stable disease lasting at least 6 months (35).

Still other approaches to targeting ErbB involve monoclonal antibodies and small-molecule inhibitors of ErbB1. Monoclonal

antibodies, such as cetuximab (Imclone Systems, New York, New York, USA) and panitumumab (Amgen, Thousand Oaks, California, USA), bind to the extracellular domain of the ErbB1 subfamily and preferentially block binding of ErbB1 stimulatory ligands (36,37). However, monoclonal antibodies directed against ErbB1 have not yet demonstrated impressive antitumor activity following single-agent treatment in patients with refractory or recurrent ovarian cancer (38). Nevertheless, intriguing preliminary activity has been observed with cetuximab plus platinum-taxane-based chemotherapy in the first-line treatment of women with advanced ovarian cancer (39). Similar to the situation with ErbB2 targeting, approaches that target ErbB1 with small molecules include developing agents that competitively and reversibly inhibit the ErbB1 RTK activity. Small-molecule inhibitors targeting ErbB1 include those with specificity for ErbB1 RTK, including gefitinib (AstraZeneca London, UK) and erlotinib (OSI Pharmaceuticals, Mellville, New York, USA), and those targeting the RTKs of both ErbB1 and ErbB2 receptor subfamilies (e.g., lapatinib, ARRY-543) (23,36). Still others, as previously discussed, form irreversible covalent linkages with the cysteine residues in the RTK domains of several types of ErbB receptors. CI-1033 is an example of an irreversible inhibitor of all four ErbB family member RTKs, whereas EKB-569 irreversibly inhibits the RTK activity of both ErbB1 and ErbB2 (26–28,32,33). The relative therapeutic merits of antibodies versus small molecules, inhibitors of a single ErbB RTK versus multiple RTKs, and reversible versus irreversible receptor binding are not known, but antibodies, in contrast to small molecules, induce rapid receptor internalization and degradation (40). In clinical evaluations of small-molecule inhibitors of ErbB1 RTK in patients with advanced non-small cell lung, colorectal, renal, head and neck, and ovarian carcinomas, largely not prescreened for mutations and/or expression of ErbB1, low rates of tumor regression have been observed (36,41–44). Few studies have been performed to date in gynecologic malignancies; however, epidermoid carcinomas of gynecologic origin commonly express all ErbB receptor targets, but the ErbB family members do not appear to be major drivers of proliferation. Although ErbB1 mutations have been reported in some ovarian epithelial carcinomas, mutation rates are much lower compared to non-small cell lung cancer (43). In an early phase 2 study of erlotinib in previously treated patients with ErbB-expressing ovarian carcinoma, 3 (10%) of 30 heavily pretreated subjects had partial responses and 15 (50%) had stable disease as their best response (44). Thus far, negligible anticancer activity has also been observed with erlotinib and gefitinib administered as single agents in other studies, as well as with small-molecule inhibitors of ErbB1 (44). However, most clinical evaluations of signal transduction inhibitors in gynecologic malignancies to date have not been randomized and therefore have not been adequately designed to assess the degree to which these agents affect tumor growth rates, time to tumor progression, and overall survival. Another important challenge is to discern which patients have the highest likelihood of benefiting from treatment with ErbB-targeted therapies based on the biologic features of their tumors, as well as determining the optimal means to combine these novel therapies with other anticancer agents.

Targeting the MAPK Pathway (Ras/Raf/Mitogen-Activated ERK Kinase)

Following activation of membrane-bound members of the Ras family of small GPCRs, proliferative signals are relayed to downstream intracellular signaling elements along the MAPK pathway, most prominently to the Raf family kinases, which in turn trigger mitogen-activated ERK kinase (MEK)/extracellular

signal-regulated kinase (ERK1/ERK2) (45–52). Likewise, Ras can directly relay survival signals by activating the PI3K/Akt/*PTEN* “cell survival” pathway (45–52). Ras activation through the MAPK pathway modulates the activity of nuclear transcription factors, including Fos, Jun, and AP-1, which regulate the transcription of genes required for proliferation (45,49–52).

MAPK represents the convergence of a broad array of signals from membrane receptors, and the network of phosphorylation-mediated signals emanating from MAPK is equally expansive. Functionally, MAPK circuits are three-tiered kinase modules (45–47,49–52). The Raf-1-MEK-ERK module is employed ubiquitously in the transduction of cell-type specific growth and differentiation signals from RTKs and GPCRs (45–47). Signaling through MAPK also mediates inflammatory and stress response to stimuli such as cytokines, FasL, and tumor necrosis factor (TNF). Additionally, the MAPK pathway does not function in isolation, but instead is integrated into other cellular signaling networks that impact upon MAPK signaling. Since cells are almost always receiving many types of stimuli, response outputs represent the integration of many signaling pathways, and slight modifications in the quality and quantity of stimuli can vastly alter transcriptional profiles, cell cycle commitment, and the equilibrium between cell survival and apoptosis. Corresponding to the prominence of MAPKs in numerous signaling events, perturbations in the MAPK signaling pathway can profoundly influence cellular integrity. Developmental therapeutic efforts are currently being directed at several components of the MAPK pathway, particularly the Raf-1-MEK-ERK module (45–47).

Targeting Raf

Since the Raf family of signaling elements is immediately downstream of Ras, which has not been successfully inhibited by targeting Ras maturation (i.e., Ras farnesylation), Ras expression (e.g., antisense oligonucleotides [ASOs]), and structural elements, and because Raf mutations result in autonomous growth and transformation, Raf has become an important target for therapeutic development (45–48,53). The Raf family is composed of three related serine-threonine protein kinases, Raf-1, A-Raf, and B-Raf, which act, in part, as downstream effectors of Ras signaling. Raf-1 is ubiquitous, whereas B-Raf is found mainly in neural tissue, and A-Raf is most abundant in urogenital organs, including the ovary, kidney, testes, and prostate. B-Raf and A-Raf, like Raf-1, are Ras effectors, but the specificity of their activities is not well understood. Raf mutations have also recently described and mutated B-Raf, which results in elevated kinase activity and transforming properties, which is found in 66% of malignant melanomas and at a lower frequency in many other cancers (45). Furthermore, Raf appears to play a role in tumorigenesis, as it can be activated independently of Ras by protein kinase C- α and promotes the expression of the multidrug resistance gene (53–55). Activated Ras interacts directly with the amino-terminal regulatory domain of the Raf kinase, resulting in a cascade of reactions that include direct activation of MEK (45–47,53–55). The serine-threonine kinase Raf-1, a well-characterized downstream effector of Ras, is activated in a stepwise sequence of events that include phosphorylation, recruitment to the plasma membrane, and binding to activated Ras (49–52). Following activation, Raf-1 in turn activates MEK through phosphorylation of two separate serines. Raf-1 is the protein product of the *c-raf* proto-oncogene.

Since Raf kinase is the first committed step in the MAPK pathway, it is an attractive target for therapeutic development since successful targeting may block growth signaling from a diverse array of stimuli (45–48,53). Furthermore, there is a large body of experimental evidence indicating that inhibition

of Raf kinase can reverse the phenotype of Ras-transformed cells and block tumor growth (53).

Several approaches to targeting Raf, including ASOs and small molecules, are being evaluated. ISIS 5132 (CGP 69846A; ISIS, Carlsbad, California, USA) is a 20-base phosphorothioate ASO designed to hybridize to the 3' untranslated sequences of the *c-raf-1* gene (56–58). Binding of ISIS 5132 to Raf-1 mRNA promotes RNAaseH-mediated mRNA degradation and reduced Raf-1 protein synthesis in a nucleotide sequence-specific and concentration-dependent fashion. ISIS 5132 inhibits expression of *c-Raf* mRNA, as well as the proliferation of ovarian, lung, colon, cervical, prostate, and colon carcinoma cell lines (53,56,57). Acute toxicities, including fever; fatigue; transient, asymptomatic prolongation of activated partial thromboplastin time; and activation of alternate complement activation, have been attributed to the phosphorothioate backbone (53,58). Another approach involves the development of small-molecule inhibitors of Raf kinase, such as sorafenib (Bayer Corporation Pharmaceutical Division, West Haven, Connecticut, USA), a bis-aryl urea designed to specifically inhibit the ATP-binding site of Raf kinase (53,59,60). The importance of therapeutics that effectively target cells driven by *ras* mutations cannot be overstated since *ras* mutations occur in 30% of human malignancies. Additionally, tumor cells with the predominant *ras* mutation *K-ras* are not effectively targeted by farnesyltransferase inhibitors due to alternative prenylation pathways that can take the place of farnesyltransferase, thereby conferring resistance. *Ras* mutations drive growth signals downstream through Raf and other MAPK signaling elements (45–47,53). Sorafenib is active in tumors that overexpress growth factor receptors, as well as in those with *K-ras* mutations, and the agent has shown robust activity against human colon, pancreatic, lung, and ovarian cancers in preclinical studies (53,59,60). However, sorafenib is promiscuous, inhibiting tyrosine kinase activity of vascular endothelial growth factor receptor (VEGFR) 1 and VEGFR2, and it is not known if Raf inhibition is responsible for the agent's anticancer activity *in vivo*. In fact, sorafenib has received regulatory approval in the United States and many other countries for treatment of advanced renal cancer, most likely due to its VEGFR2 inhibitory actions, and it has demonstrated clinical activity in liver, lung, breast, ovarian, and other solid malignancies in both early- and late-stage clinical trials (53). Toxicities include stomatitis, vomiting, diarrhea, fatigue, skin rash, hand-foot syndrome, lymphopenia, and anemia (53). Other small-molecule inhibitors of Raf kinase are also under development.

Targeting MEK

MEK (also called MAPK kinase [MAPKK]) is a dual-specificity kinase in that it activates ERK by phosphorylating both tyrosine and threonine residues. Two related genes code for MEK1 and MEK2 (45–47,49–52). Both MEK proteins play critical roles in Ras signaling. However, MEK1 and MEK2 differ in ERK binding affinities and, possibly, in their abilities to activate ERK. In the mitogen-activated Ras/Raf/MEK/ERK cascade, Raf generally activates the dual-specific serine-threonine and tyrosine kinases MEK1 and MEK2, which then activate ERK1 and ERK2. MEK has not been identified as an oncogene product in human malignancies; however, it is a critical point of integration of input from many other protein kinases. In addition, Ras is restricted in its substrate specificity, with the MAPKs being the only important substrates. Therefore, MEK is a target of great interest for cancer therapeutic development, and several small-molecule MEK inhibitors (ARRY-886, Array

BioPharma; PD325901, Pfizer), which have been associated with impressive preclinical activity, are in clinical development (61–65).

Targeting ERK

In mammalian cells, there are two closely related genes that code for ERK1 and ERK2. Following activation, ERKs enter the nucleus of cells where they are phosphorylated and, in turn, activate transcription factors, which leads to the expression of genes involved in growth and differentiation (45–47, 49–52). Although no direct inhibitors of ERK are currently in clinical development, ERK is actively being pursued as a strategic target for therapeutic development.

Targeting the PI3K/ Akt/PDEN Pathway

Cellular survival involves an active “decision” that is monitored continuously and determined by a balance of signals that promote either survival or apoptosis. These signals relay information about the availability of growth and survival factors, supply of nutrients and oxygen, cellular stress, and genomic integrity, and activate death receptors. Sufficient survival signaling enables cellular repair under conditions of limited cellular and genomic damage, whereas insufficient survival and/or heightened oppositional signaling can trigger cell death via the PI3K/Akt/PDEN pathway. On the other hand, irreparable DNA damage may lead to diminished survival signaling, resulting in apoptosis to prevent the propagation of deleterious mutations. Also, many types of amplified, overexpressed, and aberrant signaling elements in the PI3K/Akt/PDEN pathway increase survival signaling (66–72). For example, PI3K and the serine-threonine protein kinase Akt (also known as protein kinase B) are amplified or overexpressed in many ovarian, endometrial, and cervical cancers, and may even play a causal role in the development of several types of gynecologic cancer (66–76).

PI3K, a nonreceptor kinase, can be activated by numerous signals generated by growth factor receptors, including the ErbB family, platelet-derived growth factor receptor (PDGFR), insulin-like growth factor receptor (IGF-IR), VEGFRs, integrins, and GPCRs. The main effector of the PI3K/Akt/PDEN pathway, Akt, phosphorylates phosphoinositides, which in turn generate 3-phosphorylated phospholipids (PI3Ps) that act as membrane tethers for proteins with pleckstrin homology (PH) regions, including Akt and phosphoinositide-dependent kinase 1 (PDK1). Binding of Akt to membrane PI3Ps results in the translocation of Akt to the plasma membrane, bringing Akt in contact with PDK1, which is responsible for phosphorylation events required to activate Akt. Akt is the focal point for survival signals emanating from growth and survival receptors (66–72). In its activated state, Akt inhibits apoptosis by phosphorylating antiapoptotic substrates, including Bcl-2, Bcl_{xL}-antagonist causing cell death (BAD), forehead homolog 1, glycogen synthase-3, IκB kinase, and caspase-9. The PI3Ks, Akt, and PDK1 regulate many cellular processes, including proliferation, survival following antiapoptotic signaling, carbohydrate metabolism, and motility, and there is emerging evidence that these kinases are important components of the molecular mechanisms of disease such as cancer, diabetes, and chronic inflammation (66–68).

The dominant influence of Akt on cellular survival is suggested by the causal role of activating mutations of several elements of the Akt pathway in the development of many cancers (66,67). Growth factor RTKs, integrin-dependent cell adhesion

elements, and GPCRs activate PI3K, both directly and indirectly, through adaptor molecules. The tumor suppressor oncogene *PTEN* is a negative regulator of Akt activation, and deletions or mutations of *PTEN*, in many types of cancer, particularly endometrial, ovarian (especially the endometrioid variant), and breast cancers, and high-grade astrocytomas, permit genomically compromised cells to survive and accumulate further DNA damage, which in turn leads to neoplastic transformation (66,77). Conversely, *PTEN* mutations are uncommon in cervical cancer, but loss of *PTEN* expression through epigenetic mechanisms is common in cervical cancer and appears to be associated with poor survival (78,79). In addition to the influence of PI3K/Akt hyperactivity on enhanced survival signaling in many types of cancer, including gynecologic malignancies, hyperactive signaling through the PI3K/Akt/*PTEN* pathway is associated with resistance to inhibitors of ErbB1 and ErbB2, as well as many other classes of molecular targeting and cytotoxic agents (66–76,80–82). Although efforts are being directed at developing specific small-molecule inhibitors of PI3K, PDK1, and Akt, they have largely resulted in nonspecific kinase inhibitors such as wortmannin and LY294002 (Eli Lilly, Indianapolis, Indiana, USA). Nevertheless, more specific inhibitor candidates, including PX-866 (ProlX, Tucson, Arizona, USA), SF1126 (Semafore, Indianapolis, Indiana, USA), a prodrug of LY294002, and p110alpha subunit inhibitors (Piramed; Slough, UK), are in preclinical or early clinical development. Therapeutics targeting signaling elements upstream of PI3K, such as inhibitors of the IGF-IR, and downstream of PI3K and Akt, such as molecular target of rapamycin (mTOR) and the antiapoptotic protein Bcl-2, are in more advanced stages of development.

Targeting mTOR-Dependent and Rapamycin-Sensitive Pathways

mTOR (also called FRAP, RAFT1, and RAPT1) is a member of the PI3K related kinase (PIKK) family of protein kinases, which link proliferative stimuli to cell cycle progression and nutrient utilization (7,83–88). mTOR, which plays a critical role in transducing proliferative signals mediated through the PI3K/Akt/*PTEN* signaling pathway, and vice versa, regulates protein translation by altering the phosphorylation state of the translational regulator eukaryotic initiation factor 4E-binding protein (4E-BP1) and a 70-kDa S6 kinase known as p70^{S6k} (Fig. 18.3). In addition to its central role in modulating protein synthesis, mTOR plays a fundamental role in other critical cellular functions that affect cell growth and proliferation, such as angiogenesis and cytoskeletal organization (7,83–88). The regulation of mTOR is complex, involving several associated proteins and pathways. mTOR is repressed by tuberlin, which is a product of the tuberous sclerosis complex-2 (TSC2) (7,83–88). Following Akt activation, TSC2 is inactivated by phosphorylation, which in turn results in mTOR activation. Effectors of mTOR include p70^{S6k} and 4E-BP1. Phosphorylation of 4E-BP1 results in the dissociation of 4E-BP1 from eIF4E, thereby relieving the inhibition of 4E-BP1 on eIF4E-dependent translation initiation (7). eIF4E overexpression enhances cell growth and transforms cells by increasing the translation of key growth-promoting proteins, including cyclin D1, c-Myc, and the VEGF ligands. Deregulation of upstream growth-promoting pathways that converge on mTOR induce aberrant mTOR activity and relay unchecked growth signals that

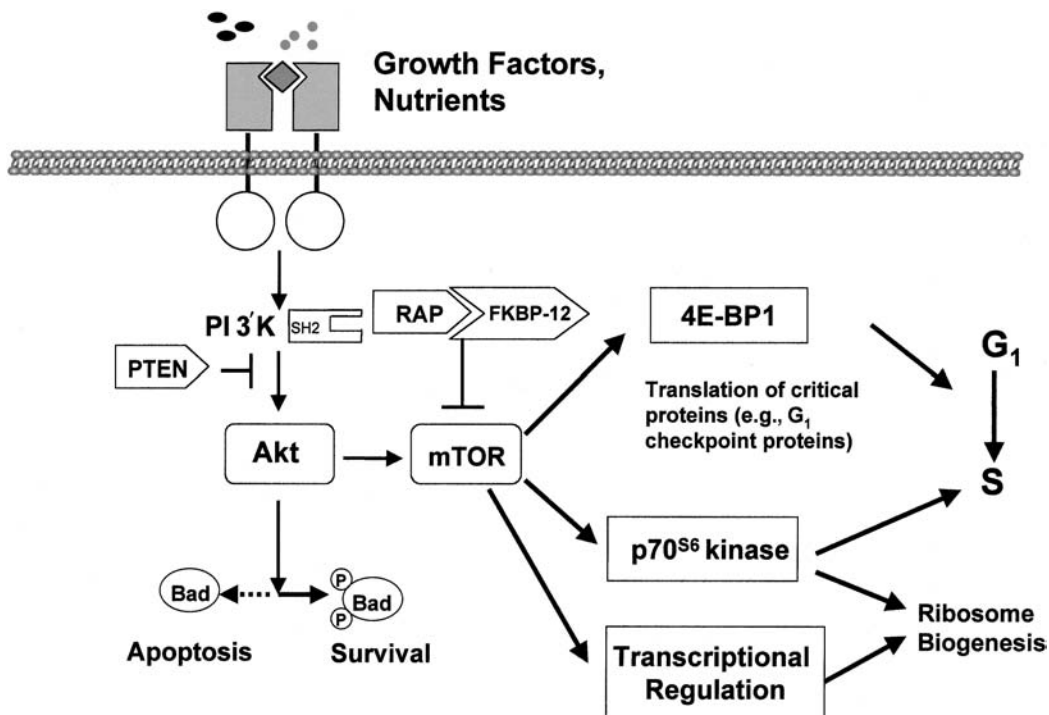

FIGURE 18.3. Rapamycin-sensitive signal transduction pathway. Growth factors and nutrients induce signaling along several pathways including the PI3K cell survival pathway, which relay proapoptotic signals downstream, as well as growth stimulatory signals downstream through mTOR. Rapamycin (RAP) and RAP analogs bind to the immunophilin FK506 binding protein-12 (FKBP-12). The RAP-FKBP-12 complex blocks the kinase activity of mTOR, which, in turn, inhibits 4E-BP1, p70^{S6k}, and other translational regulators. The inhibition of 4E-BP1 and p70^{S6k} decreases ribosomal biosynthesis and the translational of mRNA of specific proteins essential for cell-cycle progression from G₁ to S phase.

result in cellular growth, proliferation, and carcinogenesis. Dysregulation of mTOR signaling occurs in many types of human cancer, and activation of the mTOR pathway occurs frequently in gynecologic malignancies, particularly ovarian and endometrial cancers (7,83–90). In fact, aberrant phosphorylation of mTOR has been detected in more than 70% of primary endometrial cancers, most likely through *PTEN* mutations and activation of other PI3K/Akt/*PTEN* pathway elements (7,83–90).

Targeting mTOR

In preclinical studies, inhibition of mTOR function abolishes the proliferative and nutrient utilization signals mediated through the PI3K/Akt/*PTEN* signaling pathway, resulting in cell cycle arrest and tumor growth inhibition (7,83–90). The prototypic mTOR inhibitor, rapamycin, a macrolide fungicide isolated from *Streptomyces hygroscopicus*, exerts potent antimicrobial, immunosuppressant, and antineoplastic actions (7,83–90). Because of its profound immunosuppressive actions, rapamycin was initially developed and received regulatory approval for prevention of allograft rejection following organ transplantation. However, rapamycin confers impressive antiproliferative activity in a diverse range of experimental cancers. Malignant tumors with aberrations of signaling elements that activate the PI3K pathway, particularly *PTEN* deletions and hyperactivation of PI3K and Akt, are especially sensitive to inhibition of mTOR following rapamycin treatment (7,84,85,87,89–94). Rapamycin strongly inhibits the growth of cervical, ovarian, and endometrial cancers *in vitro*, which is associated with reduced phosphorylation of downstream targets, as well as the reversal of resistance to chemotherapeutic agents (7,84,85,87,89–94).

The antiproliferative actions of rapamycin and rapamycin analogs appear to be principally due to their ability to bind to the intracellular immunophilin FKBP-12, thereby forming a complex that binds to and inhibits the activity of mTOR (7,83–88). The inhibition of mTOR blocks the activation of 4E-BP1, p70^{s6k}, and other translational modulators (Fig. 18.4), which in turn inhibits the synthesis of proteins required for G₁

to S phase traverse and ribosomal biosynthesis. However, the poor solubility and chemical instability of rapamycin preclude its administration on a variety of dose schedules, and several rapamycin analogs are more amenable to parenteral administration such as temsirolimus (CC-1777; Wyeth Ayerst), which has undergone regulatory approval for the treatment of renal cancer in the United States, and both everolimus (RAD001; Novartis, Basel, Switzerland) and AP23573 (Ariad, Cambridge, Massachusetts, USA), which are undergoing clinical development (7,84,85,93–96). The toxicities of these rapamycin analogs are similar to those of rapamycin (e.g., mild cytopenias, fatigue, elevations of serum triglycerides and liver functions), but infectious complications due to protracted immunosuppression have not been noted to date. In clinical studies, regression of several types of advanced cancer, including breast, renal, and lung carcinomas, lymphoma, and soft-tissue sarcoma, has been reported. In addition to conferring clinical benefit in renal cancer, robust activity in mantle cell lymphoma has also been noted with temsirolimus. Clinical evaluations in patients with endometrial and ovarian carcinomas are ongoing (7,84,85,93–96). Preliminary results of a phase 2 study of temsirolimus in patients with recurrent or metastatic endometrial cancer indicate modest activity, with confirmed partial responses in 5 (26%) of 19 evaluable patients, and stable disease as best response in 12 (63%) other patients. Responses have been observed irrespective of *PTEN* status (95).

Targeting Insulin-Like Growth Factor and Related Elements

The critical roles of IGF-IR and its related signaling elements in the growth and development of both normal and cancer cells are increasingly being recognized (96–100). These signaling elements are highly conserved and may have evolved to regulate cellular proliferation in response to nutrient availability. In addition to their roles in balancing cellular proliferation and apoptosis, the IGF-IR and its close counterpart, the insulin

FIGURE 18.4. Schematic representation of the intrinsic and extrinsic pathways of apoptosis. The intrinsic pathway is mediated by Bcl-2 family members at the mitochondria that releases cytochrome-c and activates the proapoptotic protein apoptotic protease activating factor-1 (Apaf-1) and the cascade of caspases. The extrinsic pathway is mediated by the TNF family of receptors at the cellular membrane. Note: TNF, tumor necrosis family; FADD, Fas associated death domain.

receptor (IR), play key roles in regulating energy metabolism, body size, longevity, and various organ-specific functions (96–100). Experimental studies in animal model systems have provided evidence that the proliferative and metastatic potentials of cancer cells are enhanced by IGF-IR activation either due to higher levels of circulating IGF-1 or autocrine production of ligands by cancer cells (101). The critical role of IGF-IR signaling in controlling cellular renewal has led to interest in targeting the IGF-IR as a therapeutic strategy against cancer (96,98,101,102).

The IGF-IR and its ligands, IGF-1 and IGF-2, play key roles in the development, maintenance, and progression of cancer (98,101–108). IGF-IR activation stimulates cellular proliferation and differentiation and protects cells from undergoing apoptosis in the face of robust proapoptotic stimuli. Overexpression of the IGF-IR in cancer cells, often in concert with overexpression of IGF ligands, results in enhanced cancer cell proliferation and survival. In contrast, the IGF-2R does not transduce signals, but instead acts as a “sink” for IGF-2, which exerts its biologic effects through the IGF-IR (98,108).

IGF-1 and -2 are potent mitogens in a broad range of cancers, including those derived from human prostate, breast, colon, ovary, and lung cancers, melanoma, and multiple myeloma, and their growth stimulatory effects are mediated through the IGF-IR (98,101,109). Furthermore, high circulating levels of IGF-1 have been associated with an increased risk of developing many types of cancer (104). In experimental systems, the growth of cancers that express the IGF-IR is influenced by circulating IGF-1, which is produced by tissues remote from the cancer. However, some cancers appear to be controlled, at least to some extent, by locally synthesized IGF-1 and/or IGF-2, which act in an autocrine or paracrine manner. It has also been proposed that cancers may be highly dependent on the host for the ligand during early stages of cancer progression, but later acquire the capacity to produce ligands in an autocrine fashion, which relates to genotypic and phenotypic changes suggestive of a more aggressive behavior. IGF-IR signaling can also become exaggerated or aberrant due to molecular abnormalities involving downstream signaling elements. One example is the loss of function of the tumor-suppressor gene *PTEN*, which encodes a phosphatase that typically attenuates proliferative signals originating from the IGF-IR and other RTKs (98,110,111).

Signaling through the IGF-IR protects cancer cells from many types of insults, including those due to cytotoxic chemotherapeutic agents, ionizing radiation, and therapeutics targeting steroid and peptide-hormone receptors, and effective strategies against IGF-IR may thwart these protective effects (96,98,109,112). The hypothesis that targeting the IGF-1R will increase the efficacy of other anticancer therapeutics is largely based on evidence that survival signals originating at the receptor limit the efficacy of agents that may otherwise induce apoptosis. Furthermore, resistance to the anti-ErbB2 antibody trastuzumab is associated with activation of IGF-IR signaling, and IGF-IR blockade can restore sensitivity (112). These observations, together with other examples, such as synergistic induction of apoptosis when small cell lung cancer is targeted using inhibitors of c-KIT or IGF-IR, suggest that IGF-IR blockade sensitizes certain cancers to other kinase inhibitors (113). Consequently, inhibition of IGF-IR signaling has been shown to increase the susceptibility of tumor cells to chemotherapeutic agents and ionizing radiation, indicating that it is an attractive target for therapeutic development (114). Furthermore, IGF signaling can induce secretion of VEGF, which is central to the promotion of deregulated malignant angiogenesis, implying that there is an angiogenic component to the biologic activity of the IGF-IR signaling cascade (109). It would therefore follow that strategies designed to

inhibit the IGF-IR would suppress VEGF secretion, potentially slowing vascular expansion in proliferating tumors. Indeed, therapeutics targeting IGF-IR may enhance the activity of anti-VEGF treatment by potentially suppressing secretion of tumor-associated VEGF.

Several therapeutic strategies, including small-molecule RTK inhibitors and monoclonal antibodies directed against the human IGF-IR, have been shown to inhibit the proliferation of a broad range of cancers both *in vitro* and *in vivo* (96,98,109). In response, there has been considerable interest to develop effective targeted agents to inhibit the IGF-IR signaling pathway. Antibody strategies targeting the extracellular domain of the IGF-IR may be more advantageous than small-molecule kinase inhibitors by being highly selective against the IGF-IR, given its close homology to the IR kinase domain.

Various fully human IgG1 monoclonal antibodies, including IMC-A12 (ImClone Systems), AMG-479 (Amgen), R-1507 (Roche, Nutley, New Jersey, USA), M-0646 (Merck, Whitehouse Station, New Jersey, USA), and AVE-1642 (Sanofi-Aventis, Paris, France) and an IgG2 fully human monoclonal antibody (CP-751,871, Pfizer), have been engineered to selectively bind to the IGF-IR, thereby antagonizing ligand binding and signaling through downstream MAPK and PI3K/Akt/*PTEN* pathways (115). Early clinical evaluations of these antibodies are ongoing (109,116–118). In addition, several small-molecule inhibitors of IGF-IR, including OSI-906 (OSI Pharmaceuticals) and BMS-536924 (Bristol-Myers Squibb, Princeton, New Jersey, USA), are also being evaluated. There is also extensive preclinical evidence that therapies directed against IGF-IR are effective against a wide range of cancers, but their antitumor activities appear to be enhanced when they are combined with cytotoxic chemotherapeutics and/or other types of targeted therapies. IgG1 monoclonal antibodies also have the capacity to engage host immune effectors, thereby inducing antibody-dependent cellular cytotoxicity and complement-mediated cellular cytotoxicity as supplemental anticancer mechanisms; however, the contributions of various immune effectors in conferring anticancer activity is not known.

Favorable cytotoxic interactions between inhibitors of IGF-IR and many types of chemotherapeutic agents, including alkylating agents, platinating agents, Vinca alkaloids, taxanes, antimetabolites, and inhibitors of topoisomerase I and II, *in vitro* and in xenograft and orthotopic models of human cancer have been noted (109,119,120). For example, impressive antitumor activity has been noted following treatment of well-established human tumor xenografts with the anti-IGF-IR antibody IMC-A12 combined with the anti-ErbB1 antibody cetuximab (109,121). Additionally, IGF-IR and related signaling elements have been demonstrated to be activated in trastuzumab-resistant *HER2/neu*-amplified breast cancer, and experimental results suggest that IGF-1R blockade can restore trastuzumab sensitivity (109,122,123). In addition, the anti-angiogenic effects noted when the IGF-IR pathway is blocked in preclinical studies suggest that combinations of therapeutics targeting both IGF-IR and malignant angiogenesis may produce favorable antitumor interactions (109). Lastly, favorable interactions between inhibitors of IGF-IR and therapeutics targeting Raf/MEK/ERK and PI3K/Akt/mTOR pathways have been reported (109). Perhaps the most impressive interactions to date have been demonstrated between inhibitors of mTOR (rapamycin analogs) and IGF-IR (110). There is experimental evidence that treatment of cancer cells with mTOR inhibitors induces expression and activation of IGF-IR and downstream signaling elements, especially Akt, which may ultimately impede the effectiveness of mTOR inhibitors (110). Interestingly, IGF-IR targeting sensitizes cancer cells to mTOR inhibitors, whereas treatment with IGF-1 reverses the antiproliferative effects of mTOR inhibitors. These observations suggest that feedback up-regulation of IGF-IR and downstream signaling

in response to inhibiting mTOR may be thwarted by combined treatment with inhibitors of both mTOR and IGF-IR.

Targeting the Platelet-Derived Growth Factor Receptor

The platelet-derived growth factor (PDGF) family consists of four different polypeptide chains (PDGF-A, PDGF-B, PDGF-C, and PDGF-D) that exert cellular effects through two types of protein kinase receptors (PDGFRs), PDGF- α and PDGF- β (124–127). Ligand binding to the PDGFR induces receptor dimerization and phosphorylation of the RTK domain, which results in activation of several downstream signal transduction pathways, including MAPK, PI3K/Akt/*PTEN*, Src-family kinase, signal transducers, and activators of transcription factors (Stat) and phospholipase C (124–126). Overexpression of PDGF and the PDGFR has been shown to play a role in the development of cancer through autocrine stimulation of cancer cells, development of angiogenesis, and modulation of tumor interstitial pressure (124–126). Overexpression of PDGFR seems to result principally from deregulated expression, but genetic abnormalities, including PDGFR- α amplification and a constitutive activating mutation characterized by a deletion in exons 8 and 9, have also been identified. *In situ* hybridization studies have shown that both PDGF- α and PDGF- β are expressed mainly in tumors, whereas endothelial cells appear to principally express PDGFR- β (127,128). These results suggest that the paracrine effects of PDGF and PDGFR may also be relevant. In many cancers, including ovarian carcinoma and malignant glioma, PDGFR- α overexpression is common and associated with a poor prognosis (129–131). Experimental studies of gliomagenesis have suggested that PDGFR pathways not only play a key role in cell proliferation, but modulate differentiation by de-differentiating mature cells, thereby preventing glial differentiation, and even promote expansion of cancer stem cells (132,133).

Targeting PDGFR

The utility of the PDGFR as a potential target for cancer treatment is suggested by the results of experimental studies evaluating both small molecules and antibodies designed to inhibit the PDGFR (124–127,134). Inhibition of PDGFR is associated with decreased phosphorylation of the downstream effectors ERK and Akt, principal signaling elements of the MAPK and PI3K/Akt/*PTEN* pathways, respectively. The PDGF ligand/PDGFR axis is also crucial for malignant angiogenesis. Several small-molecule inhibitors of RTK, including imatinib and sunitinib, block PDGFR signaling, but these and other known small-molecule RTK inhibitors are promiscuous, as they inhibit other kinases as well (128). However, phase 2 results with imatinib in PDGFR-expressing malignancies, including ovarian cancer and glioma, have demonstrated that these agents have limited activity in unselected patients (135). Nevertheless, the lack of clinical activity observed with these promiscuous small-molecule therapeutics may be explained by poor tumor penetration and/or preclusive toxicities due to off-target effects. Later generation small-molecule inhibitors of PDGFR, which are much more selective for the PDGFR, such as CP-868,596 (Pfizer), are in early clinical development (136). Furthermore, a neutralizing, fully human IgG1 monoclonal antibody to human PDGFR- α , IMC-3G3 (ImClone Systems), which does not cross-react with the PDGFR- β , is also under clinical evaluation (137). The K_d of IMC-3G3 is 40 pmol/L and it blocks both PDGF-AA and PDGF-BB ligands from binding to PDGFR- α . In addition to blocking ligand-induced cell mitogenesis and receptor autophosphorylation,

IMC-3G3 inhibits phosphorylation of the downstream signaling in both the MAPK and PI3K/Akt/*PTEN* pathways in both transfected and tumor cell lines expressing PDGFR- α . Furthermore, IMC-3G3 significantly inhibits the growth of xenografts derived from PDGFR- α -expressing human glioma and sarcoma, indicating that the antibody may be useful in treating PDGFR- α expressing cancers.

Regulators of Apoptosis as Anticancer Targets

Enhancing or restoring apoptotic mechanisms to improve the effectiveness of chemotherapy, therapeutic radiation, and hormone therapy, particularly in malignancies with deficient apoptotic triggering mechanisms, is the principal goal of therapeutic strategies targeting apoptosis. Rationally derived therapeutics directed at the regulation of the Bcl-2 family members that are the main components of the *intrinsic pathway of apoptosis* are in late clinical trials, whereas therapeutics aimed at targeting the TNF receptor (TNFR) family, a main component of the *extrinsic pathway of apoptosis*, are in earlier clinical developmental stages.

There is a hierarchical organization to the pathways of cellular apoptosis, as shown in Figure 18.4. The intrinsic and extrinsic pathways of apoptosis converge on a final common biochemical pathway that executes apoptotic cell death and requires the activation of a family of tightly regulated intracellular cysteine proteases called caspases (138–141). These pathways utilize different downstream caspase family members to activate a series of common downstream caspases, including caspase-3, -6, -7, -8, and -9. These downstream caspases induce enzymatic activation of many other proteins involved in apoptosis, leading to a cascade of proteolysis of other caspases and cellular proteins. Caspase activation and downstream proteolysis either destroy or damage many cellular “housekeeping” elements such as protein kinases, signal transduction proteins, cytoskeletal proteins, chromatin-modifying proteins, repair proteins, and inhibitory subunits of endonucleases.

Targeting the Intrinsic Pathway of Apoptosis

The intrinsic pathway of apoptosis is a mitochondrial-membrane-dependent pathway mediated by the Bcl-2 family of proteins (138–143). The *bcl-2* gene was originally identified as the chromosomal breakpoint of the translocation of a protein of chromosome 18 to 14 in follicular B-cell non-Hodgkin’s lymphoma, and its translated protein belongs to a superfamily of apoptosis regulatory gene products, including antagonists of apoptosis (Bcl-2, Bcl-X_L, Bcl-2, Bfl-1, and Mcl-1) and agonists (Bax, Bak, Bcl-X_s, Bad, Bid, Bik, Bim, and Hrk) (138–143). The interactions of death antagonist with agonist proteins, as well as their relative ratios, determine how cells respond to apoptotic signals. This death/life balance is mediated, at least in part, by the selective and competitive dimerization of both antagonists and agonists (138–143). Many of the pro- and anti-apoptotic members of this regulatory family, such as Bax, act at the level of the outer mitochondrial membrane (138–143). Following mitochondrial membrane disruption, cytochrome *c* and other protease activators, including caspases -2, -3, and -9, and apoptosis-inducing factors, particularly apoptosis protease activating factor-1 (Apaf-1), are released. Cytochrome *c*, along with deoxyadenosine triphosphate, binds to and modifies the conformation of the Apaf-1 complex, which results in the activation of caspase-9. Many novel therapeutic agents that perturb

the dynamic equilibrium between pro- and antiapoptotic proteins enhance the effectiveness of chemotherapy, radiation, and hormonal therapy.

Targeting Bcl-2

Targeting the Bcl-2 antiapoptotic protein, which is overexpressed in gynecologic and many common human malignancies and impedes apoptosis following apoptotic stimuli, makes Bcl-2 an attractive target for therapeutic intervention (138,140,142–150). Oblimersen sodium (Genta, Berkeley Heights, New Jersey, USA) is an 18-mer phosphorothioate ASON directed at the first six codons of the human Bcl-2 open reading frame (138,140,143,147). ASONs hybridize to the complementary sequence present on the target mRNA, followed by RNaseH-mediated degradation of mRNA. Modifying the phosphate backbone of the ASON, such as with phosphorothioate substitutions, enables resistance to protein degradation and enhances stability in the plasma and intracellular environments. Experimental studies have suggested that oblimersen sodium treatment leads to sequence-specific and dose-dependent degradation of Bcl-2 mRNA with subsequent inhibition of Bcl-2 protein expression (138,140, 142,143,147). Furthermore, several lines of evidence suggest that oblimersen sodium treatment enhances the effectiveness of other anticancer therapeutics, particularly cytotoxics. Normal and aberrant Bcl-2 expression mediates cellular resistance to apoptosis produced following treatment with many types of chemotherapeutics, including alkylating agents, antimetabolites, mitomycin, irinotecan, Vinca alkaloids, and taxanes, and Bcl-2 ASON treatment has been shown to markedly enhance the antitumor activity of many of these agents, especially the taxanes and alkylating agents (138,140, 142,143,147,151,152). In fact, antimicrotubule agents like the taxanes and Vinca alkaloids induce Bcl-2, thereby reducing its ability to heterodimerize with Bax and ultimately inducing apoptosis. These actions are enhanced when oblimersen sodium is combined with antimicrotubule agents (138,140,151,152).

Many studies have examined the feasibility of administering oblimersen sodium alone or in combination with various chemotherapeutic agents (138,140,142,143,147). Its principal toxicities when administered as either a protracted intravenous infusion or subcutaneously include hyperglycemia, transient hepatic transaminase elevations, fever, fatigue, thrombocytopenia, leukopenia, and local inflammation at the injection site. The early observations of clinical activity against lymphomas and leukemias, particularly chronic lymphocytic leukemia, with oblimersen sodium administered as a single agent may be due to the pivotal role of Bcl-2 expression in the etiology of these disorders and provide “proof of principle” that Bcl-2 inhibition may restore normal apoptotic processes in tumors with Bcl-2 regulation (138,140,142,143,148). In many other malignancies, however, Bcl-2 expression may not be as critically important to cell survival, except in the presence of external apoptotic stimuli such as chemotherapy and irradiation. Other therapeutics under evaluation designed to decrease Bcl-2 expression include the RNA antagonist SPC2996 (Santaris, Copenhagen, Denmark), which is a 16-mer oligonucleotide that binds to Bcl-2 mRNA with high affinity and resists digestion by nucleases (153).

Small-molecule and peptide inhibitors of Bcl-2, which essentially inhibit Bcl-2-Bax heterodimer formation, are undergoing early clinical development (140,143,149,150,154–157). One small-molecule inhibitor, HA14-1, which was discovered using a computer screening strategy based on the predicted structure of the Bcl-2 protein surface, binds to a surface pocket of Bcl-2. Another small molecule, AT-101 (Ascenta Therapeutics, San Diego, California, USA), an orally bioavailable pan-Bcl-2

inhibitor that triggers apoptosis of cancer cells by directly inhibiting the activity of Bcl-2, Bcl-XL, and Mcl-1, is also undergoing evaluations in both solid and hematologic malignancies (156). Other small-molecule inhibitors of Bcl-2 structure and function in early clinical evaluations include ABT-263 and ABT-737 (Abbott Laboratories, Abbott Park, Illinois, USA), and GX15-070MS (Gemin X Biotechnologies, Montreal, Canada) (157).

Several agents targeting other components of the intrinsic pathway of apoptosis in preclinical or early clinical development include small molecules and ASONs that target Bcl-X_L and antiapoptotic regulatory proteins, including clusterin, survivin, and TRPM-2. Still other efforts are being directed at the antiapoptotic protein Bax by perturbing the proteasome and/or ubiquitin protein degradation pathways or Bax gene transfection (138,140,142,143,157–161; see section on Targeting Regulators of Protein Trafficking). Another class of promising targets for therapeutic development is the apoptosis interfering proteins, such as survivin and clusterin, which inhibit downstream apoptotic processes (140–143,158–161). Survivin is highly expressed in most cancers, including ovarian cancer, and has been associated with resistance to chemotherapeutic agents and poor clinical outcome. In experimental models, therapies targeting survivin often produce antitumor activity without overt toxicity; however, the consequences of prolonged survivin inhibition in normal cells have not been evaluated thoroughly. Promising therapeutic approaches include those that are aimed at suppressing survivin expression using ASON, ribozyme, siRNA, and shRNA technologies, as well as antagonizing survivin function by inhibiting specific cyclin-dependent kinases. Alternatively, small molecule suppressants of survivin, such as YM-155 (Astellas Pharma US, Inc., Deerfield, Illinois, USA), which has demonstrated preliminary clinical activity in both hematopoietic and solid malignancies, are in clinical development (161). Similar strategies that target clusterin, represented by the ASON OGX-011 (OncoGenex; Vancouver, Canada) (162), are also undergoing clinical evaluation.

Targeting the Extrinsic Pathway of Apoptosis

The extrinsic pathway of apoptosis refers to the activation of caspase-8 as a result of apoptosis-inducing ligands that bind to the TNFR family. The TNFR family consists of the receptors TNFR1, Fas (Apo1), DR3 (Apo2), DR4 (TNF-related apoptosis-inducing ligand [TRAIL] R1), DR5 (TRAILR2), and DR6 (71). Critical adaptor proteins, particularly TNF- α receptor associated death domain (TRADD) or Fas associated death domain (FADD) protein, mediate intracytoplasmic signals from the receptor using death domain proteins to interact with the receptor and death effector domains to interact with procaspase-8 (138,140,142,163–167). The proteins engage proteases and cleave the N-terminal of caspase-8, thereby activating the caspase cascade.

Targeting TRAIL Receptors

There are several homeostatic mechanisms that regulate cell death in the extrinsic pathway. Decoy receptors for Fas ligands and TRAIL (TRAIL R3/DcR1 and TRAIL R-4/DcR2) compete for ligand and modulate apoptotic signals. Moreover, several intracellular proteins interact with death domain proteins to inhibit the signal transduction of apoptosis. These proteins include the protein silencer of death domains and FAP1, which may represent a mechanism of resistance to Fas-inducing

apoptosis (166). In addition, members of the death effect domain family (e.g., FLP) compete with procaspase-8 for the binding with FADD and inhibit apoptosis (167). Deregulation of these mediators may lead to malignant transformation. Mutations or deletions in the FAS gene have been found in cells from patients with many types of malignancies. It is also likely that the intrinsic and extrinsic apoptotic pathways are linked at many critical juncture points. For example, abrogation of TRAIL-mediated apoptosis occurs in some cancer cell lines secondary to overexpression of Bcl-2 family proteins, whereas TNF- α mediated expression of nuclear factor (NF)- κ B activates several Bcl-2 family genes that have antiapoptotic functions (168).

TNF, which has the potential to induce apoptosis in tumor cells and mediates inflammatory processes, is the prototypic ligand for the TNFR family (169). TNF- α and Fas ligands are not candidates for drug therapy due to their nonspecific activation of multiple TNFRs and their causality of septic shock and fulminant hepatic failure in animals (170). However, recombinant soluble human TRAIL has entered clinical development since it is capable of inducing apoptosis in a broad spectrum of human cancers *in vitro*, but not in normal cells (138,140,142,164–167). Moreover, antitumor activity without toxicity has been observed in xenograft models. The selectivity of TRAIL in mediating apoptosis in tumor cells and not normal cells has not been elucidated, but the overexpression of death receptors and/or a relative absence of decoy receptors in tumor cells have been proposed as explanations. However, preclinical studies demonstrating apoptosis in human hepatic cells *in vitro* have raised concerns about the clinical development of TRAIL, but recent evidence indicates that different versions of recombinant soluble human TRAIL may confer varying propensities for hepatocyte toxicity (171). In early clinical evaluations, recombinant soluble human TRAIL ligands against DR4 and DR5 (rhApo2L/TRAIL; Genentech and Amgen) have been well tolerated without relevant hepatotoxicity (172).

Monoclonal antibodies with agonist-like properties at the DR4 and DR5 sites may represent alternate strategies for the induction of apoptosis via the extrinsic pathway. Following antibody-antigen complex formation, caspase activation and apoptosis induction occur, resulting in tumor regression of human tumor xenograft (138,140,142,164–167,173,174). The affinity for DR4 binding appears to be less important for agonist activity than the specific binding site on the receptor (173). This implies that the specific agonist site exists within the receptor and suggests that widely divergent results may be achieved with different antibodies directed to the same target DR4 (174). Clinical investigations of humanized and fully human antibodies directed against DR4 (HGS-ETR1; Human Genome Sciences, Rockville, Maryland, USA) and DR5 (HGS-ETR2; lexatumumab; Human Genome Sciences; AMG-655; Amgen) have been ongoing (175–177).

Targeting Regulators of Protein Trafficking

Targeting the Heat-Shock Protein Complex

Since the structure and function of proteins are highly dependent on their precise three-dimensional structures, targeting chaperone proteins, which are responsible for protein folding, is a logical therapeutic strategy against cancer (178–180). Geldanamycin analogs target the adenosine triphosphate (ATP) binding site of Hsp-90, an abundant and highly conserved chaperone protein that plays an important role in generating, regulating, and degrading signaling elements and other critical proteins (181–183). Proteins that are folded by

Hsp-90 include the cyclin-dependent kinases (cdks) 4 and 6, focal adhesion kinases that are involved in integrin signaling, components of the MAPK and PI3K/Akt/*PTEN* pathways, and the proangiogenic hypoxia-inducible factor-1 α (178–180,184). During malignant transformation, the essential chaperoning functions of heat-shock proteins (HSPs) are subverted to facilitate rapid somatic evolution. Functioning as biochemical buffers for the numerous genetic lesions that are present within tumors, chaperones, especially Hsp-90, allow mutant proteins to retain or even gain function while permitting cancer cells to tolerate the imbalanced signaling that oncoproteins create. The first Hsp-90 inhibitor to enter clinical trials, 17-allylamino-17-demethoxygeldanamycin (17-AAG), is a less toxic derivative of geldanamycin, whose administration is precluded by hepatotoxicity and suboptimal pharmaceutical properties. However, more potent, water soluble geldanamycin analogs and unrelated agents, including 17-(demethoxy), 17-dimethylaminoethylamino geldanamycin (17-DMAG), CNF1010 (Biogen IDEC, San Diego, California, USA), KOS-953 (Kosan Biosciences, Hayward, California, USA), IPI-504 (Infinity, Cambridge, Massachusetts, USA), and the totally synthetic, orally bioavailable Hsp-90 inhibitor CNF2024 (Biogen IDEC), are undergoing early clinical evaluations (181–188). Although objective antitumor activity has been reported with 17-AAG as a single agent, inhibitors of Hsp-90 are much more likely to confer relevant activity in combination with therapeutics that induce apoptosis since disruption of antiapoptotic signaling occurs following treatment with Hsp-90 inhibitors, which can enhance the proapoptotic effects of cytotoxic agents (181–184).

Targeting the Ubiquitin-Proteasome Protein Degradation Pathway

The principal mechanism that is responsible for intracellular protein degradation is the ubiquitin-proteasome pathway (183, 189–192). This pathway “tags” protein substrates with polyubiquitin chains, marking them for degradation into peptides and free ubiquitin. The process is modulated by the proteasome, which is a large multimeric protease that is found in all eukaryotic cells. Many important proteins, such as the cyclins, cyclin-dependent kinase inhibitors, and transcription factors (e.g., NF- κ B) are tagged by the ubiquitin-proteasome pathway, and therefore the pathway plays a critical role in neoplastic growth and metastasis. Inhibiting the proteasome perturbs the cyclical degradation of these critical proteins, thereby resulting in the accumulation of cyclin-dependent kinase inhibitors and ultimately cell-cycle arrest and apoptosis. Several small-molecule inhibitors of the proteasome pathway have recently been identified, particularly the dipeptide boronate derivatives (189–192). Bortezomib (Millennium Pharmaceuticals, Cambridge, Massachusetts, USA), a peptidyl boronic acid and highly selective inhibitor of the chymotryptic site within the 20S proteasome, has recently received regulatory approval for treating patients with drug-refractory multiple myeloma (92,93). Bortezomib is capable of permeating the membrane of tumor cells, reversibly inhibiting the proteasome, and blocking cell division in the G₂/M phase of the cell cycle, which in turn leads to apoptosis. The agent also inhibits the degradation of wild-type p53 and stabilizes p21, which induces G₁ arrest by inhibiting cyclin D-, E-, and A-dependent kinases and activating NF- κ B. In preclinical studies, bortezomib demonstrates broad anticancer activity, with mechanism-based toxicities related to the degree of proteasomal inhibition. These studies predicted that severe toxicity would occur when proteasome activity is inhibited by at least 70% to 80%, and therefore the achievement of this magnitude of proteasome inhibition was a pharmacologic goal in early clinical studies.

Based on impressive activity in preclinical studies when bortezomib is combined with a wide variety of cytotoxic agents, clinical evaluations of bortezomib and other proteasome pathway inhibitors, as well as relevant combination regimens, are being performed in patients with gynecologic and other malignancies.

Targeting Epigenetic DNA Modifications

Targeting processes that result in post-translational or *epigenetic* modifications in histone proteins associated with DNA is a rational approach to anticancer therapeutic development (193–195). To date, therapeutic targeting has focused on covalently modifying the amino-terminal tails of histones, which package eukaryotic DNA into units that are folded into chromatin fibers. Highly conserved histone proteins (H1, H2A, H2B, H3, and H4) and the nucleosomes they form with DNA are the basic blocks of eukaryotic chromatin, the organization of which determines gene expression (193–195).

Nucleosomes form the basic repeating unit of chromatin and consist of DNA wrapped around a histone octamer that is in turn formed by four histone partners including an H3-H4 tetramer and two H2A-H2B dimers. Extending out from the nucleosome are the charged amino-terminal tails of the histones. The tail of histone H4 appears to extend into the adjacent nucleosome to interact with the H2A-H2B complex, indicating that the histone tails might regulate higher order chromatin structure. As depicted in Figure 18.5, the amino acid histone tail domains are targets for various post-translational modifications, including acetylation, methylation, phosphorylation, ADP-ribosylation, and ubiquitination. How the code is established and maintained remains to be determined, but many modification sites are close enough to each other that modification of a histone tail by any one enzyme might influence the rate and efficiency at which subsequent enzymes use the newly modified tails as substrates. In essence, interfering with these modifications modulates histone-associated proteins and gene expression. Covalent modifications of core histone tails by histone acetyltransferases (HATs), histone methyltransferases (HMTs), kinases, and especially histone deacetylases (HDACs) regulate gene expression (193–195).

Targeting Histone Deacetylase

HATs catalyze the acetylation of the ϵ -NH₂ group on lysine residues with histone tails leading to transcriptional activation, whereas HDACs function in opposition by deacetylating lysine residues and inducing transcriptional repression through chromatin condensation (196). Transcriptional aberrations may be among the leading contributors to conferring the neoplastic phenotype, which is the case in acute promyelocytic leukemia, in which aberrant transcriptional repression mediated by HDACs is a common mechanism utilized by oncoproteins. Alterations in chromatin structure can impact on normal cell differentiation and lead to malignant tumor formation. Furthermore, the fact that HDAC inhibitors are active against a wide variety of cancers *in vitro* and in human tumor xenograft models, and that defects in the acetylation machinery are found in most epithelial and hematologic malignancies, including ovarian cancer, suggest that the pharmacologic inhibition of HDAC may have broad therapeutic ramifications (197). In preclinical investigations, many structurally diverse compounds have been shown to bind to HDAC; promote histone acetylation; induce cell cycle arrest, differentiation, or apoptosis; and possess prominent antitumor activity. HDAC inhibitors that are currently approved for the treatment of underdevelopment as anticancer therapeutics include (a) short-chain fatty acids (e.g., butyrates); (b) hydroxamic acids (e.g., suberoylanilide hydroxamic acid [vorinostat; Merck], oxamflatin, LAH-824 [Novartis], LBH-589 [Novartis], PXD-101 [CuraGen, Branford, Connecticut, USA]), (c) benzamides (e.g., MS-275 [Mitsui, Chiba, Japan], MGCD0103 [MethylGene, Montreal, Canada]); and (d) cyclic peptides (e.g., depsipeptide [Gloucester, Cambridge, Massachusetts, USA], trapoxin A, apicidin) (195,196). The results of phase 1 studies, particularly of hydroxamic acid derivatives, demonstrated antitumor activity at doses below the maximum tolerated dose (MTD). The first evidence of robust antitumor activity with the HDAC inhibitors occurred in patients with persistent or recurrent cutaneous T-cell lymphoma, resulting in vorinostat receiving regulatory approval. Synergy has also been observed between the HDAC inhibitors and various classes of anticancer agents, and the spectrum of anticancer activity demonstrated in preclinical studies has been broad (195,196).

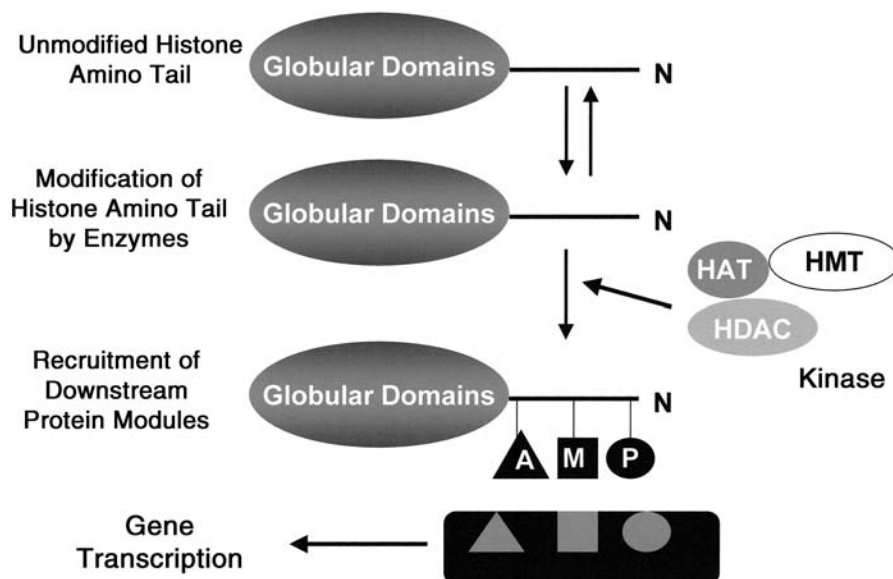

FIGURE 18.5. Covalent post-translational modifications on the histone amino tail domain. Pictured are the enzymes HAT, HDAC, HMT, and kinases that covalently modify histones. *Note:* HAT, histone acetyltransferase; HDAC, histone deacetyltransferase; HMT, histone methyltransferase; A, acetyl group; M, methyl group; and P, phosphate.

At a more fundamental level, it will be important to understand the nature of the molecular basis of the selectivity of HDAC inhibitors in altering gene transcription, and whether there are differences in the biologic function of different HDACs. Furthermore, it will be helpful to understand why normal cells are apparently more resistant to the apoptotic effects of HDAC inhibitors, as well as the role of non-histone substrates of HDACs, such as transcription factors, in the suppression of cell growth. Most importantly, the reasons for the differential sensitivity of the HDAC inhibitors must be understood. This knowledge will undoubtedly contribute to both the further understanding of the process of transformation and the development of effective agents to treat many types of cancer.

Targeting DNA Methylation

The most extensively characterized epigenetic alteration is DNA methylation (193–195,197). Cytosine methylation of the palindromic CpG dinucleotide sequence has been the most widely known and studied epigenetic modification; however, DNA methylation of non-CpG sequences has also been reported. CpG islands are defined as DNA regions with greater than 500 base pairs containing CG content of at least 55%. Hypermethylation of CpG islands near the promoter region of genes usually silences their expression. The biologic effects of the loss of gene function caused by promoter hypermethylation are analogous to those caused by genetic mutations. The gene silencing effects of hypermethylation of CpG islands have been explained by several mechanisms. Perhaps the most plausible one is that methylated CpG islands in the promoter region inhibit binding of transcription factors to their CpG-containing recognition sites. Another theory proposes the involvement of methylated CpG-binding proteins. The list of hypermethylated genes in all types of cancers, particularly hematologic malignancies, has increased tremendously over the last several decades, and more candidate tumor suppressor genes are expected to be identified (193–195,197). In ovarian cancer, for example, epigenetic silencing by hypermethylation of the connective tissue growth factor gene promoter results in a loss of gene function, which may be a factor in the carcinogenesis of ovarian cancer in a stage-dependent and/or histologic subtype-dependent manner (198). Aberrant DNA methylation that results in the transcriptional silencing of proapoptotic genes appears to be involved in conferring acquired resistance to many types of chemotherapy agents (199–201). In a study of plasma DNA from patients with ovarian cancer, methylation of the DNA mismatch repair gene *hMLH1* was demonstrated to be increased at relapse (201). For this reason, the methylating agent 2'-deoxy-5-azacytidine (decitabine; MGI Pharma, Minneapolis, Minnesota, USA) in combination with carboplatin is being evaluated in women with recurrent ovarian cancer in a phase 2 study (197,202).

The concept of modifying DNA methylation as a therapeutic strategy has been validated by the demonstration that demethylating agents induce clinical benefit in patients with various hematologic malignancies and premalignancies (197,198). The nucleoside analogs decitabine and 5-azacytidine (azacytidine; Pharmion, Boulder, Colorado, USA), both of which have received regulatory approval for treatment of myelodysplastic syndrome, do not directly inhibit DNA methyltransferases (DNMTs). Instead, they incorporate into DNA as cytidine analogs and form covalent intermediate complexes with DNMT, which ultimately undergoes degradation. 5-Azacytidine also incorporates into RNA, thereby interfering with protein translation, resulting in cell death. Development of more selective demethylating agents that may target cancer cells preferentially is under way (197,198).

Novel Cytotoxic Targets and Agents

A number of novel cytotoxic agents with unique mechanisms of action are being evaluated in patients with ovarian cancer in an effort to identify therapeutics that would not be cross-resistant with taxane and platinating compounds.

Targeting the DNA Minor Groove

Trabectedin

Trabectedin (ecteinascidin-743 [ET-743], Pharmamar, Madrid, Spain), a tetrahydroisoquinoline alkaloid isolated from the marine ascidian *Ecteinascidia turbinata*, is a DNA minor-groove interactive agent with specific affinity for guanine-cytosine-rich sequences (203,204). Trabectedin-guanine adducts are formed only in double-strand DNA and these adducts are reversible upon DNA denaturation. Nuclear magnetic resonance and x-ray crystallographic studies have demonstrated that two of three subunits (A and B) bind to nucleic acids in the minor groove of DNA, but subunit C, which lacks DNA binding capabilities, acts as a molecular hinge that facilitates binding of trabectedin to critical nuclear proteins (203–208). In essence, trabectedin's dual affinity for DNA and proteins produces DNA-trabectedin-protein cross links. Adducts induced by trabectedin are unique because no DNA repair machinery pathway examined to date is capable of removing them, whereas cells deficient in nucleotide excision repair show increased drug resistance (209). Because loss of repair proteins is common in human tumors, expression levels of selected repair factors may be useful in identifying patients who might benefit from trabectedin treatment. Recent studies have also indicated that trabectedin interacts with nuclear histones and transcription factors, including E2F1, c-fos, NF- κ B, and SP-1. Additionally, trabectedin perturbs cell cycle progression and induces G₁ arrest, delayed S-phase traverse, and G₂/M arrest (206,208). Cell cycle arrest induced by trabectedin has been observed in p53 mutated cell lines, suggesting that this effect is p53 independent. Trabectedin does not inhibit topoisomerase I and II, but does perturb microtubules and intermediate filament bundles.

Trabectedin is of particular interest for development in gynecologic malignancies because it has been demonstrated to enhance the cytotoxic effects of platinating agents (208). In contrast to apoptosis mediated by platinating agents, trabectedin-mediated apoptosis following the induction of DNA damage is enhanced by the nucleotide excision repair pathway and inhibited by the mismatch repair pathway (207). Tumor cells that are resistant to platinating agents because of the up-regulation of the nucleotide excision repair pathway are therefore likely to be especially sensitive to trabectedin, and the combination of both agents may be more effective at inducing cytotoxicity than either agent alone (207,209). Trabectedin has also demonstrated substantial antiproliferative activity against many types of hematologic and solid cancers *in vitro*, with IC₅₀ values ranging from 1 pM to 10 nM. These investigations, as well as studies conducted in a human tumor-cloning assay, indicate that the antiproliferative effects of trabectedin are much greater with continuous treatment than short-term exposure. Substantial antiproliferative effects in both murine and human tumor xenografts, including those derived from human melanoma, breast, ovarian, renal, lung, and prostate cancers, have been noted. In addition, the antiproliferative activity of trabectedin has been demonstrated to be similar to that of cisplatin and paclitaxel against human ovarian tumor xenografts (208).

In early clinical evaluations, trabectedin's antitumor activity has been especially notable in patients with soft-tissue sarcoma, breast cancer refractory to the anthracyclines, and ovarian cancer resistant to platinating agents and taxanes (203,206,210,211). The principal toxicities include reversible transaminitis, emesis, and myelosuppression; however, these adverse effects appear less common on intermittent divided-dose schedules. A pooled analysis of 294 ovarian cancer patients who participated in three phase 2 trials of trabectedin as second- or third-line treatment, including 108 and 186 patients who were either resistant or sensitive to their last platinum treatment, respectively, demonstrated overall response rates and median time to progression of 8% and 2.1 months, respectively, in platinum-resistant patients, and respective values were 34% and 5.8 months in platinum-sensitive patients. The median duration of response was 5.8 months, and patients receiving the agent as a 3- or 24-hour infusion every 3 weeks demonstrated significantly higher response rates (33% vs. 16%, $p = <0.0001$) and median time to tumor progression (5.8 vs. 2.8 months, $p = 0.0001$) than those treated on a weekly divided-dose schedule. The most common drug-related adverse events were fatigue, noncumulative neutropenia, and transaminitis. Low incidences of febrile neutropenia, neurotoxicity, stomatitis, and alopecia were noted. The merits of trabectedin in patients with relapsed ovarian cancer were evaluated in a phase 3 trial in which 672 patients with advanced recurrent or refractory cancers were randomized to treatment with either liposomal doxorubicin plus trabectedin or liposomal doxorubicin alone. Progression-free survival was significantly increased in patients receiving the combination (7.3 versus 5.8 months; hazard ratio, 0.79; P value = 0.019).

Targeting the Folate Receptor Type α

There has been cumulative evidence that suggests that the folate receptor type α (FRA), which is a glycosylphosphatidylinositol-linked transmembrane protein with high affinity for folates and some antifolates, is overexpressed in mesothelioma and ovarian, uterine, some brain, and other cancers, and may confer the means by which selective tumor targeting can be achieved (212–216). Furthermore, expression of the FRA is very low in most adult normal tissues but is high in several types of cancer, providing the rationale for developing antifolates that are transported primarily by the FRA rather than by the reduced folate carrier. Among the approaches that are being used to target the FRA include the humanized monoclonal antibody MORAb-003 (Morphotek; Exton, Pennsylvania, USA) and the small-molecule thymidylate synthase inhibitor BGC945 (BTG, London, UK), which appears to be highly selective for the FRA (216–221). Binding of MORAb-003 to FRA can prevent phosphorylation of substrates specific for Lyn kinase, suppress proliferation of cells that overexpress the FRA, mediate tumoricidal effects via antibody-dependent cellular and complement-dependent mechanisms, and suppress growth *in vivo* of FRA-expressing tumor xenograft models. Toxicology studies in nonhuman primates found no evidence of toxicity with MORAb-003 at suprapharmacologic doses, which was confirmed in phase 1 studies in patients with advanced solid malignancies (218). A phase 2 study of MORAb-003 in patients with advanced ovarian cancer in first relapse has begun (219).

Along the same lines, a novel series of cyclopenta[*g*]quinazoline analogs of folic acid that are potent thymidylate synthase inhibitors (K_i ~0.2 to 1 nM) and at least 500-fold more selective for human cancer cell lines with high expression of the FRA compared to those with low expression, have been synthesized

(220,221). Pharmacokinetic studies in KB tumor-bearing mice have demonstrated selective retention of BGC945, a lead compound in this series in tumors relative to normal tissues. Furthermore, pharmacodynamic measurements have demonstrated inhibition of thymidylate synthase only in tumor tissue. The agent is in late-stage preclinical development.

Targeting DNA Alkylation

Canfosfamide

Canfosfamide (TLK-286; Telik, Palo Alto, California, USA) is a small-molecule prodrug that is metabolically activated by glutathione S-transferase P1-1 (GST P1-1) to release a highly reactive alkylating nitrogen mustard moiety (222–224). The enzyme GST P1-1 is overexpressed in ovarian, breast, lung, and many other human cancers, and its enzyme activity in cancer appears to relate to resistance to commonly used chemotherapeutic drugs, especially alkylating agents (222–224). Following intratumoral uptake of canfosfamide, drug activation and DNA damage ensue, which is followed by apoptosis. Myelosuppression is the principal toxicity of the agent (224,225). In a phase 2 study of canfosfamide in recurrent ovarian cancer, 5 (15%) of 34 evaluable patients had objective responses, including one complete response lasting longer than 3 years, and 12 (35%) patients had stable disease as their best response (226). Sixty percent and 40% of patients were alive at 12 and 18 months, respectively. However, a phase 3 study known as ASSIST-1, which enrolled 461 patients with advanced ovarian cancer that had progressed following first-line platinum-based therapy plus second-line treatment with either liposomal doxorubicin or topotecan, did not meet its primary endpoint of improving overall survival nor its secondary endpoint of improving progression-free survival (227). Patients were randomized to treatment with canfosfamide or either topotecan or liposomal doxorubicin, provided that they had not received prior treatment with these agents (227). Median survival on the canfosfamide arm was 8.5 months compared with 13.6 months on the active control arm ($p < 0.01$). Median progression-free survival was 2.3 months on the canfosfamide arm compared with 4.3 months on the active control arm. Based on more recent phase 2 study results, in which the combination of carboplatin plus canfosfamide resulted in an impressive rate of objective responses in heavily pretreated ovarian cancer patients whose disease had either progressed during or shortly after platinum-based treatment, the efficacy of canfosfamide plus liposomal doxorubicin is being compared to liposomal doxorubicin alone in second-line platinum-refractory or -resistant ovarian cancer in a phase 3 trial known as ASSIST-5 (228). In a preliminary analysis of the platinum-resistant subset, response rates were 31.5% and 10.5% in patients treated with canfosfamide plus liposomal doxorubicin alone, respectively. Median progression-free survival had not been reached for the combination, whereas it was 3.5 months for liposomal doxorubicin alone.

Targeting Immune Tolerance

Cytotoxic T-Lymphocyte-Associated Antigen 4

Many cancer-associated gene products that induce immune recognition, and are potential targets for therapeutic development against cancer but host immune reactions, rarely impact upon the progression of most advanced human cancers. The weak immunogenicity of nascent tumors contributes to this failure.

Therapeutic vaccines that enhance dendritic cell presentation of cancer antigens increase specific cellular and humoral responses, resulting in tumor destruction in some cases. The attenuation of T-cell activation by cytotoxic T-lymphocyte-associated antigen 4 (CTLA4) further limits the therapeutic impact of tumor immunity (229,230). CTLA4, a CD28-family receptor expressed mainly on CD4+ T cells, binds the same ligands as CD28 (CD80 and CD86 on B cells and dendritic cells), but with higher affinity than CD28 (229–232). However, in contrast to CD28, which enhances cell function when bound at the same time as the T-cell receptor, CTLA4 inhibits T-cell function. CTLA4 is also found intracellularly in regulatory T cells, which may be of functional significance. In experimental systems, the administration of antibodies that block CTLA4 function inhibits the growth of moderately immunogenic tumors, and in combination with cancer vaccines, augments the rejection of poorly immunogenic tumors, albeit with a loss of tolerance to normal differentiation antigens (229–232).

Various antibodies to CTLA4 are currently being evaluated in late-stage clinical trials in patients with advanced melanoma, and in phase 2 trials in patients with ovarian and other cancer types (231). These fully human antibodies include the IgG₁ construct ipilimumab (MDX-010; Medarex, Princeton, New Jersey, USA, and Bristol-Myers Squibb) and the IgG₂ construct ticilimumab (CP675,206; Pfizer). Patients with advanced malignant melanoma who received treatment with either of these CTLA4 antibodies have experienced tumor regression with prolonged time to progression, and objective anticancer activity has also been observed in patients with advanced lymphoma and ovarian, prostate, and renal cancers (231–238). Interestingly, antitumor activity is often characterized by short-term tumor progression followed by delayed tumor regression, and an important, possibly unique clinical observation is the protracted nature of both objective responses and stable disease. Adverse effects, including rash, colitis, and hepatitis, appear to be immune mediated and may represent breaking of tolerance to self-antigens (239). Interestingly, these toxicities have been directly related to time to tumor progression in high-risk melanoma patients who have undergone resection of their primary tumor (239).

Targeting Mitosis

Targeting Microtubules

Several natural products, which are structurally different from the taxanes but share mechanisms of action and show comparable activities, have been identified. The furthest along from a clinical development standpoint are the epothilones, which are 16-member macrolides derived from myxobacterium (240–245). Similar to the taxanes, the epothilones induce formation of microtubules that are long, rigid, and resistant to destabilization by cold temperature and calcium. The epothilones are at least as potent as the taxanes and induce mitotic arrest and microtubule bundling. Furthermore, these agents exert prominent cytotoxic activity in tumors with multidrug resistance conferred by overexpression of P-glycoprotein and other resistance proteins. Experimental studies have also indicated that the epothilones and taxanes differ in terms of resistance conferred by point mutations in β -tubulin; however, the significance of tubulin mutations in conferring clinical resistance to antimicrotubule agents is not clear. Several members of the epothilone B family, including epothilone B itself (patupilone; EPO-0906, Novartis) and the epothilone B analog ixabepilone (BMS-247550; Bristol-Myers Squibb), that are furthest along in

clinical development have demonstrated impressive activity against human xenografts derived from ovarian, breast, and colorectal cancers, many of which are clearly resistant to the taxanes (240–245). Objective antitumor activity has been noted in patients with many types of advanced cancer; however, notable activity has largely been restricted to tumor types that are known to be responsive to the taxanes. These include breast, ovarian, and non-small cell lung cancers, but activity has been noted in patients whose disease has failed to respond to treatment with taxane analogs (246–252). The most advanced studies of ixabepilone are in patients with metastatic breast cancer, and an impressive degree of clinical activity has been noted in breast cancer patients whose tumors are clearly refractory to taxanes (248). A phase 2 trial of patupilone in patients with ovarian cancer refractory to platinating agents has recently been completed and preliminary data indicate a modest degree of activity (247). Similarly, promising antitumor activity has been noted in ovarian cancer patients treated with other epothilone analogs, including major responses in 4 (31%) of 13 eligible ovarian cancer patients in first or second relapse and a platinum-free interval of less than 6 months following treatment with the fully synthetic epothilone B analog ZK-EPO (Scherring AG, Berlin, Germany) (240,252).

Other natural products and semisynthetic antimicrotubule agents that are in clinical development interact with tubulin in the Vinca-alkaloid or colchicine-binding domains (240,243). Among the best characterized are the dolastatins, which consist of a series of oligopeptides isolated from the sea hare *Dolabella auricularia* (253–255). Two of the most potent dolastatins, dolastatin-10 and -15, noncompetitively inhibit the binding of Vinca alkaloids to tubulin, inhibit tubulin polymerization and tubulin-dependent GTP hydrolysis, stabilize the colchicine-binding activity of tubulin, and have cytotoxic activity in the picomolar to low nanomolar range. Dolastatin-10 and the semisynthetic dolastatin analogs depsipeptide tasi-dotin (ILX651; Genzyme, Boston, Massachusetts, USA) and TZT-1027 (Daiichi, Tokyo, Japan), which bind in the Vinca domain, are undergoing clinical development (254–258).

Phomopsin A, halichondrin B, homohalichondrin B, and spongistatin 1, which competitively inhibit Vinca alkaloid binding to tubulin, are being evaluated in preclinical or early clinical evaluations (240,243,259–262). Halichondrin B (E7389; Eisai, Ridgefield Park, New Jersey, USA), a large polyether macrolide originally isolated from the marine sponge *Halichondria okadae*, and two less complex synthetic macrocyclic ketone analogs, ER-076349 and ER-086526, are in early clinical development (263,264). These compounds bind to tubulin, inhibit tubulin polymerization, disrupt mitotic spindle formation, induce mitotic arrest, and possess growth inhibitory properties in the subnanomolar range and show marked activity in preclinical studies. Experimental data also suggest that tumors expressing higher levels of the β III tubulin isotype may be more responsive to treatment with both E7389 and the hemiasterlin analog E7974 (Eisai). If confirmed clinically, such preclinical insights may lay the foundation for preferentially treating patients whose tumors may be particularly sensitive to these agents. E7389 has also demonstrated clinical activity in patients with recurrent metastatic breast cancer following treatment with taxanes, and clinical evaluations are ongoing in ovarian cancer and other malignancies. E7389 and HTI-286 (Wyeth), which are synthetic forms of the natural product hemiasterlin derived from a marine sponge (261,262), are also in clinical development (265,266). Hemiasterlin and its analogs bind to the Vinca-peptide site in tubulin, disrupt normal microtubule dynamics, and depolymerize microtubules. HTI-286 also appears to be a much weaker substrate for the P-glycoproteins than the Vinca alkaloids and taxanes (240,243,261,262).

Targeting Established Tumor Vasculature

Most efforts targeting the tumor vasculature are aimed at inhibiting tumor angiogenesis, but several antimicrotubule agents disrupt existing tumor vasculature (267–270). Since the late 1990s, the combretastatins and *N*-acetylcolchicinol-O-phosphate, which bind to the colchicine-binding domain on tubulin, have undergone clinical development as antivasculature agents. These agents include combretastatin-A-4 3-O-phosphate, combretastatin A-1-phosphate (Oxigene, Waltham, Massachusetts, USA), ZD6126 (AstraZeneca), and AVE8062A (Sanofi-Aventis). Although several of these agents have exhibited preliminary antitumor activity in early clinical evaluations, cardiovascular toxicity has been problematic. Another experimental agent, 5,6-dimethylxanthenone-4-acetic acid (DMXAA or ASA404; Antisoma, London, UK, and Novartis), a small molecule, has demonstrated robust antivasculature and antitumor activity in preclinical studies (270). DMXAA induces a cascade of events leading to the release of vasoactive substances, including serotonin, TNF, and nitric oxide, from host cells, as well as hemorrhagic necrosis in experimental tumor models (270). Clinical evaluations of DMXAA plus chemotherapy in patients with ovarian cancer and other cancer types are in progress (271).

Targeting Mitotic Kinesins

Although tubulin is the most abundant protein component of the mitotic spindle apparatus, many other proteins, particularly mitotic kinesins, play critical roles in the mechanics of mitosis and in progression through the premitotic cell cycle checkpoint. Kinesins are motor proteins that translate chemical energy released by the hydrolysis of adenosine triphosphate into mechanical force for movement along microtubules, transport of many types of cargo, and the intracellular organization of the mitotic spindle and other microtubule-containing structures (272–274).

The mitotic kinesins are a subgroup of kinesin motor proteins that function exclusively in mitosis in proliferating cells (272). During mitosis, different, highly specialized mitotic kinesins play critical roles in various aspects of mitotic spindle assembly, including the establishment of spindle bipolarity, spindle pole organization, chromosome alignment and segregation, and regulation of microtubule dynamics. The establishment of mitotic spindle bipolarity is among the earliest events in spindle assembly and it requires the kinesin motor protein KSP (also known as Eg5), which has no known role other than that played in mitosis (272). The low expression of KSP mRNA in normal tissues is consistent with preferential expression of KSP in proliferating cells relative to normal adjacent tissues. As essential elements in mitotic spindle assembly and function, KSP and mitotic kinesins provide attractive targets for intervention to thwart the cell cycle. A therapeutic targeting KSP may prove at least as effective as the taxanes and Vinca alkaloids without the potential for neurotoxicity or other adverse effects associated with interfering with tubulin function in nondividing cells. Furthermore, combinations of therapeutics targeting KSP and tubulin dynamics may exhibit additive or synergistic cytotoxicity. Ispinesib (SB-715992; Glaxo SmithKline, and Cytokinetics, South San Francisco, California, USA), a polycyclic, nitrogen-containing heterocycle, was the first KSP-targeting therapeutic to enter clinical trials (273). The agent, which is 10,000-fold more selective for KSP relative to other members of the kinesin superfamily, blocks assembly of functional mitotic spindles, thereby causing cell cycle arrest in mitosis and cell death (273). Ispinesib has demonstrated objective antitumor activity in patients with breast and ovarian cancers; however, activity

noted in ovarian cancer has been modest to date (275,276). Other KSP inhibitors, some of which have increased potency and/or specificity for KSP, including SB-743921 (Glaxo SmithKline and Cytokinetics), MK-0731 (Merck), ARRY-649 (Array Biopharma, Boulder, Colorado, USA), are in early clinical investigations (277–279).

Targeting Mitotic Kinases

Several mitotic kinases, particularly the aurora kinases, are being assessed as strategic targets for anticancer therapeutic development (274,280–284). The aurora kinases, which encompass three known family members known as aurora-A, -B, and -C, regulate chromosome segregation and cytokinesis during mitosis. Aberrant expression and activity of these kinases, which may lead to aneuploidy and tumorigenesis, occur in many types of human cancer. Additionally, aurora-A and -B kinases have distinct roles in mitosis. Aurora-A kinase, which is typically found in the pericentrosomal region, recruits several important components to the mitotic spindle, such as γ -tubulin, while the mitotic spindle is forming from the daughter centrosomes (285). In addition, aurora-A kinase is overexpressed in a large proportion of ovarian cancers and is associated with centrosome amplification and poor survival, rendering it a potential useful prognostic marker and therapeutic target (286). Alternatively, aurora-B kinase is localized to the interphase chromosomes proximal to the centromer, and as chromosome condensation occurs at the start of mitosis, both aurora-A and -B kinases share responsibility for phosphorylating histone H3 (274,280,281). In addition, both kinases have distinct roles in the function of the contractile ring that participates in the formation of two daughter cells. Aurora-C kinase appears to have a highly specialized, albeit as yet undetermined, role in mitosis. Recently, highly potent and selective small-molecule inhibitors of aurora-A and -B kinases, including VX-680 (also known as MK-0457, Cambridge, Massachusetts, USA), MLN-8054 (Millennium, Cambridge, Massachusetts, USA), AS703569 (R763) (Rigel Pharmaceuticals, South San Francisco, California, USA), and AZD1152 (AstraZeneca), which block cell cycle progression and induce apoptosis in experimental models of human cancer, have entered clinical development (287–290). Early results indicate that neutropenia is their principal toxicity.

Like the aurora family of kinases, the polo-like, Nek, and other kinase families participate in the centrosome cycle and modulate spindle function (274,280,282–284), while Bub1, BubR1, and Mps1 kinases regulate the spindle assembly checkpoint. Some members of these families, particularly the polo-like kinases, are being evaluated as potential targets for therapeutic intervention. Small-molecule inhibitors of polo-like kinase that are in early clinical development include BI2536 (Boehringer Ingelheim, Ingelheim, Germany) and ON01910.Na (Onconova, Lawrenceville, New Jersey, USA), and have demonstrated broad-spectrum antitumor activity against both solid and hematologic malignancy in preclinical studies, as well as synergistic activity when combined with some types of cytotoxic agents (291, 292).

RADIATION THERAPY: ADVANCES IN THE 21st CENTURY

Radiation therapy (RT) has been used in the treatment of gynecologic malignancies for more than a century (293). Over the years, numerous technologic advancements have been introduced, including high-energy (megavoltage) linear

accelerators, high-dose-rate (HDR) brachytherapy, and computed tomography (CT)-based treatment planning. These and other important innovations have markedly improved the quality and delivery of radiation in women with gynecologic tumors.

Despite such advancements, the basic approach to the planning and delivery of radiation in these patients has remained relatively unchanged. This is particularly the case with external beam RT. After determining the site to be treated, a limited number of treatment fields (typically two to four) are selected. Select variables (e.g., beam energy, weighting) are then altered iteratively, producing a treatment plan that irradiates the target tissues while avoiding, as best as possible, the nearby normal tissues. Finally, fields are shaped with customized blocks to further reduce the dose to neighboring normal tissues.

Intensity-Modulated Radiation Therapy

In recent years, a novel approach to the planning and delivery of radiation has been introduced, known as intensity-modulated RT (IMRT) (294,295). Unlike conventional RT approaches, IMRT conforms the radiation dose to the shape of the target tissues in three dimensions (3D), thereby sparing the nearby normal tissues. While used predominantly in patients with head and neck tumors and prostate cancer, increasing interest has been focused recently on IMRT in gynecology patients. In fact, in a recent practice survey of IMRT use in the United States (296), gynecologic tumors were the fourth most common site treated with IMRT, with 35% of respondents reporting having treated a gynecology patient.

The majority of the IMRT literature to date has focused on head and neck tumors and prostate cancer (297–300). In these sites, IMRT has been associated with lower rates of adverse treatment sequelae due to reductions in the volume of normal tissues irradiated. Reducing the irradiation of normal tissues has also allowed the delivery of higher than conventional doses, improving tumor control. The rationale underlying IMRT in gynecology patients is similar. Standard approaches result in the irradiation of considerable volumes of normal tissues, exposing women to a wide range of untoward sequelae, particularly related to the gastrointestinal tract (301,302). Sparing of normal tissues also allows the use of higher doses, an appealing approach in patients at high risk for locoregional recurrence (303,304). IMRT may also provide a means of treating cervical cancer patients unable to undergo brachytherapy, improving their chance of cure (305).

IMRT and Inverse Planning

IMRT is an advanced form of 3D conformal RT (3DCRT) that utilizes computer-optimized intensity-modulated beams to generate highly conformal dose distributions (306). Although first used in the 1990s, the concepts underlying IMRT are not new. In fact, IMRT was first proposed in the 1960s (307). Its implementation in clinical practice, however, had to await the development of sophisticated computerized optimization programs (308).

Unlike conventional approaches, IMRT planning is an *inverse* process whereby the treatment planner delineates the target and normal tissues on a planning CT scan (309). Specific dose-volume constraints are then entered for the target and normal tissues and the optimization program generates a treatment plan that best satisfies these goals. This approach is distinguished from the trial-and-error forward conventional planning method. Inverse planning is a powerful tool. Whereas conventional approaches result in an acceptable plan, inverse planning generates the optimal one.

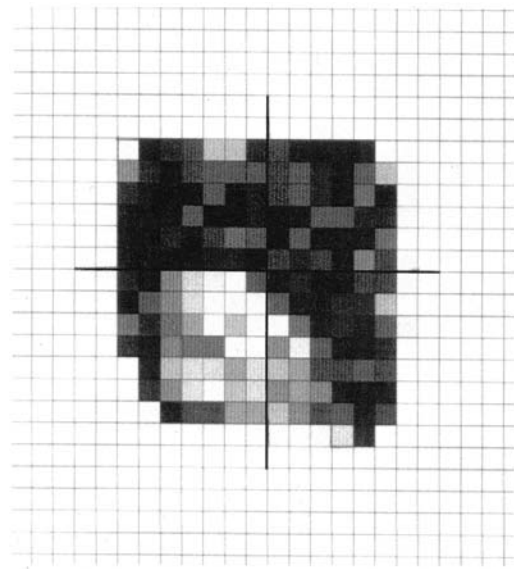

FIGURE 18.6. Intensity profile of an intensity-modulated radiation beam used in a patient with cervical cancer. Black regions represent areas of high intensity, and white regions represent areas of low intensity.

During the optimization process, each radiation beam is divided by the computer into small “beamlets” whose intensity is varied until the desired dose distribution is obtained. The resultant intensity profile of each beam is often quite complex and cannot be determined manually (Fig. 18.6). When cast into a patient, these intensity-modulated beams result in highly conformal dose distributions, which are nearly always superior to those achieved with conventional planning, particularly in patients with complex shaped targets (309). Such plans are distinguished by rapid dose gradients outside the target, resulting in considerable sparing of neighboring normal tissues (306). An example IMRT plan in a gynecologic patient is shown in Figure 18.7.

IMRT is typically delivered using a linear accelerator equipped with a multileaf collimator whose “leaves” (typically 0.5 to 1.0 cm in width) move in and out of the beam’s path under computer control (306,309). The longer the leaves remain open at a particular position, the greater the intensity of radiation. Other available approaches include helical Tomotherapy and customized compensators.

FIGURE 18.7. Example IMRT in a patient with cervical cancer undergoing posthysterectomy pelvic IMRT. Note that the high-dose isodose lines conform to the laterally situated internal and external iliac lymph nodes and the posteriorly situated presacral nodes.

PET-guided IMRT for cervical carcinoma with positive para-aortic lymph nodes—a dose-escalation treatment planning study. *Int J Radiat Oncol Biol Phys* 2003;55:28–35.

IMRT Process

The IMRT process begins at simulation. Unlike in conventional approaches, a contrast-enhanced planning CT scan is performed, typically using a CT simulator. Attention is focused on optimal patient immobilization, given the rapid dose gradients in IMRT plans (306). At the University of Chicago, an upper and lower body alpha cradle is fabricated and indexed to the treatment table for gynecology patients undergoing IMRT (310,311). Such an approach has improved patient setup accuracy. Patients at most centers are simulated and treated in the supine position. Others, however, favor prone positioning (312).

At simulation, bladder, rectal, oral, and intravenous contrast may be used to add in the visualization of the target and normal tissues. Intravenous contrast is particularly useful since the pelvic vessels serve as surrogates for the lymph nodes. A vaginal marker is placed to identify the vaginal cuff. Two targets are delineated on the planning CT: a gross target (GTV) and a clinical target (CTV) volume (313). The GTV consists of all visualizable tumor (primary and other sites including enlarged lymph nodes). Unfortunately, the primary tumor is often poorly visualized even when contrast is used. Ongoing work is evaluating the incorporation of other imaging modalities, for example, magnetic resonance imaging (MRI) and positron emission tomography (PET) (314), into the planning process to improve target delineation (Fig. 18.8).

The CTV in an individual gynecology patient undergoing IMRT is a function of the tumor site treated. In women receiving adjuvant intensity-modulated pelvic RT, the CTV consists of the upper vagina, parametria, presacral region, and pelvic lymph nodes (common, internal, and external iliacs) (310,311). Contrast-enhanced vessels are included with a 0.5- to 1.0-cm margin to cover the pelvic lymph nodes. In patients with an intact uterus, the entire uterus is often included. If more comprehensive volumes are treated, the CTV may also include the para-aortic (315) and/or inguinal (316) lymph nodes. The CTV is uniformly expanded at most centers by 1 cm in three dimensions, creating a planning target volume (PTV) to account for setup uncertainty and organ motion.

Normal tissues contoured on the planning CT scan may include the bladder, rectum, and small bowel. The bone marrow within the iliac crests is often outlined, particularly when chemotherapy is planned (317–320). Controversy exists whether the iliac crests alone should be contoured or all the pelvic bone marrow sites (317). Recent data have suggested that delineation of the active (red) marrow sites is possible by incorporating a technetium 99m scan in the planning process (Fig. 18.9) (321). Depending on the site treated, other normal structures may include the kidneys (315) and femoral heads (316).

IMRT planning continues with dose specification. In most gynecology patients undergoing pelvic IMRT, 45 Gy is delivered in 1.8-Gy daily fractions. Given the inherent inhomogeneities

of IMRT planning, larger fractions are not recommended. More complicated dose prescriptions are used in women undergoing a simultaneous integrated boost (SIB), where different parts of the target receive different daily (and total) doses (317,322). If the whole abdomen is treated, 30 Gy in 150-cGy daily fractions is recommended (311).

A more challenging task is the specification of dose-volume constraints for the PTV and normal tissues. Such constraints serve as input parameters used in the inverse planning optimization process and are entered in the form of dose-volume histograms (DVH), a graphical representation of the volume of an organ receiving a particular dose. Priority is given to PTV coverage. However, in all IMRT plans, a small percentage of the PTV may receive below the prescription dose. A common approach is to cover $\geq 98\%$ of the PTV with the prescription dose. Input parameters for the normal tissues are less intuitive. The parameters used in intensity-modulated whole pelvic radiation therapy (IM-WPRT) patients treated at our center were derived empirically over a number of years (Table 18.2). The goal for most normal tissues is to minimize the volume receiving high doses (323). In other organs, however, the volume receiving low doses may be equally or more important (319).

Albeit many aspects of IMRT planning are automated, one still selects the number of beams, and their angles and energy. Typically, seven or nine equally spaced coplanar beams are used (51.4- and 40.0-degree increments, respectively) delivered with 6- or 15-MV photons. Fewer beams result in poorer conformity; more beams do not improve the overall quality of the plan. At other centers, other beam configurations are used. In the future, beam number and configuration may be incorporated in the optimization process (324).

Using inverse planning, the treatment-planning computer then generates a dose distribution that best satisfies the input constraints. At most centers, a number of potential plans are generated by varying the input parameters. Plan evaluation and selection is a time-consuming process. Each plan is evaluated qualitatively slice by slice for dose conformity and the presence and magnitude of hot and cold spots. Each plan is also evaluated quantitatively by assessing the PTV and normal tissue DVHs. A reasonable approach is to ensure that $\geq 98\%$ of the PTV receives the prescription dose. Cold spots should only be considered acceptable along the periphery of the PTV; they are never acceptable within the CTV, particularly within the GTV. Similarly, hot spots should be minimized, particularly along the anterior rectal and posterior bladder walls in patients subsequently undergoing brachytherapy.

Both before and during IMRT, rigorous quality assurance (QA) is essential. A full discussion of QA procedures used in these patients is beyond the scope of this text and interested readers are referred elsewhere (311). Several QA procedures including independent monitor unit checks and verification of calculated IMRT dose distributions using both phantom and film dosimetry have been proposed.

TABLE 18.2

INPUT PLANNING PARAMETERS FOR IM-WPRT PATIENTS, UNIVERSITY OF CHICAGO

	Goal (Gy)	Volume below goal (%)	Minimum (Gy)	Maximum (Gy)
PTV	45	3	42.8	47.3
Organ	Limit (Gy)	Volume above limit (Gy)	Minimum (Gy)	Maximum (Gy)
Bladder	35.1	40	27.9	42.8
Rectum	35.8	54	27.5	42.8
Small bowel	38.1	0	8.2	42.8

Note: IM-WPRT, intensity-modulated whole pelvic radiation therapy; PTV, planning target volume.

Preclinical Data

Numerous investigators have compared IMRT and conventional planning in gynecologic patients, demonstrating the benefits of IMRT planning. Of note, most have focused on women undergoing pelvic irradiation in an attempt to reduce the volume of small bowel irradiated. Representative studies are summarized in Table 18.3.

Roeske et al. (310) compared conventional and intensity-modulated pelvic RT plans in ten gynecologic patients. Although PTV coverage was similar, the volume of small bowel receiving the prescription dose in the IMRT plans was decreased by a factor of two (17.4% vs. 33.8%; $p = 0.0005$) compared with the conventional approach. The volumes of rectum and bladder irradiated were also reduced by 23%. Other investigators have reported reductions in small bowel irradiation using IMRT planning ranging from 40% to 70% (326–328). Marked reductions in the volume of bladder and rectum irradiated have also been reported (328).

While most attention has been focused on small bowel sparing, Lujan et al. (317) demonstrated that IMRT planning could also minimize the volume of pelvic bone marrow irradiated in gynecology patients undergoing pelvic RT (Fig. 18.10). Bone marrow (within the iliac crests) was contoured in ten women and added as a constraint in the planning process. Although the volume receiving 10 Gy was slightly increased, IMRT planning reduced the bone marrow volume treated at all dose levels above 15 Gy, an important finding given the exquisite radiosensitivity of bone marrow. Of note, the addition of bone marrow as a constraint did not compromise PTV coverage or the sparing of other normal tissues.

Several investigators have evaluated IMRT planning in gynecologic patients treated with more comprehensive fields. In ten locally advanced cervical cancer patients undergoing extended field (pelvic plus para-aortic) RT, Portelance et al. (315) noted significant reductions in the small bowel, bladder, and rectum using IMRT planning compared to conventional two- or four-field approaches. Hong et al. (329) evaluated IMRT planning in ten endometrial cancer patients undergoing whole abdomen radiation therapy (WART). PTV coverage was improved, particularly near the kidneys (under the conventional blocks). Moreover, the volume of pelvic bones (and thus bone marrow) receiving 21 Gy or higher was reduced by 60% (Fig. 18.11). Duthoy et al. similarly noted a benefit to IMRT planning in gynecology patients undergoing WART (328).

Several IMRT studies have focused on gynecologic patients undergoing pelvic-inguinal RT. In vulvar cancer patients, Beriwal et al. (330) noted improved sparing of the small bowel

and rectum using IMRT. Garofalo et al. (316) reported that IMRT planning reduced the volume of all normal tissues irradiated, including the small bowel, bladder, rectum, and bone marrow. Of particular note, the dose to the femoral heads was also significantly reduced. In contrast, Gilroy et al. (331) noted that higher doses to the pelvic tissues and greater setup complexity were seen with IMRT. However, the sole goal of this study was to reduce the dose to the femoral heads. No attempt was made to spare the small bowel and other pelvic tissues.

IMRT has also been evaluated as a means to deliver higher than conventional doses in gynecology patients. Lujan et al. (320) found that dose escalation was feasible using an SIB technique in patients with involved pelvic nodes, without compromising normal tissue sparing. Mutic et al. (314) proposed a PET-guided SIB approach to irradiate involved para-aortic lymph nodes in advanced cervical cancer patients. In their exploratory study, 59.4 Gy could be delivered to PET-positive para-aortic nodes, while maintaining acceptable doses to the normal tissues. Kavanagh et al. (322,332) presented an SIB technique to treat the primary tumor and/or involved lymph nodes to higher dose in cervical cancer patients. Others have reported similar results using the SIB approach in patients with involved para-aortic lymph nodes (333).

IMRT as an alternative for brachytherapy has received considerable attention (305,334). In cervical cancer patients unable to receive brachytherapy, Roeske and Mundt (335) found that a total dose of 75 Gy or higher was feasible with IMRT. Select patients could receive doses as high as 81 Gy to the residual tumor. Low et al. (336) proposed a technique known as applicator-guided IMRT as a replacement for brachytherapy. As envisioned, an applicator would be placed in the cervix to localize the tumor and reproducibly position the bladder and rectum during treatment. MRI and/or PET imaging would be used to delineate the tumor with treatment delivered using conventional HDR dose schedules.

Clinical Studies

Mundt et al. (337,338) have provided a series of detailed analyses of acute gastrointestinal toxicity in gynecology patients undergoing intensity-modulated pelvic RT. In their most recent analysis (338), acute gastrointestinal sequelae were compared in 40 IMRT and 35 conventional RT patients, with the two groups well balanced in terms of tumor site, stage, surgery, radiation dose, and chemotherapy. IMRT was found to be associated with less grade 2 or higher acute gastrointestinal toxicity (60% vs. 91%; $p = 0.002$) than conventional RT. Moreover, the percentage of IMRT and conventional pelvic RT patients requiring no (or only infrequent) antidiarrheal

medications was 75% and 34%, respectively ($p = 0.001$). Although less urinary toxicity (10% vs. 20%) was observed, this difference failed to reach statistical significance ($p = 0.22$).

These investigators have recently evaluated chronic gastrointestinal toxicity in a cohort of 30 gynecology patients treated with intensity-modulated pelvic RT with a median follow-up of 19.6 months (339). Compared to conventional pelvic RT

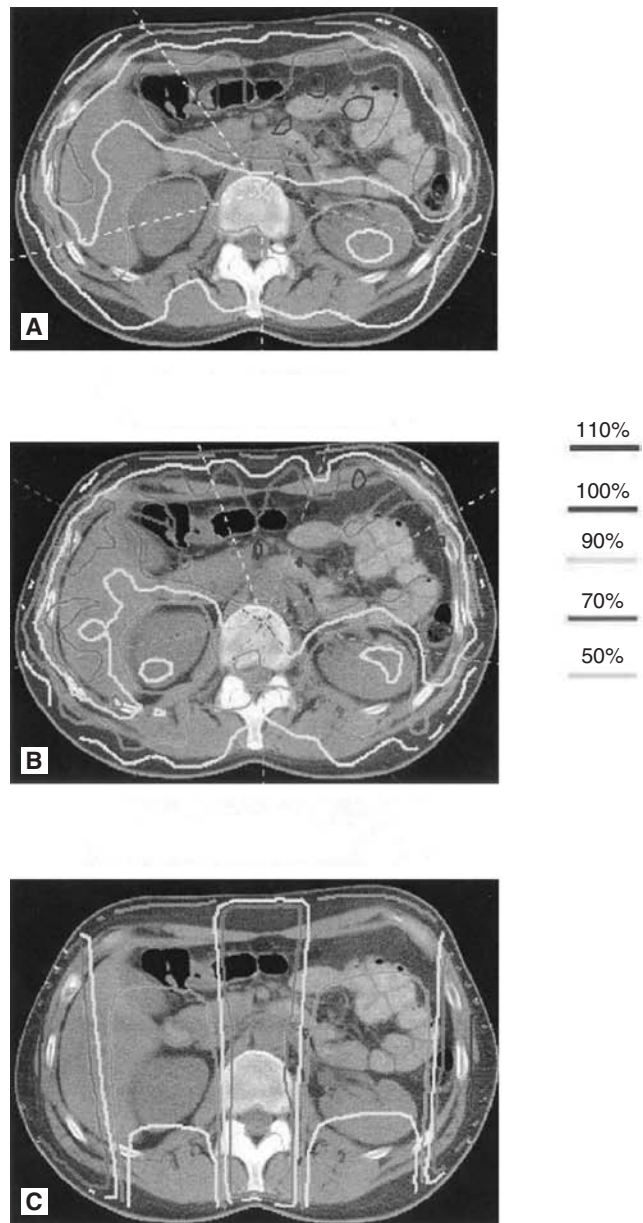

FIGURE 18.11. (See color plate section.) IMRT and conventional plan comparison in a gynecology patient treated with whole abdominal irradiation. A: IMRT plan with five gantry angles. patients, IMRT patients experienced less chronic gastrointestinal sequelae (11.1% vs. 50.0%; $p = 0.001$). On multivariate analysis controlling for age, stage, chemotherapy, surgery, and length of follow-up, IMRT was correlated with less chronic toxicity ($p = 0.01$; odds ratio [OR] 0.16; 95% CI, 0.04 to 0.67).

Others have similarly reported favorable acute and chronic toxicity profiles in gynecology patients undergoing IMRT (340), even those treated to more comprehensive volumes (341,342). For example, Gerszten et al. treated 22 locally advanced cervical cancer patients with a SIB IMRT technique (341). PET-positive para-aortic lymph nodes received 55 Gy in 2.2-Gy fractions, while the remainder of the pelvis and para-aortic regions received 45 Gy in 1.8-Gy fractions. All patients received concomitant cisplatin. No patient developed grade 3 or

higher acute sequelae. Grade 2 or higher acute gastrointestinal and genitourinary toxicity was noted in 10% and 10% of patients, respectively.

Brixey et al. (318) compared the acute hematologic toxicity in women undergoing intensity-modulated versus conventional pelvic RT. Whereas sequelae were infrequent in RT alone patients, conventional RT patients treated with concomitant chemotherapy developed more grade ≥ 2 leukopenia (60% vs. 31.2%; $p = 0.08$) and a lower white blood cell count nadir (2.8 vs. 3.6; $p = 0.05$) than IMRT plus chemotherapy patients. The conventional RT patients also developed a lower absolute neutrophil count nadir (1,874 vs. 2,669; $p = 0.04$). Of note, these benefits were realized even though bone marrow was not entered as a constraint in the planning process, but was simply spared owing to the highly conformal nature of the IMRT plans.

In a recent analysis, Mell et al. (319) reported the importance of sparing all pelvic bone marrow sites in gynecology patients undergoing concomitant chemotherapy and pelvic IMRT, not simply the bone marrow within the iliac crests. Patients in whom the total pelvic bone marrow receiving 10 Gy or higher (V_{10}) was $>90\%$ had a higher rate of grade ≥ 2 leukopenia (73.7% vs. 11.1%, $p < 0.01$) compared to those in whom the pelvic bone marrow V_{10} was $<90\%$. The corresponding rates of having one or more chemotherapy cycles held were 47.4% and 16.7%, respectively ($p = 0.08$).

As gynecologic IMRT matures, an increasing number of studies focused on tumor control have been published. Knab et al. (343) treated 31 stage I-III endometrial cancer patients with adjuvant intensity-modulated pelvic RT following hysterectomy. At a median follow-up of 24 months, no pelvic recurrences were seen. Similarly, Beriwal et al. (340) noted no pelvic failures in 47 endometrial cancer patients undergoing adjuvant intensity-modulated pelvic RT at a median follow-up of 20 months.

Two series have reported the outcomes of intact cervical cancer patients undergoing IMRT (344,345). Kochanski et al. treated 44 stage IB-IIIb cervical cancer patients with intensity-modulated pelvic RT (nearly all received concomitant chemotherapy) followed by intracavitary brachytherapy (344). At a median follow-up of 23 months, the 3-year actuarial pelvic control in the stage I-IIa and stage IIB-IIIb patients was 93% and 53%, respectively. Beriwal et al. (345) reported an 80% pelvic control rate in 36 stage IB-IVA cervical cancer patients at a median follow-up of 18 months.

Excellent pelvic control rates have been reported in cervical cancer patients undergoing IMRT following radical hysterectomy. In a series of 18 clinical stage I-II patients (many with positive pelvic lymph nodes) treated with adjuvant pelvic IMRT, Kochanski et al. (344) reported a 3-year pelvic control of 94%. Chen et al. (346) noted a 93% pelvic control in a similar group of patients treated with intensity-modulated pelvic RT, all of whom received concomitant chemotherapy.

Based on these promising results, the Radiation Therapy Oncology Group (RTOG) has launched a multi-institution phase 2 trial (RTOG 0418) evaluating the tolerance and efficacy of IMRT in gynecology patients following hysterectomy. The results of this important trial will help establish the role of IMRT in these women.

Future Directions

Just as IMRT is becoming increasingly accepted in gynecologic cancer patients, the next revolution has begun, namely, *image-guided* RT (IGRT). IGRT involves the use of imaging to improve target delineation and treatment delivery.

In terms of its role in target delineation, as described earlier in this chapter, promising approaches have been developed incorporating PET (314,333) and SPECT (321) in the IMRT

planning process. PET may be extended to the planning of brachytherapy in cervical cancer patients (347). MRI may also prove beneficial (348), in particular, nanoparticle-enhanced MRI techniques to improve the delineation of pelvic lymph node regions (Fig. 18.12) (348).

Numerous vendors have recently introduced in-room imaging solutions allowing patients to be imaged daily in the treatment room on the treatment table immediately prior to treatment. Several vendors have developed on-board imaging devices, consisting of x-ray imagers mounted to the linac gantry providing the means to generate high-quality planar and volumetric images (Fig. 18.13). Such techniques may substantially improve the ability to accurately align patients on the table, reducing the need for large safety margins around the target tissues. More importantly, daily imaging may address concerns about internal organ motion, particularly in patients with an intact uterus undergoing IMRT (349).

Perhaps the most exciting application of IGRT, however, is the potential to *adapt* treatment to changes in the tumor during treatment. It is well known that cervical cancers respond rapidly during pelvic RT. Consequently, the highly conformal IMRT plans generated *prior* to treatment may no longer be optimal *during* therapy. Van de Bunt et al. illustrated this problem by performing MRI scans on 14 cervical cancer patients undergoing definitive irradiation prior to treatment and after 30 Gy (349). On average, the cervical tumor decreased by 46% in size (Fig. 18.14). Replanning significantly improved the sparing of the rectum in these patients. Moreover, in patients with bulky cervical tumor (>30 cc), replanning also improved sparing of the small bowel.

The clinical application of adaptive IGRT approaches is not yet ready for prime time. Numerous hurdles need to be first overcome. For example, rapid and accurate automated segmentation programs are needed. Moreover, deformable image registration programs are required to allow doses to be accurately calculated as the anatomy changes. Finally, additional computational power is also needed to allow segmentation, deformable registration, and reoptimization to be performed in a timely fashion, preferably while the patient is on the treatment table. All of these topics are currently the subject of active research.

Conclusion

IMRT represents a true revolution in the treatment of gynecologic tumors. Preclinical and clinical data have been extremely promising to date, suggesting that IMRT can improve the planning and delivery of radiation in these patients. Nonetheless, carefully designed prospective clinical trials are needed to fully ascertain the potential benefits and risks of IMRT in gynecology patients. Attention is now turning to IGRT approaches, both to improve target delineation and treatment delivery, in patients undergoing IMRT. It is hoped one day that true adaptive image-guided IMRT will be a reality in these patients.

ADVANCES IN FERTILITY-SPARING SURGERY

Minimally invasive and laparoscopic surgery for gynecologic oncology are discussed in detail in other chapters. The utility of advanced operative laparoscopy in gynecologic oncology expanded following advancements in laparoscopic retroperitoneal surgery, particularly pelvic and aortic lymphadenectomy. The performance of a laparoscopic retroperitoneal dissection opened the door for more advanced laparoscopic gynecologic cancer applications and operations, including the

FIGURE 18.12. (See color plate section.) Guidelines for CTV delineation for gynecologic tumors to cover the common iliac (CI), subaortic presacral (PS), internal iliac (II), obturator (Ob), and medial (EIm) and anterior (EIa) external iliac lymph nodes based on nanoparticle-directed MR imaging. *Source:* Printed with permission from Taylor A, Rockall AG, Reznick RH, et al. revival of radical vaginal surgery (350) and the complete laparoscopic management and staging of selected patients with a variety of gynecologic malignancies. The potential oncologic effects of laparoscopy and pneumoperitoneum will continue to be debated (351); however, the results from emerging clinical trials and published retrospective series are reassuring.

Fertility-Sparing Radical Trachelectomy for Stage I Cervical Cancer

This operation is a major innovation in the surgical therapy of early cervical cancer, and the laparoscopic/vaginal approach is described well under the laparoscopy chapter in this book.

Although the concept of a radical abdominal trachelectomy was described and performed on women with cervical cancer by Aburel in Rumania in the last century (352,353), the

abdominal procedure initially did not become popular, and fertility-sparing surgery in cervical cancer remained limited to conization for women with very early lesions and a strong desire to retain reproductive function. The radical vaginal approach to trachelectomy was developed by Professor Daniel Dargent in 1987 in France (354). It is a modification of the radical vaginal hysterectomy with two main purposes: treat early cervical cancer, and preserve uterine morphology and reproductive function. One of the main advantages in learning the radical vaginal hysterectomy is that the experience gained allows the surgeon to offer radical trachelectomy to selected young women with early invasive cervical cancer who wish to preserve their fertility (355). To date, several series are available in the English literature to document feasibility and safety, and many healthy births have been documented in women treated for early cervical cancer with this approach, including a case of pregnancy after radical trachelectomy and pelvic irradiation (356). The general eligibility criteria for

FIGURE 18.13. Varian Medical Systems on-board imaging (OBI) system with the electronic portal imaging device (EPID) mounted at right angles to the megavoltage beam.

radical vaginal trachelectomy vary but may include women age less than 44 with a very strong desire to preserve fertility, no clinical evidence of impaired fertility, lesion size less than 3 cm, FIGO stage IA-IB1 lesions, no involvement of the upper endocervical canal, and negative regional lymph nodes (357).

In a series of 96 radical trachelectomies performed between April 1987 and May 2002 at Hospital Edouard Herriot in Lyon, France, one second cancer (bilateral suprarenal glands cancer) and four recurrences were observed (358). The retrospective

unifactorial analysis demonstrated that the maximal tumoral diameter (2 cm or more) and the depth of infiltration (1 cm or more) were the only two significant factors of risk. Age less than 30 years and the presence of lymphovascular space involvement were likely to be risk factors, but the level of statistical significance was not reached. Histology other than squamous, infiltration of the parametrium, and involvement of the vaginal cuff had no prognosis impact. The chances for recurrence were 19% for patients affected by a tumor 2 cm or more and 25% for the patients affected by a tumor 2 cm or more with a depth of infiltration 1 cm or more (358).

Technique of Radical Vaginal Trachelectomy

A laparoscopic pelvic with or without para-aortic node dissection is completed and multiple frozen sections are obtained from selected nodal packages and any suspicious nodes. Once all frozen sections are negative the vaginal component is started.

Cystoscopy and the insertion of bilateral temporary retrograde ureteral catheters are at the surgeon's discretion (359). The catheters may help identify the ureters in difficult cases and are removed at the end of the procedure. If there is concern of ureteral injury, the catheter can be changed over a guide wire to a double-J stent. The stent may be left in place for 4 to 6 weeks.

The radical vaginal trachelectomy is begun by delineating an adequate vaginal margin (usually 1 to 2 cm). Eight Kocher clamps are placed circumferentially around the cervix on the vaginal mucosa. A dilute solution of vasopressin is used to liberally inject the vaginal mucosa between the Kocher clamps (Fig. 18.15). This step helps separate the planes of dissection.

The assistants place two Brieski vaginal wall retractors at the 2 and 10 o'clock positions. A scalpel is now used to circumferentially incise the vaginal mucosa. The lateral incisions are shallow and the anterior and posterior incisions are deep. The

FIGURE 18.14. (See color plate section.) Delineation on magnetic resonance images of a patient with cervical cancer undergoing definitive RT: (A) pretreatment sagittal, (B) intratreatment sagittal, (C) pre-treatment axial, and (D) intratreatment axial. Note the significant decrease in size of the bulky central cervical tumor. Source: Reprinted with permission from van de Bunt L, van der Heide UA, Katelaars M, et al. Conventional, conformal and intensity-modulated radiation therapy treatment planning of external beam radiotherapy for cervical cancer: the impact of tumor regression. *Int J Radiat Oncol Biol Phys* 2006;64: 189–196.

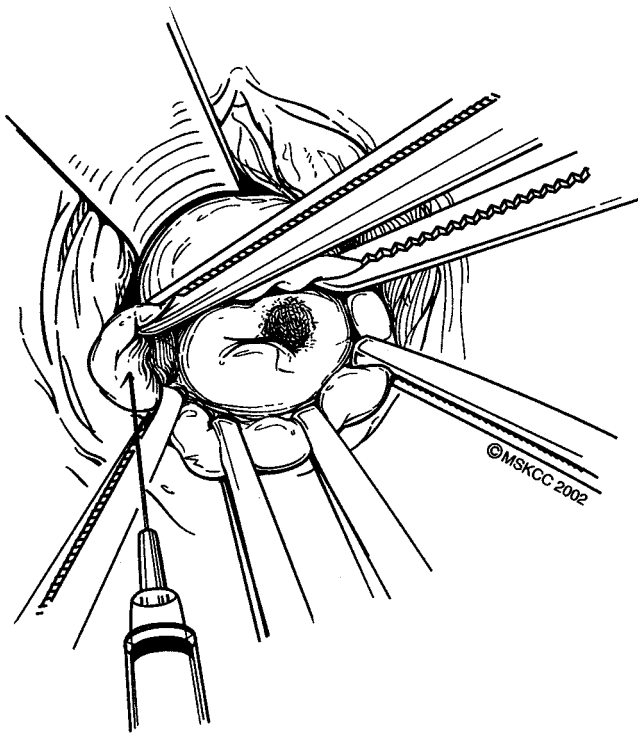

FIGURE 18.15. Preparing the vaginal margin.

shallow lateral incisions allow traction to be put on the parametria and pulled downward.

The Kocher clamps can now be removed, and the anterior and posterior vaginal mucosa can be folded over the ectocervix. The Krobach clamps are aligned horizontally to keep the ectocervix covered (Fig. 18.16).

The posterior cul de sac can now be sharply entered (Fig. 18.17). This allows the uterosacral ligaments to be isolated and the inferior portion of this ligament can be divided. By releasing the posterior attachments there is greater uterine descensus, which is helpful for the more difficult anterior dissection.

FIGURE 18.16. Incising the vaginal mucosa.

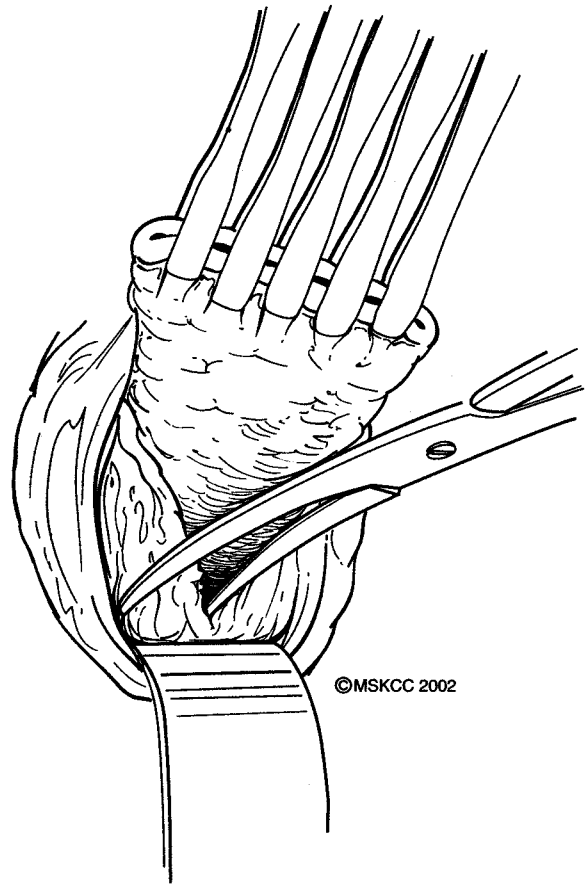

FIGURE 18.17. Posterior colpotomy.

The anterior portion of the dissection begins with sharply developing the vesicouterine space. The posterior vaginal retractor is removed, and the downward traction is placed on the specimen with the Krobach clamps. During this portion of the procedure, the surgeon should keep the axis of the scissors perpendicular to the axis of the vagina. This maneuver helps avoid tunneling into the bladder. Once the vesicouterine space is developed, the paravesical spaces must be opened. The left paravesical space is opened by placing two Kocher clamps on the vaginal mucosa at the 1 and 3 o'clock positions. By doing such, a small dimple is noted in between the two Kocher clamps. The Metzenbaum scissors are used to gently spread this dimple, tunnel under the vaginal mucosa, and enter the left paravesical space. The tissue between the paravesical and vesicouterine space is the left bladder pillar. The knee of the left ureter can now be palpated in the left bladder pillar (Fig. 18.18).

The inferior aspect of the left bladder pillar can now be transected. This frees the knee of the left ureter and allows it to be pushed superiorly. After doing such, two curved Heaney clamps can be placed across the parametrium to obtain an adequate margin. The parametrium is now divided between the two clamps, and the pedicle is secured with a suture ligature. The cervicovaginal branch of the left uterine artery is doubly clamped, divided, and secured with a suture ligature (Fig. 18.19).

The procedures of opening the paravesicle space, dividing the inferior aspect of the bladder pillar, and dividing the parametrium and cervicovaginal branch of the uterine artery are repeated on the right side. Once the branches of the uterine

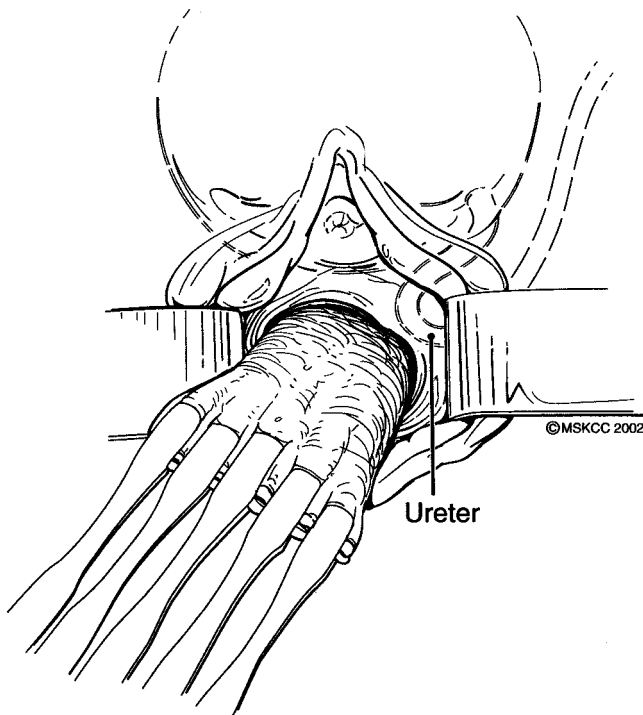

FIGURE 18.18. Identifying the ureter.

artery have been secured, the cervix can be amputated. An endocervical and endometrial curettage is performed, and frozen-section analysis is performed on the endocervical margin and endocervical/endometrial curettage. It is preferable to leave one centimeter of cervical stump to place a cerclage with permanent suture (Fig. 18.20).

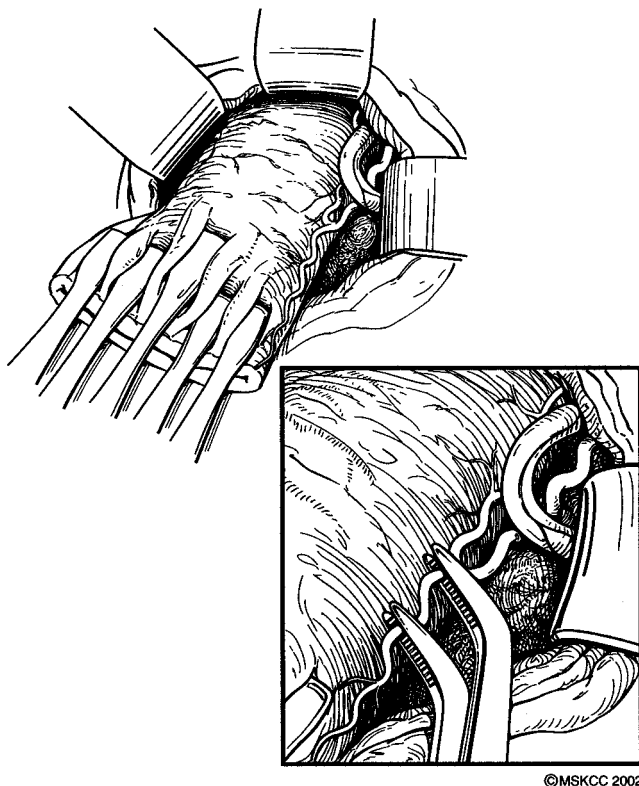

FIGURE 18.19. Ligating the paracervical vessels.

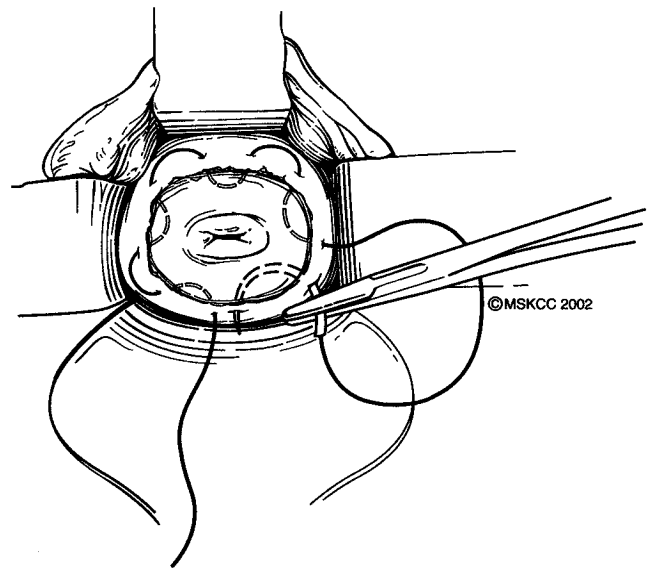

FIGURE 18.20. Inserting permanent cerclage.

The vaginal mucosa can now be reapproximated to the cervical stump to complete the vaginal portion of the procedure. Laparoscopy is the final step in the procedure to ensure pelvic hemostasis.

Fertility-Sparing Radical Abdominal Trachelectomy for Cervical Carcinoma

Technique of Fertility-Sparing Radical Abdominal Trachelectomy

A laparotomy and a bilateral complete pelvic lymphadenectomy are performed usually via a transverse lower abdominal incision in a similar manner to patients undergoing a radical abdominal hysterectomy. The limits of nodal dissection are the deep circumflex iliac vein caudally and the proximal common iliac artery cephalad. Any suspicious lymph nodes are sent for frozen-section analysis. A fertility-sparing approach should be abandoned if positive lymph nodes are identified. Sentinel lymph node identification is also a reasonable option and may allow for pathologic ultrastaging of these sentinel nodes. The removal of para-aortic nodes is also considered for lesions of stage IB1 or greater.

The intent of the radical abdominal trachelectomy is to resect the cervix, upper 1 to 2 cm of the vagina, parametrium, and paracolpos in a similar manner to a type III radical abdominal hysterectomy but sparing the uterine fundus or corpus (Figs. 18.21 and 18.22).

The procedure is begun by developing the paravesical and pararectal spaces and dissecting the bladder caudal to the mid vagina. The round ligaments are divided and large Kelly clamps are placed on the medial round ligaments to manipulate the uterus. Care is taken not to destroy the cornu or the utero-ovarian pedicles. The infundibulopelvic ligaments with ovarian blood supply are kept intact. Care is also taken not to injure the fallopian tubes or disrupt the utero-ovarian ligament. The uterus is manipulated with clamps at the round ligaments or using a Collin-Buxton-type clamp (Fig. 18.23).

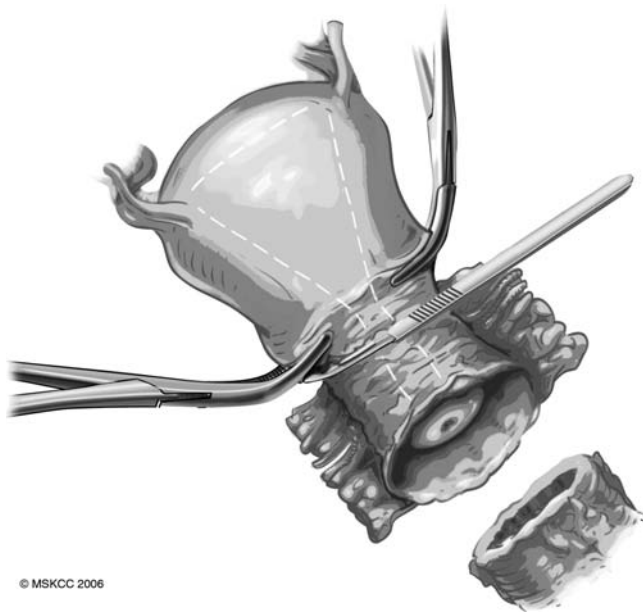

The uterine vessels are then ligated and divided at their origin from the hypogastric vessels. The parametria and paracolpos with uterine vessels are mobilized medially with the specimen, and a complete ureterolysis is performed similar to

FIGURE 18.21. The intent of the radical abdominal trachelectomy is to resect the cervix and upper 1 to 2 cm of the vagina.

a type III radical abdominal hysterectomy. The posterior cul de sac peritoneum is incised and the uterosacral ligament divided; similarly, the parametria and paracolpos are divided. Using a vaginal cylinder (Apple Medical Corporation, Marlborough, Massachusetts, USA), the desired length of vaginectomy is performed, and the specimen is completely separated from the vagina (Fig. 18.24) and placed in the mid pelvis, keeping its attachment to the utero-ovarian ligaments. Alternatively, a Wertheim clamp can be placed at the desired length of the vagina and the specimen separated (Fig. 18.25).

FIGURE 18.22. The intent of the radical abdominal trachelectomy is to resect the cervix and upper 1 to 2 cm of the vagina, parametrium, and paracolpos in a similar manner to a type III radical abdominal hysterectomy, but sparing the uterine corpus.

FIGURE 18.23. (See color plate section.) The uterus is manipulated by clamps on the round ligaments, avoiding the utero-ovarian pedicles or using a Collin-Buxton-type clamp.

FIGURE 18.24. (See color plate section.) After completely separating the parametria, ligating the uterine vessels at their origins, and completing the ureterolysis, an anterior colotomy is performed, facilitated by a vaginal cylinder (Apple Medical Corporation, Marlborough, Massachusetts, USA).

FIGURE 18.25. (See color plate section.) Alternatively, a Wertheim clamp can be used to determine the vaginal resection margin.

FIGURE 18.26. Estimating the resection margin of abdominal trachelectomy.

The lower uterine segment is then estimated (Fig. 18.26), and clamps are placed at the level of the internal os. Using a knife, the radical trachelectomy is completed by separating the fundus from the isthmus or upper endocervix at approximately 5 mm below the level of the internal os, if possible (Figs. 18.27 and 18.28).

The uterine fundus with preserved attachments to the utero-ovarian ligaments, placed in the superior part of the pelvis, and the specimen, consisting of radical trachelectomy and parametria with suture marking the vaginal cuff at 12 o'clock, is sent for frozen-section marking evaluation of its endocervical margin. The uterine fundus is inspected and curettage of the endometrial cavity is performed as well as a shave disc margin on the remaining cervical tissue, which is sent for frozen-section analysis (Fig. 18.29A). This is performed to ensure that the reconstructed uterus to vagina is disease free. A frozen-section analysis is also obtained on the distal vaginal margin, if clinically indicated (Fig. 18.29B–C).

FIGURE 18.27. Clamps are placed at the level of the internal os.

FIGURE 18.28. (See color plate section.) Using a knife, the radical trachelectomy is completed by separating the fundus from the isthmus or upper endocervix at approximately 5 mm below the level of the internal os, if possible.

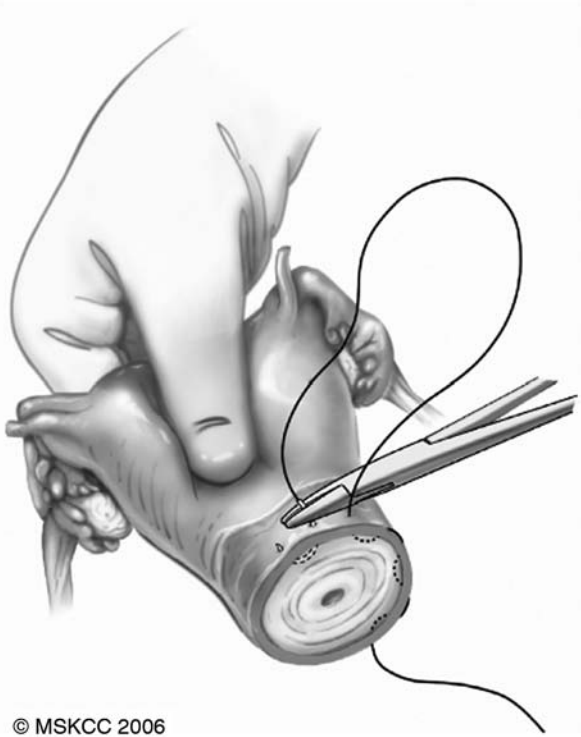

FIGURE 18.29. (See color plate section.) **A:** Endometrial and upper endocervical curettage as well as a shave margin on the remaining tissue, which is sent for frozen-section analysis prior to reconstruction. **B:** Frozen section is obtained on the endocervical margin. **C:** Frozen section is obtained circumferentially on the vaginal cuff, if needed.

FIGURE 18.30. A permanent cerclage with #0 Ethibond on a Ferguson needle is placed.

If all frozen sections tested are benign and at least a 5 mm clear margin is obtained on the endocervical edge, a permanent cerclage with #0 Ethibond on a free Ferguson needle (knot tied posteriorly) may be placed prior to the reconstruction (Figs. 18.30 and 18.31). The uterus is reconstructed to the upper vagina with six to eight #2-0 absorbable sutures (Figs. 18.32–18.34). No drains are placed. Standard antibiotic prophylaxis and routine postoperative care are prescribed.

An alternative approach would be to separate the fundus from the cervix prior to the colpotomy, pack the fundus with the intact utero-ovarian blood supply in the upper pelvis,

FIGURE 18.31. Once the permanent cerclage is placed, the knot is tied posteriorly.

© MSKCC 2006

FIGURE 18.32. Reconstruction of the uterine corpus to upper vagina after the cerclage is placed.

place retraction clamps on the cervix, and perform the radical trachelectomy. The role of cystourethroscopy with bilateral temporary ureteral catheterization is optional.

ROBOTICALLY ASSISTED LAPAROSCOPIC SURGERY

The etymology of the word robot is from Czech (*robota*) meaning compulsory labor. The word robot was first introduced in Karel Capel's play "Rossum's Universal Robots" in Prague in 1921 (360).

FIGURE 18.33. (See color plate section.) The uterine fundus is reattached to the vaginal apex with six to eight interrupted #2-0 absorbable sutures.

FIGURE 18.34. (See color plate section.) The reconstructed fundus with remaining blood supply from the intact utero-ovarian ligaments—uterine serosa without evidence of fundal ischemia.

Industry has used mechanical robots successfully for fine, delicate, repetitive tasks for decades. Recently, robots have been introduced into clinical medicine and surgery. The initial devices in the 1980s were used for stereotactic biopsies and neurosurgery; however, currently more advanced systems are routinely being used in cardiac, thoracic, orthopedic, urologic, general, and gynecologic surgery.

Voice activation of some types of equipment in the operating room, such as the laparoscope or the light source, has also become commonly available, and advances in computer software have allowed a computer controller to translate a surgeon's movements from the handles located in a console to the robotic arms that hold the surgical instruments. This remote console may be placed away from the surgical field.

Telerobotic surgery refers to the utilization of a surgical system where the robot is manipulated by input devices under the surgeon's control and the surgeon may be remote from the operating room. The approved telerobotic devices in the United States that are used in gynecologic surgery are the Intuitive Surgical daVinci System and the Computer Motion AESOP (automated endoscopic system for optimal positioning) system. The ease of accomplishing difficult tasks and the potential advantages over traditional laparoscopy are partly due to the increased number of degrees of freedom, the vividness of the three-dimensional imaging, band filtration with more precision, and less tremor. In addition, the sitting position provides improved ergonomics and comfort by recreating the eye-hand motor axis.

On the other hand, the potential disadvantages of the current models are size and weight, limitation in surgical field, cost, limited trocar and energy source options, and absence of haptics (no sense of force feedback from the instruments).

Animal trials in telerobotic surgery have demonstrated favorable results. Robotic technology has the potential to make laparoscopic microsuturing easier. Robotics have been used to perform uterine horn reanastomosis in a live porcine model, and this application appeared safe in creating laparoscopic microsurgical anastomoses with adequate lumen patency rates achieved during the acute phase and at 4-weeks follow-up (361). In another pilot animal study, the feasibility and safety of using a robotic device "Zeus" to perform complex gynecologic surgery such as adnexectomy and hysterectomy in ten female pigs was undertaken. After 1 week of observation the animals were sacrificed and the surgical site

was explored. The procedures were uneventful and no complications were noted. The authors concluded that this technology has the potential to be used for more complex gynecologic procedures (362).

Clinical experience in gynecology is limited but increasing as more surgeons are accepting minimally invasive approaches. To date there are few published clinical trials. The initial trials have focused on laparoscopic microsuturing such as that performed during coronary bypass surgery or tubal anastomosis. Preliminary results have demonstrated that laparoscopic coronary bypass surgery with the internal mammary artery can be achieved.

In an initial study to compare robotic versus human laparoscopic camera control, the AESOP was utilized in 50 patients undergoing routine gynecologic endoscopic surgical procedures. The elimination of the camera holder allowed two surgeons to perform complex laparoscopic surgery faster than without the robotic arm (363).

Robotic surgery in gynecology appeared useful and applicable in performing laparoscopic microsurgical tubal reanastomosis after tubal sterilization. Eight patients with previous laparoscopic tubal sterilization who requested tubal reanastomosis underwent laparoscopic tubal reanastomosis using a remote-controlled robot. The robot, with three-dimensional vision, allows the surgeon to perform ultra-precise manipulations with intra-abdominal articulated instruments while providing the necessary degrees of freedom (364). Microsurgical applications in gynecologic general surgery (robotic tubal reanastomosis) appear to be acceptable indications for this technology (365).

Recently, a case series of 11 patients reporting the use of robotic surgery for performing hysterectomy and bilateral salpingo-oophorectomy demonstrated feasibility and safety. Four trocars were used: one for the camera, two for the robotic arms controlled by the operating surgeon from the surgeon's console, and an additional port for use by the surgical assistant. All patients tolerated the procedure and recovered satisfactorily (366). The daVinci surgical system (Intuitive Surgical, Mountainview, California, USA) has also been used to perform endoscopic ovarian transposition. The ovaries were mobilized on their respective infundibulopelvic ligaments and sutured to the ipsilateral pericolic gutters (367). Trials and pilot investigations of telerobotic surgery in gynecologic oncology are ongoing, and it appears that the utilization will continue to increase to applications where the current device can be used in part of the operation to perform a specific, highly precise objective such as fine suturing or dissection.

In experienced hands, robotic operative times for simple and radical hysterectomy appear shorter than those obtained by conventional laparoscopy, and robotic technology may be preferable to conventional laparoscopy for the surgical treatment of selected gynecologic malignancies and complex operations for benign disease such as hysterectomy, myomectomy, and extensive pelvic endometriosis (368).

In addition, robotic radical hysterectomy in early-stage cervical carcinoma patients was also recently reported (369). No conversions to laparotomy were observed in the robotic group. Median operation time was 241 minutes and the authors demonstrated technical feasibility of robotic-assisted laparoscopic radical hysterectomy in early-stage cervical carcinoma.

This technology will undoubtedly improve with full integration into new operating room systems, additional degrees of freedom, small size devices, easier use, and improved optics and surgical instrumentation.

From investigations in nongynecologic applications, it appears that the results of robotic-assisted surgery compare favorably with those of conventional laparoscopy with respect to mortality, complications, and length of stay. Robotic-assisted surgery, in the pilot phase, appears safe and effective

and its role in surgery will likely expand as the technology evolves; however, there are currently limited data to justify the routine use of these systems over laparoscopy in terms of patient outcomes or reduced complications (370).

CHAPTER 19 ■ PATHOGENESIS AND DIAGNOSIS OF PREINVASIVE LESIONS OF THE LOWER GENITAL TRACT

THOMAS C. WRIGHT JR

INTRODUCTION

The high level of public and professional interest in various aspects of preinvasive lesions of the lower genital tract is due to many factors. Perhaps the most important is the marked increase over the last four decades in the number of patients in North America and Western Europe diagnosed with human papillomavirus (HPV)-associated disease. This increase is due partly to a heightened awareness of various clinical and pathologic manifestations of HPV infections, the recent introduction of prophylactic vaccines against specific high-risk types of HPV, and to the increased use of highly sensitive tests for the detection of HPV infections and cervical cancer precursors. In addition, a real increase in the prevalence of HPV infections appears to have taken place during this time. HPV-associated genital tract disease is the most commonly diagnosed sexually transmitted disease in the United States. Over half of men and women who are sexually active will be infected at some point in their lives. The Centers for Disease Control and Prevention (CDC) estimates that approximately 20 million Americans 15 to 49 years of age are infected with HPV (1). This represents approximately 15% of all individuals in this age group. About half of these are sexually active adolescents and young adults 15 to 24 years of age.

Cervical cancer precursors also appear to have increased in prevalence over the last 2 decades in the United States and Western Europe. According to the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) program, an increase in the incidence of high-grade cervical cancer precursors began to be detected in the early 1980s in white women under the age of 50 in the United States (2). In 1980 the incidence of carcinoma *in situ* of the cervix in white women under the age of 50 years was 27 per 100,000; by 1995, it had increased to 41 per 100,000 women (3). Currently, the median reporting rate for abnormal cervical cytology in the United States is approximately 9%, with wide variations depending on the characteristics of the population screened and the particular cytology laboratory being used (4). Based on rates of cytologic abnormalities obtained by the College of American Pathologists, we can estimate that approximately 1,548,000 women receive a cytologic result of low-grade cervical cancer precursors each year in the United States, and another 2,790,000 have equivocal cytologic changes referred to as atypical squamous cells (4).

DEFINITIONS AND TERMINOLOGY OF PREINVASIVE LESIONS OF THE LOWER GENITAL TRACT

The terminology used to classify preinvasive lesions of the lower genital tract has changed many times over the last 50 years and is continuing to do so. Unfortunately, these changes, and the lack of a uniform terminology, have been an ongoing source of confusion for the clinician. Despite recent attempts to simplify the classification and make the terminology more uniform, as much controversy exists today as existed 30 years ago regarding the appropriate definitions of preinvasive lesions of the lower genital tract.

Cervix—Squamous Lesions

For more than a century, it has been recognized that invasive squamous cell carcinomas of the cervix are associated with lesions histologically and cytologically identical to invasive cervical carcinoma but that lack the capacity to invade the subepithelial stroma. Because of their unique spatial and temporal relationships with cervical cancer, these intraepithelial lesions were referred to as carcinoma *in situ*. As cytology-based cervical cancer screening programs were being introduced in the 1950s it became clear that there were also squamous epithelial abnormalities whose histologic and cytologic features were less severe than carcinoma *in situ*. These lesions were referred to as *dysplasia* and were often divided into three grades (e.g., *mild*, *moderate*, or *severe*) based on the degree of cytologic or histologic abnormality (5). Dysplastic lesions were believed to represent lesions that were biologically less ominous than carcinoma *in situ*. In the late 1960s a series of descriptive studies that used a variety of techniques, including electron microscopy, tissue culture, chromosome analysis, DNA ploidy analysis, and radioautography, suggested that dysplastic lesions, carcinoma *in situ*, and invasive carcinoma formed a continuum rather than a series of discrete steps. In 1973, based on follow-up studies of patients with cervical cancer precursor lesions and studies of the biology of these lesions, Richart proposed that the term *cervical intraepithelial neoplasia* (CIN) be used to encompass all forms of cervical cancer precursor lesions, including dysplasia and carcinoma

in situ (6). The CIN terminology divided cervical cancer precursor lesions into three groups or grades. CIN 1 corresponded to mild dysplasia, and CIN 2 corresponded to moderate dysplasia. Since studies had shown that pathologists could not reproducibly distinguish between severe dysplasia and carcinoma *in situ*, CIN 3 encompassed both of these lesions. The CIN terminology stressed the concept that all cervical cancer precursors formed a continuum and that lesions of all grades of severity had the potential to progress to invasive cancer if left untreated. Since the risk for progression of any individual lesion is unknown (i.e., by light microscopy it is impossible to categorize the lesions as to which will persist or progress), the CIN terminology emphasized that all “precursor” lesions should be treated. Inherent in this reasoning was the acknowledgment that appropriate treatment and eradication of precursors (irrespective of their histologic grade) greatly reduces a patient’s risk for subsequently developing invasive cervical cancer.

The CIN terminology provided information in a context that made approaches to clinical management straightforward and became the most widely used terminology for cervical cancer precursors. However, over the last 15 years, tremendous advances in our understanding of the pathogenesis of cervical cancer precursors have taken place. These advances have changed both our pathologic nomenclature and our approach to clinical management of cervical cancer precursor lesions. It is now clear that the CIN (continuum) concept of cervical cancer precursors has certain limitations. For example, the spectrum of histologic changes grouped together as CIN is now recognized to represent two distinct biologic entities. One entity is a productive HPV infection rather than a neoplasm or cancer precursor. The characteristic histologic feature of a productive HPV infection is the presence of HPV cytopathic effect (e.g., koilocytosis with multinucleation, perinuclear halos, nuclear enlargement, and nuclear atypia). These productive HPV infections can be associated with any HPV type including “low-risk” HPVs as well as “high-risk” or oncogenic HPV types. The other HPV-associated biologic entity should be considered to be an actual neoplasm or cancer precursor, rather than simply a productive viral infection. These neoplasms or “true precursors” are invariably monoclonal and are usually associated with “high-risk” or oncogenic HPV types such as 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 68, 73, or 82 (5,7). These lesions are frequently aneuploid and often demonstrate specific loss of heterozygosity (LOH) at chromosomal loci observed in invasive cervical cancers (8,9).

These advances in our understanding of the biology of preinvasive lesions of the cervix have led to suggestions that the terminology used to refer to cervical cancer precursors be modified (5). The proposed terminologies abolish the three-tiered CIN 1, 2, and 3 classification and replace it with a two-tiered classification. To allow histopathologic findings to be easily correlated with cytologic findings, one of the proposed classifications follows that of the Bethesda system for cytologic diagnosis, which uses the terms “high-grade squamous intraepithelial lesion” and “low-grade squamous intraepithelial lesion” to report cytologic diagnoses (10). In this proposed classification system, lesions previously classified as mild dysplasia, koilocytotic atypia, koilocytosis, flat condylomata, and CIN 1 are grouped together into a single entity termed *low-grade squamous intraepithelial lesion* (i.e., low-grade SIL or LSIL), and lesions previously classified as CIN 2 and 3 are grouped together into a single entity termed *high-grade squamous intraepithelial lesion* (i.e., high-grade SIL or HSIL). A similar modification of the CIN system of nomenclature was also suggested. In this modified scheme CIN 1 was termed low-grade CIN 1 and CIN 2 and 3 were combined under the high-grade CIN 2,3 rubric. Table 19.1 compares the different terminologies.

In this chapter we use a two-tiered terminology (e.g., CIN 1 and CIN 2,3) because it is the most widely used terminology in the United States and was adopted for clinical guidelines at the 2001 Consensus Conference, and a decision was made to continue with this terminology for the 2006 Consensus Guidelines (11,12). However, two points should be emphasized about the use of any terminology for cervical cancer precursors. First, it is important to remember that the histologic appearance of a lesion does not unequivocally predict whether it represents a simple productive viral infection or a neoplasm. Although the majority of histologically high-grade lesions contain “high-risk” or oncogenic HPV types, are monoclonal proliferations, and are aneuploid, the converse is not true. Lesions that are histologically low-grade are quite heterogeneous with respect to their associated HPV types, clonal status, and ploidy. Some histologically low-grade lesions can be classified as productive viral infections; others contain “high-risk” or oncogenic HPV types and have the biologic features of a precursor lesion. Therefore, histologic appearance does not necessarily predict the biologic behavior of an individual lesion. Second, it must be emphasized that different terminologies are currently in use by different pathology laboratories. Although most laboratories in the United States have switched

TABLE 19.1

COMPARISON OF DIFFERENT TERMINOLOGIES FOR CERVICAL SQUAMOUS NONINVASIVE LESIONS

Older terminology	CIN ^a terminology	The Bethesda system	Modified CIN terminology
Flat condyloma Koilocytosis Koilocytotic atypia Mild dysplasia	CIN 1	Low-grade squamous intraepithelial lesion (LSIL)	CIN 1 (low-grade CIN)
Moderate dysplasia Severe dysplasia Carcinoma <i>in situ</i>	CIN 2 CIN 3	High-grade squamous intraepithelial lesion (HSIL)	CIN 2,3 (high-grade CIN)

^aCIN, cervical intraepithelial neoplasia.

to the two-tiered or modified CIN terminology, some continue to utilize the terms dysplasia and carcinoma *in situ*. This is expected to change over the next several years since the World Health Organization (WHO) recently switched to the CIN terminology (13).

Cervix—Glandular Lesions

Interest in glandular lesions of the cervix has been stimulated by an apparent increase in the number of women, especially those under the age of 35, who are being diagnosed with invasive adenocarcinoma of the cervix and glandular precursor lesions. Large series of women with invasive cervical cancers as well as cancer registries have demonstrated that the relative proportion of adenocarcinomas to squamous cell carcinomas of the cervix has been increasing over the last 3 decades. Most large series from the 1950s and 1960s reported that 95% of invasive cervical cancers were squamous cell carcinomas and only 5% were adenocarcinomas. However, beginning in the 1970s, case series began reporting that 75% to 80% of invasive cervical cancers were squamous cell carcinomas and that 20% to 25% of cases were either adenocarcinomas, adenosquamous cell carcinomas, or undifferentiated carcinomas. This relative increase is clearly demonstrated by the clinical series of Shingleton et al. (14). During the 1974 to 1978 period, adenocarcinomas accounted for 7% of all cervical cancers, whereas by 1979 to 1980 they accounted for 19%. Similarly, cancer registries from the United States and Europe have reported that the ratio of adenocarcinomas to squamous cell carcinomas has increased over the same period (15–17). During the 1996 to 2000 period adenocarcinomas accounted for 25% of all invasive cervical cancers in whites in the U.S. SEER database (3). In the Finnish Cancer Registry, 6% of cervical cancers were classified as adenocarcinomas in 1953 to 1957, whereas by 1978 to 1982, 17% were classified as adenocarcinomas (15).

In the U.S. SEER registry, the incidence of invasive adenocarcinoma of the cervix has increased from 1.23 per 100,000 in 1976 to 1980 to 1.76 per 100,000 in 1996 to 2000 (3). Much of this increase is due to young women 15 to 34 years of age. Among white women in this age group the incidence increased from 0.6 to 1.2 per 100,000. Cancer registries from Norway and the United Kingdom have also reported increases in the absolute incidence of invasive adenocarcinomas of the cervix in women 35 years or younger (16,18). It is important to note, however, that despite the increased incidence of invasive adenocarcinoma in young women and the clear increase in the relative proportions of adenocarcinomas to squamous cell carcinomas over the last 3 decades, the absolute number of invasive adenocarcinomas has not actually increased when women of all age groups are combined. Instead, the number of women with invasive squamous cell carcinomas has decreased, producing a relative increase.

The first indication that precursor lesions existed for invasive adenocarcinomas of the cervix was the description by Helper et al. in 1952 of highly atypical endocervical cells lining architecturally normal endocervical glands adjacent to frankly invasive adenocarcinomas of the cervix (19). Friedell and McKay subsequently described two additional patients with similar histologic findings and coined the term adenocarcinoma *in situ* (AIS) to refer to these glandular lesions that were histologically highly atypical, but noninvasive (20). Inherent in the use of the term adenocarcinoma *in situ* to refer to these lesions was the acknowledgment that these lesions were precursors to invasive adenocarcinoma of the cervix. In addition to the highly atypical glandular lesions referred to as adenocarcinoma *in situ*, glandular lesions with a lesser degree of histologic abnormality than adenocarcinoma *in situ* are

also found in the cervix. These low-grade glandular lesions have been referred to by a variety of terms including *endocervical dysplasia*, *atypical hyperplasia*, and more recently, *endocervical glandular atypia* (5). By way of analogy to squamous lesions, some authors have suggested that the term *cervical intraepithelial glandular neoplasia* (CIGN) be used to refer to all of these noninvasive glandular lesions. Using the CIGN terminology, atypical hyperplasia is classified as either CIGN grade 1 or 2 depending on the degree of cytologic atypia and mitotic activity present and adenocarcinoma *in situ* is classified as CIGN grade 3. In the United States between 1976 and 2000 the incidence of adenocarcinoma *in situ* has increased steadily in women 15 to 74 years of age. In 1976 to 1980 the incidence in white women was 0.21 per 100,000; this increased to 1.25 per 100,000 by 1991 to 1995 (3). Increases were greatest among young women.

It is important to note that although there is considerable evidence indicating that adenocarcinoma *in situ* is a precursor for invasive adenocarcinoma of the cervix, there is little evidence to support such a role for the lower-grade glandular abnormalities. Because the terms endocervical dysplasia and CIGN imply a relationship between the low-grade lesions and invasive adenocarcinoma that is not documented, some prefer the more noncommittal term endocervical glandular atypia to refer to the low-grade lesions that lack the features of adenocarcinoma *in situ* (5).

Vulva and Vagina

The nomenclature used for preinvasive lesions of the vulva and vagina has tended to parallel that used for the cervix. The original description of preinvasive lesions of the vulva was made in 1912 by Bowen, who described a lesion of the thigh and buttock that he termed “precancerous dermatosis.” These lesions were grossly red and scaly and were characterized microscopically by significant cellular atypia. Clinically, they either persisted or recurred. Bowen believed that these lesions, which subsequently came to be called *Bowen’s disease*, were precursors to invasive squamous cell carcinomas of the vulva. Since this original description, a number of other terms have been used for lesions with significant cellular atypia that lack invasion. These include erythroplasia of Queyrat, atypical hyperplasia, dysplasia, atypia, carcinoma *in situ*, carcinoma *in situ* simplex, and intraepithelial carcinoma.

In the 1980s many clinicians and pathologists began to apply the intraepithelial neoplasia terminology widely used for describing cervical cancer precursors to the vulva. Thus the term *vulvar intraepithelial neoplasia* (VIN), together with a grade of 1 to 3, was adopted (21). Similarly, the term *vaginal intraepithelial neoplasia* (VAIN), together with a grade of 1 to 3, is widely used to describe preinvasive lesions of the vagina. It should be pointed out, however, that data that suggest a continuum between all grades of vulvar and vaginal preinvasive lesions and invasive squamous cell carcinoma at these sites are significantly less compelling than that for the cervix. In 2004 the International Society for the Study of Vulvar Disease (ISSVD) proposed a new terminology for vulvar lesions. In their new nomenclature, VIN 1 is eliminated and the term VIN is used to apply only to high-grade lesions, which are subdivided into *VIN, usual type* (which encompasses former VIN 2 or VIN 3 of the warty, basaloid, and mixed types) and *VIN, differentiated type* (22). This proposed nomenclature fails to take into account that a significant proportion of VIN 1 lesions are actually associated with “high-risk” types of HPV and this terminology has not been widely adopted for use in the United States (23).

NATURAL HISTORY OF PREINVASIVE LESIONS OF THE LOWER GENITAL TRACT

Cervix

A variety of epidemiologic and long-term follow-up studies support the concept that certain epithelial lesions are precursors of invasive squamous cell carcinoma of the cervix. Several different methods have been used to study the natural history of different types of cervical cancer precursors. When cytologic screening programs for cervical cancer were introduced to previously unscreened populations in the 1940s and 1950s, a large difference in the mean age of patients with invasive cervical cancer and patients with "dysplasia" became apparent (Table 19.2). In the study by Reagan et al., the mean age of patients with "dysplasia" was 34 years, the mean age of patients with carcinoma *in situ* was 42 years, and the mean age of patients with invasive cancer was 48 years (24). Similar age distributions were observed by Patten in his studies (25). These data were interpreted to imply that it takes over 10 years for a dysplastic lesion to progress to carcinoma *in situ* and invasive cancer.

The most direct way to study the natural history of cervical cancer precursors is to study cervical lesions prospectively without therapeutic intervention. Before widespread acceptance of the fact that a high percentage of carcinoma *in situ* lesions inevitably progress to invasive cancer, patients with carcinoma *in situ* were followed prospectively in several studies. These studies, with all their attendant methodologic problems (including lack of standardized histologic criteria, small patient numbers, inadequate and short patient follow-up, and wide differences in results) form the basis of our estimates of the premalignant potential of carcinoma *in situ*. Now that the premalignant potential of carcinoma *in situ* is universally accepted, it would obviously be unethical to repeat these prospective follow-up studies of carcinoma *in situ* lesions using more contemporary methods.

In 1961, Kottmeier reported on a group of 31 women with carcinoma *in situ* who were followed for at least 12 years (26). Twenty-two (72%) of these women subsequently developed invasive cancer. Similarly, Koss et al. in 1963 reported a long-term follow-up study of 67 women with biopsy-confirmed carcinoma *in situ* (27). In this study, a lower frequency of progression was detected than in the study by Kottmeier (Table 19.3). Sixty-one percent of carcinoma *in situ* lesions persisted, and only 6% progressed to invasive cancer. However, the follow-up time was only 3 years. A larger study of the natural history of carcinoma *in situ* was that of Green and Donovan from New Zealand (Table 19.3) (28). On the basis of a short-term follow-up study of patients with carcinoma *in situ*, it was initially

TABLE 19.2
**AGE DISTRIBUTION OF CERVICAL CANCER
PRECURSORS**

Cytology	Mean age at diagnosis (yr)	
	Patten (25)	Reagan et al. (24)
Dysplasia	34.7	34
Slight	32	—
Moderate	35.7	—
Marked	38.4	—
Carcinoma <i>in situ</i>	42.3	41.5
Invasive cancer	51.7	48.2

proposed that carcinoma *in situ* either had a low malignant potential or took much longer than 20 years to develop into invasive cancer. However, on long-term follow-up of a group of 817 patients whose Pap smears reverted to normal, 12 patients (1.5%) subsequently developed invasive carcinoma (29). Of the group of 131 patients with persistently abnormal Pap smears (followed for 4 to 23 years), 29 (22%) developed invasive carcinoma of the cervix or vaginal vault, and 90 (69%) had persistent carcinoma *in situ*. This and other follow-up studies clearly demonstrate that, once established, carcinoma *in situ* has a significant potential for progression to invasive cancer, and progression is a slow process, usually requiring a decade or more.

Whether carcinoma *in situ*, once established, can spontaneously regress in the absence of therapy is controversial. Based on the studies of Kottmeier and Green it would appear that, once established, carcinoma *in situ* only rarely regresses spontaneously (26,29). However, other follow-up studies have found that about one third of carcinoma *in situ* lesions regress during follow-up (30). Evaluation of data obtained from the British Columbia population-based screening program suggests that the cumulative incidence of carcinoma *in situ* is significantly higher than the cumulative incidence of invasive cervical cancer (31). Similar data has been obtained from cytologic screening programs in Sweden. This cytologic data has been interpreted as indicating that many cases of carcinoma *in situ* regress spontaneously (31,32).

Many prospective studies have also followed the transitions between different grades of CIN. These studies have obtained quite different estimates of the frequency of mild dysplasia, the likelihood of progression from low-grade to high-grade precursors, and the time required for this progression. The major reasons for these differences include the use of cervical biopsy rather than cytology to document the presence

TABLE 19.3

of an abnormality in some studies. Cervical biopsies can remove small precursor lesions in their entirety and therefore can alter natural history. In addition, prospective studies have differed in study design and pathologic criteria used to grade cervical lesions.

The two most widely quoted follow-up studies are the historical cohort study from Toronto published by Holowaty et al. and the prospective clinical trials of Nasiell et al. The Toronto study utilized a historical cohort of women whose cervical cytology was evaluated at a single large laboratory in an era (1962 to 1980) during which CIN lesions were managed conservatively in Canada (33). Rates of regression and progression were estimated using actuarial methods and through linkage to the Ontario cancer registry. Both mild and moderate dysplasias were found to be more likely to regress than progress. The risk of mild dysplasia progressing to severe dysplasia or worse was approximately 1% per year. In contrast, the risk of moderate dysplasia progressing was 16% at 2 years and 25% at 5 years (Table 19.4). The majority of both mild and moderate dysplasias showed spontaneous clearance and much of the clearance occurred within 2 years of diagnosis.

Nasiell et al. reported on 555 women with a single Pap smear showing mild dysplasia who were followed colposcopically and cytologically without major treatment (34). Biopsies were performed in only 14% of these patients. In this series, 62% of the patients with a mean follow-up time of 39 months developed normal Pap smears, with apparent regression of

their mild dysplasia. Persistent dysplasia occurred in 22% of the patients, with a mean follow-up of 52 months. Progression to severe dysplasia, carcinoma *in situ*, and invasive carcinoma occurred in 16% of the patients, with a mean follow-up of 48 months. Two patients who were lost to follow-up in this study subsequently developed invasive carcinoma, which was detected 79 months and 125 months, respectively, after a diagnosis of mild dysplasia. A number of other studies have investigated cohorts of women with moderate dysplasia. In a study of identical design to that used to study the biologic behavior of mild dysplasia, Nasiell et al. followed patients originally diagnosed cytologically as having moderate dysplasia. By life table analysis, progression to severe dysplasia, carcinoma *in situ*, and invasive carcinoma occurred in 33% of the patients after 12 or more years of follow-up (35).

Melnikow et al. performed a comprehensive meta-analysis of studies in which women with a cytologic result of SIL were followed (36). The analysis included 13,226 women with a cytologic result of LSIL who were followed for at least 6 months and had a median weighted follow-up of 29 months. There were 10,026 women with HSIL who had a median weighted follow-up of 25 months. The pooled estimates for regression to normal were 47% for LSIL and 35% for HSIL (Fig. 19.1). Rates of progression of LSIL were 7% at 6 months and 21% at 24 months. For HSIL the 6- and 24-month pooled progression rates were 7% and 24%. The pooled progression rates for invasive cancer at 6 and 24 months for LSIL were 0.04% and 0.15%, respectively. For HSIL they were 0.15% at 6 months and 1.44% at 24 months.

Mitchell et al. performed a systematic review of the different studies investigating the natural history of untreated biopsy-confirmed CIN, most of which were conducted in the 1970s and 1980s (Table 19.5) (37). Many of these studies are older and used the carcinoma *in situ* terminology. The higher the grade of lesion, the more likely it is to persist and the less likely it is to regress. Overall, it appears that approximately 57% of CIN 1 spontaneously regresses in the absence of therapy, 32% persist as CIN, and 11% progress to carcinoma

FIGURE 19.1. Pooled estimates of the rates of spontaneous regression (left panel) of a cytologic diagnosis of LSIL and HSIL obtained from the literature. Pooled estimates of the rates of spontaneous progression of LSIL and HSIL after 6 months (circles) and 12 months (squares) are shown (right panel). Progression for HSIL is from CIN 2 to CIN 3 or carcinoma *in situ*. Bars represent 95% confidence intervals. Source: Modified with permission from Melnikow J, Nuovo J, Willan AR, et al. Natural history of cervical squamous intraepithelial lesions: a meta-analysis. *Obstet Gynecol* 1998;92:727–735.

in situ. The rates of persistence and progression are greater for CIN 2,3. Forty-three percent of CIN 2 lesions regress, 35% persist, and 22% progress to carcinoma *in situ*. The equivalent rates for CIN 3 lesions were 32% regression, 56% persistence, and 12% progression to carcinoma *in situ*. Overall, the progression of all grades of CIN to invasive cancer in the published observational studies is 1.7%. The rate at which CIN progresses appears to be relatively slow.

Until recently it was generally believed that it took many years for a low-grade lesion to progress to a high-grade lesion. Mathematical modeling studies based on the prevalence of cytologic abnormalities in an unscreened population suggested that it takes on average almost 5 years for a mild dysplasia to progress to carcinoma *in situ* (5). More recent studies indicate, however, that high-grade lesions can develop quite rapidly after an incident HPV infection. A prospective study of college students found that the median length of time from first detection of an HPV infection to detection of CIN 2,3 was only 14.1 months (38). The finding that CIN 2,3 lesions can develop quite rapidly after initial HPV infections has been confirmed in the HPV vaccine trials (39).

Vulva

Studies on the natural history of VIN lesions are much fewer than for CIN. Partly because of the paucity of studies, the relationships between VIN and invasive squamous cell carcinoma of the vulva appear to be less straightforward than those documented between CIN and invasive squamous cell carcinoma of the cervix. Unlike the cervix, in which the majority of carcinomas are associated with a CIN lesion, only a third of invasive vulvar squamous carcinomas have a coexisting VIN 3 lesion (40). A review of six published follow-up studies found that only 16 of 330 patients (4.8%) with VIN progressed to invasive cancer (41). Solitary lesions in postmenopausal women had the highest risk of progression; multifocal lesions in women of reproductive age rarely progressed, although well-documented cases of young patients with VIN 3 who have developed cancer exist. In a series from Denmark, Hording et al. reported that only 4% of 73 women with VIN 3 developed invasive cancer during follow-up (median follow-up was 5 years) (42).

What is generally not emphasized when this data is discussed is that most of the patients in these follow-up studies were treated for their VIN or followed for relatively short periods of time. This fact explains, in part, the low incidence of progression. In one of the few long-term follow-up studies of women with VIN, Jones and Rowan found that only 3% of 105 women with treated VIN developed invasive vulvar cancer. In contrast, of eight women between the ages of 28 and 73 years with biopsy-documented VIN 3 who were followed without further treatment, seven developed invasive squamous cell carcinoma of the vulva within 8 years of diagnosis (43).

RISK FACTORS FOR THE DEVELOPMENT OF LOWER GENITAL TRACT CANCERS AND PREINVASIVE LESIONS OF THE LOWER GENITAL TRACT

Cervix

Risk Factors

A large number of epidemiologic studies have analyzed risk factors for the development of cervical cancer and its precursors.

Although the risk factors are similar for both cervical cancer and its precursors, the association with the risk factors is generally much stronger for cervical cancer than for precursor lesions. The major risk factors found in most studies are markers of sexual behavior such as number of sexual partners, early age of first pregnancy and first intercourse, sexually transmitted diseases, and parity. In addition, lower socioeconomic class, cigarette smoking, oral contraceptive use, specific HLA-DR haplotypes, and immunosuppression from any cause are associated with both cervical cancer and its precursors (Table 19.6).

It has been known for almost a century that cervical cancer has many of the characteristics of a sexually transmitted disease. The observations that the disease is much more frequent in married women than in celibate women, that it was more common in prostitutes and incarcerated women than in the general population, and that it was highly associated with a woman's lifetime number of male sexual partners all argue for venereal transmission. The fact that a woman's risk is increased not only by the number of sexual partners that she has had, but also by the number of sexual partners that her male partner or partners has had, strengthens the epidemiologic evidence that cervical cancer behaves as a sexually transmitted disease (44). With so much evidence favoring the sexual transmission of cervical cancer, many investigators have searched for an etiologic agent among the known sexually transmitted diseases.

Virtually every known sexually transmitted infection has been suggested as the etiologic agent for cervical cancer and, in more recent times, for cervical cancer precursors. The list includes *Treponema pallidum*, *Trichomonas vaginalis*, *Candida albicans*, *Chlamydia trachomatis*, and the herpes simplex viruses (HSV). There is now considerable evidence for a role for both *C. trachomatis* and HSV as cofactors in the pathogenesis of HPV-associated cervical neoplasia. One recent case-control study found that among HPV-infected women there was a two-fold risk for cervical cancer associated with having antibodies to *C. trachomatis* (45). This risk is similar

TABLE 19.6

RISK FACTORS FOR CERVICAL CANCER AND ITS PRECURSOR LESIONS

DEMOGRAPHIC FACTORS

- Older age
- Race (e.g., black, Hispanic, American Indian)
- Residence in selected parts of Africa, Asia, or Latin America
- Low socioeconomic status
- Low educational level

BEHAVIORAL AND SEXUAL FACTORS

- Large number of sexual partners
- Early age at first coitus
- Cigarette smoking
- Long-term contraceptive use
- Diet low in folate, carotene

MEDICAL/GYNECOLOGIC FACTORS

- Multiparity
- Early age at first pregnancy
- History of sexually transmitted diseases (especially herpes genitalis or HPV-associated lesions)
- Lack of routine cytologic screening
- Immunosuppression (any cause)
- Specific HLA-DR haplotypes

to the 2.5-fold increased risk observed with seroconversion in a prospective seroepidemiologic study (46). The prevalence of antibodies to HSV is also increased among women with cervical cancer. Smith et al. performed a pooled analysis of clinical samples from seven case-control studies of cervical cancer. After adjusting for HPV status and sexual behavior, HSV seropositivity was associated with an approximately twofold increased risk of cervical cancer (45). It has been suggested that both *C. trachomatis* and HSV act as cofactors in HPV-associated neoplasia, possibly through the induction of cervical inflammation (47).

Human Papillomavirus

Over the last 15 years, considerable evidence has been accumulating rapidly to implicate HPV in the pathogenesis of cervical cancer and its preinvasive precursors. Epidemiologic and molecular studies have found that there is a consistent and strong relationship between HPV infection and cervical neoplasia, that the temporal sequence between infection and the development of cancer is correct, that the association between HPV and cervical cancer is relatively specific, and that the epidemiologic findings are consistent with the natural history and biologic behavior of HPV infections and cervical cancer (48).

Studies that use sensitive molecular methods to detect and type HPV in cervical lesions have found that almost all cervical cancers and their precursors contain “high-risk” HPV DNA. For example, in a large study that analyzed over 1,000 invasive cervical cancers from all over the world using polymerase chain reaction (PCR), high-risk types of HPV were identified in over 90% of the invasive cervical cancers (49). Moreover, the same types of HPV were identified in cancers from all different geographic locations. When cases that were initially classified as HPV DNA negative were re-tested with PCR methods, high-risk HPV types were identified in almost all (50). This indicates that essentially all cervical cancers are caused by specific high-risk types of HPV.

Large case-control studies have identified HPV infection as a risk factor in the development of CIN and cervical cancer. For example, a recent pooled analysis of data from 11 case-control studies shows that HPV was detected in 1,739 of 1,918 patients with cervical cancer (91%) compared to 259 of 1,928 control women (13%). The pooled odds ratio for cervical cancer associated with any HPV type was 158 (51). Prospective studies indicate that the temporal sequence between HPV infection and the development of cancer is what would be expected for a causal agent. HPV infection occurs first and high-grade cervical cancer precursors or cancer occur subsequently. For example, in a study of colposcopically negative women in New York City, the incidence of CIN was significantly higher in women who were HPV-16 or -18 DNA positive compared to those who lacked “high-risk” HPV DNA (52). Moreover, persistent infection with “high-risk” types of HPV was much more closely linked with the subsequent development of CIN 2,3 than was detection of high-risk HPV DNA at a single visit. In a recent study of college students it was found that over a 3-year period, 27% of those with incident HPV-16 or -18 infections developed CIN 2,3 lesions, whereas no CIN 2,3 lesions developed in HPV DNA negative women (38).

Taken together, these epidemiologic studies clearly demonstrate that there is a strong and consistent association between specific types of HPV DNA and invasive cervical cancer and its precursor lesions, and that exposure to HPV precedes the development of cervical disease. When combined with the enormous body of molecular evidence demonstrating a role for HPV in the development of cervical

cancer and CIN, these findings clearly indicate that HPV infection, acquired through sexual contact, is a “necessary cause” of both CIN and invasive cervical cancer (53,54). Based on this data, the International Agency for Research on Cancer (IARC) of the WHO has classified HPV-16 and -18 and all of the other “high-risk” types of HPV as carcinogens in humans (55).

Smoking, Diet, and Oral Contraceptives

In addition to risk factors associated with sexual behavior, several other risk factors such as low socioeconomic class and cigarette smoking have also been associated with the development of cervical cancer (44). In a comprehensive review of the literature, Szarewski and Cuzick concluded that a positive association between cigarette smoking and the development of cervical cancer had been reported by the majority of studies designed to address this question (56). Several mechanisms could account for the association between cigarette smoking and cervical cancer. One is the secretion of cigarette smoke by-products, including nicotine and cotinine, in cervical mucous of tobacco users and women passively exposed to cigarette smoke (57). DNA adducts (e.g., structurally altered DNA sequences) are significantly more common in the cervical epithelium of smokers than in nonsmokers, and it has been suggested that the secretion of cigarette smoke by-products might have a direct mutagenic effect on the cervical epithelium (58). Another possible mechanism that could account for the association is the effect of smoke by-products on the number of Langerhan's cells in the cervix (59).

The use of combined oral contraceptives has also been found to be a risk factor for the development of cervical cancer and its precursors in some studies. In a meta-analysis of 28 studies evaluating the risk of cervical cancer in women on oral contraceptives, Smith et al. found that the relative risk of invasive cervical cancer increased with increasing duration of contraceptive use. After 10 years of use, the summary relative risks were 2.2 (95% CI, 1.9 to 2.2) for all women and 2.5 (95% CI, 1.6 to 3.9) for HPV-positive women (60). A recent reanalysis of epidemiologic studies involving over 50,000 women confirmed an increased risk of cervical cancer in oral contraceptive users (61). Associations between exogenous hormones and cervical disease could be explained by a number of mechanisms including direct promoting effects of estrogens and progestins on the HPV genome, as well as by indirect effects such as a reduction in blood folate levels, which is occasionally observed in women on oral contraceptives. Whether an association exists between endogenous hormone levels and invasive cervical cancer is even more controversial. There is no association between age at menarche or age at menopause and the risk of invasive cervical squamous cell carcinoma. It has been suggested that the strong association observed between early age of first parity and risk for cervical cancer reflects risk of exposure to a sexually transmitted agent at an early age, rather than an influence of endogenous hormones (62).

Only a few studies have focused on relationships between cervical cancer and diet, but some evidence suggests that a diet low in either vitamin A or C may be associated with an increased risk. Other studies have not detected an association between dietary intake of beta-carotene or retinol and CIN. A recent review of the role of antioxidant nutrients on cervical disease concluded that there are six studies that have properly controlled for HPV (47). In all six, an inverse relationship was observed between serum beta-carotene and cervical carcinogenesis. In studies that measured carotenoids other than beta-carotene, inverse associations between cervical neoplasia and serum lycopene and alpha-carotene have been

observed (47). Folate deficiency has also been considered to be a risk factor. A recent case-control study reported that folate deficiency enhances the effects of other risk factors such as parity, HPV-16 infection, and cigarette smoking on the development of CIN (63).

Immunosuppression

Immunosuppression is another risk factor for the development of both CIN and cervical cancer. In studies of patients with renal transplants, transplant recipients have a relative risk of 13.6 for the development of cervical carcinoma *in situ* compared to women in the general population (64). Over the last decade it has become widely accepted that there is also an association between cervical disease and infection with the human immunodeficiency virus (HIV) (64). HPV infections are more prevalent and tend to be more persistent in HIV-infected women (65). Numerous studies have documented a higher prevalence of cervical neoplasia among HIV-infected women compared to various control groups of HIV-uninfected women (64). There also appears to be an increase in invasive cervical cancer. Among women in New York City, the standardized incidence ratio for cervical cancer is 9.2 times higher in HIV-infected compared to noninfected women (66). It is clear that the invasive cervical cancers that do develop in HIV-infected women act aggressively and respond poorly to standard forms of therapy (67). Invasive cervical cancer was designated in 1993 as an AIDS case-defining illness by the CDC (68).

HUMAN PAPILLOMAVIRUS

Classification

Papillomaviruses are a diverse group of viruses that are widely distributed in mammals and birds. Papillomavirus isolates are traditionally described as *types*. The characteristic features of papillomaviruses are a double-stranded, circular DNA genome of about 8,000 base pairs, a nonenveloped virion, and an icosahedral capsid composed of 72 capsomers. The papillomaviruses are now classified as a separate family of viruses termed Papillomaviridae. To date 118 papillomavirus types have been completely described. Papillomaviruses are highly species specific and are classified based on their species of origin and the extent of DNA relatedness between viral isolates. Human papillomaviruses are epitheliotropic. They infect epithelial cells of the skin and mucous membranes, often producing local epithelial proliferation or warts at the sites of infection. There has been only limited success in propagating HPV in either tissue or culture.

Within a given species, many types and subtypes of papillomaviruses may exist. Since the capsid proteins of different papillomaviruses are antigenically similar, papillomaviruses are subdivided into genotypes and subtypes based on the extent of DNA relatedness as determined by DNA hybridization under stringent conditions, rather than into serotypes based on structural antigenic features. In order to be classified as a distinct type, the E6, E7, and L1 gene sequences (about one third of the genome) must differ by more than 10% from those of other, known HPV types. In addition to types, there also are subtypes or variants of specific types. In order to be considered a subtype or variant, the different viruses must differ by 2% to 5% from the original isolate. In humans, more than 100 types of papillomaviruses have been characterized. Although the different types are structurally similar, they have significant specificity with regard to the anatomic location of the epithelia that they infect

and the type of lesions that they produce at the site of infection (69). For example, HPV types 1, 2, 4, 26, 27, 29, 41, and 57 are associated with common warts (*verrucae vulgaris*); types 1, 2, and 4 with deep plantar warts; and type 7 with common warts on the hands of meat handlers (butcher's warts). HPV types 5, 8, 9, 12, 14, and others are associated with flat warts and cancers in patients with epidermodysplasia verruciformis, which is a rare, heritable, lifelong skin disease characterized by the development of multiple flat warts throughout life. These warts may progress to skin cancer.

Over 30 types of HPV that infect the anogenital tract have been described (Table 19.7). These different types of HPV tend to be associated with different types of lesions. HPV-6 is the most common HPV type found in association with exophytic condylomata of the male and female anogenital tract in adults (70). Most exophytic condylomata that are not associated with HPV-6 are associated with HPV-11. Exophytic condylomata are occasionally associated with HPV types 16 or 31, but are almost never found in association with HPV-18. In adults, cutaneous HPV types such as HPV-1 or -2 are seldom associated with exophytic condylomata. However, a significant proportion of condylomata acuminata in children are associated with HPV-2, which is a common cutaneous HPV type (71). Small, raised, plaque-type warts on the penis are also commonly associated with "low-risk" HPV types (72).

More than 80% of CIN lesions are found to be associated with HPV when sensitive, molecular methods are used to detect HPV DNA. CIN 1 is quite heterogeneous with regard to associated HPV types (7,73). CIN 1 can be associated with any of the anogenital HPV types that have been identified in women in the general population. Although studies performed in the mid-1980s indicated that HPV-6 and -11 were the predominant types of HPV associated with CIN 1, subsequent studies have detected HPV-6 and -11 in less than 10% of CIN 1 lesions. HPV-16 and -18, combined, are detected in about one third of all CIN 1 lesions. Multiple types of HPV are often identified in women with CIN 1 (74).

In contrast to CIN 1, almost half of all CIN 2,3 lesions are associated with HPV-16 (7,75). The prevalence of HPV-16 in women with high-grade SIL (CIN 2,3) varies from 30% to 77% in different studies. A meta-analysis of the distribution of HPV types in CIN 2,3 lesions recently concluded that HPV-16 is identified in 45.3%, HPV-18 in 6.9%, and HPV-31 in 8.6% (Fig. 19.2) (75). Fifty-two percent of CIN 2,3 lesions are associated with either HPV-16 or -18. HPV types 31, 33, 58, and 52 are the next most common types found in CIN 2,3. Multiple types of HPV are uncommonly detected in women with CIN 2,3 (74). The associations between specific types of HPV and invasive cervical cancers are similar to those observed in women with CIN 2,3 (Fig. 19.2) (7,75). HPV-16 is

FIGURE 19.2. Distribution of HPV types determined by PCR in cases of invasive cervical cancer and biopsy-confirmed CIN 2,3. *Source:* Modified from Smith JS, Lindsay L, Hoots B, et al. Human papillomavirus type distribution in invasive cervical cancer and high-grade cervical lesions: a meta-analysis update. *Int J Cancer* 2007;121:621–632.

the most common HPV type found in association with invasive cervical squamous cell carcinomas, and HPV-18 is the second most common. All other types are much less commonly found.

Based on their associations with benign epithelial proliferations, high-grade cancer precursors, or invasive cancers of the vulva, vagina, anus, and cervix, human papillomaviruses have been categorized into three groups: “high-risk” viruses that are classified as “high risk” because infection with these HPV types is associated with a high relative risk of cancer; “low-risk” viruses that are associated with a relatively low risk of invasive cervical cancer; and “possible high-risk” types that are occasionally associated with cervical cancer (Table 19.7) (51). It is important to recognize that all of the 30 different types of anogenital HPV have been isolated from cervicovaginal secretions of women lacking any colposcopic or cytologic evidence of cervical disease. The most common HPV types detected in women with no cytologic evidence of cervical disease include high-risk types such as 16, 51, 52, 31, 58, and 56 (76–78).

Genomic Organization

The overall genomic organization of all sequenced HPV types is similar. The genome contains eight open reading frames (ORFs) that are transcribed from a single DNA strand as a polycistronic message (Fig. 19.3). ORFs are DNA segments that are transcriptional units and have the capacity to encode protein. The viral DNA can be divided into three regions. First, there is an upstream regulatory region (URR) of about 400 base pairs that contains binding sites for transcriptional activators and repressors. This region plays a role in regulating the production of viral proteins and infectious particles and possibly plays a central role in determining the host range of specific types of HPV (79,80). Transcriptional control appears to be quite complex, involving multiple promoters and repressors and binding sites for a number of transcriptional factors.

Downstream of the URR is the early region. The early region encodes for proteins that play a fundamental role in viral infection and replication. Within the early region are six ORFs designated E1, E2, E4, E5, E6, and E7. The E6 and E7 ORFs are important in the immortalizing and transforming functions of HPV (81). E1 encodes the only virally encoded enzyme, an adenosine 5'-triphosphate (ATP)-dependent helicase that is required for extrachromosomal DNA replication (79,80). The E2 protein has important transcriptional regulatory activities (82). Together with E1, E2 is also required for extrachromosomal DNA replication to occur—a fundamental role in viral infection and replication. E2 also acts as a key regulator of transcription of the E6 and E7 ORFs. The E4 protein has many characteristics of a structural viral protein and is similar to the protein products of the late region (83). Like the L1 and L2 capsid proteins,

the E4 protein is expressed during the late stages of the viral life cycle at a time when complete virions are being produced. The E4 protein is thought to disrupt the normal intermediate filament matrix of infected epithelial cells and disrupt the cornified cell envelope. This is thought to facilitate the release of assembled virions from the infected epithelium and to produce the characteristic cytopathic infection (e.g., “koilocytosis”) (79). E5 appears to play a role in the early course of infection. E5 is a short transmembrane protein that stimulates cell growth by forming complexes with epidermal growth factor receptor, platelet-derived growth factor receptor, and colony stimulating factor-1 receptor (80). Unlike E6 and E7, which are required for the development of cervical cancer, E5 is often lost during the development of cervical cancers.

The late region is downstream of the early region and includes two ORFs: L1, which encodes for the major capsid protein, and L2, which encodes for the minor capsid protein. The L1 major capsid protein is highly conserved among papillomaviruses of all species and serves as a convenient source of

FIGURE 19.3. Schematic of genomic organization of HPV. *Source:* Reprinted with permission from Wright TC, Ferenczy AF, Kurman RJ. Precancerous lesions of the cervix. In: Kurman RJ, ed. *Balustein's Pathology of the Female Genital Tract*. 4th ed. New York: Springer-Verlag; 1994:229–241.

antigen for the production of antibodies to the papillomavirus. The minor capsid protein, L2, shows considerable sequence variation between different types of HPV and has been used as an antigen for the production of type-specific antibodies to HPV. Expression of L1 and L2 capsid proteins occurs late during the viral life cycle and coincides with the production of complete virions (84). Expression of L1 and L2 capsid proteins is post-transcriptionally regulated by cell-derived factors and occurs only in superficial and intermediate squamous epithelial cells. This helps explain why virion production and the resultant cytopathic effect of HPV infection are pronounced in CIN 1 and in condyloma acuminatum, but are less pronounced in CIN 2,3 and invasive cancer, which contain fewer differentiated cells. The current generation of prophylactic HPV vaccines is composed of L1 proteins that have been induced to fold into viral-like particles (VLPs) (85).

order to replicate in the differentiating epithelial cells, the virus needs to reactivate the cellular DNA replication machinery. Studies of cultured human keratinocytes have shown that the viral E7 protein is capable of reactivating the cellular DNA replication machinery in differentiated cells (88). The viral E6 protein also appears to play an important role by blocking the apoptosis that would normally occur in the differentiated cells (89). Together, these changes provide the S-phase environment necessary for vegetative viral DNA replication and complete virion formation. Coincident with the assembly of large numbers of infectious virions, the typical HPV-associated cytopathic effects occur. The cytopathic effects are most prominent in the upper layers of the epithelium and include multinucleation, nuclear enlargement, hyperchromasia, and regions of perinuclear clearing or halos (i.e., koilocytes).

HPV Life Cycle

The life cycle of HPV infections is tightly coupled with the differentiation of the stratified epithelium that is the target of infection. Unlike any other known virus families, infection requires access to the actively proliferating basal cells of the epithelium (Fig. 19.4) (86). This occurs usually at sites of microtrauma to the epithelium. Binding of HPV to the basal cells appears to involve interactions with cell surface-associated alpha 6 integrin that may act as the receptor for binding and entry into the cells (87). After HPV has entered into the basal cell, the viral genome undergoes limited replication. Within the basal cells, replication of the HPV genome is tightly controlled by cellular mechanisms and appears to be linked to cellular replication so that the viral DNA co-replicates with the host's genome. Therefore, the HPV genome is maintained at a relatively low copy number in the basal cell's nucleus as a circular or episomal form, and virally encoded proteins are expressed at very low levels. As a result, HPV-infected basal cells show no specific cytologic or histologic changes and cannot be distinguished from uninfected cells (81).

As the infected basal cells proliferate, they migrate from the basal/parabasal compartment to the suprabasal compartment. Epithelial cells that are not infected with HPV exit the cell cycle when leaving the basal/parabasal compartment. However, in

Transforming Functions of HPV

HPV E7 Oncoprotein

Characterization of the regions of the HPV genome responsible for the immortalizing and transforming functions of "high-risk" HPV types indicates that both functions reside predominantly in the E6/E7 ORFs. Phylogenetic comparisons of the E5 genes of different HPVs show a correlation between DNA sequence and a type's capacity to form tumors, suggesting that E5 may play a role in carcinogenicity (90). The E6/E7 ORFs of HPV-16 and -18 encode for several distinct proteins. The E7 protein is the major transforming and immortalizing activity of HPV (81,83). E7 is a small zinc-binding protein composed of approximately 100 amino acids that is phosphorylated in the native state and lacks enzymatic activity. The HPV-16 E7 gene product can cooperate with activated *ras* oncogenes for transformation and contains a consensus sequence for casein kinase II-mediated serine phosphorylation and a binding site for the product of the retinoblastoma (*Rb*) gene, as well as the structurally related "Rb-like pocket proteins," p130 and p10 (88). These proteins (*Rb*, p130, and p107) all play an important role in regulating cell proliferation.

Although the exact mechanism of action of E7 within cells has not been fully worked out, it is clear that the binding of

FIGURE 19.4. Life cycle of HPV infections. HPV infects cells of the basal layer where it exists in a low copy number in episomal form. It is thought that basal cells become exposed to HPV after microabrasions occur in the epithelium. Basal cells infected with HPV have a proliferative advantage and expand laterally. As HPV-infected cells progress through the more differentiated layers of the epithelium, viral replication is turned on and large numbers of copies of HPV DNA are produced. Late genes, including the viral capsid, are produced in the most superficial layers of the epithelium and infectious virions are assembled. This produces the characteristic cytopathic effects of HPV (e.g., koilocytosis).

the E7 protein to either Rb or the other “Rb-like pocket proteins” blocks the cell proliferation–inhibitory function of these endogenous tumor suppressors (81,83). E7 also activates cyclins E and A and blocks the cellular proliferation–inhibiting activities of cyclin-dependent kinase inhibitors such as WAF1 (p21) and KIP1 (p27). The end result of these activities is stimulation of cell proliferation. Binding of E7 to Rb also results in the increased expression of a cyclin-dependent kinase inhibitor INK4A (p16). Increased expression of INK4A appears to be a good marker of HPV-induced neoplasia (91).

HPV E6 Oncoprotein

Like the HPV E7 protein, the E6 protein is a small zinc-binding protein (approximately 150 amino acids long) that lacks endogenous enzymatic activity and exerts its effects through binding to cell cycle regulatory proteins, especially p53 (88). The cellular p53 protein is a transcriptional activator that has features of both a tumor suppressor gene and an oncogene. Binding of HPV E6 to p53 results in the rapid proteolytic degradation of the bound p53 through a ubiquitin-dependent pathway (81,83). This reduces the amount of p53 present within the cell and causes a loss of the p53 repair mechanism. The net effect of this is a blockage of apoptosis and an increase in cellular proliferation.

Steps in Transformation

In some HPV-infected women the viral infection takes a different course and, for poorly defined reasons, viral gene expression becomes unlinked to the state of differentiation of the infected epithelial cells. This results in a change in the topography of viral gene expression within the epithelium. One consequence of deregulated expression of the E6 and E7 HPV proteins is a dramatic increase in expression of E6/E7 in the lower layers of the epithelium (92,93). The deregulated expression of E6/E7 results in loss of normal cell cycle control of the epithelium. In addition to disrupting normal cell cycle regulation and abrogating apoptosis mechanisms, expression of the HPV E6 and E7 oncoproteins leads to genetic instability. Genetic instability is a characteristic feature of most malignant neoplasms and occurs early in the development of precancers. It is important because it allows the stepwise acquisition of multiple mutations to occur. Genetic instability is produced by alterations in the mitotic spindle apparatus. This allows aberrant mitotic events that can produce a disequilibrium with respect to the distribution of chromosomes, leading to changes in the numbers and structures of the chromosomes. It can eventually produce a change in the overall DNA content, referred to as aneuploidy. Genetic instability is thought to play a critical role in the development of cervical cancer (94). LOH studies of primary cervical tumors indicate a high frequency of allelic loss on chromosomes 3p, 4p, 4q, and 11q (95). Nonrandom, cytogenetic deletions in the region of 3p14-p21 appear to be especially important and suggest that a tumor suppressor gene important in cervical cancer may reside in this location (96).

PREVALENCE OF HPV INFECTIONS

HPV Detection Methods

The prevalence of genital tract HPV infections and the frequency of exposure to HPV in the general population vary widely in different studies. These variations are partly due to the different sensitivities of the methods used for detecting HPV infection and differences in the populations studied. Today, PCR methods are generally considered the gold standard for HPV DNA detection (97). PCR is extremely sensitive and has

the ability to detect and type all of the known anogenital HPV types. Currently, two different approaches are used to detect and type HPV DNA using PCR. One approach utilizes “type-specific” primers and the other utilizes “consensus” primers (97). Consensus primers amplify highly conserved regions of the HPV genome and are capable of detecting all, or almost all, of the anogenital HPV types.

The commercially available, Food and Drug Administration (FDA)-approved Hybrid Capture 2 HPV DNA assay has become the most widely used HPV DNA assay for clinical use (97). Hybrid Capture is a solution hybridization method that detects HPV types 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, and 68 using a pooled set of probes. The sensitivity of Hybrid Capture 2 is lower than the sensitivity of PCR, and Hybrid Capture 2 is not able to identify the specific “high-risk” type of HPV present in a sample.

Prevalence of HPV in Women

In nonpregnant women with normal Pap smears, studies that used either PCR or Hybrid Capture 2 have detected HPV DNA in cervical samples in 4% to 43% of women (98–103). These estimates appear to be an under-representation. When multiple samples are taken over time, the cumulative prevalence in cytologically negative women is generally considerably higher (65,104,105). Based on these studies, it is clear that the prevalence of HPV infection in the general population is consistently higher than the prevalence of CIN, by about one order of magnitude. The majority of women who are infected with HPV will never develop CIN 2,3 or cancer. As for cervical neoplasia, the independent risk factors for HPV DNA positivity are young age, high number of sexual partners, lower levels of education and income, and immunosuppression (106).

Several points need to be emphasized with regard to HPV DNA prevalence studies. First, it is clear that the specific populations that are studied greatly affect the results. Adolescent, sexually active women have a higher prevalence of HPV DNA positivity than do older women. Therefore, age is one of the most important factors impacting the prevalence of HPV DNA positivity (Fig. 19.5) (107). In addition, developmental status of the country of residence appears to be important.

FIGURE 19.5. Estimate of prevalence of HPV DNA positivity in women with normal cervical cytology. The estimate is based on a meta-analysis that included published studies from all regions of the world. *Source:* Adapted from de Sanjose S, Diaz M, Casellasague X, et al. Worldwide prevalence and genotype distribution of cervical human papillomavirus DNA in women with normal cytology: a meta-analysis. *Lancet Infect Dis* 2007;7(7):453–459.

The reasons for the increased HPV prevalence in less developed countries is unknown, but may relate to sexual practices among both men and women and poor hygienic conditions (107). Second, the method of cervical sampling may influence the measured prevalence. A final point is that the detection of HPV DNA is often episodic rather than constant. Several studies have shown considerable variation in HPV DNA detection in individual women on a day-to-day basis. This variability appears to be due to episodic shedding of either free virus or virally infected cells from the cervical epithelium.

The prevalence of HPV-related anogenital infections appears to be increased during pregnancy and in immunosuppressed women. One study showed that the prevalence of HPV DNA positivity increased from the first to the third trimester, and that there was a dramatic reduction in prevalence during the postpartum period (108). Although few studies document differences in the prevalence of condylomata acuminata in pregnant patients, it is frequently stated that pregnancy is associated with an increase in the prevalence of genital warts and with an increase in the size of genital warts. It has been suggested that this is due to increased vascularity, perineal moisture, and hormonal stimulation. HPV infections appear to be particularly prevalent among HIV-infected women (64).

TRANSMISSION OF HUMAN PAPILOMAVIRUS

Both genital and nongenital HPV appear to be transmitted predominately through close "skin-to-skin" or "mucosa-to-mucosa" contact and transmission is facilitated by minor trauma at the site of inoculation.

Sexual Transmission

The importance of sexual transmission is highlighted by studies of young women initiating sexual activity. In a study of 604 women attending a university, HPV DNA was detected by PCR in only 3% of women reporting no prior vaginal intercourse, 7% of women with one male sexual partner, 33% of women with two to four partners, and 53% of women with five or more male partners (109). In a prospective study that included virginal young women, Kjaer et al. found that only those women who initiated sexual activity became HPV DNA positive, and that the number of new partners was the most important determinant of HPV acquisition (110). More recently, Winer et al. reported that the rate of incident HPV infections was 25.3 per 100 years at risk among sexually active women with no new partners and increased to 114.5 and 224.4 per 100 years at risk among those with one and more than one new partners, respectively (111). Consistent condom use reduced the rate of incident infections by more than half (111). Males are frequently infected with several different types of HPV and therefore it is not unusual for a woman to become infected with multiple types of HPV (103).

The probability that an individual will be infected per sexual contact is unknown, but appears to be relatively high. The best data on the transmissibility and incubation period of genital warts is that of Oriel, who found that 60% of the sexual partners of patients with condylomata developed condylomata themselves (112). The incubation period for HPV infection ranged from 3 weeks to 8 months, with an average of 3 months. Similarly, 60% of the male consorts of women with CIN have flat, HPV-associated penile lesions (72). Age of the lesion appears to influence the infectivity of condylomata acuminata. Contact with a person whose genital warts have been present only a short time is more likely to result in transmission of the disease than contact with a person whose lesions have been

present for a long time. In some cases this incubation period can be much longer.

Perinatal and Fomite Transmission

Based on studies of small babies with anogenital warts, older children and adolescents who develop laryngeal papillomatosis, and from studies of squamous cell carcinomas of the conjunctiva and nose, it is clear that nonsexual transmission of genital HPV types can occur. Studies of young children with genital condylomata acuminata have convincingly demonstrated that nonvenereal transmission occurs since a significant proportion of genital condylomata in this age group is associated with nongenital HPV types (71). Whether nonvenereal transmission in this setting occurs through contact with fomites or through heteroinoculation is presently unclear. HPV is relatively resistant to desiccation and there are instances in which it appears that anogenital HPV types have been transferred through fomites (113,114). Another example of nonvenereal transmission is laryngeal papillomatosis. Laryngeal papillomatosis is an uncommon disorder characterized by the development of recurrent laryngeal papillomas that are associated with HPV types 6 or 11. The incidence of this uncommon disorder ranges from 0.4 to 1.1 per 100,000 (115). This disorder develops in older children and young adults and it has been suggested that the HPV infection is acquired either *in utero* or during birth.

HPV DNA has been detected in nasal and oropharyngeal swabs in neonates born to women who have genital HPV infections. One recent study detected HPV DNA in the oropharynx of 2.5% of children less than 1 year of age (116). No risk factors were identified among the mothers for HPV transmission to the infants. This and other studies suggest that vertical transmission of HPV infections can occur, but it appears that vertically acquired HPV plays little role in the development of cervical neoplasia in adults. Similarly, transmission via fomites appears to occur, although it is probably an uncommon event and unlikely to account for a significant proportion of anogenital HPV infections in adults.

OUTCOME AFTER EXPOSURE TO HPV

Infection with a high-risk anogenital HPV can result in several outcomes (Fig. 19.6) (90,117). Most women develop a transient productive viral infection that lasts for a period of months to years. During this transient infection, HPV DNA can be detected in genital secretions and exfoliated epithelial cells. Approximately one third of these women develop low-grade cytologic or histologic changes (90). Nevertheless, the vast majority of HPV-infected women spontaneously clear their infections within 1 to 2 years. Clearance appears to be mediated by cellular immune responses. Rates of clearance in different studies vary depending on whether incident or prevalent infections are being studied, but prospective follow-up studies report that less than 20% of women remain DNA positive after 24 months of follow-up (Table 19.8).

It is currently unknown what proportion of women who appear to spontaneously clear their HPV infections and become HPV DNA negative truly clear the infection from the anogenital tract and what proportion continue to have a latent, undetectable HPV infection. Studies of immunosuppressed women indicate that with increasing levels of immunosuppression, a considerable number will become HPV DNA positive even in the absence of new sexual exposures (118,119). This provides strong evidence for the presence of long-term viral latency of anogenital HPV. Reactivation of latent infections

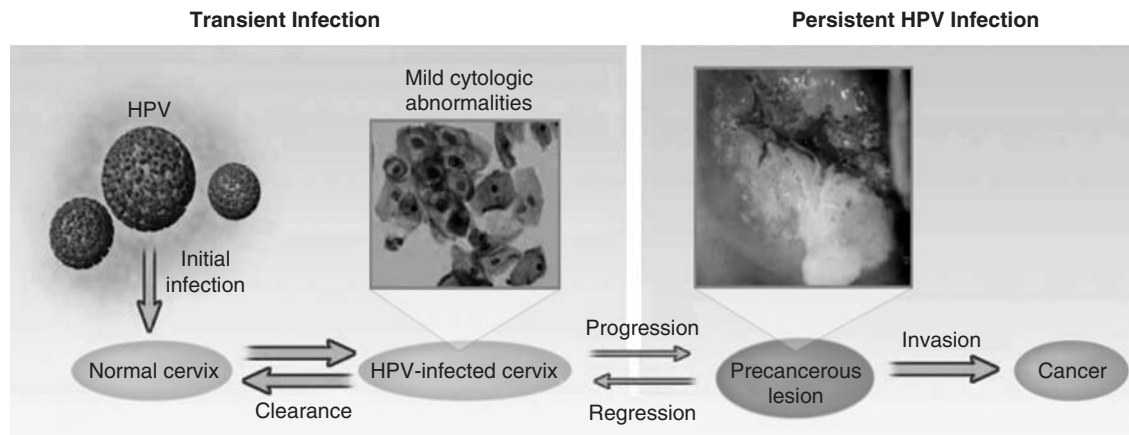

FIGURE 19.6. Natural history of HPV infections. *Source:* Adapted from Wright TC Jr, Schiffman M. Adding a test for human papillomavirus DNA to cervical-cancer screening. *N Engl J Med* 2003;348(6):489–490.

could also explain the increase in prevalence of HPV among cytologically negative older women (Fig. 19.5). The clinical significance of reactivation of latent infections in older women is probably minimal since the risk for CIN 2,3 or cancer among previously well-screened older women is quite low.

There is no accepted definition of what constitutes a clinically significant, persistent infection. Although spontaneous clearance can continue to occur even after 24 months, clinically significant, persistent infections should probably be defined as infections that last at least 2 years. Long-term, stable, persistent infections appear to occur in only about 10% of infected individuals (117). Since prevalence of infection in a population is determined by both the rate of new infections in the population and the rate of clearance of the infection, those HPV types that are most likely to become persistent will also tend to be the most commonly detected ones in the population. Persistent infections are the only clinically significant HPV infections since these are the only ones that can produce high-grade precursors that can progress to invasive cancers. Although newer studies suggest that CIN 2,3 lesions can develop within a relatively short period of time after initial infection, lesions that do not persist for at least 2 years are unlikely to have clinical significance.

PATHOLOGY OF PREINVASIVE LESIONS OF THE LOWER GENITAL TRACT

Cervix

Localization of CIN

The use of colposcopy to identify CIN and careful microscopic studies of the distribution of CIN in conization and hysterectomy specimens have greatly increased our knowledge of the clinical appearance and distribution of CIN. Colposcopic and histologic mapping studies of the position of CIN have shown that the vast majority of lesions develop in a region of the cervix called the *transformation zone*. At the time of menarche, most young women have some endocervical-type columnar epithelium present on the portio (vaginal portion) of the cervix. This endocervical-type epithelium appears salmon red to the naked eye and has been referred to as *cervical erosion*, *ectropion*, *cervical ectopy*, or *native columnar epithelium*. In response to a variety of stimuli including low

FIGURE 19.7. Impact of age on the location of the squamocolumnar junction. As females age, the location of the squamocolumnar junction on the cervix moves. The movement of the squamocolumnar junction defines the transformation zone.

pH, trauma, hormonal factors, and cervicovaginal infections, shortly after menarche the columnar epithelium gradually becomes replaced by a stratified squamous epithelium (Fig. 19.7). The replacement of columnar epithelium by a stratified squamous epithelium occurs by two different processes. One is called *squamous metaplasia* and the other is the direct ingrowth of squamous epithelium from the periphery of the portio, referred to as *epidermidization*. As these processes occur, the histologic junction between stratified squamous epithelium and endocervical-type columnar epithelium moves inward toward the external cervical os. By the age of 40 in most women the entire portio is covered by mature squamous epithelium.

The transformation zone is defined as the region of the cervix that lies between the original squamocolumnar junction and the current or anatomic squamocolumnar junction (Fig. 19.7). The transformation zone is of critical importance in cervical pathology and colposcopy because it is the site at which CIN usually develops as well as the major locus for cervical carcinomas. Although CIN often extends into the endocervical canal, it rarely extends out onto the native squamous epithelium of the portio. The mechanisms responsible for the restricted distribution of CIN on the cervix are unknown.

Origin of CIN

The majority of CIN arises in the transformation zone with one margin adjacent to the current squamocolumnar junction. Therefore, it would appear that the cell of origin of the majority of CIN is the basal cell of squamous metaplasia. The recent demonstration that alpha 6 integrin is a possible receptor for HPV supports this model since alpha 6 integrin is only expressed in basal cells and epidermal stem cells (87). Over the years, there has been some controversy as to whether CIN develops from a single focus or cell and then enlarges centrifugally over the cervix, or whether it can develop as a field effect from multiple foci. CIN 1 frequently develops from a latently-infected cervical epithelium, is often associated with multiple types of HPV, and has many of the features of a productive viral infection rather than a neoplasm. Therefore, it might be predicted that these lesions would be polyclonal in origin. Using more modern molecular techniques, Park et al. found that CIN 1 associated with “non-high-risk” HPV types are typically

polyclonal, whereas CIN 1 associated with “high-risk” HPV types are typically monoclonal, as are almost all CIN 2,3 lesions (120). This indicates that CIN 1 associated with low-risk types of HPV are biologically different at their inception from lesions that are histologically low grade but associated with “high-risk” HPV types. There is now data to suggest that some CIN 2,3 lesions develop *de novo* without a preexisting CIN 1 (121,122). In a study of 54 cytologically negative women who were HPV-16 DNA positive, 17 (31%) developed CIN on follow-up and 41% of the incident cases were first identified as CIN 3 (122). In the recent HPV vaccine trials, some CIN 3 lesions developed very quickly after initial infection with HPV-16 and did not appear to go through a low-grade precursor phase (39).

Microscopic Appearance of CIN

The two histologic hallmarks of CIN, regardless of grade, are the presence of nuclear atypia and aberrant cytoplasmic differentiation. Nuclear atypia in CIN can take many forms. In most cases, the nuclei become enlarged and an increase in the nuclear-cytoplasmic ratio occurs. The extent of nuclear enlargement usually varies from cell to cell, leading to an irregular appearance of the epithelium. Multinucleation also often occurs. The nuclei of cells in CIN are usually hyperchromatic, and the chromatin is coarsely clumped. The nuclear outline is sometimes irregular and angulated rather than round.

Aberrant cytoplasmic differentiation is also invariably found in CIN, irrespective of grade. The normal, stratified, squamous epithelium of the cervix can be divided into three layers (Fig. 19.8). The basal layer is composed of a single layer of cells that is in contact with the basement membrane. The parabasal layer is the proliferative compartment and is one to two cell layers thick. This is the site at which mitoses are observed in the normal cervix. As cells leave the parabasal layer, they become progressively more mature and develop cytoplasmic flattening. Squamous intraepithelial lesions have aberrant differentiation and deviate from this normal pattern. The extent and type of aberrant differentiation varies greatly from lesion to lesion. In the original CIN terminology, lesions were graded 1 to 3 based on the extent to which the epithelium was replaced by undifferentiated basaloid cells. Lesions were classified as follows: CIN 1 if

FIGURE 19.8. Normal stratified squamous epithelium of the cervix.

the undifferentiated cells involved only the lower third of the epithelium (Fig. 19.9A); CIN 2 if undifferentiated cells and mitoses were present up to two thirds of the way through the epithelium (Fig. 19.9B); and CIN 3 if they extended through more than two thirds of the epithelium (Fig. 19.9C).

In CIN 1, HPV cytopathic effect is usually a prominent feature and immature basaloid cells and mitotic figures are restricted to the lower third of the epithelium. The cytopathic effect of HPV can best be described as the formation of a region of perinuclear clearing or vacuolization (Fig. 19.10). Cells with a combination of nuclear atypia and perinuclear clearing are called *koilocytes*, a term derived from the Greek word *koilos*, which means hollow or empty. Not all cells with perinuclear clearing are HPV infected. The presence of perinuclear clearing, or halos, in cells without significant nuclear atypia is seen in a variety of nonneoplastic disorders as well as HPV infections. These disorders include infections with *Trichomonas* organisms, *Gardnerella vaginalis*, and *Candida* organisms. In addition, perinuclear clearing can occasionally be a feature of the atrophic epithelial changes found in postmenopausal patients or in immature squamous metaplasia. Before the recognition that all CIN are associated with HPV infections, cervical condylomata and CIN 1 were generally classified as separate histopathologic entities. With the widespread application of HPV typing to cervical lesions, it has become evident that it is impossible to distinguish on histologic grounds alone between flat cervical condylomata and CIN 1 lesions associated with “low-risk” HPV types and those associated with “high-risk” HPV types (5). Since clinical and histologic criteria do not allow segregation of low-grade lesions on the basis of oncogenic potential, distinctions between flat cervical condylomata and low-grade CIN 1 lesions are no longer clinically meaningful and have been dropped from the Bethesda terminology.

Although HPV-induced cytopathic effects are often present, they are usually less prominent in CIN 2,3 than in CIN 1. CIN 2,3 is characterized by immature basaloid cells and mitotic figures that extend into the upper two thirds of the epithelium. The immature basaloid cells usually have nuclear crowding, pleomorphism, and loss of normal cell polarity. Cytoplasm is usually minimal, which results in a high nuclear-to-cytoplasmic ratio. Another feature found in most high-grade lesions is abnormal mitotic figures (Fig. 19.11). Most squamous cell carcinomas of the cervix have chromosomal abnormalities, and many are aneuploid. This suggests that aneuploid precursor lesions are highly significant and may

FIGURE 19.9. Histology of (A) CIN 1, (B) CIN 2, (C) CIN 3.

have the capacity to progress to an invasive carcinoma if left untreated. Support for such a hypothesis comes from studies that have documented that the percentage of aneuploid CIN lesions increases as the grade of the lesion increases (9). The best histologic predictor of an aneuploid lesion is the presence of abnormal mitotic figures.

Microscopic Appearance of Endocervical Glandular Atypia and Adenocarcinoma *In Situ*

Both endocervical glandular atypia and adenocarcinoma *in situ* of the endocervix are characterized by endocervical

FIGURE 19.10. A: CIN 1 lesions are characterized by the presence of cells with perinuclear halos and nuclear atypia. B: *In situ* hybridization of a CIN 1 lesion using probes for HPV-16/18 detects HPV DNA appearing as dark staining of the nuclei of the superficial cells.

glands that are lined by atypical glandular cells and lack evidence of stromal invasion (Fig. 19.12A). In both lesions, individual endocervical cells have many of the histologic and cytologic features of invasive adenocarcinoma. The atypical endocervical cells are enlarged with hyperchromatic, elongated nuclei (Fig. 19.12B). Characteristically, the chromatin pattern is coarse and granular. There is a reduction in the amount of cytoplasm and only minimal intracellular mucin is present. A characteristic feature of both endocervical glandular atypia and adenocarcinoma *in situ* is crowding of the cells and pseudostratification. Abrupt transitions between involved and uninvolved epithelium are frequently observed.

Endocervical glandular atypia and adenocarcinoma *in situ* are differentiated from each other by their relative degrees of mitotic activity and pseudostratification. Mitotic figures are quite common and atypical mitotic figures are frequently observed in adenocarcinoma *in situ*. There is

marked pseudostratification of the endocervical cells that form two or three cell layers. This results in cribriforming and complex papillary infoldings of the epithelium into the gland lumens. In contrast, mitotic figures are relatively uncommon in endocervical glandular atypia, and the atypical endocervical cells are not pseudostratified. Instead they form a single row of cells. Cribriforming and papillary infoldings are also infrequent in endocervical glandular atypia.

Architectural features are used to distinguish between adenocarcinoma *in situ* and invasive endocervical adenocarcinoma. Invasion is diagnosed when atypical glands extend beyond the depth of the normal, uninvolved endocervical glands. This is usually approximately 5 to 6 mm from the surface. Features suggestive of invasion include desmoplasia or stromal reaction around the involved glands, exuberant gland budding, back-to-back glands, and papillary projections from the endocervical surface.

FIGURE 19.12. Adenocarcinoma *in situ* of the cervix. **A:** Adenocarcinoma *in situ* is characterized by glands lined by atypical endocervical cells that frequently form papillary projections into the glandular lumen. **B:** At higher magnification, the endocervical cells are pseudostratified and there are numerous mitotic figures.

Vulva

Gross Appearance of Vulvar HPV-Associated Lesions

Anogenital warts can be categorized into three separate types based on their gross appearances (123). One is a hyperplastic, cauliflower-like lesion called condyloma acuminatum. These raised exophytic lesions are pink to white and are found in moist areas such as the labia, perianal region, glans penis, inner aspect of the prepuce, and the urethral meatus. Another is a small sessile plaque type of wart. These are most common on the penile shaft. The final type is a keratotic, verruca vulgaris-like wart.

Vulvar condylomata occur in women of all age groups but have a peak incidence from ages 20 to 24. They vary in size from small, easily treated lesions to large, inflamed masses that tend to recur after treatment (Fig. 19.13). A key feature of HPV infection of the lower female genital tract is that it often involves multiple sites and is multifocal. For example, 22% to 32% of female patients with vulvar condylomata will have concurrent cervical lesions (124,125). Therefore, it is essential that the entire lower genital tract be examined carefully in all patients with vulvar condylomata. Vulvar lesions with a typical gross appearance of condylomata are readily recognized and are rarely confused with other lesions. However, when the appearance is atypical, the differential diagnosis can include almost any raised vulvar lesion, including condyloma latum, molluscum contagiosum, fibropapilloma, lymphoma, hidradenoma, and even verrucous carcinoma

FIGURE 19.13. Gross features of vulvar condyloma acuminatum. *Source:* Used with permission courtesy of Dr. D. Townsend, University of California. From Wright TC, Richart RM. Pathology quiz: condyloma acuminatum. *Contemp OB/GYN* 1990;4:5.

if the lesion is large. In atypical cases, a biopsy of the lesion is mandatory and usually diagnostic. The classic histologic features of condylomata acuminata are papillomatosis, acanthosis with hyperkeratosis, parakeratosis, and the presence of nuclear atypia with multinucleation and koilocytosis (Fig. 19.14). As mentioned previously, condylomata acuminata are usually associated with HPV types 6 and 11. Human papillomavirus DNA can be detected by *in situ* hybridization in more than 90% of cases of condylomata acuminata (Fig. 19.14) (126).

Many patients have small genital epithelial lesions that are clinically suggestive of plaque-type anogenital warts and are better visualized after the application of 4% acetic acid but histologically lack characteristic HPV-associated cytopathic effects. These lesions are particularly common in men and occur on the corona glandis and along each side of the frenulum of the penis. The term *pearly penile papules* has been used for these lesions (127). In females, a common mimic of condylomata acuminata is *micropapillomatosis labialis* (128). Micropapillomatosis labialis occurs at the introitus and appears as multiple, soft papillary projections that are characteristically bilateral and symmetric (Fig. 19.15). Although micropapillomatosis labialis can histologically be mistaken for an HPV-related lesion, multiple studies have failed to detect HPV DNA in a significant number of cases (128). Another common entity that is often confused with condyloma acuminatum, especially by pathologists, is benign fibropapilloma of the anogenital region.

Like CIN 2,3, vulvar intraepithelial neoplasia has been increasing in incidence over the last two decades (129,130). Vulvar intraepithelial neoplasia usually presents as a slightly raised, sharply demarcated lesion that can be black, white, gray, red, or brown, depending on the age, race, and complexion of the patient (Fig. 19.16). These lesions tend to be unifocal in older patients and multifocal in younger patients. The margins are often irregular, and the lesions vary in size from

several millimeters to large, confluent lesions that involve the entire vulva. The majority of lesions are 1 to 3 cm in diameter. Most commonly, VIN develops on the labia minora, around the anus, and at the introitus (131). The clitoris and urethra are less commonly involved.

Bowenoid papulosis is considered by many to be a separate entity. It is a disease characterized by multiple small papules that are often violaceous and occasionally coalesce to form large plaques. The lesions develop on the vulvar skin and occasionally on the abdomen. Bowenoid papulosis is a disease of young women, with a peak incidence in the third decade. However, despite the relatively innocuous gross appearance of Bowenoid papulosis, this lesion is identical histologically to VIN 3. Invasive vulvar carcinoma may arise in untreated cases of Bowenoid papulosis.

Microscopic Appearance of Vulvar Intraepithelial Neoplasia

Microscopically, VIN lesions are similar to CIN lesions. The four major histologic features are increased numbers of undifferentiated cells with nuclear atypia, alterations in epidermal maturation with disorganization, parakeratosis and hyperkeratosis, and the presence of abnormal mitotic figures (Fig. 19.17). Although the ISSVD has recommended that VIN lesions no longer be graded and that VIN 1 lesions not be diagnosed, in most centers VIN lesions continue to be histologically graded on a scale of 1 to 3, using criteria identical to those used for the original CIN terminology for cervical cancer precursors (22,132). Nuclear atypia in VIN typically involves the basal and parabasal cell layers as well as cells in the upper, more differentiated cell layers. Nuclear size in VIN varies from small and hyperchromatic to pleomorphic and large.

VIN lesions tend to have three histopathologic appearances termed *warty*, *basaloid*, and *differentiated* (133). Separation into these three subtypes is based predominately

FIGURE 19.17. Microscopic features of VIN 3.

on nuclear size and the amount of cytoplasmic differentiation. In general, invasive vulvar cancers that are HPV DNA positive occur in younger women and are associated with the warty and basaloid variants of VIN (134). In the ISSVD terminology these histologic types of VIN are grouped together as *VIN, usual type* (22). In contrast to the warty and basaloid variants of VIN which are associated with HPV DNA positive vulvar cancers in younger women, differentiated VIN is found in older women and tends to be associated with HPV DNA negative invasive vulvar cancers (135). This type of VIN was originally referred to as *carcinoma in situ, simplex type*. Differentiated VIN often occurs adjacent to well-differentiated invasive vulvar cancers and is often associated with either squamous hyperplasia or lichen sclerosis of the vulva (133).

These histologic variants, especially the warty and basaloid forms, are frequently found together in the same patient. Moreover, there is no data to suggest that histopathologic type has a significant impact on either rates of progression to invasive vulvar cancer or response to standard therapies. One additional point needs further clarification. Although the histologic distinction between cervical condylomata and CIN 1 is no longer thought to be possible, vulvar condylomata and VIN are still distinguished from one another. The reason for retaining this distinction for the vulva is that the vast majority of vulvar condylomata are caused by HPV-6 or -11, which are low-oncogenic-risk HPV types (70). The development of invasive vulvar carcinoma from a preexisting condyloma acuminatum is an extremely rare event. Histologically, the distinction between vulvar condylomata and VIN is made on the basis of two features: the presence or absence of abnormal mitotic figures and the presence or absence of nuclear atypia that involve the basal and parabasal cell layers.

Vagina

Vaginal intraepithelial neoplasia lesions are generally white with sharp borders. They are best evaluated with colposcopy after the application of 4% acetic acid. In general, vascular changes are not striking in VAIN lesions, although punctation is occasionally seen. The histologic features of VAIN are identical to those of CIN and VIN.

CYTOLOGIC SCREENING FOR CERVICAL CANCER AND ITS PRECURSORS

Background

Cytology-based cervical cancer screening programs were first introduced in the mid-20th century and are now widely recognized as being able to reduce both the incidence of, and mortality from, invasive cervical cancer. Strong evidence for their effectiveness comes from comparison of incidence and mortality trends of invasive cervical cancer with screening activity in a given country or region. The Nordic countries provide some of the best evidence for a linkage between screening and reductions in both incidence and mortality from cervical cancer (54). In order to be effective, these programs require good coverage of the target population and appropriate management of screen-positive women (54). The importance of coverage is seen in the cervical cancer rates in the United Kingdom. Prior to 1988 there was a recommendation by the National Health Service (NHS) for routine cytologic screening, but coverage of the population was relatively low and cervical cancer rates

FIGURE 19.18. Impact of increasing screening coverage on the age-standardized incidence of invasive cervical cancer in the United Kingdom, 1971–1995. *Source:* Adapted from Quinn M, Babb P, Jones J, Allen E. Effect of screening on incidence of and mortality from cancer of cervix in England: evaluation based on routinely collected statistics. *BMJ* 1999;318:904.

remained relatively high (Fig. 19.18) (136). In 1988 the NHS introduced a national call-recall system, improved quality control in the laboratories, and provided financial incentives to general practitioners to encourage high rates of screening in their patients. As a result of this program, the incidence of invasive cervical cancer began to quickly drop.

Accuracy of Cervical Cytology

Despite the proven effectiveness of cervical cytology in reducing the incidence of cervical cancer, over the last several years the accuracy of cervical cytology has been questioned. Two factors need to be considered when assessing the accuracy of any diagnostic test including cervical cytology. One is whether the test is specific in detecting a given condition; the other is the sensitivity of the test for detecting a given condition. Several meta-analyses have been conducted and have concluded that both the sensitivity and specificity of cervical cytology is lower than previously thought (137,138). The first analysis by Fahey et al. estimated that the mean sensitivity of a conventional cervical cytology was 58% and the mean specificity was 69%, when used in a screening setting (Fig. 19.19) (137). The second meta-analysis by Nanda et al. considered different cytologic cut-offs and endpoints (138). When a cytologic cut-off of atypical squamous cells of undetermined significance (ASC-US) is used and the endpoint is biopsy-confirmed CIN 1 or worse, the average sensitivity of conventional cytology was 68% and the average specificity was 75% (Fig. 19.19). When the cytologic cut-off was LSIL and the endpoint was biopsy-confirmed CIN 2,3 or worse, the average sensitivity was 81% and the specificity was 77%.

A number of factors influence the false-negative rate of cervical cytology. Of key importance is the use of a proper technique for sampling the cervix. Since the majority of CIN and cancers involve the transformation zone, sampling devices have been specifically designed to sample this area. Sampling the endocervical canal also reduces the false-negative rate. This sample can be taken with an endocervical brush (e.g., Cytobrush) or one of the newer collection devices such as a cell broom. Saline-moistened cotton-tipped applicators should not be used since the number of endocervical cells that are obtained with a cotton-tipped applicator is less than the number obtained with a Cytobrush and several studies have reported a higher CIN detection rate when Cytobrushes are used (139). Other important factors for reducing the false-negative rate are the rapid fixation of cells to prevent artifactual changes secondary to air-drying and the use of a cytology laboratory with stringent quality control standards.

Although a false-negative rate of 20% to 40% for a cancer screening test appears to be unacceptably high, the test has been effective despite its limitations due to the natural history of the disease, and the use of cervical cytology has reduced the incidence of cervical cancer by almost 80% in the United States over the last 3 decades (140). The effectiveness of cervical cancer screening is attributable to the fact that invasive cervical cancer requires many years to develop from a CIN 2,3 lesion (5). If cervical cytology is performed on a routine basis, it is unlikely that a CIN 2,3 lesion will remain undetected, although such cases do rarely occur. The current screening recommendation from the American Cancer Society and the American College of Obstetricians and Gynecologists is that cervical cancer screening should be initiated approximately

FIGURE 19.19. Estimates of the sensitivity (circles) and specificity (squares) of conventional cervical cytology obtained from two meta-analyses (those of Fahey et al. left side with bars showing 95% confidence intervals and Nanda et al. right side with bars representing range of values in different studies). *Source:* Modified with permission from Fahey MT, Irwig L, Macaskill P. Meta-analysis of Pap test accuracy. *Am J Epidemiol* 1995;141:680, and Nanda K, McCrory DC, Myers ER, et al. 3 years after the initiation of sexual intercourse, but no later than age 21 years (141,142). After 30 years of age, the interval between cervical cytology examinations can be extended to 2 to 3 years in women who have had three consecutive negative cervical cytology screening test results, who have no history of CIN 2,3, and are neither immunocompromised nor exposed to diethylstilbestrol (DES) (141,142). There is currently no consensus as to when to stop screening. The American Cancer Society recommends that screening can be discontinued in women 70 years and older with three documented negative screening tests within the preceding 10 years and no history of cervical cancer, DES exposure, or immunosuppression (142). The U.S. Preventative Services Task Force recommends discontinuing screening at age 65 years in women who have had adequate recent screening and who are not otherwise at high risk for cervical cancer (143). Routine screening is not recommended for women who have undergone a hysterectomy for benign indications and who have no prior history of CIN 2,3.

Obtaining an Optimal Cervical Cytology

To obtain an optimal cervical cytology, it is necessary to observe several simple guidelines. The patient should be instructed not to douche, wash her vagina, or have intercourse for 24 hours before obtaining the specimen. Cervical cytology should not be obtained during menses or within 1 week after stopping intravaginal antibiotics or antifungal agents. Cervical cytology should be taken before a bimanual exam, using a minimal amount or no lubricant. It is preferable not to apply acetic acid to the cervix before the cervical cytology is taken. An Ayre-type spatula or cell broom type of device should be used and rotated around the cervix several times with firm pressure. A Cytobrush is immediately placed in the external os, rotated 180° only, and withdrawn. The sample is immediately fixed and labeled with the patient's name and date of birth.

Liquid-Based Cytology

Liquid-based cytology (LBC) is now widely used in the United States for cervical cytology. Three liquid-based cytology methods are currently available in the United States. These are the ThinPrep Pap Test marketed by Cytec Corporation, SurePath marketed by BD Diagnostics, and MonoPrep Pap Test marketed by MonoGen, Inc. ThinPrep and MonoPrep use a filter method to collect a monolayer of epithelial cells and separate the epithelial cells from blood, mucus, and inflammatory debris. SurePath uses a density centrifugation method to enrich for epithelial cells and reduce blood and inflammatory cells.

A major reappraisal is underway in the screening community of the performance of LBC. When it was first introduced, LBC was believed to provide a significant advantage compared to conventional cervical cytology with respect to sensitivity for the identification of women with CIN 2,3 or cancer. However, most of the studies that compared LBC with conventional cytology had methodologic problems such as the use of historical controls, and others simply reported increases in the number of cases cytologically diagnosed as squamous intraepithelial lesions (SIL). Very few studies measured histologic endpoints and the few studies that actually utilized histologic endpoints did not blind the pathologists evaluating the histology to the cytologic findings. Only one small study was randomized.

Recently two systematic reviews of the published literature comparing the performance of LBC with conventional cytology were published (144,145). One included a total of 56 studies, 52 of which provided enough information to evaluate differences between LBC and conventional cytology (144). These 52 included more than a 1.25 million slides. Of the studies that were evaluated, none were of "ideal quality" and only five were of "high quality." When all of the studies were taken into

account and combined it was concluded that they saw no evidence that LBC reduced the proportion of unsatisfactory slides nor that it has better performance than conventional cytology with respect to the identification of women with CIN 2,3. The reviews concluded that large randomized trials were needed.

Since the first systematic review was conducted, two large randomized trials comparing LBC with conventional cytology have been published. One was conducted in South Africa and no significant difference was observed in the sensitivity of LBC and conventional cytology in the detection of CIN 2,3 or cancer (Table 19.9) (146). An Italian randomized study also failed to find that LBC is more sensitive than conventional cytology but did find a 43% reduction in positive predictive value (PPV) with LBC due to an increase in the number of abnormalities (Table 19.9) (147). After the publication of these two large trials, another systematic review and meta-analysis of LBC found that there were only six other published studies that were appropriately designed to allow a comparison of the performance of LBC and conventional cytology (148). This review concluded that there is no evidence that LBC is either more sensitive or more specific than conventional cytology.

Having said this, it is important for clinicians to recognize that there are other advantages of LBC. The greatest of these appears to be the availability of residual fluid for "reflex" HPV testing in women with ASC-US as well as testing for other pathogens such as *Chlamydia*. Moreover, almost all cytologists agree that it is easier to evaluate LBC specimens than conventional cytology specimens and it is unlikely that cytology laboratories will want to switch back to conventional cytology now that the conversion to LBC has taken place.

Terminology of Cytologic Reports

The Bethesda system terminology is used for reporting cervical cytology results in the United States. The Bethesda system underwent significant modifications in 2001 (Table 19.10) (10). The major features of the 2001 Bethesda system are that it requires (a) an estimate of the adequacy of the specimen for diagnostic evaluation; (b) a general categorization of the specimen as being either "negative for intraepithelial lesion or malignancy," as having an "epithelial cell abnormality," or as

TABLE 19.10**THE 2001 BETHESDA SYSTEM****SPECIMEN ADEQUACY**

separate epithelial changes secondary to inflammation or repair from those associated with cervical cancer precursors whenever possible. Nondiagnostic squamous cell abnormalities are included in a category of *atypical squamous cells* (ASC). ASC is used when a specimen has features suggestive, but not diagnostic, of an SIL. This category is further subdivided into two subcategories: atypical squamous cells of undetermined significance (ASC-US); and atypical squamous cells—cannot exclude HSIL (ASC-H). The risk of a woman with ASC-US having biopsy-confirmed CIN 2,3 is approximately 7% to 17% and the risk of a woman with ASC-H is approximately 40% (11). Nondiagnostic glandular cell abnormalities are included in a category of *atypical glandular cells* (AGC). This category is further subdivided into either *not further classified* or *atypical glandular cells, favor neoplasia*.

Cytologic Features of CIN

The features used to diagnose SIL cytologically are similar to those used to diagnose CIN in histopathologic specimens. These features include nuclear enlargement with an increase in the nuclear-cytoplasmic ratio, nuclear hyperchromaticity, irregular nuclear membranes, and multinucleation. Perinuclear clearing, or halos, is also commonly present. An example of normal superficial cells is shown in Figure 19.20A. In LSIL, cytologic changes are seen predominantly in superficial cells (i.e., more mature cell types, Fig. 19.20B). In HSIL, the cytologic changes are seen in intermediate and parabasal cells (i.e., less mature cell types, Fig. 19.20C).

USE OF COLPOSCOPY

Over the last 25 years, colposcopy combined with colposcopically directed cervical biopsies has become the primary modality by which women with abnormal Pap smears are evaluated. Colposcopic examination consists of viewing the cervix with a long-focal-length, dissecting-type microscope at a magnification of about 16 \times after a solution of dilute (4%) acetic acid has been applied to the cervix. The acetic acid solution acts to remove and dissolve the cervical mucus and causes CIN lesions to become whiter than the surrounding epithelium (acetowhite). This coloration allows the colposcopist to identify and biopsy epithelial lesions. In addition to allowing the detection of acetowhite areas, colposcopy also allows for the detection of blood vessel patterns that can indicate high-grade CIN lesions and the detection of invasive cancers. Colposcopy and appropriately directed biopsy have greatly facilitated the management of patients with preinvasive lesions of the cervix because they allow the clinician to rule out invasive cancer and determine the limits of preinvasive disease. Conservative ablative treatment modalities such as cryosurgery, laser ablation, and electrofulguration, as well as excisional methods such as loop electrosurgical excision procedure (LEEP) can then be used to treat preinvasive disease, with success rates similar to those obtained with cone biopsies.

MANAGEMENT OF CYTOLOGIC ABNORMALITIES AND CIN**Overview**

In 2006 the American Society for Colposcopy and Cervical Pathology sponsored a consensus workshop to update the 2001 Consensus Guidelines for the Management of Women with Cytological Abnormalities and Cervical Cancer Precursors

“other” (i.e., having endometrial cells in a woman 40 years of age and older); and (c) a descriptive diagnosis that includes a description of epithelial cell abnormalities. This system provides clear criteria for determining whether a specimen is adequate for evaluation. In addition, the terminology closely correlates with histopathologic terminology. The terms *low-grade squamous intraepithelial lesion* (LSIL) and *high-grade squamous intraepithelial lesion* (HSIL) are used to designate cytologic changes that correlate with CIN 1 and CIN 2,3, respectively. In addition, the Bethesda system attempts to

FIGURE 19.20. Cervical cytology. **A:** Normal superficial cells. **B:** Low-grade SIL (CIN 1) in which the cells are multinucleated with slightly enlarged hyperchromatic nuclei and perinuclear halos. **C:** High-grade SIL (CIN 2,3) with cells with high nucleocytoplasmic ratios.

(12,147). These guidelines are widely used in the United States and are evidence-based with each recommendation accompanied by a grading of both the strength of the recommendation and the strength of the data supporting the recommendation. The complete recommendations and management algorithms are available at www.asccp.org.

Atypical Squamous Cells

A vexing group of patients for both clinicians and cytologists are those whose cervical cytology is atypical (i.e., not normal) but lack the characteristic features of SIL or cancer. In the past, many cytology laboratories subdivided atypical smears into two categories: atypical, reparative-inflammatory changes (i.e., benign atypia); and atypical smears, suggestive but not diagnostic of CIN. The 2001 Bethesda system classifies specimens that have reparative-inflammatory changes as being “negative for intraepithelial lesion or malignancy.” In the current terminology only those specimens that have features suggestive of SIL should be classified as ASC. Irrespective of the classification system used, clinicians need to be aware that a cytologic result of ASC is the least reproducible cytologic category (149). The number of cytology specimens that are diagnosed as ASC varies greatly among different cytology laboratories and patient populations. The reported incidence of atypical Pap smears that fall into this category varies greatly from 1% to over 10% (4). These differences reflect the difficulties encountered by cytologists in determining the significance of minor degrees of cytologic atypia and in reproducibly recognizing these changes. In the most recent report from the College of American Pathologists (CAP), the median ASC rate from reporting laboratories from the United States was 5% (4).

The clinical significance of an ASC result depends on a number of factors including the age of the patient, the patient’s history, and the subclassification of the result (e.g., ASC-US or ASC-H). The prevalence of biopsy-confirmed CIN 2,3 found in women undergoing colposcopy for an ASC cytology is generally reported as being 5% to 17% (12). A study of 46,009 women undergoing routine cytologic screening in the Northern California Kaiser Permanente Medical Group found that 3.5% had a diagnosis of ASC-US (150). At colposcopy, 13% of these women were diagnosed with CIN 1, 7% with CIN 2,3, and one woman had invasive cervical cancer. In the large, multicenter ASC-US/LSIL Triage Study (ALTS), 15% of the women referred with ASC were found to have biopsy-confirmed CIN 2,3 at the initial colposcopic examination and 20% had biopsy-confirmed CIN 1 (151). Overall, it appears that between one third and one half of all women diagnosed as having CIN 2,3 have ASC as their initial abnormal cervical cytology result (152,153). Although the risk that a woman with ASC has invasive cervical cancer is quite low (about one per thousand) the very large number of women with this cytology interpretation (2.5 million annually) guarantees that each year approximately 2,500 women with invasive cervical cancer will have only equivocal results on their cervical cytology. Therefore, women with ASC-US need to receive some form of follow-up evaluation, but consideration should be given to preventing unnecessary inconvenience, anxiety, cost, and discomfort.

Atypical Squamous Cells of Undetermined Significance

Three methods are in widespread use for the management of women with ASC. These are immediate colposcopy, HPV DNA testing, and a program of repeat cervical cytology. A number of studies have directly compared the sensitivity and specificity of repeat cervical cytology and HPV DNA testing

Management of Women With Atypical Squamous Cells of Undetermined Significance (ASC-US)

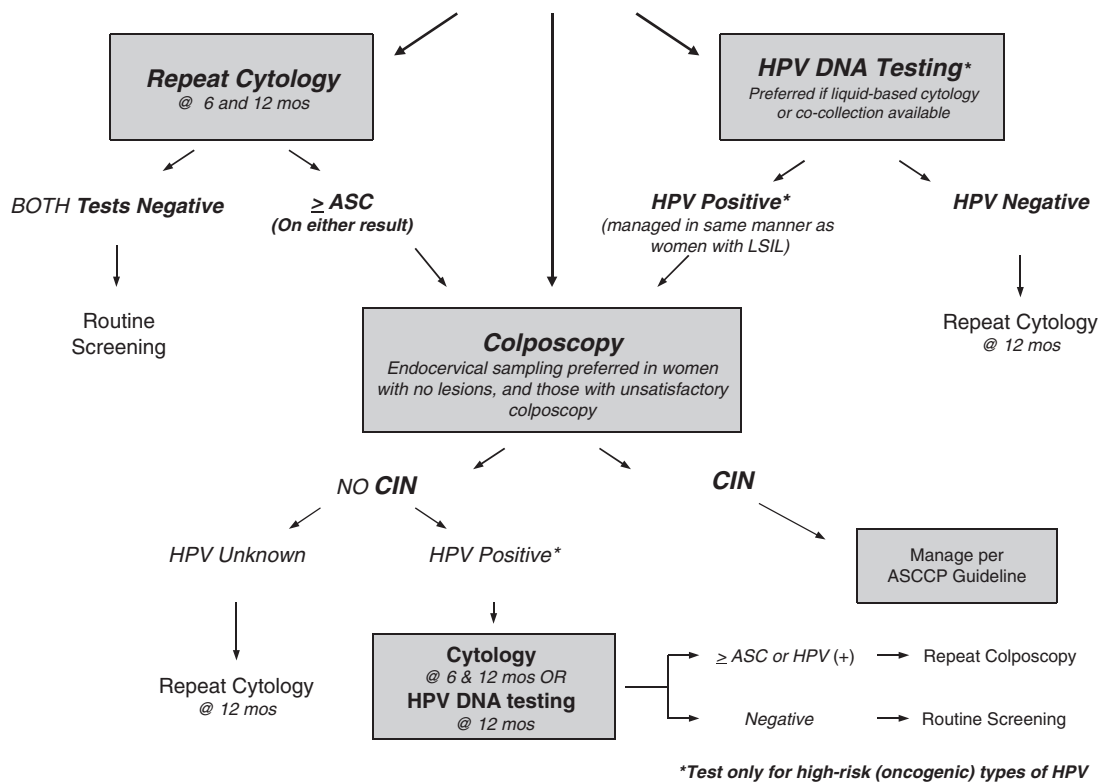

FIGURE 19.21. 2006 Consensus Guidelines for the management of women with ASC-US. Source: Used with permission from the American Society of Colposcopy and Cervical Pathology.

for identifying women with CIN 2,3 (154). In every single study, HPV DNA testing identified more cases of CIN 2,3 than did a single repeat cervical cytology, but referred approximately equivalent numbers of women for colposcopy. Moreover, cost-effectiveness modeling using mathematical models has demonstrated that HPV DNA testing for women with ASC-US is a highly attractive alternative to immediate colposcopy or a program of repeat cytology when the initial ASC-US cytology was obtained from a liquid-based sample or when a co-collected HPV test was taken at the time a conventional cytology was obtained (155,156). Based on this evidence, the 2006 American Society for Colposcopy and Cervical Pathology (ASCCP) Consensus Conference concluded that although all three of the methods traditionally used to manage women with ASC-US (i.e., colposcopy, repeat cytology, and HPV DNA testing) are safe and effective, high-risk HPV DNA testing is the preferred approach to managing women with ASC-US whenever liquid-based cytology is used for screening or co-collection of a sample for HPV DNA testing can be performed (12). Figure 19.21 provides the algorithm recommended for the management of women in the general population with ASC-US. This algorithm is appropriate for women of all ages with ASC-US.

The prevalence of HPV DNA positivity is much higher in young women with ASC-US than in older women. For example, in the ALTS study only 31% of women 29 years and older with ASC were HPV DNA positive compared to 65% of those under 29 years old (157). Rates are even higher in adolescents with ASC-US (158). Therefore, the 2006 Consensus Guidelines do not recommend the use of HPV DNA testing in adolescents, defined as females 13 to 20 years of age (12). Instead,

adolescents should be managed using annual repeat cytologic examinations and only referred to colposcopy if the repeat Pap tests are diagnosed as HSIL or are persistently abnormal for a period of 2 years (12).

Management options for pregnant patients with ASC-US are identical to those for nonpregnant patients with the exception that it is acceptable to defer the colposcopic examination until the patient is 6 to 8 weeks post-partum (12).

Atypical Squamous Cells—Cannot Exclude HSIL

The prevalence of biopsy-confirmed CIN 2,3 is considerably higher among women referred for the evaluation of an ASC-H cervical cytology than it is for women referred for the evaluation of ASC-US. CIN 2,3 is identified in 24% to 94% of women with ASC-H (11). Therefore, for the purposes of management, ASC-H should be considered to be an equivocal HSIL result. Because of this high risk, the 2006 Consensus Guidelines recommend that all women with ASC-H be referred for a colposcopic evaluation (12). If CIN is not identified, follow-up utilizing either repeat cytology at 6 and 12 months or high-risk HPV DNA testing at 12 months is acceptable (Fig. 19.22).

Low-Grade Squamous Intraepithelial Lesions

As with ASC-US, there is considerable variation between populations and laboratories in the rate at which LSIL is reported. In 2003 the median rate of LSIL reported from the College of American Pathology survey was 2.6%, but rates as high as 7.0% were reported from 5% of the laboratories (4). In 1996

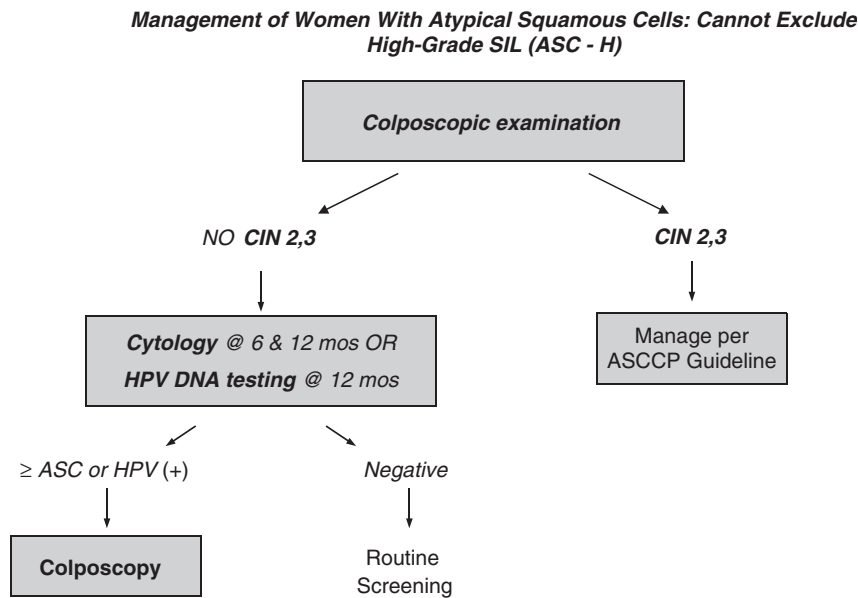

FIGURE 19.22. 2006 Consensus Guidelines for the management of women with ASC-H. *Source:* Used with permission from the American Society of Colposcopy and Cervical Pathology.

the median rate of LSIL in the United States was only 1.6% (159). The increase appears to be due to the introduction of liquid-based cytology (144). A cytologic result of LSIL is a very specific indicator of the presence of high-risk types of HPV. In ALTS, 83% of the women referred for the evaluation of LSIL were high-risk HPV DNA positive (160). However, a cytologic result of LSIL is a poor predictor of the grade of CIN that will be identified at colposcopy. CIN 2,3 is identified at colposcopy in 15% to 30% of women with LSIL on cervical cytology (152,159,161). Therefore, the 2006 Consensus Guidelines recommend that all women in the general population with a cytologic result of LSIL be referred for a colposcopic evaluation (Fig. 19.23) (12). This allows women with significant disease to be rapidly identified and reduces the risk of women being lost to follow-up. A diagnostic excisional procedure is not required when a woman with LSIL cytology is found to have an unsatisfactory colposcopic examination.

The risk of invasive cervical cancer is very low in adolescents and prospective studies have shown that over 90% of LSIL will spontaneously clear over a period of years in adolescents (162,163). Therefore, adolescents with LSIL (<21 years of age) are considered to be a “special population” and it is now recommended that they should not receive colposcopy, but instead should be followed using yearly Pap tests for a period of 2 years (12). Another special population is postmenopausal women with LSIL. In some studies, the prevalence of HPV DNA in postmenopausal women with LSIL is lower than in premenopausal women and the prevalence of CIN 2,3 also declines in postmenopausal women with LSIL (157,164). Therefore, the 2006 Consensus Guidelines indicate that postmenopausal women with LSIL can be managed in the same manner as women with ASC-US. This allows the use of reflex HPV DNA testing to determine which of these women require colposcopy.

High-Grade Squamous Intraepithelial Lesions

The cytologic result of HSIL is uncommon, accounting for only about 0.7% of all cervical cytology results, but the

prevalence varies with age (4). In one U.S. study the prevalence of HSIL was 0.6% in women 20 to 29 years of age, but only 0.1% in women 50 to 59 years of age (165). A diagnosis of HSIL confers a significant risk for CIN 2,3 and invasive cervical cancer (4,166). CIN 2,3 or cancer has been identified at a single colposcopic examination in 53% to 66% of women with HSIL and in 84% to 97% of those evaluated using a loop electrosurgical excision procedure (LEEP) (12). Invasive cervical cancer is identified in approximately 2% of women with HSIL (167). Therefore, women with a cytologic result of HSIL should be referred for either a colposcopic evaluation or an immediate LEEP (Fig. 19.24) (12). Subsequent management depends on whether or not the patient is pregnant and whether the colposcopic examination is satisfactory. If CIN 2,3 is not identified after colposcopy, the colposcopic examination is satisfactory, and endocervical sampling is negative, either a diagnostic excisional procedure or follow-up using colposcopy and cytology at 6-month intervals is acceptable for 1 year. If a repeat HSIL cytologic result is found at either the 6- or 12-month visit, a diagnostic excisional procedure is recommended. Nonpregnant women with HSIL who have an unsatisfactory colposcopic examination also require a diagnostic excisional procedure.

Biopsy-Confirmed CIN 1

Women with a histologically confirmed CIN 1 lesion represent a heterogeneous group. A number of studies have clearly demonstrated a high level of variability in the histologic diagnosis of CIN 1. In the ALTS study, only 43% of biopsies that were originally diagnosed as CIN 1 at the clinical centers were subsequently classified as CIN 1 by the reference pathology committee. Forty-one percent were downgraded to normal, and 13% were upgraded to CIN 2,3 (149). It should also be noted that there is a very high rate of spontaneous regression of CIN 1 in the absence of treatment. One prospective Brazilian study found that 90% of women with a cytologic diagnosis of LSIL spontaneously regressed within 24 months (168). A Dutch study found that over 4 years, 70% of women with

Management of Women With Low-Grade Squamous Intraepithelial Lesions (LSIL) *

Management of Women With High-Grade Squamous Intraepithelial Lesions (HSIL) *

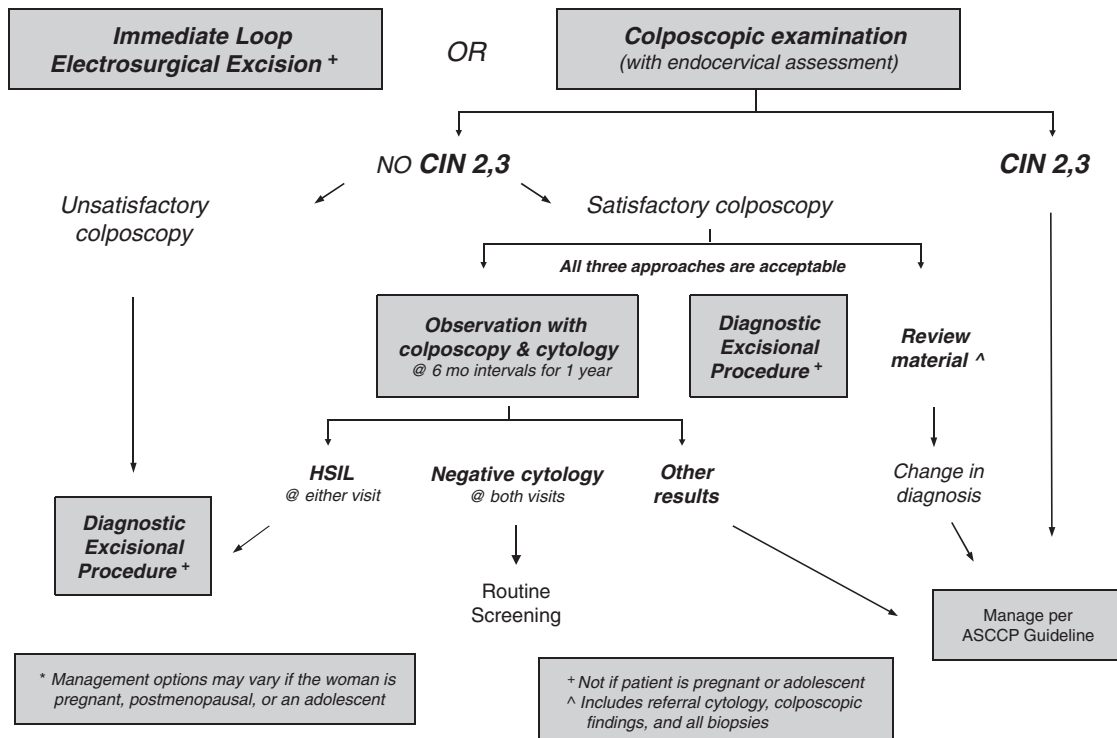

FIGURE 19.24. 2006 Consensus Guidelines for the management of women with HSIL. Source: Used with permission from the American Society of Colposcopy and Cervical Pathology.

LSIL infected with high-risk types of HPV spontaneously cleared their infections (169). Recent studies indicate that CIN 1 only rarely progresses to CIN 2,3. In the ALTS study most of the CIN 2,3 lesions that were subsequently diagnosed in women who had initially been diagnosed with CIN 1 appear to represent lesions that were missed at the time of the initial colposcopic examination (170). Since the risk of an undetected CIN 2,3 or glandular lesion is expected to be higher in women referred for the evaluation of an HSIL or AGC on cytology, women with CIN 1 preceded by HSIL or AGC cervical cytology can be managed more aggressively than women with CIN 1 preceded by ASC-US, ASC-H, or LSIL cytology.

Because of the above considerations, the 2006 Consensus Guidelines state that women with biopsy-confirmed CIN 1 preceded by ASC-US, ASC-H, or LSIL should have follow-up with either HPV DNA testing every 12 months or repeat cervical cytology every 6 to 12 months. If CIN 1 persists for at least 2 years, either continued follow-up or treatment is acceptable. For women with a satisfactory colposcopic examination, acceptable treatments include the use of ablative (e.g., cryotherapy, electrofulguration, or laser ablation) or excisional modalities such as loop electrosurgical excision (148). All treatment modalities are considered acceptable since randomized, controlled clinical trials comparing cryotherapy, laser ablation, and LEEP for treating biopsy-confirmed CIN have reported no significant differences in either complication rates or success rates and a comprehensive review of controlled and randomized trials of various treatment modalities found no significant differences in outcomes after treatment in women with CIN with satisfactory colposcopic examinations (171). Before treating any grade of CIN using an ablative modality such as cryotherapy, it is important to perform an endocervical sampling in order to ensure that an unsuspected lesion is not present in the endocervical canal. For women with biopsy-confirmed CIN 1 preceded by HSIL or AGC cytology, either a diagnostic excisional procedure or follow-up with colposcopy and cytology at 6-month intervals for 1 year is acceptable, provided the colposcopic examination is satisfactory and endocervical sampling is negative (148).

Biopsy-Confirmed CIN 2,3

Women with an untreated, histologically confirmed CIN 2,3 lesion are felt to have a significantly high risk of progressing to invasive cervical cancer to warrant routine treatment. Provided the colposcopic examination is satisfactory and there is no suggestion of invasive disease (e.g., by either colposcopy, cytology, or histology) both ablative and excisional treatment modalities are considered acceptable forms of treatment (148). In patients with recurrent CIN (either CIN 1 or CIN 2,3) it is preferred that an excisional treatment modality be used. A diagnostic excisional procedure is recommended for all women with biopsy-confirmed CIN 2,3 and an unsatisfactory colposcopic examination.

The risk of recurrent CIN 2,3 or invasive cancer after treatment remains elevated for many years after treatment. A large follow-up study from the United Kingdom reported that the cumulative risk of invasive cervical cancer was 5.8 per 1,000 after 8 years of follow-up, which is approximately 100 times higher than in women in the general population (172). The size of the original CIN 2,3 lesion appears to be an important determinant of the rate of recurrence. Large lesions have a higher failure rate than small lesions. The 2006 Consensus Guidelines recommend that after treatment for CIN 2,3 women be followed up using either (a) HPV DNA testing at 6 to 12 months, (b) cytology alone at 6-month intervals, or (c) a combination of cytology and colposcopy at 6-month intervals. After two negative cytology results are obtained, routine

screening is recommended for at least 20 years (148). When CIN is identified at the margins of a diagnostic excisional procedure, it is preferred that the 4- to 6-month follow-up visit include endocervical sampling.

CHAPTER 20 ■ VULVA

DAVID H. MOORE, WUI-JIN KOH, WILLIAM P. MCGUIRE,
AND EDWARD J. WILKINSON

Malignant tumors of the vulva are rare and account for less than 5% of all cancers of the female genital tract. In 2007 there were an estimated 3,490 new cases of, and 880 deaths from, invasive vulva carcinoma (1). Consequently, most physicians who provide primary health care for women may never encounter a patient with vulvar cancer. Although an occasional patient will present without symptoms, the vast majority of women with vulvar cancer initially present with complaints such as irritation, pruritis, pain, or a mass lesion that does not resolve. The time interval between the onset of symptoms and the diagnosis of cancer is usually protracted by the patient, who ignores her symptoms or attempts a number of self-remedies, and the physician, who may prescribe empiric topical therapies without proper physical examination or tissue biopsy confirmation. Jones and Joura evaluated the clinical events preceding the diagnosis of squamous cell carcinoma of the vulva and found that 88% of patients had experienced symptoms for more than 6 months, 31% of women had three or more medical consultations prior to the diagnosis of vulva carcinoma, and 27% had applied topical estrogen or corticosteroids to the vulva (2).

The vulva is covered by keratinized squamous epithelium, and expectedly the majority of malignant vulva tumors are squamous cell carcinomas. Consequently, our current understanding of the epidemiology, spread patterns, prognostic factors, and survival data for vulvar cancer is derived almost exclusively from retrospective observations and a few prospective studies of squamous cell carcinomas. Malignant melanoma is the second most common cancer of the vulva. Although there is some consensus regarding the behavior and treatment of vulva melanoma, its rarity precludes the conduct of prospective clinical trials. A number of other malignant tumors may also arise on the vulva including basal cell carcinoma, adenocarcinomas (derived from Bartholin's glands, eccrine sweat glands, Pager's disease, or ectopic breast tissue), and a host of very rare soft-tissue sarcomas, including leiomyosarcomas, malignant fibrous histiocytomas, liposarcomas, angiosarcomas, rhabdomyosarcomas, epithelioid sarcomas, and Kaposi's sarcomas. Finally, the vulva may be secondarily involved with malignant disease originating in the bladder, anorectum, or other genital organs.

The traditional therapeutic approach to vulvar cancer has been radical surgical excision of the primary tumor and inguinal femoral lymph nodes. As our clinical understanding of this disease evolved, it became evident that survival could be improved with the administration of postoperative radiation therapy to selected patients at high risk for local regional failure. More recent developments have included the administration of radiation therapy and concurrent chemotherapy in the postoperative setting, and as primary therapy for locally advanced tumors not amenable to radical surgery. An individualized approach to vulvar cancer management, often employing

multiple modalities in an effort to achieve excellent disease control with better cosmetic results and sexual function, is now the norm. These and other topics pertinent to the principles of management of women with vulvar cancer are the subjects of this chapter.

ANATOMY

The vulva consists of the external genital organs including the mons pubis, labia minora and majora, clitoris, vaginal vestibule, perineal body, and their supporting subcutaneous tissues (3). The vulva is bordered superiorly by the anterior abdominal wall, laterally by the labiocrural fold at the medial thigh, and inferiorly by the anus. The vagina and urethra open onto the vulva. The mons pubis is a prominent mound of hair-bearing skin and subcutaneous adipose and connective tissue that is located anterior to the pubic symphysis. After puberty it is covered by coarse pubic hair. The labia majora are two elongated skin folds that course posterior from the mons pubis and blend into the perineal body. The skin of the labia majora is pigmented and contains hair follicles and sebaceous glands. The labia minora are a smaller pair of skin folds medial and parallel to the labia majora that extend inferiorly to form the margin of the vaginal vestibule. Superiorly, the labia minora separate into two components that course above and below the clitoris, fusing with those of the opposite side to form the prepuce and frenulum, respectively. The skin of the labia minora contains sebaceous glands, but is not hair-bearing and has little or no underlying adipose tissue. The clitoris is supported externally by the fusion of the labia minora (prepuce and frenulum) and is approximately 2 to 3 cm anterior to the urethral meatus. It is comprised of erectile tissue organized into the glans, body, and two crura. The glans has a concentration of nerve endings important for normal sexual response. Two loosely fused corpora cavernosa form the body of the clitoris and extend superiorly from the glans, ultimately dividing into the two crura. The crura course laterally beneath the ischiocavernosus muscles and attach to the ischial rami.

The vaginal vestibule is situated in the center of the vulva and is demarcated circumferentially by the labia minora and inferiorly by the perineal body. Both the vagina and urethra open onto the vestibule. Anteriorly, numerous small vestibular glands are located beneath the vestibular mucosa and open onto its surface adjacent to the urethral meatus. The vestibular bulbs, a loose collection of bilateral erectile tissue covered superficially by the bulbocavernosus muscle, are located laterally. The Bartholin's glands, two small, mucus-secreting glands situated within the subcutaneous tissue of the posterior labia majora, have ducts opening onto the posterolateral portion of the vestibule. The perineal body is a 3- to 4-cm band of skin and

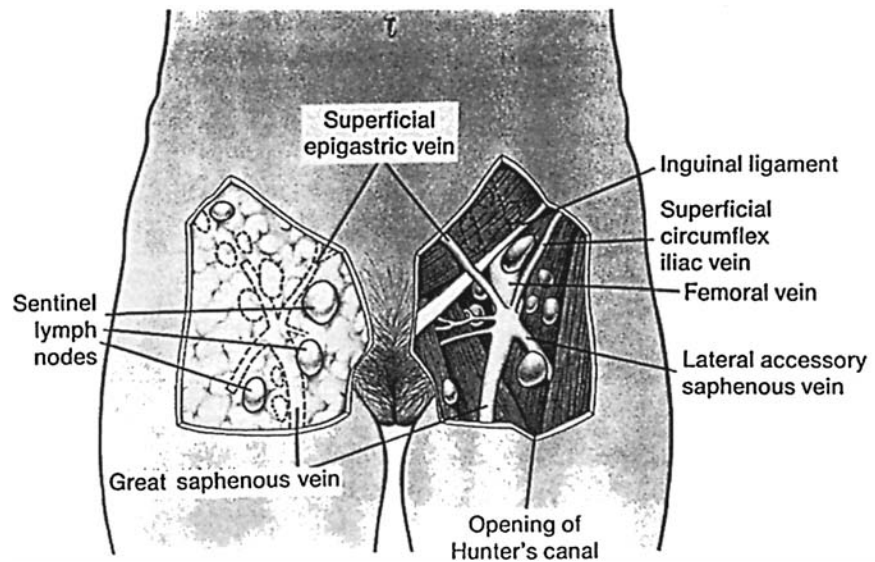

FIGURE 20.1. The superficial inguinal lymph nodes comprise eight to ten subcutaneous nodes located between Camper's fascia and the cribriform fascia. These nodes are immediately adjacent to the saphenous vein and its branches. *Source:* Reprinted from DiSaia PJ, Creasman WT, Rich WM. An alternative approach to early cancer of the vulva. *Am J Obstet Gynecol* 1979;133:825–832.

subcutaneous tissue located between the posterior extension of the labia majora, and separates the vaginal vestibule from the anus and forms the posterior margin of the vulva.

The vulva has a rich blood supply derived primarily from the internal pudendal artery, which arises from the anterior division of the internal iliac (hypogastric) artery, and the superficial and deep external pudendal arteries, which arise from the femoral artery. The internal pudendal artery exits the pelvis

and passes behind the ischial spine to reach the posterolateral vulva, where it divides into several small branches to the ischiocavernosus and bulbocavernosus muscles, the perineal artery, artery of the bulb, urethral artery, and dorsal and deep arteries of the clitoris. Both external pudendal arteries travel medially to supply the labia majora and their deep structures. These vessels anastomose freely with branches from the internal pudendal artery. Innervation of the vulva is derived from multiple sources and spinal cord levels. The mons pubis and upper labia majora are innervated by the ilioinguinal nerve (L1) and the genital branch of the genitofemoral nerve (L1-2). Either of these nerves may be easily injured during pelvic lymph node dissection with resulting paresthesias. The pudendal nerve (S2-4) enters the vulva in parallel with the internal pudendal artery and gives rise to several branches that innervate the lower vagina, labia, clitoris, perineal body, and their supporting structures.

The vulva lymphatics run anteriorly through the labia majora, turn laterally at the mons pubis, and drain primarily into the superficial inguinal lymph nodes. Elegant lymphatic dye studies by Parry-Jones demonstrated that vulva lymphatic channels do not extend lateral to the labiocrural folds and generally do not cross the midline, unless the site of dye injection is at the clitoris or perineal body (4). Several small lymphatics may drain from the clitoris under the pubic symphysis directly into the pelvic nodes. Many of these observations have been substantiated by surgical-pathologic studies and sentinel lymph node mapping studies that are discussed later.

The vulva lymphatics drain to the superficial inguinal lymph nodes located within the femoral triangle formed by the inguinal ligament superiorly, the border of the sartorius muscle laterally, and the border of the adductor longus muscle medially. About ten superficial inguinal lymph nodes lie along the saphenous vein and its branches between Camper's fascia and the cribriform fascia overlying the femoral vessels (Fig. 20.1). The superficial nodes are located within the triangle formed by the inguinal ligament superiorly, the border of the sartorius muscle laterally, and the border of the adductor longus muscle medially (Fig. 20.2) (5). Lymphatic drainage proceeds from the superficial to the deep inguinal (or femoral) nodes, which are located beneath the cribriform fascia and medial to the femoral vein. There are usually three to five deep nodes, the most superior of which is Cloquet's node

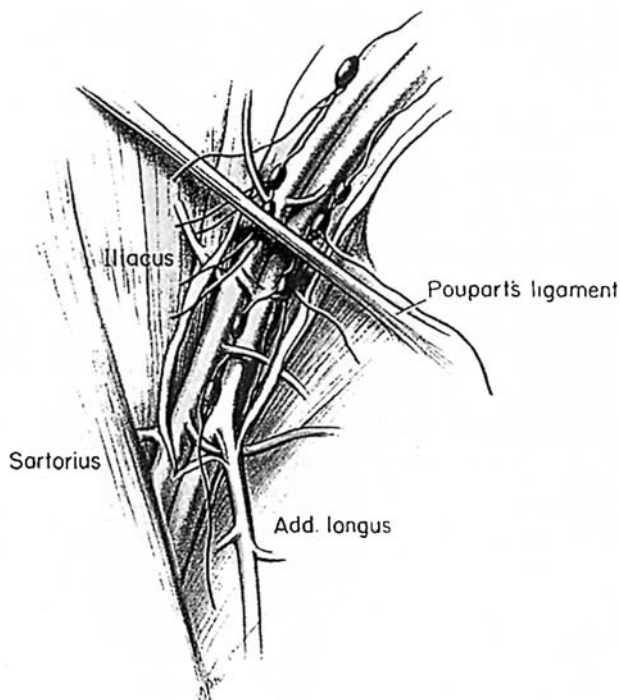

FIGURE 20.2. Anatomic diagram of the right groin with the superficial structures removed demonstrates the saphenous vein and the boundaries of inguinal dissection—the sartorius muscle, inguinal ligament, and adductor longus muscle. *Source:* Reprinted from Plentl AA, Friedman EA, eds. *Lymphatic System of the Female Genitalia*. Philadelphia: WB Saunders; 1971.

FIGURE 20.3. The lymphatic drainage of the vulva initially flows to the superficial inguinal nodes then to the deep femoral and iliac groups. Drainage from midline structures may flow directly beneath the symphysis to the pelvic nodes. *Source:* Reprinted from Plentl AA, Friedman EA, eds. *Lymphatic System of the Female Genitalia*. Philadelphia: WB Saunders; 1971.

located under the inguinal ligament. The deep inguinal nodes drain superiorly into the medial portion of the external iliac nodes and then upward through the pelvic and aortic lymph node chains (Fig. 20.3).

EPIDEMIOLOGY

Most vulvar cancers occur in postmenopausal women, although more recent reports suggest a trend toward younger age at diagnosis (6,7). Observational studies have suggested associations between hypertension, diabetes mellitus, and obesity with vulva carcinoma (8). However, it is not clear whether these represent independent risk factors or merely coexisting medical conditions common to the aging process. More recent analysis has not confirmed the prognostic significance of these diagnoses (9).

Several infectious agents have been proposed as possible etiologic agents in vulvar carcinoma, including granulomatous infections, herpes simplex virus, and human papillomavirus (HPV). Reports associating vulvar cancer with granuloma inguinale, lymphogranuloma venereum, or syphilis are largely historical and anecdotal (8). The observed coexistence of vulvar cancer with these granulomatous infections may only reflect such patients' risk for any sexually transmitted disease (9). Kaufman et al. identified serologic evidence of infection with herpes simplex virus type 2 and carcinoma *in situ* of the vulva in a small group of women (10). However, they were unable to isolate whole virus antigens, again suggesting an association with a sexually transmitted infection but failing to establish a direct causal link between the two.

Recent areas of investigation have focused on the neoplastic potential of HPVs. Strong associations between vulvar condylomata and the later development of vulvar cancer have

been identified (9). In addition, HPV DNA has been isolated from both invasive and carcinoma *in situ* lesions (11,12). HPV type 16 appears to be most common, but types 6 and 33 have also been identified (13,14). HPV DNA can be identified in approximately 70% to 80% of intraepithelial lesions, but is seen in only 10% to 50% of invasive lesions. HPV-related cancers may exhibit distinguishing clinical and histologic features, leading some to suggest a stratification scheme for vulvar cancers based on the presence or absence of an HPV association (15). Although much of the information linking past or current vulvar HPV infection with neoplastic transformation is enticing, the evidence for a causative relationship is presently inconclusive.

Brinton et al. conducted a case-control analysis and identified women with a history of genital condylomata, those with a previous abnormal Papanicolaou smear, and those who smoked as having an increased risk for vulvar cancer (9). Those who both smoked and had a history of genital warts had a 35-fold increase in risk when compared with women without these factors (Table 20.1). Chronic immunosuppression has also been linked to invasive vulvar tumors (6). HPV infection and nonspecific immune suppression may act as cofactors in the development of some vulvar cancers.

Both chronic vulvar inflammatory lesions, such as vulvar dystrophy or lichen sclerosus, and squamous intraepithelial lesions, particularly carcinoma *in situ*, have been suggested as precursors of invasive squamous cancers (Fig. 20.4). Carli et al. suggested a possible role of lichen sclerosus as a precursor to vulvar cancer based on their observation that 32% of vulvar cancer cases not HPV related were associated with lichen sclerosus (16). However, Hart et al., in a large pathologic review, were unable to identify transitions from lichen sclerosus to vulvar cancer (17). In an observational study of women with carcinoma *in situ*, seven of eight untreated cases progressed to invasive carcinoma within 8 years, and four of 105 treated women presented with invasive tumors from 7 to 18 years later (18). In a subsequent study of 405 cases of vulvar intraepithelial neoplasia (VIN) 2 to 3, Jones et al. found that 3.8% of patients had developed invasive cancer despite therapy, and ten untreated patients had developed invasive cancer in 1.1 to 7.3 years (mean 3.9 years) (19). Although some intraepithelial lesions regress spontaneously, it appears that a significant number persist or progress to invasive cancer. Recent incidence analyses from the United States and Norway have identified a two- to threefold increase in carcinoma *in situ* lesions from the 1970s to the 1990s (20,21). However, a concomitant rise in the incidence of invasive vulvar cancers has not yet been seen. This discrepancy leads to several alternative hypotheses: (a) affected women have not reached the age at which invasive lesions are seen; (b) aggressive treatment of preinvasive disease has prevented the development of invasive tumors; or (c) the causes of *in situ* and invasive lesions are not strongly related (21).

Trimble et al. have postulated that squamous carcinoma of the vulva may represent a final common endpoint of heterogeneous etiologic pathways (22). According to their studies, two histologic subtypes—with basaloid or warty features—are associated with HPV, whereas keratinizing squamous carcinomas are not. Furthermore, basaloid or warty carcinomas are associated with classic risk factors for cervical carcinoma, including age at first intercourse, lifetime number of sexual partners, prior abnormal Papanicolaou smears, smoking, and lower socioeconomic status. Keratinizing squamous carcinomas are weakly linked to these factors, and in some cases not at all. Flowers et al. have reported that mutations in the p53 tumor suppressor gene are more frequently found in HPV negative vulvar carcinomas versus those associated with HPV (23). The p53 tumor suppressor gene has several key regulatory functions, including the control of cell growth and proliferation.

TABLE 20.1

RELATIVE RISKS OF *IN SITU* AND INVASIVE VULVAR CANCERS BY SELECTED RISK FACTORS

	<i>In situ</i> series			Invasive series		
	No. of cases	RR	95% CI	No. of cases	RR	95% CI

Source: Reprinted from Brinton LA, Nasca PC, Mallin K, et al. Case-control study of cancer of the vulva. *Obstet Gynecol* 1990;75:864.

The common denominator in the development of vulvar carcinoma appears to be functional inactivation of the p53 tumor suppressor gene, either by genetic mutation in HPV negative tumors or by inactivation through the expression of HPV gene products (24).

Mitchell et al. evaluated 169 women with invasive vulvar cancers and noted that second genital squamous neoplasms

occurred in 13% of cases (25). The risk of a second primary tumor was significantly increased in cancer cases with HPV DNA, intraepithelioid growth pattern, or adjacent dysplasia. These observations support the concept that some squamous lesions may be initiated by sexually transmitted viruses capable of producing neoplastic change within the entire field of the lower genital tract. The obvious clinical implication is that a patient with an established squamous lesion of the vulva, vagina, or cervix needs to be evaluated and monitored for new or coexistent lesions at other sites.

FIGURE 20.4. This T1 lesion arose from a background of lichen sclerosis and demonstrates the typical irregular surface features and superficial ulceration of a squamous-cell carcinoma. The biopsy site is marked with a suture.

CLINICAL PRESENTATION

Most women with vulvar cancer present with pruritus and a recognizable lesion. Selecting the most appropriate site for biopsy in women with condylomata, chronic vulvar dystrophy, multifocal dysplasia, or Paget's disease can be difficult, and multiple biopsies may be required. Optimal management for any patient presenting with a suspicious lesion is to proceed directly to biopsy under local analgesia. Tissue biopsies should include the cutaneous lesion in question and contiguous underlying stroma, so that the presence and depth of invasion can be accurately assessed.

Although other techniques to facilitate the assessment of vulvar lesions (e.g., toluidine blue stain or exfoliative cytology) have been described, they are less accurate than, and should not be considered a substitute for, tissue biopsy. As noted previously, one of the greatest clinical pitfalls in the management of women with vulvar cancer is delay in diagnosis. The goals of immediate evaluation with outpatient biopsy are to provide an accurate and definitive diagnosis and to avoid delay in the

FIGURE 20.5. This patient ignored symptoms and an obvious tumor for more than a year. Although uncommon, such late presentations occur. Therapy options are limited.

planning of appropriate therapy. Unfortunately, some women ignore or deny obvious symptoms and lesions for long periods of time and present with advanced disease (Fig. 20.5). The presentation in such cases is generally dominated by local pain, bleeding, and surface drainage from the tumor. Metastatic disease in the groin lymph nodes or at distant sites may also be symptomatic.

DIAGNOSTIC EVALUATION

The evaluation of the patient with vulvar cancer must take into consideration the clinical extent of disease, the anticipated treatment plan, and the presence of coexisting medical illnesses. Initial evaluation should include a detailed physical examination with measurements of the primary tumor, assessment for extension to adjacent mucosal or bony structures, and possible involvement of the inguinal lymph nodes. Women with small cancers and clinically negative groin nodes require few diagnostic studies other than those for preoperative clearance. Additional radiographic and endoscopic studies should be considered for those with large primary tumors or suspected metastases. Potentially useful studies include barium enema, proctosigmoidoscopy, cystourethroscopy, computed tomography (CT) scan, and intravenous pyelography. Fine needle aspiration biopsy from sites of suspected metastases may eliminate the need for surgical exploration in some patients with advanced tumors. Because neoplasia of the

female genital tract is often multifocal, evaluation of the vagina and cervix—including cervical cytologic screening—should always be performed in women with vulvar neoplasms.

STAGING SYSTEMS

The International Federation of Gynecology and Obstetrics (FIGO) adopted a modified surgical staging system for vulvar cancer in 1989, which remained relatively unchanged in their 1995 recommendations (Table 20.2) (26). The previous clinical system provided reliable information regarding the primary lesion but an inaccurate assessment of groin node involvement in 20% to 30% of cases. The frequent discrepancy between clinical staging and surgical-pathologic findings spurred the acceptance of the current surgical evaluation of the inguinal lymph nodes. The American Joint Committee on Cancer has published a tumor-node-metastasis (TNM) classification scheme that is correlated with the FIGO staging system (Table 20.3) (27). Tumor assessment is based on physical examination with endoscopy in cases of bulky disease. Nodal status is determined by the surgical evaluation of the groins. The presence or absence of distant metastases is based on an unspecified diagnostic workup tailored to the patient's clinical presentation.

A microinvasive substage (IA) is defined as tumors ≤ 2 cm in diameter and depth of invasion ≤ 1 mm. Prior attempts to define a microinvasive substage were hindered by the lack of uniformity in defining the techniques for measuring depth of invasion and the cut-off level for a depth of invasion that provided a reliably low risk of lymph node metastasis (28,29). The technique recommended by the International Society for the Study of Vulvar Disease and the International Society of Gynecologic Pathologists to assess depth of stromal invasion is to measure from the base of the epithelium at the nearest superficial dermal papillae to the deepest point of tumor penetration (30).

PATTERNS OF SPREAD

Vulvar cancers metastasize in three ways: (a) local growth and extension into adjacent organs; (b) lymphatic embolization to regional lymph nodes in the groin; and (c) hematogenous

TABLE 20.2

FIGO STAGING OF VULVAR CARCINOMA

Stage	Clinical findings
Stage 0 Stage I	Carcinoma <i>in situ</i> ; intraepithelial carcinoma Tumor confined to the vulva or perineum; 2 cm or less in greatest dimension; no nodal metastasis Stage IA: stromal invasion ≤ 1.0 mm Stage IB: stromal invasion > 1.0 mm
Stage II	Tumor confined to the vulva or perineum; more than 2 cm in greatest dimension; no nodal metastasis
Stage III	Tumor of any size with adjacent spread to the urethra, vagina, or the anus or with unilateral regional lymph node metastasis
Stage IVA	Tumor invades upper urethra, bladder mucosa, rectal mucosa, pelvic bone, or bilateral regional node metastases
Stage IVB	Any distant metastasis, including pelvic lymph nodes

TABLE 20.3

AMERICAN JOINT COMMITTEE ON CANCER STAGING (1992)

PRIMARY TUMOR (T)			
TX	Primary tumor cannot be assessed		
T0	No evidence of primary tumor		
Tis	Carcinoma <i>in situ</i> (preinvasive carcinoma)		
T1	Tumor confined to the vulva or to the vulva and perineum, 2 cm or less in greatest dimension		
T2	Tumor confined to the vulva or to the vulva and perineum, more than 2 cm in greatest dimension		
T3	Tumor invades any of the following: lower urethra, vagina, or anus		
T4	Tumor invades any of the following: bladder mucosa, upper urethral mucosa, or rectal mucosa, or is fixed to the bone		
REGIONAL LYMPH NODES (N)			
NX	Regional lymph nodes cannot be assessed		
N0	No regional lymph node metastasis		
N1	Unilateral regional lymph node metastasis		
N2	Bilateral regional lymph node metastases		
DISTANT METASTASIS (M)			
MX	Presence of distant metastasis cannot be assessed		
M0	No distant metastasis		
M1	Distant metastasis (pelvic lymph node metastasis is M1)

dissemination to distant sites. Objective clinical descriptions of local growth have been categorized in the TNM staging system (Table 20.3). These descriptive definitions are clinically useful in that local surgical resection with a wide margin is almost universally feasible in women with T1 or T2 tumors, occasionally possible in those with T3 lesions, and impossible in those with T4 tumors without resorting to an exenterative operation.

A more precise understanding of the lymphatic drainage of the vulva has been key to developing an individualized surgical approach to vulvar cancer. The lymphatic dye studies described by Parry-Jones demonstrated that the dermal lymphatic network of the vulva courses superiorly to the area of the mons pubis and then turns laterally to drain into the superficial lymph nodes of the ipsilateral groin (4). Lymphatic channels from the superficial group then perforate the cribriform fascia to the deep inguinal (femoral) nodes. Observations following cutaneous dye injection showed that lymphatic drainage from lateral sites was to the ipsilateral groin. No lymphatic channels were located beyond the labiocrural fold, and crossover

FIGURE 20.6. Stanley Way's schematic representation of the potential routes of lymphatic spread from vulvar cancer based on his clinical observations. Source: Reprinted from Way S. *Malignant Disease of the Female Genital Tract*. New York: Churchill Livingstone; 1951.

drainage to the opposite groin was rare. Drainage from midline injections could be bilateral (31). Some channels from the clitoral area appeared to drain beneath the symphysis directly to the pelvic nodes. These anatomic descriptions confirmed the clinical impressions originally outlined by Way (Fig. 20.6) (32,33). More recent experience with intraoperative mapping has demonstrated that lymphatic drainage from most vulvar sites proceeds initially to a "sentinel" node located within the superficial inguinal group (34). However, aberrant channels coursing directly to deep inguinal, contralateral superficial inguinal, and pelvic lymph nodes were observed in a few cases. These infrequent anatomic variations may ultimately provide the explanation for unanticipated lymph-node failure.

Inguinal node metastasis can be predicted by the presence of certain parameters, including lesion diameter >2 cm, poor differentiation, increasing depth of stromal invasion, and invasion of lymphovascular spaces (35). Clinically important observations regarding nodal metastases include the following: (a) the superficial inguinal nodes are the most frequent site of lymphatic metastasis; (b) in-transit metastases within the vulvar skin are exceedingly rare, suggesting that most initial lymphatic metastases represent embolic phenomena; (c) metastasis to the contralateral groin or deep pelvic nodes is unusual in the absence of ipsilateral groin metastases; and (d) nodal involvement generally proceeds in a stepwise fashion from the superficial inguinal to the deep inguinal and then to the pelvic nodes.

Spread beyond the inguinal lymph nodes is considered distant metastasis. This may occur as secondary or tertiary level lymphatic metastases to the pelvic/aortic nodes or as a result of hematogenous dissemination to more distant sites, such as bone, lung, or liver. Distant metastases are uncommon at initial presentation, and more often are seen in the context of recurrent vulvar cancer.

PATHOLOGY

Most vulvar malignancies arise within squamous epithelium. Although the vulva does not have an identifiable transformation zone, as in the cervix, squamous neoplasms arise most commonly on the labia minora, clitoris, fourchette, perineal body, or medial aspects of the labia majora areas in which keratinized stratified squamous epithelial junction with the nonkeratinized squamous mucosa of the vestibule (36).

Most vulvar squamous carcinomas arise within areas of epithelium involved by some recognized epithelial cell abnormality. Approximately 60% of cases have adjacent VIN. In cases of superficially invasive squamous carcinoma of the vulva, the frequency of adjacent VIN approaches 85%

(29,37). Lichen sclerosus, usually with associated squamous cell hyperplasia, and/or differentiated VIN, can be found adjacent to vulvar squamous cell carcinoma in 15% to 40% of the cases (38,39). Granulomatous disease is also associated with vulvar squamous cell carcinoma; however, this is not a commonly associated finding in the United States. Thus, vulvar squamous cell carcinoma precursors can be considered in two distinct groups: those associated with HPV, usually associated VIN, and those that are not (e.g., those associated with lichen sclerosus, chronic granulomatous disease).

Vulvar Carcinomas

Squamous Cell Carcinomas

The term microinvasive carcinoma is not recognized as meaningful in reference to the vulva because there are no commonly agreed on pathologic criteria established for this term. The International Society for the Study of Vulvar Disease (ISSVD) proposed a substage of FIGO stage I, stage IA, as a solitary squamous carcinoma of the vulva measuring 2 cm or less in diameter with clinically negative nodes, with depth of tumor invasion 1 mm or less (40). The depth of invasion is defined as the measurement from the epithelial dermal junction of the most superficial adjacent dermal papillae to the deepest point of invasion (41,42). Tumor thickness is measured from the overlying surface epithelium, or the bottom of the granular layer if the surface is keratinized, to the deepest point of invasion, as specified by the International Society of Gynecologic Pathologists (ISGYP), the World Health Organization, and FIGO (Fig. 20.7) (26,43).

FIGURE 20.7. Methods for measurement for vulvar superficially invasive carcinomas: (A) Depth of invasion: the measurement from the epithelial stromal junction of the most superficial dermal papillae to the deepest point of invasion. This measurement is defined as the depth of invasion and is used to define stage IA vulvar carcinoma. The measurement (B) is the thickness of the tumor: from the surface of the lesion to the deepest point of invasion. Measurement (C) is from the bottom of the granular layer to the deepest point of invasion. This is also defined as thickness of the tumor in cases where there is a keratinized surface. The International Society of Gynecologic Pathologists and the World Health Organization recommend that both the depth of invasion and thickness of tumor, as well as method of measurement, be defined in the pathology reports. Source: Reprinted with permission by Edward J. Wilkinson, MD.

Stage I squamous carcinomas of the vulva, with a reported depth or thickness of 5 mm or more, have a lymph node metastasis rate of 15% or higher. Tumors with a depth or thickness of 3 mm have a lymph node metastasis rate averaging 12%. Therefore, a 3- or 5-mm tumor thickness is not acceptable as one considered superficial and of no or little risk of metastasis. Tumors with a depth or thickness of 1 mm or less carry little or no risk of lymph node metastasis (44,45).

The Gynecologic Oncology Group (GOG) correlated morphologic features of vulvar carcinoma with tumor invasion. Their findings were remarkably similar to those of the ISSVD (46). Because the GOG study did not measure tumor depth by the standards defined by the ISSVD, a reported case with 1-mm invasion with lymph node metastasis cannot be considered as an ISSVD stage IA tumor. The depth of invasion and thickness of tumor are separately defined, because considerable variations can exist among measurements from various superficial points in tumors of approximately 1 mm (Fig. 20.8) (45). There are significant differences between tumor depth of invasion and thickness when superficially invasive tumors are measured; vulvar epithelium can be up to 0.77 mm thick, which can significantly influence the difference between the depth of invasion and the measurement of tumor thickness (47). Tumors with invasion deeper than 1 mm can be readily measured by determining thickness, but tumors with surface ulceration may have a thickness, as measured from the surface, significantly less than the depth of invasion. With large tumors, thickness may be the only reliable measurement because of the lack of identifiable adjacent dermal papillae.

In addition to tumor stage and depth or thickness, other pathologic features include vascular space invasion, growth pattern of the tumor, grade of the tumor, and tumor type. Vascular space involvement can be defined as tumor within an endothelial lined vascular space. Strict pathologic criteria require that the tumor be attached to the wall of the vessel, but this is not observed in all cases. Vascular space involvement by squamous cell carcinoma of the vulva is associated with a higher frequency of lymph node metastasis and a lower overall 5-year survival rate. No reliable methods unambiguously predict lymph node metastasis by quantitation of vascular space involvement by tumor.

Tumor growth pattern influences the rate of lymph node metastasis and survival in tumors exceeding 1 mm in depth of invasion. In stage IA vulvar carcinomas, tumor growth pattern does not influence the risk of node involvement (48). Three factors describe tumor growth patterns: confluent; compact (pushing pattern); and finger-like (or spray or diffuse), a pattern also described as poorly differentiated. Confluent growth

FIGURE 20.8. Microinvasive carcinoma of the vulva. The lesion is less than 2 cm across and the depth of invasion is less than 1 mm, measured from the overlying surface epithelium.

FIGURE 20.9. Confluent pattern of invasion. The tumor has a trabecular pattern of growth associated with a marked chronic inflammatory stromal infiltrate. The tumor diameter exceeds 1 cm.

FIGURE 20.10. Finger-like growth. The tumor forms small nests surrounded by a desmoplastic stroma.

is defined as a tumor mass composed of interconnected tumor exceeding 1 mm in dimension (Fig. 20.9). Tumors with confluent growth, by definition, have a depth of invasion exceeding 1 mm. Confluent growth is characteristic of deeply invasive squamous cell carcinomas that are associated with stromal desmoplasia, resulting in fibrovascular stromal changes adjacent to the interconnected cords of tumor.

Compact (pushing; well differentiated) growth is squamous tumor growth that maintains continuity with the overlying epithelium and infiltrates as a well-defined and -circumscribed tumor mass, without islands of infiltrating tumor remote from the tumor mass. Tumors with compact growth typically have thickness of 5 mm or less and rarely invade vascular space. They are characteristically well differentiated, with the tumor cells resembling the squamous cells of the adjacent and overlying epithelium. There is usually minimal stromal desmoplasia, although there may be a lymphocytic inflammatory cell infiltrate.

Finger-like (spray or diffuse; poorly differentiated) growth is characterized by a trabecular appearance with small islands of poorly differentiated tumor cells found within the dermis or submucosa deeper than the bulk of the tumor mass. Tumors with this growth pattern are typically associated with a desmoplastic stromal response (Fig. 20.10) and a lymphocytic inflammatory cell infiltrate. Vascular space involvement is more commonly seen with this pattern of growth than with tumors with a compact pattern of growth (49). In tumors with a depth of invasion less than 5 mm, the finger-like pattern of growth is associated with a higher frequency of inguino femoral lymph node metastasis.

In some cases, a single tumor may have both compact and finger-like growth patterns. Mixed patterns, in our experience, are more commonly encountered in frankly invasive vulvar carcinomas and are rarely seen in superficially invasive tumors. The GOG has referred to tumors with a compact pattern of growth as well differentiated, and to tumors with the finger-like pattern of growth as poorly differentiated. Using this terminology, the GOG proposed the following grading system for vulvar squamous cell carcinoma:

- Grade 1 tumors are composed of well-differentiated tumor and contain no poorly differentiated element.
- Grade 2 tumors contain both patterns, with the poorly differentiated portions making up one third or less of the tumor.
- Grade 3 tumors also contain both components, with the poorly differentiated portion comprising more than one third but less than one half of the tumor.
- Grade 4 tumors have one half or more of the tumor composed of the poorly differentiated elements (50).

The GOG has reported that tumors with grade 1 histology have little risk and that the risk of lymph node metastasis increases with higher grades.

Tumors with a finger-like pattern of growth (poorly differentiated) lack laminin production compared with those that are well differentiated (51). Vulvar intraepithelial neoplasia also has associated laminin. This suggests that areas of tumor without laminin may be more active areas of tumor proliferation than areas with well-differentiated growth containing laminin. The absence of laminin in a questionable focus of invasion, as demonstrated by immunoperoxidase staining techniques, may support the diagnosis of invasion.

In a study of tumor cell proliferation using MIB-1 immunohistochemistry, a monoclonal antibody related to the proliferation-related protein KI-67, which is applicable in formation of fixed paraffin-embedded tissue, Hendricks et al. demonstrated that, in the well-differentiated tumors, the MIB-1 expression was detected in the tumor cells near the dermal tumor interface, but not in the tumor cells in the center of tumor foci or near the tumor epithelial surface (52). Poorly differentiated tumors demonstrated MIB-1 expression throughout the tumor cell population. This difference in pattern of expression in MIB-1 was statistically significant when related to survival and appeared somewhat more reliable than tumor growth pattern alone.

The ISGYP Committee of Terminology for Nonneoplastic Epithelial Disorders and Tumors recommended that the following information be included in the pathology report of all

excised vulvar squamous cell carcinomas, information also supported by the College of American Pathologists, and often used by tumor registries (53):

1. Depth of tumor invasion in millimeters
2. Thickness of the tumor in millimeters
3. Method of measurement of the depth of invasion and thickness
4. Presence or absence of vascular space (lymphatic) involvement by tumor
5. Diameter of the tumor, measured from the specimen in the fresh or fixed state
6. Clinical measurement of the tumor diameter, if available

In a multivariable retrospective analysis of 39 cases of vulvar squamous carcinoma, in addition to clinical stage and when corrected for treatment modality, pattern of tumor invasion, depth of tumor invasion, and lymph node status were all found to be significant prognostic factors. In addition, dermal desmoplasia associated with tumor invasion also had a suggestive association (54). Desmoplasia (a fibroblastic stromal tumor response) has been correlated with a higher risk of lymph node metastasis and poorer survival (55,56). Findings that did not correlate with survival were squamous cell carcinoma type, vascular space involvement by tumor, adjacent VIN, tumor nuclear grade, or associated degree of inflammatory response (54). DNA ploidy analysis (i.e., diploid versus aneuploid) of vulvar carcinoma does not appear to have significance in regard to survival (54).

Squamous cell carcinoma of the vulva, as well as VIN 3, overexpress p53 in approximately one half of the cases and have evidence of p16 methylation in approximately two thirds of the cases (57). However, p16 methylation appears to be an early event and a relatively frequent genetic change in vulvar neoplasia, whereas loss of pRb expression appears to be a late event being identified in invasive squamous carcinoma but not in VIN (57).

Several histopathologic types of vulvar squamous cell carcinoma are recognized. The usual types include squamous cell carcinoma, keratinizing type; squamous cell carcinoma, nonkeratinizing type; basaloid carcinoma; and warty (condylomatous) carcinoma (58). Less common types include acantholytic squamous cell carcinoma, squamous cell carcinoma with tumor giant cells and spindle cell squamous carcinoma, squamous cell carcinoma with sarcoma-like stroma, sebaceous carcinoma, verrucous carcinoma, and other rarer types (39,59).

Vulvar squamous cell carcinomas of the basaloid and warty types, as well as VIN of all but the differentiated type, are recognized to be associated with human papillomavirus, primarily HPV-16. The HPV can be detected within the tumor cells by a variety of techniques, including polymerase chain reaction (PCR), hybrid capture, and *in situ* hybridization. In addition, it is now recognized that approximately one quarter (27% ± 9%) of the women with vulvar squamous carcinoma have anti-HPV-16 antibodies expressed serologically as IgG antibodies to HPV-16 virus-like particles as measured by enzyme-linked immunosorbent assay (ELISA) (60).

The term acantholytic squamous cell carcinoma (*adenoid squamous cell carcinoma*; pseudoglandular squamous cell carcinoma) refers to squamous cell carcinomas with pseudoglandular features. These tumors are characterized by small gland-like spaces within a tumor that otherwise appears to be a poorly differentiated squamous cell carcinoma. This tumor should be differentiated from adenosquamous carcinomas that contain an obvious adenocarcinoma component (61). Adenoid squamous carcinoma does not contain sialomucin, but adenosquamous carcinoma typically contains mucin within the adenocarcinoma component. Although there are few reported cases of adenoid squamous carcinoma of the vulva, these tumors may have a more aggressive clinical behavior.

Squamous cell carcinoma with tumor giant cells has multinucleated tumor giant cells intermixed within the squamous carcinoma (62). This tumor may resemble amelanotic melanoma. Squamous cell carcinoma with tumor giant cells, unlike melanoma, does not express S100 antigen, HMB45, or Melan-A on immunoperoxidase studies. This tumor does express low-molecular-weight keratin, similar to other squamous carcinomas.

Sebaceous carcinoma of the vulva may be associated with VIN (63). These tumors have characteristics of squamous cell carcinoma but also have intermixed sebaceous elements.

Spindle cell squamous cell carcinomas consist of poorly differentiated neoplastic epithelial cells that have an elongated spindle shape and may mimic a spindle cell melanoma or a sarcoma (Fig. 20.11) (64). Squamous cell carcinoma with spindle cell stroma is a squamous cell carcinoma associated with a sarcoma like stromal/dermal response that may mimic with a primary sarcoma (65). Spindle cell squamous cell carcinomas can be differentiated from sarcomas by immunoperoxidase techniques. Like other squamous cell carcinomas, the spindle cell variant contains keratin and lacks the antigens distinctive to sarcomas of various origin. S100 antigen, HMB 45, and Melan-A are usually immunoreactive in a spindle cell melanoma and lacking in a spindle cell squamous carcinoma.

Verrucous Carcinoma

Verrucous carcinoma of the vulva typically presents as an exophytic-appearing growth that can be locally destructive. Clinically, it may resemble condyloma acuminatum. The so-called Buschke-Lowenstein giant condyloma is classified as a variant of verrucous carcinoma by the World Health Organization.

Microscopically, verrucous carcinoma is characterized by well-differentiated epithelial cells. The tumor growth pattern is characterized by a “pushing” tumor-dermal interface with minimal stroma between the acanthotic epithelium (Fig. 20.12). The surface is often hyperkeratotic, and there may be parakeratosis. Observed mitoses are characteristically normal. Within the dermis, a mild lymphocytic inflammatory cell response is usually seen. Vascular space involvement by tumor is characteristically lacking. Because of its excellent prognosis, strict

FIGURE 20.11. Spindle-cell squamous carcinoma. The tumor cells have a spindle shape and poorly defined cell junctions.

FIGURE 20.12. Verrucous carcinoma. The epithelial cells are well differentiated, and the tumor has a “pushing border” with a delicate vascular core between the epithelial elements.

histologic criteria should be used in the diagnosis of verrucous carcinoma. Squamous carcinomas with focal verrucous features should not be described or diagnosed as verrucous carcinoma.

Verrucous carcinomas are characteristically diploid, unlike typical squamous cell carcinomas of the vulva, which are usually aneuploid by DNA analysis. Verrucous tumors may be associated with HPV-6 or its variants (66).

The major differential diagnosis of squamous cell carcinoma includes keratoacanthomas, pseudocarcinomatous (pseudoepitheliomatous) hyperplasia, epithelioid sarcoma, and malignant rhabdoid tumor.

Basal Cell Carcinoma

Basal cell carcinoma is a relatively rare tumor in the vulva, comprising 2% to 4% of infiltrative neoplasms. These tumors are most commonly found in elderly women. The surface of the tumor appears granular and is well circumscribed; on palpation, the tumor is characteristically very firm. Vulvar basal cell carcinoma most commonly arises on the labia majora and is typically 2 cm or less in diameter; however, giant basal cell carcinomas have been described (67).

The epithelial cells comprising basal cell carcinoma are typically small and vary in form, with small hyperchromatic nuclei that may exhibit some nuclear pleomorphism. These tumors may have a variety of growth patterns (e.g., trabecular, insular), although peripheral nuclear palisading is a relatively consistent finding. Basal cell carcinomas often have an intraepithelial component that is contiguous with the infiltrative component, if present.

Metatypical basal cell carcinoma is a variant of basal cell carcinoma that usually occurs at mucocutaneous junctions. The term *basosquamous carcinoma* is applied to these tumors because of their microscopic features, which include basal cell carcinoma intermixed with a squamous cell carcinoma component. Nuclear pleomorphism is usually seen in metatypical basal cell carcinoma and in the basal cell and squamous cell components of the tumor. The deeper tumor cells, close to the underlying stroma, have the greatest degree of nuclear pleomorphism and the more prominent squamous features. These

tumors have a more aggressive clinical behavior than typical basal cell carcinoma. A variant of vulvar basal cell carcinoma, *adenoid basal cell carcinoma*, has gland-like features (68).

The differential diagnosis of basal cell carcinoma includes basaloid squamous cell carcinoma, Merkel cell tumor of the skin, and metastatic small cell carcinoma. Basaloid squamous cell carcinoma can be distinguished by its lack of characteristic basal cell growth pattern, and the presence of intracellular bridges. Nuclear pleomorphism is typically much greater in basaloid squamous cell carcinoma than in basal cell carcinoma. Basal cell carcinomas express Ber EP4 on histochemical study, an antigen not expressed by basaloid squamous cell carcinomas. Basaloid squamous cell carcinomas are typically associated with HPV-16, which is not typically associated with basal cell carcinoma. Merkel cell tumors and other neuroendocrine tumors of the vulva are typically subcutaneous or dermal nodules, and not intraepithelial lesions (see the section on neuroendocrine tumors).

Neuroendocrine and Neuroectodermal Tumors: Merkel Cell Tumors and Peripheral Neuroectodermal Tumor/Extrasosseous Ewing Sarcoma

Merkel Cell Tumor. Merkel cell tumors are neuroendocrine tumors of the skin occurring usually within the dermis. The tumor is composed of small, relatively uniform cells with little cytoplasm and hyperchromatic nuclei with a punctate chromatin pattern and has a high mitotic count. The tumor is infiltrative and often involves vascular spaces. Merkel cell tumors have been associated with squamous cell carcinoma and vulvar intraepithelial neoplasia (69). Merkel cell tumors are subclassified as carcinoid-like (trabecular), intermediate type, and small cell (oat cell) type. These tumors typically express neuron-specific enolase, synaptophysin, chromogranin, and low-molecular-weight keratin. Keratin study, such as with cytokeratin 20, demonstrates a distinct perinuclear cytoplasmic dot. Dense core neurosecretory granules are seen by electron microscopy. These features differentiate it from basal cell or squamous cell carcinoma. Merkel cell tumors frequently have both regional lymph node and distant metastases and are associated with a poor prognosis.

Peripheral Neuroectodermal Tumor/Extrasosseous Ewing Sarcoma. Peripheral neuroectodermal tumor/extrasosseous Ewing sarcoma (PNET) is a rare neuroendocrine vulvar neoplasm that has been reported in childhood and women of reproductive age. The tumor may present as a subcutaneous or polypoid mass and clinically may resemble a cyst, or be ulcerated (70,71). On microscopic examination the tumor is circumscribed and multilobulated, without capsule but nonencapsulated, and contains small cells with little cytoplasm and nuclei with hyperchromatic and finely granular nuclear chromatin. Some cells have small nucleoli, and mitotic figures are usually common, with mitotic counts from 3 to exceeding 10 per 10 high power fields. Numerous patterns of growth may be seen with highly cellular undifferentiated areas, areas with cyst formation containing eosinophilic proteinous material, rosettes with Homer-Wright rosettes, and follicle-like structures.

The cells of PNET have periodic-acid Schiff (PAS) staining cytoplasm that digests with diastase, and typically express CD99 and vimentin. Although, as in Merkel cell tumors, focal reactivity for synaptophysin and neuron specific enolase may be present; cytokeratin reactivity is not present but may be focally immunoreactive in some cases.

Dense core neurosecretory granules, as seen in Merkel cell tumor by electron microscopy, are not present. Cytogenetic study of these PNET tumors demonstrates translocation t(11;22)(q24;q12) in approximately 90% of cases. This translocation can also be demonstrated with fluorescence *in situ* hybridization, or reverse transcriptase polymerase chain reaction (RT-PCR) (70,71).

Urothelial/Transitional Cell Carcinoma

Urothelial carcinoma may be a primary tumor of the vulva, usually arising within the Bartholin's glands. More commonly, urothelial carcinoma is metastatic to the vulva, having arisen within the bladder or urethra (72). In rare instances the tumor presents as a Paget-like lesion of the vulva (see section on Paget's disease) (73).

Microscopically, urothelial carcinomas are composed of relatively uniform cells; nuclear pleomorphisms may be marked in high grade urothelial neoplasms. The cytoplasm is eosinophilic without apparent inclusions or keratin formations, although focal keratin formation may be seen. The tumors may exhibit papillary-like growth.

Adenocarcinoma and Carcinoma of Bartholin's Glands

Most primary adenocarcinomas of the vulva arise within Bartholin's glands. Adenocarcinoma may also arise from other glands or skin appendages of the vulva, including sweat glands and Skene's glands (74,75). Clear cell adenocarcinoma arising in endometriosis has been reported in the groin (76). Invasive vulvar Paget's disease has given rise to adenocarcinoma (Fig. 20.13). Primary malignant tumors arising within Bartholin's glands include adenocarcinoma and squamous cell carcinoma, which occur with approximately equal frequency and account for approximately 80% of all primary malignant tumors in this site. Adenoid cystic carcinomas comprise approximately 15% of all primary carcinomas, with adenosquamous carcinomas and transitional cell carcinomas each comprising approximately 5% of the primary Bartholin's gland tumors (77).

Carcinoma of the Bartholin's gland generally occurs in older women and is rare in women younger than 50. In clinical practice, it is generally advisable to excise an enlarged Bartholin's gland in a woman 50 years of age or older, especially if there is no known history of prior Bartholin's cyst. If a cyst is drained and a palpable mass persists, excision is also indicated. Fine needle aspiration of a Bartholin's mass for cytologic evaluation may help to establish a positive diagnosis.

FIGURE 20.13. Adenocarcinoma underlying Paget's disease. The adenocarcinoma is composed of small tumor clusters within the underlying dermis.

Primary carcinomas within Bartholin's glands are usually solid tumors and are often deeply infiltrative. A variety of histologic types of adenocarcinoma have been described within Bartholin's glands. Mucinous, papillary, and mucoepidermoid carcinoma tumor types have been described in addition to adenosquamous, squamous, and transitional cell carcinoma. Adenocarcinoma of Bartholin's gland is typically immunoreactive for carcinoembryonic antigen (78). Histopathologic features that identify a carcinoma arising in Bartholin's glands include a recognizable transition from Bartholin's gland to tumor. The histopathologic tumor type must be consistent with an origin from a Bartholin's gland, and the tumor must not be metastatic to a Bartholin's gland.

These malignancies are characteristically deep and difficult to detect in their early growth. Approximately 20% of women with primary carcinoma of Bartholin's glands have metastatic tumor to the inguino femoral lymph nodes at the time of primary tumor diagnosis.

Adenocarcinoma Arising in Vulvar Skin Appendages

The vulvar labia majora were once thought to be within the milk line, but this has been significantly challenged by Van der Putte, who observed that the milk line did not involve the vulva in the human (79,80). The breast-like tumors found are believed to arise from specialized anogenital glands that reside in the intralabial sulci and may be the origin of papillary hidradenoma. Both benign and malignant breast-like tumors have been observed within the vulva (81). Fibroadenoma, intraductal papilloma, and lactating adenoma have been observed. Primary adenocarcinoma of the vulva may arise in specialized anogenital glands, which reside in the intralabial sulcus, and are believed to be the origin of papillary hidradenoma of the vulva as well as the breast-like tumors seen within the vulva, and these glands may resemble breast tissue (79,80,82).

Adenosquamous Carcinoma

Adenosquamous carcinomas are epithelial tumors composed of both malignant squamous and gland-forming elements. Adenosquamous carcinomas account for approximately 5% of all tumors of Bartholin's glands. These tumors may be composed of a poorly differentiated squamous component mixed with cells bearing small glandular lumens containing mucin (29).

Adenoid Cystic Carcinoma

Adenoid cystic carcinoma arising within the vulva most commonly arises within the Bartholin's glands and comprises approximately 15% of all carcinomas of Bartholin's glands. Microscopically, adenoid cystic carcinomas are composed of relatively uniform small cells with regular, round nuclei and minimal cytoplasm. The cord-like or "nested" arrangement contains gland-like lumens that include an acellular eosinophilic material (77). Electron microscopy has documented that this material is basement membrane-like material rather than a secretion. These tumors are therefore more properly considered a variant of squamous cell carcinoma than adenocarcinoma.

Carcinomas of Sweat Gland Origin

Primary carcinomas of sweat gland origin are relatively rare within the vulva, comprising approximately 10% of all vulvar malignant tumors. A variety of sweat gland carcinomas have been described in this site, including eccrine adenocarcinoma, eccrine porocarcinoma, and clear cell hidradenocarcinoma (75). Primary adenocarcinomas of apocrine gland origin have also been described arising within the vulva, and some of these have been associated with vulvar Paget's disease. These should be distinguished from the benign papillary hidradenoma,

which typically arises in the intralabial papillary sulcus from specialized anogenital glands and contains a myoepithelial cell population, distinguishing it from adenocarcinoma (79,80,82).

Vulvar Paget's Disease and Paget-Like Lesions

Vulvar Paget's disease typically presents as an eczematoid, red, weeping area on the vulva, often localized to the labia majora, perineal body, clitoral area, or other sites. This disease typically occurs in older, postmenopausal Caucasian women, although it has been described in a premenopausal woman. Because of its eczematoid appearance, it is not unusual for vulvar Paget's disease to be misdiagnosed as eczema or contact dermatitis. Approximately 15% of women with vulvar Paget's disease have underlying primary adenocarcinoma, usually arising within apocrine glands or the underlying Bartholin's glands (Fig. 20.13). The Wilkinson and Brown etiologic classification of vulvar Paget's disease divides Paget's disease into two main groups: those of cutaneous origin and those of non-cutaneous origin (73). The two most common types of non-cutaneous Paget's disease are those associated with colorectal adenocarcinoma and those associated with bladder urothelial carcinoma. Women with Paget's disease of the colorectal type usually present with a lesion that involves the perianal skin, and this lesion is a manifestation of underlying colon or rectal adenocarcinoma. Women with Paget-like disease (Pagetoid urothelial intraepithelial neoplasia [PUIN]) typically present with a lesion involving the perurethral area and vulvar vestibule (73,82,83). In these cases there is associated bladder and/or urethral urothelial carcinoma with the extension of the neoplastic urothelial cells to the epithelium of the vulva (73,82). In cases of PUIN, total deep vulvectomy is not indicated because there is no associated underlying cutaneous adenocarcinoma. The tumor cells are from the bladder and/or urethra, representing an intraepithelial transitional cell neoplasm extending from the bladder and/or urethra (73). These cells have been reported from a vaginal cytology specimen from a woman with a PUIN lesion (84).

Cutaneous Paget's disease is most commonly a primary intraepithelial neoplasm. In such cases the intraepithelial Paget's disease may have an associated invasive Paget's disease. In rare cases, cutaneous Paget's disease may be a manifestation of an underlying cutaneous adenocarcinoma (73). Cutaneous Paget's disease is characterized by the presence of Paget's cells, which are found within the involved epithelium. A Paget's cell is relatively large, with a prominent nucleus that typically has coarse chromatin and a prominent nucleolus. On hematoxylin and eosin staining the cytoplasm is distinctly pale compared with the surrounding keratinocytes. The cytoplasm may be vacuolated or appear foamy and typically is somewhat basophilic. The Paget's cells are generally found in higher concentrations near the basement membrane, but are also seen throughout the epithelium. These cells may be clustered together and may have an acinar or gland-like arrangement (Fig. 20.14).

Paget's cells of cutaneous origin are rich in carcinoembryonic antigen (CEA), which can be identified with immunoperoxidase techniques (73). Paget's cells also express cytokeratin 7 (CK-7) and gross-cystic-disease fluid protein-15 (GCDFFP-15) (73,85). More than one half of cases may also express c-erbB2 (HER2/neu), but this was not found to influence metastasis risk (86,87). Paget's cells infrequently express CA-125, and estrogen receptor is generally negative (87,88). In some cases, Paget's disease may be associated with a distinctive squamous hyperplasia, or papillomatous hyperplasia, which must be distinguished from VIN. Immunohistochemical study for CK-7 is useful in many cases to identify the Paget's cells that are strongly CK-7 positive, whereas the adjacent epithelial cells are negative (89). Paget's cells may be aneuploid or diploid

FIGURE 20.14. Paget's disease. The large cells with prominent cytoplasm and large nuclei represent the intraepithelial Paget's cells. A few small gland-like intraepithelial structures are formed by the Paget's cells.

by DNA ploidy analysis; however, prognosis does not appear to be influenced by DNA ploidy. Invasive Paget's disease 1 mm or less in depth of invasion has reportedly little risk for recurrence (87).

The differential diagnosis of Paget's disease of cutaneous origin includes PUIN/Paget's disease of urothelial origin, Paget's disease of colorectal origin/other related adenocarcinoma, superficial spreading malignant melanoma, Pagetoid reticulosis, and the Pagetoid variant of vulvar intraepithelial neoplasia, which are keratinocytic cells resembling Paget's cells. These can all be differentiated by immunoperoxidase techniques because melanomas do not express cytokeratin, but usually express S100 protein, HMB-45, and Melan-A, which are absent in Paget's cells (90). The Paget-like cells in PUIN express uroplakin-3, but do not express GCDFFP-15. CEA is expressed in approximately two thirds of urothelial neoplasms, but is expressed in both Paget's disease of cutaneous origin and Paget's disease of gastrointestinal origin. Adenocarcinoma cells of colonic, anal, or rectal origin express CEA, as well as caudal homeobox (CDX), whereas Paget's disease of cutaneous origin does not express CDX. Pagetoid reticulosis cells express leukocyte common antigen and some other lymphoproliferative markers, but lack CEA or cytokeratin. VIN of Pagetoid type may microscopically resemble Paget's disease or melanoma, but the cells of VIN do not express CEA, S100, or melanoma antigen (68,82).

Vulvar Malignant Melanoma

Malignant melanoma of the vulva accounts for approximately 9% of all primary malignant neoplasms on the vulva, and vulvar melanoma accounts for approximately 3% of all melanomas in women. This tumor occurs predominantly in Caucasian women, with approximately one third of the cases occurring in women younger than 50, and the mean age at diagnosis is 55 years of age (91). The peak frequency occurs between the sixth and seventh decades and the highest incidence is in women 75 years of age or older, where the age-specific incidence is reported to be 1.28 per 100,000 (92). The most common presenting symptom is bleeding; however,

pruritus, pain, dysuria, and a palpable mass may all be symptoms (92). The tumor may arise from a preexisting pigmented lesion or from normal-appearing skin. The primary site on the vulva may be the clitoris, labia minora, and labia majora, where melanomas occur with approximately equal frequency (93). The tumor may be elevated, nodular, or ulcerated. Although usually pigmented, approximately one fourth are nonpigmented, amelanotic melanomas, a melanoma type that clinically and pathologically may resemble squamous carcinoma. In the clinical setting, the differential diagnosis includes pigmented condyloma acuminatum, pigmented VIN, atypical genital nevus, large vulvar nevi, melanosis of the vulva, or other malignant tumors including malignant soft-tissue tumors (82,94,95).

Vulvar malignant melanomas may be subclassified into three specific categories: superficial spreading malignant melanoma, nodular melanoma, and mucosal lentiginous melanoma, which is also referred to as mucosal/acral lentiginous melanoma (96,97). In the vulva some cases are mixed or cannot be specifically classified. Mucosal lentiginous melanomas are the type most commonly reported on the vulva, accounting for over one half the cases in larger series (92,96). Nodular melanomas are second in frequency, accounting for approximately one fifth of the cases, and have the overall worst prognosis of the melanoma types, usually related to the greater thickness and deeper invasion at the time of presentation. Superficial spreading melanomas are the least common type in the vulva. Some variation in the frequency of these types in the vulva is present in the literature, primarily related to some variations in pathologic classification (91–93,96,98–101).

Histopathologic differentiation of melanoma type is based on identification of a superficial spreading component. Mucosal lentiginous melanomas have the neoplastic melanocytes clustered in the dermal-epithelial junction and have both radial growth and vertical growth. Superficial spreading melanomas have radial growth involving four or more rete lateral to their vertical or infiltrative growth (82). Nodular melanomas show minimal or no radial growth. Superficial spreading malignant melanoma characteristically shows junctional melanocytes with radial growth, and a vertical growth pattern may be absent. The tumor cells are highly variable in appearance but commonly are relatively large, with nuclei showing minimal variation in size and containing prominent nucleoli (Fig. 20.15). These cells may or may not contain pigment. The form of the cells ranges from epithelioid to spindle shaped; in some cases, the spindle cell type may predominate. The spindle cells may be relatively small, with oval nuclei and elongated cytoplasm. They may infiltrate the adjacent dermis in cords and sheets.

FIGURE 20.15. Malignant melanoma. The tumor is within the dermis and contains dark melanin pigment. Junctional growth is seen within the overlying epithelial dermal junction.

Malignant melanomas typically express S100 antigen, HMB-45, and Melan-A, and lack cytokeratin or CEA. The microscopic differential diagnosis for superficial spreading malignant melanoma is primarily vulvar Paget's disease. Immunohistochemical techniques are essential in discriminating superficial spreading melanoma from Paget's disease (see the section on vulvar Paget's disease) (90). Nonpigmented nodular melanomas may mimic squamous cell carcinoma or spindle cell neoplasms of various types. In these circumstances, immunoperoxidase procedures are of great value, because squamous cell carcinomas typically do not express S100 protein, HMB-45, or Melan-A, and melanomas do not express cytokeratin (82).

The level of invasion and tumor thickness are essential measurements in evaluating malignant melanoma (91,98,102). The Clark level definitions describe the extent of dermal and subcutaneous involvement by the melanoma (102). Measurements for vulvar melanomas can be applied as for skin and mucous membranes, as described by Breslow (103). Malignant melanomas that have a thickness of less than 0.75 mm have little or no risk for metastasis and tumors up to 1 mm in thickness are generally considered of minimal risk of recurrence. Melanomas at Clark level 2 or thickness of 1.49 mm or less, or tumor volume of 100 mm³ also correlate with good prognosis (104). A poor prognosis is correlated with Clark level 5, thickness >2 mm, or mitotic count exceeding 10/mm². Other prognostic factors include a minimal or absent inflammatory reaction and surface ulceration (98).

Vulvar melanoma has been described associated with NRAS codon 12 mutation, as more commonly seen in sun exposure-related melanomas; however, most mucosal non-sun-exposure-related melanomas do not express Nras exon 2 mutations (105).

Melanomas arising in the vulva may metastasize to other sites within the lower female genital tract, including the cervix, vagina, urethra, and rectum. Distant metastasis is common with disseminated disease. Survival after recurrence is poor, approximately 5% (97).

Vulvar Sarcomas

Leiomyosarcoma. Leiomyosarcoma is the most frequent primary vulvar sarcoma. It most commonly arises in the labia majora or Bartholin's gland area, although these tumors may arise in the clitoris and labia minora. The tumors are generally larger than 5 cm in diameter when first diagnosed and may be deep within the subcutaneous tissue.

On microscopic examination, these tumors are composed of interlacing spindle shaped cells, sometimes with an epithelioid appearance. Features of leiomyosarcoma include an infiltrating border and metastasis. Microscopic criteria for diagnosis require determination of the mitotic figure count. In cases with minimal pleomorphism, it is generally accepted that the diagnosis of leiomyosarcoma can be made with a mitotic count of 10 or more per 10 high power fields. Tumors that have an infiltrating border or nuclear atypia with pleomorphism and mitotic count of 5 or more per 10 high power fields are classified as leiomyosarcoma. There are tumors that may show no significant atypia, have a diameter exceeding 5 cm, have an infiltrating margin, and have a low mitotic count, up to 5 per 10 high power fields. It is preferable to classify them as smooth muscle tumors of uncertain malignant potential, because the risk of recurrence is uncertain (39,106–108).

Malignant Fibrous Histiocytoma. Malignant fibrous histiocytoma arises from histiocytes with fibroblastic differentiation. It is considered the second most common sarcoma of the vulva and has its peak frequency in middle age. Malignant fibrous histiocytoma typically presents as a solitary mass that may appear somewhat brownish or pigmented, secondary to areas of focal hemorrhage within the tumor.

On microscopic examination, the tumor is characterized by a complex interlacing cellular growth pattern with marked nuclear pleomorphism, including multinucleated cells and large bizarre cells. Abnormal mitotic figures may be apparent. Microscopic variants of this tumor include inflammatory, giant cell, myxoid, and angiomatoid types (82,109). On immunoperoxidase study, these tumors contain α_1 antitrypsin and α_1 antichymotrypsin. Malignant fibrous histiocytoma is typically infiltrative, with infiltrative margins, and may involve the underlying fascia. Involvement of the fascia is associated with a higher risk of local spread and distant metastasis.

Epithelioid Sarcoma. Epithelioid sarcoma may arise within the labia majora, subclitoral area, and clitoris (110). Its microscopic features may resemble squamous carcinoma, malignant melanoma, malignant rhabdoid tumor, or lymphoma. Epithelioid sarcoma is usually relatively superficial, arising in and involving the reticular dermis, but it may occur in deeper structures.

On microscopic examination, the tumor is nodular and may have areas of necrosis. The tumor cells have an epithelioid appearance with eosinophilic cytoplasm, but there may be metaplastic components, including cartilage and bone. On immunohistochemical study, this tumor contains cytokeratin, which does not distinguish it from epithelial tumors, but is of value in differentiating it from malignant melanoma or other types of soft-tissue tumors. Epithelioid sarcoma rarely metastasizes, although local recurrence is a risk. Differential diagnosis for this tumor includes squamous cell carcinoma, malignant melanoma, lymphoma, and malignant rhabdoid tumor, all of which are capable of distant metastasis and aggressive behavior (110). Immunoperoxidase studies are of value in differentiation, but have not been of value in differentiating epithelioid sarcoma from malignant rhabdoid tumor. The distinction of these two tumors is based primarily on microscopic features.

Malignant Rhabdoid Tumor. Malignant rhabdoid tumor has been described in the vulva and, like epithelioid sarcoma, may be relatively superficial and contain tumor cells with an epithelioid appearance with eosinophilic cytoplasm. Unlike epithelioid sarcoma, malignant rhabdoid tumors have relatively pleomorphic nuclei. Metaplastic elements are usually not present. Malignant rhabdoid tumor also has eosinophilic cytoplasmic inclusions, which are not present in epithelioid sarcoma. These inclusions give some of the cells the appearance of signet ring cells. Electron microscopic evaluation of the rhabdoid tumor reveals that the eosinophilic inclusions are composed of intermediate filaments. Malignant rhabdoid tumor has a lobulated architecture but lacks necrosis or granulomatous features, which are often found in epithelioid sarcoma (107,108,110).

Malignant Schwannoma

Malignant schwannoma has been reported on the vulva, and approximately half of the cases are associated with neurofibromatosis. Most malignant schwannomas occur in women of reproductive age (111). This tumor is found primarily in the labia majora or minora, but may arise in other sites within the vulva.

On microscopic examination it is typically highly cellular and is composed of spindle cells with nuclear palisading. Metaplastic elements, such as cartilage, epithelial islands, and striated muscle, may be seen in approximately 50% of the cases. Malignant schwannoma is immunoreactive for S100 protein. In some cases, a nerve trunk can be identified adjacent to or within the tumor mass.

Yolk Sac Tumor

Yolk sac tumor (endodermal sinus tumor) is a rare germ cell tumor of the vulva, primarily arising in the labia or clitoral

areas (39,112). The age range of patients is from just under 2 to 26 years. Distinctive microscopic features are similar to endodermal sinus tumor in the ovary, including the Schiller-Duval bodies, distinctive globules that are PAS positive, and the presence of α -fetoprotein within the tumor, as demonstrated by immunoperoxidase technique.

Other Sarcomas

A partial list of primary sarcomas of the vulva includes angiosarcoma, Kaposi's sarcoma, hemangiopericytoma, rhabdomyosarcoma, alveolar soft part sarcoma, and liposarcoma (39,107,108,113,114). Sarcoma botryoides is a variant of rhabdomyosarcoma that may involve the vulva, but most cases arise within the vagina or base of the bladder. Aggressive angiomyxoma, a locally aggressive but rarely metastatic sarcoma, has also been documented arising within the vulva (50,107). Kaposi's sarcoma and angiosarcoma should be differentiated from bacillary angiomatosis, which is a benign pseudoneoplastic infectious process (115). The reader is referred to additional texts on these and other soft-tissue tumors of the vulva (39, 07,108).

Metastatic Tumors to the Vulva

Most metastatic tumors to the vulva involve the labia majora or Bartholin's glands. In the vulva they usually present as single or multiple intradermal or subcutaneous nodules, but may present as a Bartholin's gland mass (77,116–119). Metastatic tumors account for approximately 8% of all vulvar tumors, and in approximately one half of the cases the primary tumor was in the lower genital tract, including the cervix, vagina, endometrium, and ovary. Cervical carcinoma is the most common origin of contiguous metastasis. Local metastasis secondary to contiguous involvement of the vulva from urothelial carcinoma of the bladder or urethra, or ano-rectal carcinoma, may involve the vulva and present as a Paget-like lesion (see Paget's disease and Paget-like lesions in this section) or a vulvar or groin node mass (73,120). Contiguous involvement of tumors from the genital tract or ano-rectal areas are commonly associated with metastasis to regional lymph nodes and widespread metastases. Remote metastases have been observed from tumors arising in breast, kidney, stomach, lung, and other sites. Malignant melanoma and neuroblastoma can also metastasize to the vulva, as can gestational choriocarcinoma and malignant lymphomas. In approximately 10% of the cases the primary site of the metastatic tumor cannot be identified. Prognosis with metastatic tumor to the vulva is generally guarded, but is influenced by the type of tumor and the therapy available.

PROGNOSTIC FACTORS

Prognosis has been most extensively evaluated in women with squamous cell carcinomas. The major prognostic factors in vulvar cancer—tumor diameter, depth of tumor invasion, nodal spread, and distant metastasis—have been incorporated into the current FIGO staging system. These are clearly the most important predictors of tumor recurrence and death from disease (121–126). However, several additional features may be useful in refining prognosis in smaller subsets of patients.

Wharton et al. suggested the concept of "microinvasive" carcinoma of the vulva in their 1975 report and proposed eliminating groin dissection for patients with small tumors that invaded <5 mm (75). A number of later reports confirmed that 10% to 20% of patients meeting these criteria had occult groin

metastases, making the elimination of inguinal lymph node evaluation undesirable for these patients (127–130). Several authors have further attempted to define a population of microinvasive tumors whereby the risk of inguinal metastasis is negligible (46,131–135). The consensus opinion is that only tumors with less than 1 mm invasion fulfill this requirement (18,46,65,136). This is reflected in the FIGO classification of tumors invading ≤ 1 mm into stage IA (26).

Risk of local recurrence, although clearly associated with tumor size and extent, is also related to the adequacy of the surgical resection margins. Heaps et al., in their analysis of formalin-fixed tissue specimens, were able to demonstrate a sharp rise in the incidence of local recurrence for tumors with microscopic margins less than 8 mm (59). They suggested that this would correspond to a minimum margin of 1 cm in fresh, unfixed tissue. These observations were confirmed in a retrospective multivariate analysis of clinical data by Chan et al., who showed that pathologic margin distance ≤ 8 mm is an important predictor of local recurrence (137). De Hullu et al. reported nine local recurrences among 40 patients with tumor-free margins ≤ 8 mm compared to no local recurrences among 39 patients with margins > 8 mm (138). To aid the surgeon in planning surgical margins of resection, Hoffman et al. measured the radial occult microscopic spread of tumor in patients with invasive squamous cell carcinoma of the vulva. They found that the gross and microscopic periphery of most

cancers were approximately the same; however, ulcerative tumors with an infiltrative pattern of invasion were more likely to extend beyond what is grossly apparent (139).

The single most important prognostic factor in women with vulvar cancer is metastasis to the inguinal lymph nodes, and most recurrences will occur within 2 years of primary treatment (140). The presence of inguinal node metastasis portends a 50% reduction in long-term survival (141,142). A number of noninvasive imaging modalities have been studied for the evaluation of inguinal femoral lymph node metastasis, including magnetic resonance imaging, computed tomography, positron emission tomography (PET), and ultrasound. There currently is no imaging modality with a sufficiently high negative predictive value to allow for exclusion of surgical groin lymph node evaluation (143,144). Because the clinical prediction of lymph node spread is inaccurate, node status is best determined via surgical biopsy. Prognostic issues that appear to be important in evaluating lymphatic involvement are (a) whether nodal spread is bilateral or unilateral, (b) the number of positive nodes, (c) the volume of tumor in the metastasis, and (d) the level of the metastatic disease. Multiple positive nodes, bilateral metastases, involvement beyond the groin, and bulky disease are associated with poor prognosis (44,145). Rutledge et al. provided the detailed analysis of prognostic factors outlined in Table 20.4 (146).

TREATMENT

Development of the radical vulvectomy with bilateral inguinofemoral lymphadenectomy during the 1940s and 1950s was a dramatic improvement over prior surgical options and greatly enhanced survival, particularly for women with smaller tumors and negative lymph nodes (147,148). The ability to successfully resect vulvar tumors eliminated prolonged survival marked by local and regional progression of disease and associated pain, drainage, and bleeding. Long-term survival of 85% to 90% can now be routinely obtained with radical surgery. However, radical surgery can be associated with postoperative complications such as wound breakdown and lymphedema.

More recently, surgical emphasis has evolved to an individualized approach for tumors at either end of the spectrum. Many gynecologists believe that smaller vulvar tumors can be acceptably managed by less radical surgical approaches and have proposed more limited resections for certain subsets considered to represent early or low-risk disease (65,149,150). The obvious advantages of such an approach are retention of a significant portion of the uninvolved vulva, less operative morbidity, and fewer late complications. In contrast, radical surgery is frequently ineffective in curing patients with bulky tumors or positive groin nodes. Multimodality programs that incorporate radiation, surgery, and chemotherapy are now being investigated in women with these high-risk tumors based upon success with similar approaches in women with squamous cancers of the cervix (151–154). It seems fair to state that “quality of life” issues predominate at the lower end of the disease scale, whereas “survival” concerns are most important at the upper end. At present, there are limited curative treatment options for women who present with disseminated disease.

Microinvasive Tumors

Tumors demonstrating early invasion of the vulvar stroma (≤ 1 mm) have minimal risk for lymphatic dissemination. Excisional procedures that incorporate a 1-cm normal tissue margin are likely to provide curative results (155). Patients in this category represent the only subset for whom the status of the groin lymph nodes can be ignored. These so-called microcarcinomas tend to arise in younger patients with multifocal preinvasive disease and are commonly associated with HPV infections. Occult invasion in lesions thought to be intraepithelial is common (156,157). Consequently, the entire lower genital tract and vulva should be carefully evaluated before surgical resection of these lesions is attempted. The risk of vulvar recurrence or development of a new lesion at another vulvar site is significant. After primary therapy these patients should undergo frequent follow-up examinations.

Stage I and II Cancers

Traditional management of stage I and II vulvar cancer has been radical vulvectomy with bilateral inguinofemoral lymphadenectomy. The operation removes the primary tumor with a wide margin of normal skin, along with the remaining vulva, dermal lymphatics, and regional nodes. This approach provides excellent long-term survival and local control in approximately 90% of patients (158,159). Disadvantages of radical surgery include loss of normal vulvar tissue with alterations in appearance and sexual function, a 50% incidence of wound breakdown, a 30% incidence of groin complications (breakdown, lymphocyst, lymphangitis), and a 10% to 15% incidence of lower extremity lymphedema (160,161). Additional postoperative therapy, primarily irradiation, should be considered in the 10% to 20% of

patients with positive nodes with the understanding that this will further increase the incidence of lymphedema (162).

In an effort to reduce morbidity and enhance psychosexual recovery, several groups have espoused a more limited surgical approach for women with small vulvar cancers (163,164). Although some patients with T2 lesions have been treated in this manner, most have limited the conservative approach to women with T1 cancers. DiSaia et al. were the first to describe successful conservative resection of tumors measuring 1 cm or less with invasion of less than 5 mm (150). Additional reports have expanded this experience to include more patients with larger lesions and more significant invasion (Table 20.5) (65,165,166). The most frequent recommendation is to resect the primary lesion with a 1- to 2-cm margin of normal tissue and to carry the dissection to the deep perineal fascia. These operations should not be confused with the concept of excisional biopsy, which is used primarily as a diagnostic procedure.

Limited resection of the primary tumor is combined with a more conservative surgical approach to the groin, in which the ipsilateral superficial groin nodes are used as the sentinel group for lymphatic metastases (15,166,167). Bilateral superficial dissections are performed in patients whose tumors encroach on midline structures (clitoris or perineal body) (165). In patients with negative inguinal nodes, no further dissection or postoperative therapy is used. In their series of 61 patients with non-midline T1 and T2 squamous cell carcinomas of the vulva, DeSimone et al. found no patient with lymph node metastasis to the contralateral groin (168). Similarly, Gonzalez et al. reported that contralateral groin lymph node dissection was unnecessary for patients with non-midline lesions < 2 cm in size and/or with negative ipsilateral groin lymph nodes (169). Patients with positive nodes can undergo additional nodal dissection of the deep nodes and the contralateral groin or be treated with postoperative irradiation, or both. The risk of chronic groin complications and lymphedema is related to the extent of groin dissection (149). Patients with superficial and deep lymphadenectomy followed by irradiation have the greatest likelihood of morbidity.

With limited resection, survival of 90% or better is attainable for patients with stage I vulva carcinoma with acceptable anatomic appearance and function. Critics of conservative surgical approaches cite several potential risks, including potential recurrence in retained vulvar skin, inadequate assessment of the groin nodes, inadequate surgical therapy in women with nodal spread, and the potential for leaving in-transit skin metastases. Examination of the published experience using a selective approach to inguinal lymphadenectomy would suggest that unanticipated ipsilateral groin failure occurs in $\leq 5\%$ of cases (Table 20.6) (65,165,166,170), whereas contralateral groin failure is uncommon. Because randomized prospective evaluations of surgical therapy have not been performed, a critical comparison of radical vulvectomy and radical wide excision is not possible.

TABLE 20.5

PROPOSED CRITERIA FOR CONSERVATIVE SURGICAL RESECTION

Investigator	Tumor diameter	Depth of invasion	Groin dissection
Wharton et al. (75)	< 2 cm	< 5 mm	None

In an attempt to reduce treatment-related morbidity, yet retain the essential components of radical excision of the primary tumor plus groin lymph node assessment, some have introduced modifications of the classic radical operation. These include the use of “triple incision” techniques that separate the vulvectomy incision from the groin incisions, as well as techniques that use a more limited dissection of the deep inguinal nodes as compared to “complete” groin lymphadenectomy (171). Le et al. have suggested that a total of at least ten nodes from a bilateral groin dissection define an optimal surgical evaluation (172). Using anatomical groin dissections from cadavers, Hudson et al. showed that the incision or removal of deep fascia in the femoral triangle with “stripping” of the femoral vessels was unnecessary; however, some nodes of importance were present within fenestrations of the cribriform fascia covering the saphenous opening (173). Other surgical refinements that may reduce postoperative morbidity without compromising outcome include preservation of the saphenous vein (174–176). A prospective, randomized trial showed that sartorius transposition did not reduce the incidence of postoperative wound infection or lymphedema (177).

Another surgical concept that is undergoing evaluation is the potential for cutaneous lymphatic mapping to define and target the true sentinel groin nodes (178). Preliminary experience with both intraoperative lymphatic dye and radioisotope injections suggests that a sentinel node can often be identified in the groin (34,179,180). This early experience supports the concept that the assessment of lymphatic metastases may ultimately be reduced to the biopsy of one or two identifiable nodes (Fig. 20.16). Terada et al. performed sentinel lymph

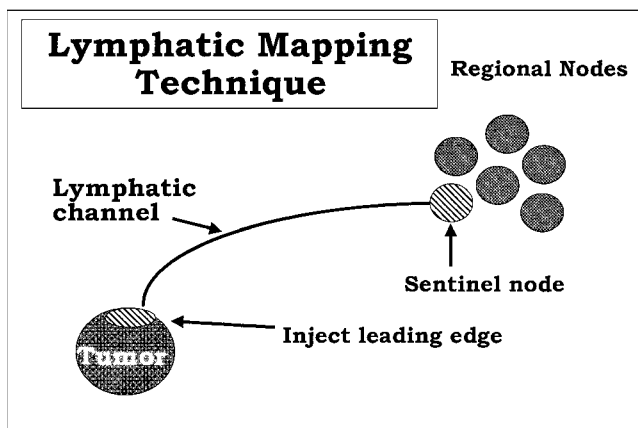

FIGURE 20.16. Intraoperative lymphatic mapping is accomplished by injecting the leading edge of the visible tumor with isosulfan blue dye. The dye is taken up by the specific node that drains the tumor site. This “sentinel” node can be visually identified and separated from other nodes within the regional group. In concept, all tumors with nodal metastases can be detected by biopsy of the sentinel node.

node mapping and biopsy for 21 patients with T1 vulvar cancer using preoperative lymphoscintigraphy and intraoperative isosulfan blue dye staining. Three patients proved to have positive sentinel lymph nodes. None of the patients with negative sentinel lymph nodes had developed a groin or distant recurrence with median follow-up of 4.6 years (181).

In summary, therapy for women with stage I and II cancers must be individualized to the patient and her tumor. Radical vulvectomy provides excellent local control and long-term survival, but has significant morbidity and sexual function limitations. More conservative approaches appear safe in most stage I settings and may be applicable in some stage II patients. The surgical approach to the groin nodes is evolving. The accuracy of the superficial inguinal nodes (or the “sentinel” node identified by intraoperative mapping) as predictors of nodal spread is currently being evaluated. If these concepts prove suitably sensitive and specific, more extensive inguinal lymphadenectomy might be abandoned.

Stage III and IV Cancers

By definition, stage III tumors extend to adjacent mucosal structures or the inguinal lymph nodes. Many are bulky, but some are of limited volume but considered high stage because of proximity to critical central structures. Some of these primary tumors can be curatively resected by radical operations, such as radical vulvectomy or some variation of pelvic exenteration and vulvectomy. Surgical resection of 1 to 1.5 cm of the distal urethra in order to achieve a negative surgical margin does not appear to compromise bladder continence (182). However, recent therapeutic efforts have focused on combined modality treatment programs involving sequenced radiation therapy or chemoradiation therapy and radical surgery. There are now ample data from retrospective series, and a few prospective trials, from which to conclude that vulvar cancers are radioresponsive and that function-sparing operations are feasible in selected patients with advanced disease who receive combined modality treatment (183,184). A similar experience has been reported for patients with stage IVA tumors. Ultra-radical (exenteration) resection may also be considered for selected patients. Although occasional cures have been described with innovative combinations of surgery, irradiation, and chemotherapy, treatment of patients with stage IVB vulvar cancer should be considered palliative.

Node Positive Cancers

An optimal management strategy for node positive patients is yet to be defined. Two factors appear to be important in the management of regional disease: radiation therapy can have a significant impact on controlling or eradicating small volume nodal disease, and surgical resection of bulky nodal disease also improves regional control and probably enhances the curative potential of irradiation. In multivariate analysis, Hyde et al. found that, for patients with clinically positive groin nodes who underwent surgery followed by radiation therapy, the method of surgical groin node dissection (nodal “debulking” versus full groin dissection) had no prognostic significance (185).

Patients who undergo bilateral inguinofemoral lymphadenectomy as initial therapy and are found to have positive nodes—particularly more than one positive node—are likely to benefit from postoperative irradiation to the groin and lower pelvis (162). Radiation therapy is superior to surgery in the management of patients with positive pelvic nodes. The morbidity of combining superficial and deep inguinal lymphadenectomy with irradiation is substantial. The highest incidences of chronic groin and extremity complications, primarily lymphedema, are seen in such cases.

Several management options are available for patients found to have positive nodes during the course of superficial lymphadenectomy when performed as a staging procedure: (a) no further surgical therapy may be performed; (b) the lymphadenectomy can be extended to include the ipsilateral deep nodes, the contralateral groin nodes, or both; or (c) postoperative irradiation can be added to any of these surgical options. Given the heterogeneity of vulvar cancer presentations, treatment individualization is necessary. If postoperative radiotherapy to the inguinal nodes is deemed necessary, it would be reasonable to limit resection to grossly positive nodes, thereby minimizing the likelihood of lymphedema following combined radical surgery and radiation. Postoperative radiation requires careful treatment planning, using CT imaging to evaluate for any measurable residual tumor and to determine appropriate groin node depth. Excellent local control and minimal morbidity have been achieved when selective inguinal lymphadenectomy and tailored postoperative adjuvant therapy were administered to carefully selected patients (165).

Recurrent Cancer

Regardless of initial treatment, vulvar cancer recurrences can be categorized into three clinical groups: local (vulva), groin, and distant. The reported experience with local recurrence on the vulva is surprisingly good. Recurrence-free survival can be obtained in up to 75% of cases when the recurrence is limited to the vulva and can be resected with a gross clinical margin (186,187). The observation that many of these vulva recurrences occur at sites remote from the initial primary tumor or that they occur years after apparently successful primary treatment suggests that some recurrences probably represent new primary tumors rather than the development of new disease. Recurrences in the groin are almost universally fatal. A few patients may be saved by resection of bulky disease and local irradiation. Patients who develop distant metastases are candidates for systemic cytotoxic therapy, which is largely palliative.

SURGICAL TECHNIQUES

Radical Vulvectomy and Bilateral Inguinofemoral Lymphadenectomy

Although a number of modifications have been described, the basic incisions for radical vulvectomy and bilateral lymphadenectomy can be described as based on either a “butterfly” or “longhorn” approach. The butterfly incisions use convex “wings” over the groin and around the anus to facilitate closure of the defect (Fig. 20.17). The longhorn incisions were developed to limit skin resection over the groin in an attempt to reduce wound breakdown (Fig. 20.18) (188). The arcing superior incision is placed from the lateral margins of the groin dissection across the mons pubis. The lateral vulvar incisions are placed at the labiocrural folds, because these topographical landmarks represent the most lateral location of the superficial vulvar lymphatics. The perianal incision is placed to allow resection of the perineal body. These incisions are taken to the level of the deep inguinal and perineal fascia and permit *en bloc* removal of both superficial and deep groin nodes, the entire vulva, and an intervening skin bridge.

After removal of the specimen, the skin and mucosal edges are undermined to permit mobilization and primary closure with delayed absorbable suture. Some degree of tension at the suture lines is unavoidable, particularly in the perineal body and periurethral areas. Closed suction drains are usually placed in the groin sites to remove excess lymphatic- and serous-fluid

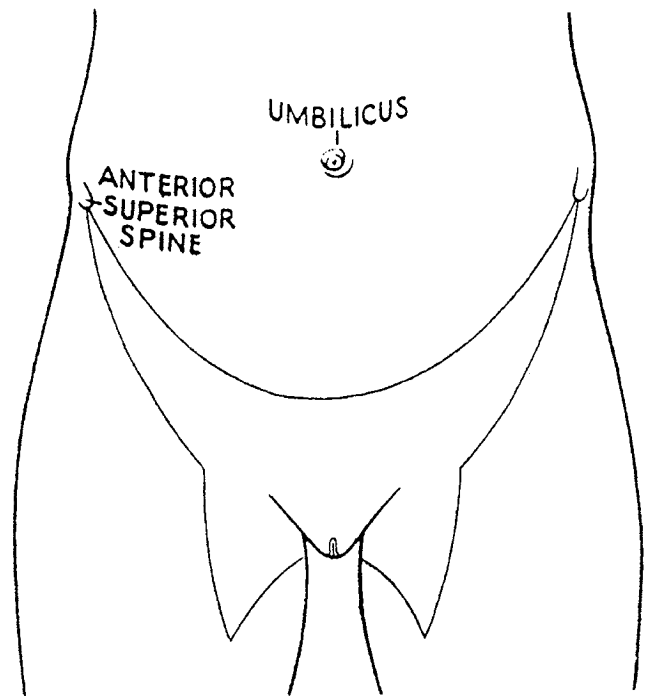

FIGURE 20.17. “Butterfly” incisions for the superior portion of a radical vulvectomy with bilateral inguinofemoral lymphadenectomy. Source: Reprinted from Way S. *Malignant Disease of the Female Genital Tract*. New York: Churchill Livingstone; 1951.

accumulations and are usually removed when drain output is minimal (5 to 14 days).

Some degree of wound breakdown is seen in approximately 50% of patients (161). Local wound care results in satisfactory secondary healing in most of these cases. Lymphocyst formation is relatively common and frequently presents as a tense but nontender groin mass. Percutaneous needle drainage is usually sufficient but occasionally replacement of a groin drain may be required. Inguinal cellulitis, lower extremity lymphangitis, and lymphedema are uncommon late sequelae. The incidence of these complications is related to the extent of groin therapy and is highest in patients treated with superficial and deep lymphadenectomy along with groin irradiation.

FIGURE 20.18. Modified skin-sparing “longhorn” incisions for *en bloc* radical resection.

Radical Wide Excision

Several names have been applied to the procedures used to resect small vulvar cancers: radical wide excision, radical local excision, wide local excision, modified radical vulvectomy, and hemivulvectomy. Regardless of preferred nomenclature, the surgical procedure should be adequately defined and described. Surgical incisions are devised to allow for at least a 2-cm resection margin encompassing the primary lesion (Fig. 20.19). Dissection is carried to the deep perineal fascia. Recent data suggest that a 1-cm margin may be adequate for some tumors (160). If this information is verified by other studies it will be most useful when planning the resection of tumors in close proximity to midline structures. Tumors that encroach on the anus or anal sphincters can be managed by radical wide excision with sphincter or flap repair, or they can be treated with combined modality therapy as outlined under the Radiation Therapy section. Most radical wide excision sites can be closed primarily. In some patients, rhomboid flaps can be used to facilitate coverage of the vulvar defect (189). Some form of inguinal lymphadenectomy, performed through a separate incision, is generally combined with radical wide excision. The necessary extent of the groin dissection is an area of current investigation.

Ambulation is begun on the day of surgery. Perineal irrigation and air drying are started 24 hours after operation. The average hospital stay for patients undergoing radical wide excision is usually 3 days or less. Wound breakdown, usually

FIGURE 20.19. Planned resection of a left labial squamous carcinoma and adjacent carcinoma *in situ* by radical wide excision. A 2-cm margin is outlined. Rhomboid-flap repair using a V-incision is anticipated. *Source:* Reprinted from Burke TW, Morris M, Levenback C, et al. Closure of complex vulvar defects using local rhomboid flaps. *Obstet Gynecol* 1994;84:1043-1047.

of minor degree, is reported in approximately 15% of cases (65,149). The incidence and severity of groin complications is proportional to the extent of the lymphadenectomy.

Triple Incision Techniques

As a radical operation, the three incision technique represents an intermediate surgical procedure with radical vulvectomy and *en bloc* inguino-femoral lymphadenectomy on one end of the spectrum and radical wide excision on the other. For this approach, radical vulvectomy is accomplished using two elliptical incisions—an inner one circumscribing the vaginal introitus and vulvar vestibule and an outer one placed at the labiocrural folds and brought across the mons pubis and perineal body. When carried to the deep perineal fascia, this resection allows complete removal of the vulvar skin in a manner identical to that achieved with radical vulvectomy; however, bilateral inguino-femoral lymphadenectomy is accomplished via separate incisions parallel to the inguinal ligaments. The three incision concept preserves the radicality of the vulvar resection while retaining skin over the groin. Consequently, the incidence of major wound breakdown is significantly reduced to approximately 15% to 20% of cases (171,190,191). As with other techniques, the incidence and severity of groin complications such as infection, wound breakdown, or lymphocyst formation are still high (192).

Inguinal Lymphadenectomy

Appropriate surgical management of the inguinal nodes is controversial and evolving. Precise recommendations are not possible, because there is a wide range of treatment philosophies. Nevertheless, the surgical approaches to the groin lymph nodes can be readily defined and described.

Excisional Biopsy

Most preoperative diagnostic dilemmas related to enlarged groin nodes can be resolved simply and accurately using fine needle aspiration biopsy. However, surgical removal of one or two lymph nodes may occasionally be considered in the management of women with vulvar cancer. Selective excision of groin lymph nodes may be considered when fine needle aspiration biopsy results are negative or equivocal, or to remove bulky positive nodes before beginning a course of combined modality therapy. A small incision is made over the palpable node and dissection is carried to the level of the lymph node mass. The involved node is freed from the adjacent subcutaneous tissues and removed. The incision is closed with skin staples or absorbable sutures. The decision to electively place a closed suction drain depends upon the extent of the dissection, the amount of subcutaneous free space, and surgeon preference. Most lymph node biopsies can be performed as outpatient procedures, and some can be accomplished under local anesthesia.

Superficial Inguinal Lymphadenectomy

Superficial inguinal lymphadenectomy involves the removal of the eight to ten lymph nodes that lie superficial to the cribriform fascia and surround the branches of the saphenous vein. This is a more meticulous and complete lymphatic dissection than that described for excisional biopsy. The anatomic boundaries of the superficial lymphatic dissection are the inguinal ligament superiorly, the border of the sartorius muscle laterally, and the border of the adductor longus muscle medially. The anterior limit is the superficial subcutaneous fascia (Camper's fascia), and the posterior limit is the cribriform fascia overlying the femoral artery, vein, and deep nodes.

The skin incision used to provide access to the groin is made parallel to the inguinal ligament approximately from a point overlying the adductor longus tendon laterally to a point below the anterior superior iliac spine. The superficial subcutaneous fat is left attached to the skin to provide blood supply, but is separated from the underlying nodal tissue by dissecting inferiorly at the level of Camper's fascia. The lymphadenectomy specimen is developed by continuing the inferior dissection along the borders of the sartorius and adductor longus muscles. As the dissection proceeds, the specimen is mobilized off the cribriform fascia. Care should be taken to identify and individually ligate the vessels that perforate this fascia. The saphenous vein is encountered at the lower medial margin of the dissection, and whenever possible should be preserved to minimize the risk for postoperative lymphedema (Fig. 20.20). The dissected specimen is forwarded for pathologic assessment. The skin incision can be closed with either staples or absorbable sutures. A closed-suction drain is placed and removed when output is <25 mL per day.

Deep Inguinal (Femoral) Lymphadenectomy

The deep inguinal (femoral) lymph nodes lie medial to the femoral vein beneath the cribriform fascia. This space contains three to five nodes, the channels of which course beneath the inguinal ligament and continue in the pelvis as the external iliac nodal chain. The most superior deep inguinal node is known as Cloquet's node.

Surgical removal of the deep nodes is performed as an extension of a superficial lymphadenectomy rather than as an isolated procedure. The usual approach is to open the cribriform fascia along the sartorius muscle at the time of the superficial lymphadenectomy. The cribriform fascia is then mobilized medially as a part of the specimen. Once the superior aspect of the femoral vein is identified and exposed, the deep nodes are removed in continuity with the superficial nodes. Some surgeons then cover the exposed femoral vessels by removing the sartorius muscle from its insertion onto the anterior iliac spine and transposing the muscle over the femoral vessels by suturing the free edge of the muscle to the inguinal ligament.

Because all of the deep nodes are consistently located medial to the femoral vein, some surgeons have recommended eliminating the removal of the entire cribriform plate (193). They suggest opening the fascia medial to the vein and removing only the adjacent nodes. This modified approach to the deep nodes

FIGURE 20.20. The patient is undergoing superficial and deep dissection of the right groin nodes. At this point in the procedure the saphenous vein, which is entering the surgical field from the right lower aspect, has been identified and preserved.

may help to reduce acute morbidity while providing a more definitive lymphatic resection. In a retrospective review of 194 patients undergoing various modifications of inguino-femoral lymphadenectomy, Rouzier et al. showed that techniques of groin node dissection that preserved the cribriform fascia and saphenous vein were associated with a decreased risk of postoperative morbidity without jeopardizing outcomes (194).

Sentinel Lymph Node Mapping and Biopsy

The concept of a "sentinel lymph node" was first introduced by Cabanas. Using lymphangiography for the clinical evaluation of penile carcinoma, he suggested that the sentinel lymph node was the first lymph node in the lymphatic pathway and the main site of metastasis (195). DiSaia et al. described the eight to ten superficial lymph nodes above the cribriform fascia as "sentinel nodes." When these lymph nodes proved negative, the risk for metastasis to the deep inguinal or pelvic lymph nodes was negligible (150). In 1992, Morton et al. introduced the use of vital blue dye (isosulfan blue) to identify lymphatic drainage from malignant melanoma (196). Levenback et al. utilized this intraoperative blue dye staining technique for sentinel lymph node identification in vulvar squamous cell carcinoma (Fig. 20.21) (178). Further work has demonstrated that blue dye staining alone has relatively low sensitivity in identifying the sentinel lymph node, particularly among patients with midline primary tumors. Lymphoscintigraphy using radioactive ^{99m}technetium administered shortly before surgery, combined with the intraoperative use of a handheld gamma probe, has significantly improved the sensitivity of sentinel lymph node identification (197).

Several earlier studies suggested that sentinel lymph node biopsy is a highly accurate procedure, with a negative predictive value approaching 100% (198–201). De Hullu et al. performed sentinel lymph node identification and biopsy in 59 women with primary vulvar carcinoma using the combination of intraoperative isosulfan blue dye staining plus preoperative lymphoscintigraphy (202). Only 60% of sentinel lymph nodes were visible with blue staining alone. With the addition of the handheld

FIGURE 20.21. Following isosulfan blue dye injection, sentinel lymph node biopsy is performed. In this case the sentinel lymph node is easily identified by the visible presence of dye. *Source:* Photo courtesy of Charles Levenback, MD, Houston, Texas, USA.

gamma probe sentinel lymph nodes were identified in 89% of groins dissected. Lymph node metastases were present in 27 groins and all were detected using sentinel lymph node identification and biopsy. The negative predictive value of a negative sentinel lymph node was 100%. Others have also reported a negative predictive value of 100% with sentinel lymph node biopsy (203,204). Because sentinel lymph nodes are subjected to a more rigorous pathologic (ultra-staging) examination, Robison et al. showed that sentinel lymph node biopsy allowed for the detection of smaller tumor foci in patients undergoing the procedure compared to patients who underwent complete groin node dissection and traditional pathologic examination (205). Others have reported that the detection of a sentinel lymph node in one groin does not preclude the presence of lymph node involvement in the contralateral groin (false negative) (206,207). Factors that may contribute to failure of sentinel lymph node identification include midline location for the primary tumor (207), and stasis of lymph flow from a node completely replaced by tumor (206,208). The prognosis associated with groin relapse is poor, and sentinel lymph node identification and biopsy should be confirmed by a prospective, randomized, controlled trial before sentinel lymph node identification and biopsy may be considered part of the standard of surgical care for vulvar carcinoma.

Surgical Resection for Recurrent Disease

The site, extent, and volume of recurrent vulvar cancer have important implications on both resectability and potential for cure. Recurrences can be categorized as local (vulva), groin, or distant (lung, bone, liver, brain). Surgical therapy plays a curative or palliative role in selected subsets of patients with recurrent disease (209).

Radical Wide Excision

As many as 75% of patients with recurrent disease limited to the vulva can be salvaged by radical wide excision or re-excision of the tumor (126,186,187). Surgical principles of recurrent vulvar tumors are identical to those for primary tumors: wide excision with a measured normal tissue margin of at least 2 cm. Particular attention is also focused on obtaining a clear deep margin. Because most patients have had prior operative therapy, primary closure of the vulvar defect is frequently more difficult. More complex reconstructive efforts may be needed to restore tissue integrity.

Pelvic Exenteration

Curative resection may still be possible when vulvar recurrence extends to the vagina, proximal urethra, or anus. Selected patients have achieved long-term survival after pelvic exenteration for such recurrences (88,210–212). The surgical approach in these cases should be individualized to the size and location of the recurrent tumor, prior therapies, and the age and overall health of the patient. Patients considered for pelvic exenteration should have a thorough preoperative evaluation to exclude the presence of regional and/or distant metastases. Frequently, anterior or posterior exenteration with an extended vulvar phase will provide excellent resection margins while allowing preservation of one major excretory system. The techniques used to perform the exenteration are identical to those routinely used for the treatment of women with recurrent cervical carcinoma. Unilateral gracilis flap repair may be combined with tailored exenteration to provide coverage for the surgical defect (213).

Resection of Groin Recurrence

Patients who develop groin recurrence are rarely curable. Untreated groin recurrence follows a particularly morbid

course characterized by pain, bleeding, skin breakdown, and infection. Palliative treatment should be considered for these patients. Surgical resection should be viewed with caution in the previously irradiated patient. Cure is unlikely with resection alone, and wound healing is impaired. The debility caused by a combination of unresolved recurrence and surgical wound breakdown is worse than that of progressive recurrence alone. Patients who develop groin recurrence without a history of prior irradiation should be considered for surgical resection in combination with preoperative or postoperative radiation therapy. The surgical approach is limited to the removal of gross tumor to the extent feasible. The operative goal is to resect or debulk the recurrence to a small volume in the hope that subsequent irradiation will achieve regional control. Tumor reduction is especially difficult when the recurrence arises within the deep compartment or encases the femoral vessels. Extended survival is possible for the few patients who achieve control of recurrent disease in the groin and do not later manifest distant metastasis. Isolated groin recurrence is a rare event, so the data to support the efficacy of this treatment are anecdotal.

Vulvar Reconstruction

With careful planning and adequate tissue mobilization, most vulvar defects can be closed primarily with absorbable sutures. When large portions of the vulva have been resected, when tissue mobility is poor, or when radiation therapy has been administered previously, primary closure may not be feasible. Alternate tissue sources must be considered for these difficult cases.

Rhomboid Flaps

The rhomboid flap is a local tissue advancement flap that draws its blood supply from the subcutaneous vascular network. These flaps can be developed at any level of the vulva. Single or combination flaps can be designed to cover a wide variety of defects. The maximal practical flap size is approximately 4 cm². Rhomboid flaps are particularly useful in providing closure of large midline defects following the radical wide excision of periclitral or perineal body tumors (189,214,215).

The rhomboid flap is designed by marking a V-shaped incision adjacent to the tissue defect needing coverage (Fig. 20.22). Flap size should correspond to the measured size of the defect. The flap incision is carried approximately 1 to 1.5 cm into the subcutaneous tissue. The flap is then developed by dissection within the subcutaneous tissue. When the adjacent tissues have been undermined, the flap can be rotated over the defect and sutured in place. Rhomboid flap repairs provide full thickness padded coverage without tension.

Myocutaneous Flaps

Several types of myocutaneous flaps—gracilis, gluteus, tensor fascia lata, rectus abdominis—have been used to provide repair and reconstruction of large vulvar and groin defects (216–221). Myocutaneous flaps, unlike local advancement flaps, include a segment of muscle and receive their blood supply and innervation through a clearly defined neurovascular pedicle. These are large, thick tissue sources that are best suited for the reconstruction of substantial defects. Although each of the flaps listed has proponents and specific advantages, the widest degree of experience has been reported for gracilis flaps. A gracilis flap can be designed to cover virtually any vulvar defect (Fig. 20.23).

The gracilis muscle is a broad flat muscle that courses through the superficial portion of the medial thigh. It is a weak adductor whose absence produces little perceptible deficit. The flap design is initiated by drawing a line from the

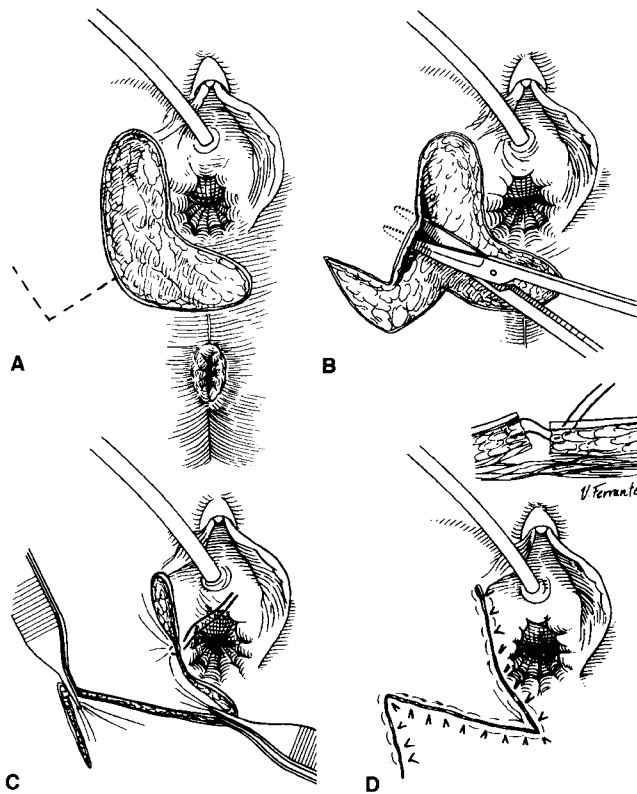

FIGURE 20.22. Technique for a unilateral rhomboid-flap repair. **A:** The flap is outlined. **B:** A 1-cm-thick flap of skin and subcutaneous tissue is raised. The area is undermined. **C:** The flap is rotated, and stay sutures are placed. **D:** Completed repair.

pubic tubercle to the medial femoral condyle. The gracilis muscle lies directly beneath this line. Flap size should be limited to a skin paddle of 6 to 8 cm × 10 to 12 cm. Smaller flaps have been associated with a lower incidence of necrosis and wound separation (213). The skin paddle incisions are carried to the gracilis fascia. The distal muscle is identified and transected 2 to 3 cm beyond the edge of the skin paddle. The myocutaneous unit is then developed by continuing the dissection more proximally. The main vascular bundle is usually encountered approximately 7 cm below the pubic tubercle. If possible, this pedicle should be

FIGURE 20.23. Diagrammatic representation of possible external placements for a gracilis myocutaneous flap. These flaps can be used to reconstruct large defects of the groin, labium majus, or perineal body. *Source:* Reprinted from Burke TW, Morris M, Roh MS, et al. Perineal reconstruction using single gracilis myocutaneous flaps. *Gynecol Oncol* 1995;57:221–225.

preserved; however, if additional mobility is required, this vascular pedicle may be sacrificed. Flap viability is thought to be retained through blood supply derived from the more proximal obturator branches. Once developed, the flap is mobilized through a subcutaneous tunnel to reach the perineum or groin. The flap can be trimmed and sutured into position.

RADIATION THERAPY

Early reports of severe local reactions and poor survival rates with primary radiation therapy of vulvar carcinomas led some previous investigators to conclude that radiotherapy had a very limited role in the curative management of these patients (222–224). The use of high doses of radiation alone, delivered with low energy photons and electrons, in patients who were mostly poor surgical candidates, resulted in a suboptimal therapeutic window between tumor control probability and normal tissue complications (225). However, more contemporary experiences, emphasizing appropriate fractionation, attention to treatment planning detail, and recognition of vulvar and low pelvic radiation tolerance limits, have clearly demonstrated that relatively high doses of irradiation can be delivered safely. In selected patients, treatment of the vulva and/or regional lymph nodes improves locoregional control rates, survival rates, and may even reduce overall treatment morbidity. Radiation therapy is now accepted as an important element in the multidisciplinary management of patients with locoregionally advanced disease.

Treating Locally Advanced Disease in the Vulva

Following initial resection of a vulvar primary tumor, various surgicopathologic features have been identified that are associated with a higher risk of local recurrence. Podratz et al. reported a 24% incidence of vulvar recurrence in 71 patients with stage III carcinoma (126). Recurrence was correlated with tumor size and nodal status. Heaps et al. reported that a close surgical margin was the most powerful predictor of local recurrence in their patients (59). They observed 21 vulvar recurrences in 44 patients with tumor margins <8 mm (deep or at the skin surface) compared with no local recurrences in 91 patients with margins ≥8 mm (after fixation). The importance of a pathologic margin distance ≥8 mm in optimizing local vulvar control and 5-year disease specific survival has also been emphasized in a recent analysis by Chan et al. (137). Lymphovascular space invasion and deep tumor penetration are also associated with a greater and increased risk of recurrence (59,127,226). Although many local recurrences are controlled with additional surgery or irradiation, salvage surgery is often morbid, and local recurrences may provide additional opportunity for regional and distant tumor spread. While no prospective trials of postoperative vulvar site radiotherapy have been completed, adjuvant radiation of the primary tumor bed in selected patients with close margins or other high-risk features does improve vulvar tumor control (227).

Alternatively, in patients who present with more advanced primary tumors, radiation therapy may be delivered preoperatively. Advocates of this approach have listed several theoretical advantages for patients with locally advanced vulvar carcinomas:

1. Less radical resection of the vulva may be adequate to achieve local tumor control after preoperative treatment of the vulva with irradiation.
2. Tumor regression during radiation therapy may allow the surgeon to obtain adequate surgical margins without sacrificing important structures such as urethra, anus, and clitoris.

- Radiation treatment alone may be sufficient to sterilize microscopic regional disease when the inguinal nodes are clinically normal and may mobilize fixed and matted nodes, facilitating subsequent surgical excision.

Although the published experiences with preoperative single-modality radiation therapy are small, several investigators have reported excellent responses and high local control rates after treatment of advanced tumors with relatively modest doses of radiation therapy followed by local resection (228–232). These reports provided emerging evidence that radiation could significantly debulk advanced local disease and allow for more conservative, viscera-sparing surgery, while preserving good local control.

More recently, a number of published series have suggested the therapeutic benefit of concurrent chemoradiation, typically followed by limited surgical resection, in addressing locally advanced disease (Table 20.7) (49,72,154,233–249). These trials were initially prompted by extrapolation from excellent results reported with chemoirradiation of carcinoma of the anus (250,251). Typical regimens have included combinations of irradiation with 5-fluorouracil (5-FU) and cisplatin or mitomycin C. Most studies included small numbers of patients with various disease presentations, including patients with very advanced or recurrent lesions, and none of these experiences can be compared meaningfully with results of treatment with preoperative irradiation alone. However, most investigators have observed impressive regressions of advanced lesions with chemoradiation, suggesting that responses may be better than would be expected with irradiation alone. Randomized trials of the role of chemoirradiation have not been done and are unlikely to be feasible given the small number of patients, and heterogeneity of clinical presentation, with this disease. However, recent trials that demonstrated improved local control and survival when concurrent cisplatin-containing chemotherapy was added to radiation treatment of cervical cancers (119,152,175) suggest that this

approach may also be useful for women with other locally advanced lower genital tract neoplasms (151,152,252).

The most compelling data in support of concurrent chemoradiation in the management of locally advanced disease comes from a large prospective phase 2 trial performed by the Gynecologic Oncologic Group (GOG protocol 101). In this study, 71 evaluable patients with locally advanced T3 or T4 disease who were deemed not resectable by standard radical vulvectomy underwent preoperative chemoradiation. Chemotherapy consisted of two cycles of 5-FU and cisplatin. Radiation was delivered to a dose of 47.6 Gy, using a planned split-course regimen, with part of the radiation given twice daily during the 5-FU infusion. Patients underwent planned resection of the residual vulvar tumor, or incisional biopsy of the original tumor site in the case of complete clinical response, 4 to 8 weeks after chemoradiotherapy. A complete clinical tumor response was noted in 33 of 71 (47%) patients. Following vulvar excision or biopsy, 22 patients (31%) were found to have no residual tumor in the pathologic specimen. In all, only 2 of 71 patients (3%) had unresectable disease after chemoradiation, and in only 3 patients was it impossible to preserve urinary and/or gastrointestinal continuity following complete resection of the primary tumor residuum. With a median follow-up interval of 50 months, 11 patients (16%) have developed locally recurrent disease in the vulva (154). These results are all the more notable considering the relatively low dose of radiation used in these typically bulky, advanced tumors.

It is important to be cautious in designing aggressive treatment protocols for this group of patients, who are often elderly, with coexistent medical problems. Serious pulmonary toxicity has been observed in patients treated with bleomycin (237,243). In the largest published series of patients treated with mitomycin C and 5-FU, hematologic tolerance was acceptable, but the administered dose of mitomycin C was more conservative than is usually used in the treatment of anal cancers (244). Other investigators have confirmed the increased toxicity associated

TABLE 20.7

CONCURRENT CHEMOIRRADIATION IN THE MANAGEMENT OF LOCALLY ADVANCED OR RECURRENT CARCINOMA OF THE VULVA

Investigators	No. of patients	Chemotherapy	RT dose (Gy)	No. with recurrent or persistent local disease after RT □ surgery	Follow-up (months)
Moore et al. (154)	73	5-FU + CDDP	47.6	15 (21%)	22–72

with concurrent chemoradiation, especially with the use of mitomycin C–based regimens (248).

The use of concurrent weekly cisplatin with radiation has been widely tested in patients with locally advanced cervical cancer, and found to be therapeutically beneficial and well tolerated (151,153). In an attempt to further improve clinical and pathologic complete response, and ultimate local tumor control rates, the GOG is conducting another prospective phase 2 trial (GOG protocol 205), which combines weekly cisplatin with daily fractionated radiotherapy, followed by resection of residual primary tumor (or biopsy of the initial tumor bed if a clinical complete response is achieved). Radiation will be given to a total dose of 57.6 Gy (representing a 20% dose escalation over that used in GOG 101) to the gross tumor volume using careful treatment planning and boost techniques, and the previously used 2-week planned break has been eliminated. A stated objective of GOG 205 is to determine if the pathologic complete response can be increased to 45%, compared with the 31% pCR rate seen in the preceding GOG 101 study. Sufficient activity has been noted in the preliminary first accrual stage of 25 patients that the larger second stage of GOG 205 is now continuing active accrual.

Following chemoradiation for locally advanced disease, it remains undefined if surgery is necessary in those who achieve complete clinical response. In GOG 101, about 70% of patients who achieved complete clinical response were found to have no pathologic residual in the surgical specimen. At this point, we continue to recommend biopsies of the original tumor bed in patients who achieve complete clinical response. In those with residual vulvar disease after chemoradiation, surgical resection would be individualized and tailored to the extent and location of residuum.

Treatment of Regional Disease

Although radical inguinal lymphadenectomy has historically been considered the treatment of choice for regional management of invasive vulvar carcinoma, a number of retrospective studies have suggested that regional prophylactic radiation therapy is an effective method of preventing groin recurrences with minimal morbidity (253–257). In a review of 91 patients treated electively for cancers with primary drainage to the inguinal nodes, Henderson et al. observed only two failures after treatment with 45 to 50 Gy in 5 weeks, and both of these were outside the radiation treatment fields. Complications were rare, with only one case of mild leg edema, which may not have been treatment related (253). In another review of patients treated for vulvar carcinomas, Peterit et al. found no difference in the groin recurrence rate for clinically negative inguinal nodes treated with radical lymphadenectomy or radiation therapy, even though the irradiated patients had more advanced primary tumors (255). In a large single-institution retrospective analysis, Katz et al. reported no differences in the inguinal relapse rates for patients treated with prophylactic groin irradiation compared with those undergoing lymph node dissection (256). Leiserowitz et al. had no groin recurrences in 23 patients with locally advanced, clinically N0 vulvar cancers after prophylactic treatment of the groins with concurrent chemoirradiation (257).

The GOG tried to define the optimal approach to clinically negative inguinal nodes in a trial that randomized patients between inguinal node irradiation and radical lymphadenectomy (followed by inguinopelvic irradiation in patients with positive nodes) after resection of the primary tumor (258). This study was closed after entry of only 58 patients when there appeared to be a higher rate of groin recurrence in the radiation treatment arm. However, this study has been criticized because the treatment protocol was not CT-based, recommended combination photon and electron dosing to a depth of 3 to 4 cm, and likely delivered an inadequate dose to the inguinal nodes (259,260).

While the role of prophylactic radiotherapy in the undissected but high-risk groin remains controversial, there is strong evidence that adjunctive radiation therapy improves regional tumor control and survival in patients who have documented nodal metastases following inguinal node dissection. Retrospective studies suggested that patients with metastases to multiple nodes or extranodal tumor extension had an increased risk of groin recurrence after radical surgery and therefore may benefit from radiation therapy (261,262). However, the critical role of radiation therapy was not appreciated until 1986, when Homesley et al. published results of a prospective GOG trial in 114 patients with inguinal metastases (162). In that study, all patients underwent radical vulvectomy and inguinal lymphadenectomy. Patients who had positive inguinal nodes were randomized intraoperatively to receive either pelvic node dissection or postoperative irradiation to the pelvis and inguinal nodes. This trial was closed before the projected accrual goal because an interim analysis revealed a statistically significant overall survival advantage for the radiation treatment arm ($p = 0.03$). The differences between the 2-year survival rates of patients treated with radiation therapy or pelvic dissection were most marked for patients presenting with clinically positive nodes (59% and 31%, respectively) and for those with two or more positive groin nodes (63% and 37%, respectively). There was no significant difference in survival between the treatment groups for patients with only one microscopically positive node, although the authors commented that the number of patients in this subset was insufficient for reliable analysis. The most striking difference in the patterns of recurrence for the two treatment groups was the much larger number of inguinal failures among patients who were treated with surgery alone (Fig. 20.24). These groin recurrences were rarely if ever salvageable. The vulva, regardless of tumor pathologic risk factors, was not included in the radiation treatment fields in this study, and approximately 9% of patients in both treatment arms had recurrences at the primary site at the time of the analysis, raising the question of whether selective radiation to the vulva may have decreased local recurrences. It is important to recall that while subset analysis showed the most dramatic benefit to adjuvant radiotherapy for clinically positive adenopathy or ≥ 2 pathologically involved nodes in the the Homesley study (162), the trial was closed early because of an overall survival benefit before subset analysis. The role of adjuvant radiation for patients with a single positive groin node following inguinal node dissection remains unresolved. A recent retrospective review of patients with only a

FIGURE 20.24. Sites of disease recurrence in patients treated with adjuvant radiation therapy to the pelvis and inguinal region or with pelvic node dissection following radical vulvectomy and bilateral inguinal lymphadenectomy. *Source:* Modified from Homesley HD, Bundy BN, Sedlis A, et al. Radiation therapy versus pelvic node resection for carcinoma of the vulva with positive groin nodes. *Obstet Gynecol* 1986;68:733–740.

single positive inguinal nodal metastasis from vulvar cancer suggests that adjuvant radiation may provide therapeutic benefit if the groin node dissection was less extensive in scope (263).

Successful use of concurrent chemotherapy and radiation therapy following radical hysterectomy in cervical cancer patients with positive lymph nodes suggests that concurrent chemoradiotherapy might be valuable for patients with node positive vulvar cancer (152). Although a randomized trial was initiated to address the role of adjuvant chemoradiation following resection of node positive tumors, the study was deemed infeasible and closed due to the relative rarity of these cancers and lack of patient accrual.

However, the role of preoperative chemoradiation has been assessed in patients who present with bulky, unresectable inguinal adenopathy. In the GOG 101 study of preoperative chemoradiation for local regionally advanced vulvar cancer, there was a cohort of 42 evaluable patients with N2 or N3 nodal disease that were deemed initially unresectable. Patients received 47.6 Gy of radiotherapy in split-course fashion, with two concurrent cycles of 5-FU and cisplatin as described above. Three to eight weeks later, planned inguino femoral lymph node dissection was performed. In only two patients (5%) did nodal disease remain unresectable. The surgical specimen showed histologic clearance of nodal disease in 15 patients (36%). At a median follow-up of 78 months only one of 37 (3%) patients who completed the full prescribed regimen of preoperative chemoradiation and bilateral inguino femoral node dissection relapsed in the groin (264). This study, while nonrandomized, provides further evidence of the efficacy of combined chemoradiotherapy in the management of locally regionally advanced vulvar cancer and in patients with significant regional adenopathy. Given the high risk of distant relapse with node positive vulvar cancer, especially in those with ≥ 2 involved nodes (265), it seems reasonable to consider adjuvant chemoradiation for such high-risk patients, provided that careful attention is paid to treatment planning and amelioration of toxicity.

Radiation Therapy Technique

Techniques commonly used for treatment of vulvar carcinoma reflect the need to encompass the lower pelvic and inguinal nodes as well as the vulva, while minimizing the dose to the femoral heads. One approach is to treat with an anterior field that encompasses the inguinal regions, lower pelvic nodes, and vulva, and a narrower posterior field that encompasses the lower pelvic nodes and vulva but excludes the majority of the

FIGURE 20.25. The radiation dose to the femoral heads can be reduced by delivering part of the dose to inguinal nodes with appropriate-energy electron fields. In this example, a wide anterior 6 MV field encompasses the primary site as well as the inguinal and pelvic nodes. Electron fields are placed anteriorly to overlap slightly with the exit of a narrower posterior 18 MV field that encompasses the primary and pelvic nodes.

femoral heads. If the fields are evenly weighted to the midplane of the pelvis using 6 MV photons, the contribution of the anterior field to the groin nodes (at 3 to 5 cm depth) will generally be 60% to 70% of the dose to the mid pelvis. The difference may be made up by supplementing the dose to the lateral groins with anterior electron fields of appropriate energy (Fig. 20.25). Kalnicki et al. described another technique, using a partial transmission block, that also reduces the dose to the femoral heads (266). CT scans are used to determine the appropriate electron energy and to detect enlarged nodes that may not be appreciated on clinical exam. Gross disease in the groin or vulva may be boosted with *en face* electron fields. In some cases, interstitial implants or *en face* electron fields may be used to boost the dose to the primary site (267,268). If radiation is directed to the regional nodes only, with intentional sparing of the vulva, care must be taken to avoid a large “midline” block, which may lead to higher medial groin and vulvar failures (269).

The complex anatomy of the vulva and its regional lymphatics, interwoven with adjacent critical normal tissues, has led some investigators to propose the use of intensity modulated radiation therapy (IMRT) in the management of vulvar cancer (Fig. 20.26) (270). IMRT theoretically and dosimetrically

Vulvar cancer – locally advanced T4N2

FIGURE 20.26. Intensity modulated radiation therapy (IMRT) in the management of vulvar cancer
 Source: From Beriwal S, Heron D, Kim H, et al. Intensity-modulated radiotherapy for the treatment of vulvar carcinoma: a comparative dosimetric study with early clinical outcome. *Int J Radiat Oncol Biol Phys* 2006;64:1395–1400.

allows for greater sparing of the bladder, rectum, and small bowel centrally, femoral necks laterally, and uninvolved buttock and perineal skin compared to traditional anteroposterior or four-field techniques. However, issues regarding the appropriate definition of target volumes at risk, including altered lymphatic pathways secondary to advanced tumor presentations, as well as patient and organ motion, will need to be carefully considered and assessed before IMRT can be deemed a standard radiotherapeutic approach in patients with vulvar cancer.

Acute Complications of Radiation Therapy

Acute radiation reactions are brisk, and doses of 35 to 45 Gy routinely induce confluent moist desquamation. However, with adequate local care, this acute reaction usually heals within 3 to 4 weeks. Sitz baths, steroid cream, and treatment of possible superimposed *Candida* infection all help to minimize the discomfort. If the patient is sufficiently flexible, she may be placed in a frog-leg position during treatment to minimize the dose and ensuing skin reaction on the medial thighs; care must then be taken, however, to deliver an adequate dose to the vulvar skin. Although most patients will develop confluent mucositis by the fourth week of treatment, this is usually tolerated if the patient is warned in advance and assured that the discomfort will resolve after treatment is completed. Although a treatment break is occasionally required, delays should be minimized, because they may allow time for repopulation of tumor cells.

Late Complications of Radiation Therapy

Many factors add to the late morbidity of radiation treatment in patients with vulvar carcinoma. Patients with advanced vulvar carcinomas often are treated with radiation therapy following radical surgery, which may include extensive dissection of the inguinal and possibly pelvic nodes. Large ulcerative cutaneous lesions frequently have superimposed infection. Patients are often elderly and may have complicating medical conditions, such as diabetes, multiple prior surgeries, and osteoporosis. The contribution of concurrent chemotherapy to local morbidity is not yet clearly defined, but may contribute to bowel and bone complications (271,272).

The incidence of lower extremity edema after inguinal irradiation alone is negligible (253,255,256,262). Although radiation therapy probably contributes to the incidence of peripheral edema following radical node dissection, no difference was evident in the GOG randomized study (162). However, the investigators admitted that evaluation of lymphedema was not a major consideration of the study and that the complication may have been underreported. Femoral head fractures have occasionally been reported in patients treated with irradiation to the inguinal nodes (231,244,253). Techniques that limit the dose to the femoral heads to less than 35 Gy should minimize the risk

of this complication. It is not known whether severe osteoporosis contributes to femoral head complications. In general, with careful treatment planning techniques, the risk of major late complications following regional nodal radiation, either electively or adjuvant to lymph node dissection, is low (256). It has been suggested that concurrent chemotherapy may increase the risk, but this remains to be adequately substantiated (271).

The effect of radiation therapy on the long-term cosmesis and function of the vulva is poorly understood. Although treatment with irradiation or chemoradiation and wide excision is becoming a more accepted alternative to extensive surgery for selected patients, and major complication rates appear to be acceptable, very little has been reported regarding more subtle late effects of such treatment in the vulva. Late effects are dose related. Although Frischbier and Thomsen reported a 24% incidence of late ulceration in a large number of patients treated primarily with electron beam radiation therapy to the vulva, the relatively large dose per fraction (3 Gy/d) that was used probably contributed to this high incidence (273). Better information will become available only as treating physicians record and report the late cosmetic and functional results of treatment (274).

CHEMOTHERAPY

Data on the use of chemotherapeutic agents for the treatment of vulvar malignancies are limited; the incidence is low, the majority of patients are cured with surgery with or without postoperative radiation therapy, and thus chemotherapy has been used primarily as a salvage therapy. Patients with advanced vulvar cancers tend to be older, making them poor candidates for cytotoxic therapy because of concomitant diseases that increase the likelihood for significant adverse effects. Furthermore, recurrent vulvar cancer often occurs in the setting of extensive prior surgery and/or radiation therapy, making tolerance to cytotoxic therapy poor. No single institution has a large enough patient population to allow adequate phase 2 testing of cytotoxic agents.

Squamous Cell Carcinoma

Squamous carcinoma is the only cell type for which reproducible information exists on the value of cytotoxic therapy. Several drugs have undergone phase 2 testing in squamous vulvar cancer (Table 20.8) (111,275–278). Only doxorubicin and bleomycin appear to have activity as single agents. Although methotrexate has been claimed to have activity, data are inadequate for confirmation. Cisplatin, a drug that has demonstrated broad activity in most gynecologic tumors (e.g., epithelial ovary, endometrial adenocarcinoma, endometrial

mixed mesodermal tumors, and squamous carcinoma of the cervix), has notably little activity in vulvar and vaginal squamous tumors. This lack of activity, however, is based on treatment of refractory patients only. No trials of this agent as a presurgical cytoreductive regimen have been attempted. With the recent dramatic results obtained with concurrent cisplatin-based chemotherapy and radiation therapy in locally advanced squamous cancer of the cervix, one must consider a similar approach in the patient with locally advanced squamous cancer of the vulva.

Several drug combinations have also been used in squamous vulvar cancer. These combinations consisted principally of drugs without clear evidence of single-agent activity in phase 2 studies. Nevertheless, these combinations have been evaluated as initial therapy for patients with inoperable disease. Significant responses have allowed operative intervention in some patients. Combinations used in vulvar squamous cancer are inventoried in Table 20.9 (47,279,280). As noted above, the significant response rates observed with primary chemotherapy in inoperable disease presentations and the poor response rates in refractory disease should lead investigators to the earlier consideration of using cytotoxic therapy in stage III and IV vulvar cancers. Toxicity with these regimens has been reported as tolerable, although some patient selection for good performance status was probably operational. In the one well-reported trial, 64% of patients had mucositis (21% severe), and infections or fever occurred in 35% (280). Bleomycin lung disease was responsible for one death. Patients should be selected who are at lowest risk for chemotherapy associated toxicity (i.e., no concomitant disease, normal organ function, younger age).

There are some increasing reports of the concomitant use of cytotoxic therapy with irradiation, usually as primary therapy in advanced and inoperable disease (Table 20.7). This approach may have increased impetus based on recent reports from several large randomized trials demonstrating superior outcome for combined chemoradiation over radiation therapy alone in locally advanced squamous cancer of the cervix (151–153,252). It is not possible from such study designs to specifically comment on the effects of chemotherapy on the disease. Nevertheless, these studies are cited because chemotherapy may have played a role in the end result. The largest experience was recently reported by the GOG, in which 73 patients with T3 or T4 cancers were treated with split-course radiation therapy with concomitant chemotherapy (cisplatin, 75 mg/m² on day 1,

and 5-FU, 1,000 mg/m²/d on days 1–5). Irradiation of the primary tumor in a split course was followed by resection of residual primary tumor and inguino-femoral nodes. Those patients with unresectable groin nodes received chemoradiation to both the primary tumor and involved nodes. Seven patients never underwent surgery for various reasons. After chemoradiation, 46% of patients were grossly tumor free. Of the 54% with gross residual disease, only five had positive margins at resection. Only 3% of the patients completing planned chemoradiation and surgery had residual unresectable disease, and in only three patients was it not possible to preserve urinary and/or gastrointestinal continence. Survival data from this study remain immature, but demonstrated that this approach is feasible with acceptable toxicity (primarily decreased wound healing and enhanced cutaneous reactions) and with a possible decrease in the need for more radical surgery (154). Landoni et al. treated 58 advanced primary and 17 recurrent disease patients with 5-FU (750 mg/m²/d on days 1–5) and mitomycin C (15 mg/m² on day 1) at the beginning of each of two courses of irradiation separated by 2 weeks (total dose of 54 Gy). Primary chemoradiation was followed by wide local excision and inguinal lymphadenectomy. A total of 89% of patients completed planned radiation therapy and chemotherapy, and 72% underwent surgery. Response was noted in 80%, and pathologic complete response was observed in both primary and nodes in 31%. Three treatment related deaths were also recorded (240). Lupi et al. treated 31 patients with mitomycin C and 5-FU using the same doses as in the previous study and split-course irradiation to only 36 Gy. Response was noted in 29 of 31 (94%), but postoperative morbidity was noted in 65% and mortality in 14%. Of patients with positive inguinal nodes, 55% (five of nine) were rendered pathologically disease free at surgery. Recurrence was noted in 32%, and survival was not reported (241). Whalen et al. treated 19 patients with clinical stage III/IV vulva carcinoma and clinically negative nodes with 45 to 50 Gy and 5-FU (1,000 mg/m²/d continuous intravenous infusion over 96 hours at weeks 1 and 5) and mitomycin C (10 mg/m² on day 1 only). A response rate of 90% and a local control rate of 74% was observed. Survival was not reported (245). Cunningham et al. treated 14 patients who were not candidates for radical vulvectomy with cisplatin (50 mg/m²) and 5-FU (1,000 mg/m²/d over 96 hours) in combination with 50 to 65 Gy irradiation to vulva and bilateral

FIGURE 20.27. Invasive squamous vulvar carcinoma. Survival by FIGO stage. *Source:* Patients treated at M. D. Anderson Cancer Center 1944–1990; data courtesy of F. N. Rutledge.

groins and 45 to 50 Gy to the pelvis. Surgery was not performed in complete responders. There was a 64% complete response rate and only one recurrence in that group, with mean follow-up of 36 months. All partial responders died of disease. Toxicity was moderate, with five patients requiring treatment delay due to desquamative reactions and one late bowel complication (234). Thomas et al. treated 33 patients with stage II, III, or IV disease: 9 with definitive radiation therapy and chemotherapy as a preoperative adjuvant, 9 with definitive radiation therapy and chemotherapy, and 15 with radiation therapy and chemotherapy after local recurrence following surgery. Chemotherapy consisted of infusional 5-FU given at a dose of 1,000 mg/m²/d over 4 to 5 days; six patients also received low-dose mitomycin C. Various doses and techniques of irradiation were used. Seven of nine patients treated with neoadjuvant therapy remained free of disease at 5 to 45 months, one after local excision of a vulvar recurrence. Of the nine patients receiving curative intent radiation therapy and chemotherapy, six were alive without evidence of disease at 5 to 43 months. Of the 15 patients treated after recurrence, 7 were alive without evidence of disease for 5 to 45 months. It is impossible to determine the role of chemotherapy in these patients, but it appears that combined modality therapy offers the potential for long-term disease control without radical surgery (244).

RESULTS OF THERAPY

The overall results of therapy for women with squamous cancers of the vulva are excellent. Approximately two thirds of patients present with early-stage tumors. Five-year survival rates of 80% to 90% are routinely reported for stage I and II disease (281). As anticipated, survival rates for patients with advanced disease are poor: 60% for stage III cases and 15% for stage IV (Fig. 20.27).

Several strategies to enhance survival for women with vulvar cancer are evident. High-risk patients can be educated and screened more consistently for the development of early cancer. Women with human papillomavirus infections, *in situ* vulvar disease, long smoking history, and other genital neoplasms are at risk for developing vulvar cancer. Careful screening targeted at women with these high-risk factors may lead to improvements in early diagnosis.

The survival rate for women with nodal spread is one half that of women without nodal disease who have similarly sized primary tumors (Fig. 20.28). A more precise understanding of lymphatic flow and tumor spread might enable us to better identify those patients with subclinical metastases who now present with unanticipated groin or distant failure. Better treatment options for node positive patients are needed, possibly multimodality therapy that incorporates irradiation, chemotherapy, or both with surgery.

MANAGEMENT OF OTHER VULVAR MALIGNANCIES

Because nonsquamous vulvar malignancies are exceedingly rare, relatively little definitive information is available regarding optimal treatment and long-term outcome. Most available information is derived from isolated case reports or small series spanning long periods of time.

Malignant Melanoma

Malignant melanoma is the second most common vulvar malignancy (97,282,283). Vulvar melanomas are most commonly seen in postmenopausal Caucasian women. Typical presentations include an asymptomatic pigmented lesion or an identified mass that may be painful or bleeding (Fig. 20.29). A definitive diagnosis is established by biopsy. Immunohistochemical staining for melanoma-specific antigen and S100 may be helpful in uncertain cases. Melanomas may arise from existing pigmented vulvar lesions or as new isolated primary tumors. Consequently, any pigmented vulvar lesion should be considered for biopsy. Melanomas are staged according to one of the three available microstaging systems, which base prognosis on either depth of local invasion or tumor thickness (Table 20.10) (103,284,285). Inguinal lymph node and distant metastases are frequent.

The primary treatment modality for vulvar melanoma is radical surgical excision. Radical vulvectomy with bilateral inguinofemoral lymphadenectomy has been the historical treatment of choice (282,283,286,287). Because most failures are distant, ultra-radical local resection does not appear to enhance survival. Furthermore, many patients with vulvar melanoma are elderly with coexisting medical problems, and less radical surgery may be a more realistic option without compromising survival (288). More recent reviews recommend some form of hemivulvectomy or radical wide excision, with or without inguinal lymphadenectomy (286,287). Depth of invasion and the presence of ulceration are significant prognostic factors, and should be considered in treatment planning. Look et al. reported that none of the patients with lesion depth of ≤ 1.75 mm experienced a recurrence, and suggested that these patients could be

FIGURE 20.29. Nodular, darkly pigmented malignant melanoma of the left labium majus.

TABLE 20.10

MICROSTAGING SYSTEMS FOR VULVAR MELANOMAS

	Clark et al. (284)	Chung et al. (285)	Breslow (103)

V	Into subcutaneous fat	Into subcutaneous fat	>3 mm

treated with wide local excision. In contrast, all patients with lesion depth of >1.75 mm recurred despite radical tumor excision (99). Based on information derived from large series of patients with cutaneous melanomas at nongenital sites, regional lymphadenectomy should probably be considered a prognostic rather than a therapeutic procedure (289). In a multivariate analysis of 644 patients with vulvar melanoma, Sugiyama et al. reported 5-year disease-specific survival rates of 68%, 29%, and 19% for patients with zero, one, and two or more positive lymph nodes, respectively (290). Lymphadenectomy can be avoided in patients with superficial melanomas (level III), for whom the risk of metastatic disease is negligible. Sentinel lymph node identification and biopsy have been increasingly applied to the surgical management of cutaneous malignant melanomas; however, data regarding sentinel lymph node biopsy for vulvar melanomas are insufficient.

Radiation therapy may be useful in enhancing local and regional control for some high-risk patients. Despite reported complete clinical response rates and local tumor control rates of 50% to 70% for patients with localized recurrences treated with radiation therapy, alone or in combination with hyperthermia, these modalities have rarely been used in the primary treatment of vulvar melanoma (291,292). Doses in the range of 40 to 50 Gy, delivered in fractions of 4 to 8 Gy (one to three weekly fractions), have been described as more effective (293).

Systemic chemotherapy, in either an adjuvant or salvage setting, is considered palliative, but responses are truly rare and adverse effects may be significant. Biologic and immunologic approaches to the treatment of malignant melanoma are currently being evaluated. The Southwest Oncology Group reported their results of a randomized trial of an adjuvant allogeneic tumor vaccine in patients with intermediate thickness, node negative melanoma. There was no evidence of improved disease-free survival among patients randomized to receive vaccine (294).

Overall survival rates in women with vulvar melanoma are approximately 50% (97,282,287). Patients with superficial lesions have an excellent chance for cure after surgical resection, but patients with deeper lesions or metastases at the time of diagnosis have a more limited prognosis. These patients are good candidates for investigational trials.

Verrucous Carcinoma

Verrucous carcinomas are locally invasive and rarely metastasize (295). Consequently, treatment by radical wide excision is usually curative (296). Local recurrence can occur, especially when the tumor has been inadequately resected. Although radiation therapy has been reported to cause anaplastic transformation in some cases of verrucous carcinoma, this finding has not been observed by others (297,298).

Basal Cell Carcinoma

Basal cell carcinomas should be removed by excisional biopsy using a minimum surgical margin of 1 cm (299). Lymphatic or distant spread is exceedingly rare (300). Local recurrence may occur, particularly in tumors removed with suboptimal resection margins.

Adenocarcinoma

Patients presenting with apparent vulva adenocarcinoma should first undergo an extensive clinical evaluation to determine whether the lesion in question represents a primary versus metastatic tumor. Despite the paucity of data regarding the evaluation and treatment of vulva adenocarcinoma, resection of localized disease by radical wide excision, hemivulvectomy, or radical vulvectomy seems appropriate (301). The incidence of groin node metastases is approximately 30% (302). Some form of inguinal lymphadenectomy should be included with primary surgical resection. Radiation therapy may have a role in enhancing local control for women with large primary tumors or inguinal metastases. The effectiveness of chemotherapy is unknown, although a single case report documents a response with pegylated liposomal doxorubicin in adenocarcinoma of the vulva (303).

Paget's Disease

Paget's disease is associated with an underlying invasive adenocarcinoma component in approximately 15% of cases (304,305). As many as 20% to 30% of patients will have or will later develop an adenocarcinoma at another nonvulvar location (306,307), although more recent series suggest a lower incidence of secondary malignancies (308). Observed sites of non-vulvar malignancies developing in patients with extramammary Paget's disease include breast, lung, colorectum, gastric, pancreas, and upper female genital tract. Screening and surveillance for tumors at these sites should be considered in patients with Paget's disease.

Paget's disease should be resected with a wide margin. If underlying invasion is suspected, the deep margins should be extended to the perineal fascia. Some suggest careful assessment of the surgical margins using multiple frozen sections to ensure complete excision (309,310). This approach can be cumbersome and may not influence the long-term incidence of recurrence. Pierie et al. showed that patients with microscopic positive margins had a significantly higher rate of recurrence; however, with extended follow-up all patients eventually recurred (311). Others have shown that despite surgical efforts to the contrary, microscopically positive margins are frequent, and disease recurrence is common regardless of margin status (312). Repeat local excision of recurrent disease is usually effective in the absence of invasion (313).

Vulvar Sarcomas

The specific histologic types are described in the pathology section of this chapter. All types of vulvar sarcoma are rare, but leiomyosarcoma, malignant fibrous histiocytoma, and rhabdomyosarcoma predominate (106,314). Cures have occasionally been obtained with aggressive resection of either primary or locally recurrent disease. The results of regional and systemic therapy for leiomyosarcoma are disappointing. These patients are excellent candidates for clinical trials. Rhabdomyosarcoma seems to be more responsive to both

FIGURE 20.30. Multiple in-transit lymphatic metastases from a cloacogenic carcinoma of the rectum. A large constricting lesion was evident on rectal examination.

chemotherapy and radiation. The current treatment of choice is to combine chemoradiation with limited surgical resection of residual disease (314,315).

Metastatic Tumors to the Vulva

Treatment of secondary vulvar tumors should be directed against the primary tumor. As with bulky vulvar cancers, a multimodal approach seems to provide some opportunity for long-term survival along with enhanced local tumor control and organ preservation.

Cutaneous vulvar lymphatic metastases may occur as in transit tumor emboli from anorectal tumors or as retrograde flow metastases when bulky tumors of the cervix or uterus obstruct the normal lymphatic drainage patterns (Fig. 20.30). These metastases are multiple and are often bilateral. Their histology reflects that of the primary tumor. Because this metastatic pattern is associated with advanced tumors, the primary tumor should be readily detectable by examination.

FUTURE DIRECTIONS

Vulvar cancer is an uncommon neoplastic disease and its relative rarity is a major obstacle in designing prospective randomized trials. Current trends in its management are focusing on a more individualized approach that emphasizes conservative vulva surgical resection when feasible, the use of reconstructive procedures to preserve or restore vulva function, potential reduction in groin complications through sentinel lymph node biopsy, and multimodality therapy for advanced or disseminated disease. Most data supporting these concepts are preliminary. Further investigation is likely to result in ongoing refinement of the criteria used to select patients for

specific surgical procedures. The greatest gaps in our present understanding of this disease and its treatment include (a) the uncertain role of infectious and epidemiologic factors in the development of the primary tumor; (b) the lack of consensus regarding the extent of groin dissection required to accurately assess lymphatic spread; (c) the lack of a well-defined management plan for patients with lymph node metastases; (d) the absence of proven systemic therapy for women with distant spread or recurrence; (e) scant information to evaluate the components and timing of combined modality treatment; and (f) poor understanding of different forms of treatment on the psychosexual adjustment of patients. These all represent areas of current investigation. Additional clinical experience should help to establish a rational approach to therapy that maximizes the potential for cure while minimizing morbidity.

CHAPTER 21 ■ VAGINA

HIGINIA R. CÁRDENES, JEANNE M. SCHILDER,
AND LAWRENCE M. ROTH

ANATOMY

The vagina is a muscular dilatable tubular structure averaging 7.5 cm in length that extends from the cervix to the vulva. It lies dorsal to the bladder and urethra, and ventral to the rectum. The upper portion of the posterior wall is separated from the rectum by a reflection of peritoneum, the pouch of Douglas. The vaginal wall is composed of three layers: the mucosa, muscularis, and adventitia. The inner mucosal layer is formed by a thick, nonkeratinizing, stratified squamous epithelium overlying a basement membrane containing many papillae. The epithelium normally contains no glands but is lubricated by mucous secretions originating in the cervix. Beneath the mucosa lies a submucosal layer of elastin and a double muscularis layer, highly vascularized with a rich innervation and lymphatic drainage. The muscularis layer is composed of smooth muscle fibers, arranged circularly on the inner portion and longitudinally in the outer portion. A vaginal sphincter is formed by skeletal muscle at the introitus. The adventitia is a thin, outer connective tissue layer that merges with that of adjacent organs.

The proximal vagina is supplied by the vaginal artery branch from the uterine or cervical branch of the uterine artery. It runs along the lateral wall of the vagina and anastomoses with the inferior vesical and middle rectal arteries from the surrounding viscera (1). The accompanying venous plexus, running parallel to the arteries, ultimately drains to the internal iliac vein. The lumbar plexus and pudendal nerve, with branches from sacral roots 2 to 4, provide innervation to the vaginal vault (Fig. 21.1). The lymphatic drainage of the vagina is complex, consisting of an extensive intercommunicating network. Fine lymphatic vessels coursing through the submucosa and muscularis coalesce into small trunks running laterally along the walls of the vagina. The lymphatics in the upper portion of the vagina drain primarily via the lymphatics of the cervix; the upper anterior vagina drains along cervical channels to the interiliac and parametrial nodes; the posterior vagina drains into the inferior gluteal, presacral, and anorectal nodes. The distal vaginal lymphatics follow drainage patterns of the vulva into the inguinal and femoral nodes and from there to the pelvic nodes. Lymphatic flow from lesions in the mid vagina may drain either way (2). However, because of the presence of intercommunicating lymphatics along the terminal branches of the vaginal artery and near the vaginal wall, the external iliac nodes are at high risk even in lesions of the lower third of the vagina. Such a complex lymphatic drainage pattern has significant implications for therapeutic planning. Therefore, bilateral pelvic nodes should be considered to be at risk in any invasive vaginal carcinoma, and bilateral groin nodes should be considered to be at risk in those lesions involving the distal third of the vagina.

EPIDEMIOLOGY AND ETIOLOGIC RISK FACTORS

Primary vaginal cancer, defined as a lesion arising in the vagina without involvement of the cervix or vulva, is a rare entity, representing only 1% to 2% of all female genital neoplasias (3). Most vaginal neoplasms, 80% to 90%, represent metastasis from other primary gynecologic (cervix or vulva) and nongynecologic sites, involving the vagina by direct extension or lymphatic or hematogenous routes. Creasman et al. (4) published the National Cancer Data Base (NCDB) report in 1998, based on 4,885 patients with primary diagnosis of vaginal cancer registered from 1985 to 1994. Approximately 92% of the patients were diagnosed with *in situ* or invasive squamous cell carcinoma (SCC) or adenocarcinomas, 4% with melanomas, 3% with sarcomas, and 1% with other or unspecified types of cancer. In the NCDB report, invasive carcinomas accounted for 72% of the carcinoma cases, or 66% of all vaginal cancers. *In situ* carcinomas accounted for 28%, SCC represented 79% of invasive vaginal carcinomas, and adenocarcinomas represented 14%. Adenocarcinomas represent nearly all the carcinomas in patients younger than 20 years of age and are seen less frequently with advanced age (4).

Carcinoma of the vagina is considered to be associated with advanced age, with the peak incidence occurring in the sixth and seventh decades of life. However, vaginal cancer is increasingly being seen in younger women, possibly due to human papillomavirus (HPV) infection or other sexually transmitted diseases. Only about 10% of patients are 40 years of age or younger (5). In the NCDB report, only 1% of the carcinoma patients were less than 20 years old at the time of diagnosis, and over 80% of those patients had *in situ* lesions. As patient age increased, the number of invasive tumors increased, reaching a peak in patients aged 70 to 79 years. The percentage of *in situ* carcinomas decreased to only 11% in patients over 80 years old (4). A decrease in the incidence of primary vaginal tumors has been noted in recent years, possibly because of early detection with cervical cytology or more rigid diagnostic criteria, which have eliminated from this category primary cancers arising from adjacent organs, such as the cervix, vulva, or endometrium.

Vaginal Intraepithelial Neoplasia and Squamous Cell Carcinoma

Potential risk factors for SCC include prior history of HPV infection, cervical intraepithelial neoplasia (CIN), vulvar intraepithelial neoplasia (VIN), immunosuppression, and possibly previous pelvic irradiation. HPV is the likely etiologic agent of

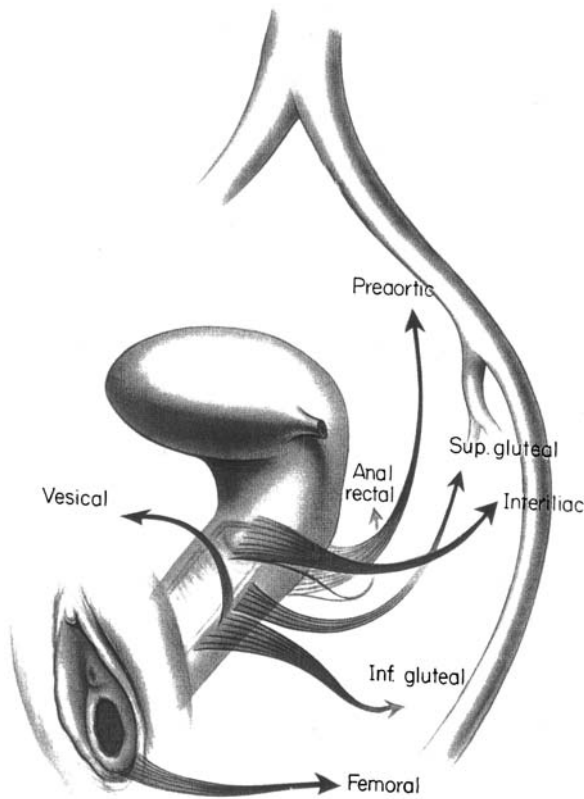

FIGURE 21.1. Lymphatic drainage of the vagina. *Source:* Reprinted from Plentl AA, Friedman EA. Lymphatic system of the female genitalia. In: Plentl AA, Friedman EA, eds. *The Morphologic Basis of Oncologic Diagnosis and Therapy*. Philadelphia: WB Saunders; 1971:55, Fig. 5-2. Used with permission.

SCC and its precursor lesion, vaginal intraepithelial neoplasia (VAIN). HPV has been recovered from 80% of VAIN lesions and 60% of invasive SCC of the vagina (6,7). In a case-control study of VAIN and early-stage cancer of the vagina, Brinton et al. (8) reported a 2.9-fold increase in therapy for genital warts and a 3.8-fold increase in prior abnormal Papanicolaou (Pap) smears in patients with VAIN compared to controls. This association likely represents the sequelae of infection with high-risk HPV strains (HPV-16, -18, -31, and -33) (9). The process most commonly occurs in the upper vagina, and it is frequently multifocal. Approximately one half of the lesions are associated with concomitant CIN or VIN (10).

In studies reporting on groups of women with VAIN and SCC of the vagina, the following risk factors have been identified: five or more sexual partners, sexual debut before age 17 years, smoking, low socioeconomic status, a history of genital warts, prior abnormal cytology, and prior hysterectomy (6–8). Weiderpass et al., in a population-based study of 36,856 women, found that alcoholic women had an excess risk for cancer of the vagina, probably related to higher incidence of HPV infection associated with lifestyle factors such as promiscuity, smoking, use of contraceptive hormones, and dietary deficiencies (11).

Patients with previous cervical carcinoma have a substantial risk of developing vaginal carcinoma, presumably because these sites share exposure and/or susceptibility to endogenous or exogenous carcinogenic stimuli. Ten percent to 50% of patients with VAIN–carcinoma *in situ* (CIS) or invasive carcinoma of the vagina have undergone prior hysterectomy or radiotherapy (RT) for CIS or invasive carcinoma of the cervix (12–23). The interval from therapy for cervical cancer or preinvasive disease to the development of carcinoma of the vagina averages nearly 14 years, but there have been cases

with the vaginal primary manifesting 50 years after therapy for cervical cancer (15,24).

It is controversial as to whether or not prior pelvic RT is a risk factor. Boice et al. (25) reported a 14-fold increased risk of cancer of the vagina in previously irradiated women before the age of 45 years, and a dose-response relationship was found to be significant. However, Lee et al. (26) did not find prior RT to be associated with an increase in the incidence of pelvic second neoplasms. It is biologically plausible that there could be an apparent increase in risk given that prior pelvic RT would have likely been given for HPV-associated cervical carcinoma, and the antecedent HPV infection would increase the risk of SCC in the vagina. Such an association has led to the recommendation that patients treated for CIN or carcinoma of the cervix continue to undergo lifelong surveillance with vaginal cytologic evaluation even after hysterectomy (27). In addition, there is evidence that *in utero* exposure to diethylstilbestrol (DES) doubles the risk of development of VAIN. The putative mechanism is an enlargement of the transformation zone at risk, which is then at risk for infection with HPV (28).

Clear Cell Adenocarcinoma

An increased incidence of clear cell adenocarcinoma (CCA) of the vagina in young women related to *in utero* exposure to DES during the first 16 weeks of pregnancy was first reported in 1971 (29). Specific suggested mechanisms of carcinogenesis focus on the retention of nests of abnormal cells of müllerian duct origin, which, after stimulation by endogenous hormones during puberty, are promoted into adenocarcinomas. The median age at diagnosis in the DES-exposed patients is 19 years (29), whereas prior to this report, most patients with CCA of the vagina were elderly. The incidence of CCA in the exposed female population from birth to 34 years is estimated to be between 0.14 and 1.4 per 1,000. Approximately 90% of the patients had stage I–II disease at diagnosis (30,31). Hicks and Piver noted that 60% of CCA patients had been exposed to DES or similar agents *in utero*, that most cases involved the anterior upper third of the vaginal wall, and that DES-associated CCA cases had been reported from ages 7 to 34 (median, 19 years) (32). Fortunately, the incidence of this tumor has decreased in recent years, and may decrease even more since the practice of prescribing DES during pregnancy has been discontinued. Palmer et al. (33) assessed the influence of postnatal factors on the development of CCA in women exposed to DES in 244 cases compared with 244 age-matched non-DES-exposed women. Neither oral contraceptive use nor pregnancy was associated with risk of CCA (33).

Melanoma

Malignant melanoma is the second most common cancer of the vagina, accounting for 2.8% to 5% of all vaginal neoplasms (34–36). The most common location is the lower third and the anterior vaginal wall, although oftentimes it is multifocal (34–36). Trimble's examination of the Surveillance, Epidemiology, and End Results (SEER) data on 30,295 melanomas found 51 vaginal melanomas (0.3% of all melanomas), with an annual incidence of 0.026 per 100,000 and a median age at diagnosis of 66.3 years (37). In the NCDB report by Creasman et al. (4), vaginal melanomas represented 4% of primary vaginal cancers.

Sarcomas

Sarcomas represent 3% of primary vaginal cancers, and are most common in adults, with leiomyosarcoma representing 50% to 65% of vaginal sarcomas (4). Malignant mixed müllerian tumor (MMMT, carcinosarcoma), endometrial stromal

sarcoma, and angiosarcoma are less common. Embryonal rhabdomyosarcoma (RMS)/sarcoma botryoides is a rare pediatric tumor. Prior pelvic RT is a risk factor, particularly for mixed mesodermal tumors and vaginal angiosarcomas (38). Unfortunately, most of the sarcomas are diagnosed at an advanced stage. Histopathologic grade appears to be the most important predictor of outcome (39).

NATURAL HISTORY

The majority (57% to 83%) of vaginal primaries occur in the upper third or at the apex of the vault, most commonly in the posterior wall; the lower third may be involved in as many as 31% of patients (15,21,40). Lesions confined to the middle third of the vagina are uncommon. The location of the vaginal carcinoma is an important consideration in planning therapy and determining prognosis. Vaginal tumors may spread along the vaginal walls to involve the cervix or the vulva. However, if biopsies of the cervix or the vulva are positive at the time of initial diagnosis, the tumor cannot be considered a primary vaginal lesion. A lesion on the anterior wall may infiltrate the vesicovaginal septum and/or the urethra; those on the posterior wall may eventually involve the rectovaginal septum and subsequently infiltrate the rectal mucosa. Lateral extension toward the parametrium and paracolp tissues is not uncommon in more advanced stages of the disease.

The issue of regional nodal metastasis, both the incidence of occult nodal disease and the anatomic pathways of lymphatic spread, are somewhat controversial. Because the lymphatic system of the vagina is so complex, any of the nodal groups may be involved, regardless of the location of the lesion (2). Involvement of inguinal nodes is most common when the lesion is located in the lower third of the vagina. There does seem to be a significant risk of nodal metastasis for patients with disease beyond stage I. Although data on staging lymphadenectomy are sparse, two studies reported a significant incidence of nodal disease in early-stage vaginal carcinoma. In Al-Kurdi and Monaghan's series (41), the incidence of pelvic nodal metastasis was 14% and 32% for stages I and II, respectively, whereas in the Davis et al. series (24), the incidence was 6% and 26% for stages I and II, respectively. The incidence is expected to be higher for stage III, although no substantial data are available. Chyle et al. (14) noted a 10-year actuarial pelvic nodal failure rate of 28% and a 16% inguinal failure rate in patients who had local recurrence, in contrast to 4% and 2%, respectively, in the group without local recurrence ($P < 0.001$). The incidence of clinically positive inguinal nodes at diagnosis reported by several authors ranges from 5.3% to 20% (19,42).

Distant metastasis may occur, primarily in patients with advanced disease at presentation, or those who recurred after primary therapy. In the Perez et al. series (19), the incidence of distant metastasis was 16% in stage I, 31% in stage IIA, 46% in stage IIB, 62% in stage III, and 50% in stage IV. Robboy et al. reported that metastases to the lungs or supraclavicular lymph nodes represented 35% of recurrences in young women with CCA, a proportion much greater than found with squamous cell carcinoma of the cervix or vagina (43).

CLINICAL PRESENTATION

Vaginal Intraepithelial Neoplasia—Carcinoma *In Situ*

VAIN most often is asymptomatic (17). In modern practice, VAIN is usually detected by cytologic evaluation performed following hysterectomy as part of a surveillance strategy in patients with a history of CIN or invasive cervical carcinoma.

In these cases, VAIN has a predilection for involvement of the upper vagina, likely secondary to a "field effect." A discharge may be present, but is likely secondary to superimposed vaginal infections. It should be noted that evidence-based guidelines do not support routine cytologic studies following hysterectomy for noncervical pathology. The American Cancer Society released guidelines in 2002 that said surveillance cytology in such patients is *not* necessary. Rather, surveillance cytology posthysterectomy should be limited to those patients with a prior history of CIN or invasive cervix cancer (44).

Invasive Squamous Cell Carcinoma

In patients with invasive disease, irregular vaginal bleeding, often postcoital, is the most common presenting symptom followed by vaginal discharge and dysuria. Pelvic pain is a relatively late symptom generally related to tumor extent beyond the vagina (15,40). In a series of 84 patients with invasive carcinoma, including 55 with SCC, Tjalma et al. noted that 62% of patients had vaginal discharge, 16% had positive cytology, 13% had a mass, 4% had pain, and 2% had dysuria. Forty-seven percent of the lesions were located on the posterior wall and 24% on the anterior wall; 29% had involvement of both walls (45). In 10% to 20%, no symptoms were reported, and the diagnosis was made by cytologic examination (45).

Other Histologies

The most common presenting symptom in patients with CCA is vaginal bleeding (50% to 75%) or abnormal discharge. More advanced cases may present with dysuria or pelvic pain (29). Cytology is abnormal in only 33% of cases. Therefore, in addition to four-quadrant cytology, Hanselaar et al. recommended palpation of the entire vaginal vault to assess for submucosal irregularity (46). The majority of CCA lesions are exophytic, superficially invasive in the upper third of the vault near the cervix. Ninety-seven percent will be associated with mucosal adenosis (47–49).

Embryonal RMS, the most common malignant vaginal tumor in children, presents as a protruding, edematous grape-like mass. Ninety percent of these sarcomas present before the age of 5 years. The average age at presentation was 23.5 months in the Maurer et al. series (50). In adults, symptoms most commonly noted were pain accompanied by a mass.

DIAGNOSTIC WORKUP

In general, in patients with suspected vaginal malignancy, thorough physical examination with detailed speculum inspection, digital palpation, colposcopic and cytologic evaluation, and biopsy constitute the most effective procedure for diagnosing primary, metastatic, or recurrent carcinoma of the vagina. In symptomatic patients, biopsy of any abnormal exophytic or endophytic lesion noted at the time of the examination is indicated. Examination under anesthesia is recommended for the thoroughness of evaluation of all of the vaginal walls and local extent of the disease, primarily if the patient is in great discomfort because of advanced disease, in order to obtain a biopsy. Biopsies of the cervix, if present, are recommended to rule out a primary cervical tumor. The speculum must be rotated as it is slowly withdrawn from the vaginal fornix, so that the total vaginal mucosa may be visualized, and, in particular, posterior wall lesions, which occur frequently, are not overlooked.

The patient with a history of preinvasive or invasive carcinoma of the cervix found to have abnormal cytology following prior hysterectomy or RT should be offered vaginoscopy with application of acetic acid to the entire vault, followed by biopsies

as indicated by areas of white epithelium, mosaicism, punctuation, or atypical vascularity. It can be very helpful for the menopausal patient or the patient previously irradiated to use a short course of topically applied estrogen into the vaginal vault once or twice a week for 1 month prior to the colposcopy in order to foster epithelial maturation. Another method of identifying the area(s) most in need of biopsy would be, after application of acetic acid, to apply half-strength Schiller's iodine to determine if the Schiller-positive (non-staining) areas correspond with the involved areas identified following acetic acid application.

STAGING

At present, primary malignancies of the vagina are all staged clinically. In addition to a complete history and physical examination, routine laboratory evaluations including complete blood cell count (CBC) with differential and platelets, and assessment of renal and hepatic function should be undertaken. In order to determine the extent of disease, the following tests are allowed by International Federation of Gynecology and Obstetrics (FIGO) criteria: chest radiograph, a thorough bimanual and rectovaginal examination, cystoscopy, proctoscopy, and intravenous pyelogram. Cystoscopy and/or proctosigmoidoscopy should be performed on patients with symptoms suggestive of bladder and/or rectal infiltration, respectively. If the patient is in significant discomfort the examination should be conducted under anesthesia, preferably by a radiation oncologist and gynecologic oncologist who will be involved in her ongoing care. However, it can be difficult even for the experienced examiner to differentiate between disease confined to the mucosa (stage I) and disease spread to the submucosa (stage II) (13,40).

Pelvic computed tomography (CT) scan is generally performed to evaluate inguino-femoral and/or pelvic lymph nodes, as well as extent of local disease. In patients with vaginal melanoma or sarcoma, chest, abdomen, and pelvic CT scans are often part of the workup. Magnetic resonance imaging (MRI) has emerged as a potentially important imaging modality in the evaluation of vaginal cancers, predominantly the T1-weighted with contrast and T2-weighted images (51). An additional role of MRI is differentiation of tumor from fibrotic tissue in patients with suspected recurrent vaginal carcinoma (51). Positron emission tomography (PET) is evolving as a modality of potential use in the evaluation of vaginal cancer that allows detection of the extent of the primary as well as abnormal lymph nodes more often than does CT scan (52). In modern practice, for the majority of patients with disease volume and/or location requiring definitive RT to achieve cure, therapeutic planning will be guided by disease volume assessment utilizing CT, MRI, and/or PET/CT, even though such radiologic modalities are not "allowed" for purposes of staging.

The two commonly used staging systems for carcinoma of the vagina are the FIGO (Table 21.1A) (53) and the American Joint Commission on Cancer (TNM) (Table 21.1B) (54) classifications. According to FIGO guidelines, patients with tumor involvement of the cervix or vulva should be classified as primary cervical or vulvar cancers, respectively. Patients with abnormal vaginal cytology are susceptible to a "field effect," that is, dysplasia of the urogenital epithelium, including the cervix and vulva. Therefore, cervical cytology should be obtained, and directed biopsies if indicated based on abnormal cytology. If a cervical abnormality is visualized or palpated, biopsy is recommended to rule out a primary cervical malignancy. Similarly, the vulva should be carefully inspected, including application of acetic acid, with directed biopsies of abnormally staining epithelium. Perez et al. (55) proposed in 1973 that FIGO stage II vaginal cancer should be subdivided

TABLE 21.1A

FIGO STAGING SYSTEM FOR CARCINOMA OF THE VAGINA

Stage	Description
Stage 0	Carcinoma <i>in situ</i> , intraepithelial neoplasia grade 3
Stage I	Limited to the vaginal wall
Stage II	Involvement of the subvaginal tissue but without extension to the pelvic side wall
Stage III	Extension to the pelvic side wall
Stage IV	Extension beyond the true pelvis or involvement of the bladder or rectal mucosa. Bullous edema as such does not permit a case to be allotted to stage IV
IVA	Spread to adjacent organs and/or direct extension beyond the true pelvis
IVB	Spread to distant organs

TABLE 21.1B

AMERICAN JOINT COMMISSION ON CANCER (AJCC) STAGING OF VAGINAL CANCER

PRIMARY TUMOR (T)

Tx	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis/0	Carcinoma <i>in situ</i>
T1/I	Tumor confined to the vagina
T2/II	Tumor invades paravaginal tissues but not to the pelvic wall
T3/III	Tumor extends to the pelvic wall
T4/IVA	Tumor invades mucosa of the bladder or rectum and/or extends beyond the pelvis (bullous edema is not sufficient to classify a tumor as T4)

REGIONAL LYMPH NODES (N)

Nx	Regional lymph nodes cannot be assessed
N0	No regional lymph nodes
N1/IVB	Pelvic or inguinal lymph node metastasis

DISTANT METASTASIS (M)

Mx	Distant metastasis cannot be assessed
M0	No distant metastasis
M1/IVB	Distant metastasis

AJCC STAGE GROUPINGS

Stage 0	Tis N0 M0
Stage I	T1 N0 M0
Stage II	T2 N0 M0
Stage III	T1-3 N1 M0, T3 N0 M0
Stage IVA	T4, any N, M0
Stage IVB	Any T, any N, M1

into stage IIA (tumor infiltrating the subvaginal tissues but not extending into the parametrium) and stage IIB (tumor infiltrating the parametrium but not extending to pelvic side walls). However, most investigators do not use this classification, and there are few published data to support it (19,56).

PATHOLOGIC CLASSIFICATION

The most common malignant tumor of the vagina is squamous cell carcinoma. Other epithelial neoplasms are uncommon since glands are not normally present in the vaginal mucosa. Melanoma is the second most frequent malignancy. A wide variety of tumors of other types have been described. The classification of neoplasms of the vagina is shown in Table 21.2.

Squamous Cell Carcinoma

SCC represents about 80% to 90% of primary vaginal cancers. These tumors occur in older women and are most often located in the upper, posterior wall of the vagina. According to the FIGO recommendations, a tumor of the vagina that involves the cervix or vulva should be classified as a primary

TABLE 21.2

HISTOLOGIC CLASSIFICATION OF MALIGNANCIES OF THE VAGINA

SQUAMOUS TUMORS AND PRECURSORS

Squamous cell carcinoma
Vaginal intraepithelial neoplasia 3/squamous cell carcinoma
in situ

GLANDULAR TUMORS

Clear cell adenocarcinoma
Endometrioid adenocarcinoma
Mucinous adenocarcinoma
Serous adenocarcinoma

OTHER EPITHELIAL TUMORS

Adenosquamous carcinoma
Adenoid cystic carcinoma
Neuroendocrine carcinoma

MESENCHYMAL TUMORS

Sarcoma botryoides (embryonal rhabdomyosarcoma)
Leiomyosarcoma
Endometrioid stromal sarcoma (low grade)
Undifferentiated vaginal sarcoma

MIXED EPITHELIAL AND MESENCHYMAL TUMORS

Carcinosarcoma (malignant müllerian mixed tumor, metaplastic carcinoma)
Adenosarcoma
Malignant mixed tumor
Mesonephric carcinosarcoma

MISCELLANEOUS TUMORS

Melanoma
Yolk sac tumor (endodermal sinus tumor)
Peripheral primitive neuroectodermal tumor/Ewing tumor

LYMPHOID AND HEMATOPOETIC TUMORS

Malignant lymphoma (specify type)
Leukemia (specify type)

cervical or vulvar cancer, respectively. Additionally, for a neoplasm to be considered a vaginal primary, there must not have been a cervical cancer for 5 years prior to the diagnosis (57). It may be difficult or impossible histologically to distinguish a primary vaginal SCC from recurrent cervical or vulvar disease. Histologically, keratinizing, nonkeratinizing, basaloid, warty, and verrucous variants have been described. Tumors may also be graded as being well, moderately, or poorly differentiated, based on a combination of cytologic and histologic features. However, there is little correlation between tumor grade and survival (3). Most cases are moderately differentiated and nonkeratinizing. Well-differentiated tumors show prominent keratin or squamous pearl formation and intercellular bridges (Fig. 21.2). Rarely, poorly differentiated tumors have a spindle-cell appearance. Warty SCC has a papillary appearance with hyperkeratosis and koilocytosis.

Verrucous carcinoma is a rare distinct variant of well-differentiated SCC, usually with the appearance of a large, well-circumscribed, soft, cauliflower-like mass. Microscopically, the tumor exhibits a papillary growth pattern, pushing borders, bulbous pegs of acanthotic epithelium with little or no atypia, and surface maturation in the form of parakeratosis and hyperkeratosis without koilocytosis. Because of its well-differentiated character, the histologic diagnosis of verrucous carcinoma may be difficult, especially if the biopsy is superficial (58). Verrucous carcinoma may recur locally after surgery, but rarely, if ever, metastasizes. This behavioral difference justifies separating verrucous carcinoma as a distinct tumor entity.

VAIN is a precursor of SCC and is graded from 1 to 3 depending upon the degree of nuclear atypia and crowding and the proportion of the epithelium involved. VAIN 1 typically involves the lower third to one half of the epithelium, VAIN 2 one half to two thirds the thickness of the epithelium, and VAIN 3 more than three fourths of the thickness. Alternatively, VAIN can be classified as low or high grade. High grade lesions indicate involvement of the outer third of the mucosa, and include CIS, which encompasses the entire thickness of the epithelium. The true incidence of VAIN and its rate of progression to invasive carcinoma are unknown, ranging in several series from 9% to 28% (8,10,59). High-risk HPV was found in 35% of VAIN 1 and 94% of VAIN 3 lesions (60). Comparison of the distribution of HPV types in the vagina, vulva, and cervix suggests that VAIN is more closely related to CIN than to VIN. A large epidemiologic study showed a two-fold relative risk for high-grade CIN and VAIN among women exposed prenatally to DES when compared to an unexposed control group (61).

Clear Cell Adenocarcinoma and Vaginal Adenosis

DES-associated CCA has a predilection for the upper third of the vagina and the exocervix. It is frequently located at or near the lower margin of the zone of glandular tissue in the vagina or cervix. Most CCAs are exophytic and superficially invasive (47). Ninety-seven percent will be associated with mucosal adenosis (47–49). CCA is arranged in tubulocystic, solid, papillary, or mixed cell patterns, and is mainly composed of clear and hobnail-shaped cells (Fig. 21.3A, B). The clear cells are cuboidal or columnar with abundant glycogen-rich cytoplasm and distinct cell membranes. The hobnail cells have large atypical protruding nuclei rimmed by a small amount of cytoplasm (47).

Vaginal adenosis is a condition in which müllerian-type glandular epithelium is present after vaginal development is complete. Although adenosis is the most common histologic abnormality in women exposed to DES *in utero*, it is not strictly confined to this population. Adenosis is associated with 97% of vaginal and 52% of cervical CCAs (62,63). The glandular epithelium may replace the surface epithelium and/or form glands in the superficial stroma. The glandular epithelium undergoes progressive squamous metaplasia (62–65) and ultimately only stromal nodules or pegs of immature squamous epithelium containing small mucin droplets may remain (65). A few CCAs have been detected among women under surveillance for adenosis (66). Atypical adenosis of tuboendometrial type appears to be a precursor lesion of CCA (49). Whether immature squamous metaplasia in adenosis is associated with an increased risk of vaginal intraepithelial

FIGURE 21.3. Clear cell adenocarcinoma. A: Neoplasm shows a solid growth pattern. Note the tumor cells with pleomorphic nuclei, clear cytoplasm, and distinct cell borders. B: Tumor has tubulocystic growth pattern with prominent hobnail cells lining the tubules.

neoplasia or SCC is controversial (66). Rarely, clear cell adenocarcinoma of the vagina occurs in older women unrelated to DES exposure *in utero*, but sometimes in association with vaginal endometriosis (67,68). The major determinant of outcome in CCA is stage, but some pathologic features are statistically associated with better outcome, including a tubulocystic growth pattern, size less than 3 cm², and less than 3 mm of stromal invasion (47).

Other Adenocarcinomas

Primary adenocarcinoma of the vagina is rare and occurs predominantly in postmenopausal women. Reported histologic subtypes have included endometrioid, mucinous, mesonephric, and papillary serous adenocarcinomas. Only a few cases of *mucinous adenocarcinoma* have been described (69). Histologically, the tumors can resemble typical endocervical adenocarcinoma and arise in endocervicosis (70,71). Cases of primary intestinal-type adenocarcinoma can be mistaken for metastatic colonic carcinoma and rarely arise from tubular adenoma (72,73). Some cases may be related to DES exposure (74). A relationship to vaginal adenosis has been described in a patient not exposed to DES (75). Rare cases of mucinous adenocarcinoma have been described in neovaginas (76).

Endometrioid adenocarcinoma of the vagina usually arises in endometriosis (77). *Mesonephric adenocarcinoma* is a rare variant that may arise from mesonephric duct remnants that are mostly situated deep in the lateral walls of the vagina (78). Primary *serous adenocarcinoma* of the vagina has rarely been reported (79). *Vaginal metastases* from adenocarcinoma of the breast, other gynecologic primaries, or renal cell carcinomas have been described (80).

Melanoma

Melanoma is the second most common cancer of the vagina, accounting for 2.8% to 5.0% of vaginal neoplasms. The most common locations are the lower third and the anterior vaginal wall (34–36,81). Grossly, these tumors are typically pigmented, and show considerable variation in size, color, and growth patterns, being polypoid or nodular in the majority of cases (35,36). Histologically, melanoma is composed of epithelioid cells, spindle cells, or nevus-like cells; melanin pigment is often observed. Junctional activity is usually present. Premelanosomes may be identified by electron microscopy. Immunohistochemical stains are frequently positive for S100 protein, HMB-45, and melan-A tyrosinase and MART-1 are useful markers when S100 is negative or only focally positive (81). Tumor thickness correlates with prognosis, and may be measured by the method of Breslow (82). Poorly differentiated melanomas may be difficult to distinguish from sarcoma or SCC. Primary melanoma must also be distinguished from metastatic melanoma, which also presents as a polypoid mass (83).

Mesenchymal Tumors

Embryonal rhabdomyosarcoma (RMS) is a rare pediatric tumor. The botryoid variant, or sarcoma botryoides, is the most common malignant vaginal tumor in infants and children (84). Ninety percent of cases occur in children younger than 5 years of age. Sarcoma botryoides has a characteristic macroscopic appearance consisting of multiple gray-red, translucent, edematous, grape-like masses that fill the vagina, and may protrude from it. Microscopically, there is a zone of condensed round or spindle cells (the cambium layer) immediately beneath the intact vaginal epithelium. Elsewhere, the

FIGURE 21.4. Embryonal rhabdomyosarcoma (sarcoma botyroides). **A:** Note the subepithelial cambium layer. **B:** The tumor is composed of strap cells with atypical, elongated, often tandem, nuclei and edematous stroma. The eosinophilic cytoplasm shows prominent cross striations.

tumor is composed of small, dark, spindle-shaped cells sparsely distributed in a myxoid stroma. Some cells may show skeletal muscle differentiation, evidenced by intensely eosinophilic cytoplasm with cross striations (Fig.21.4A, B). Immunohistochemical stains with antibodies directed against myogenic markers, including actin, desmin, myoD1, or myogenin, facilitate the recognition of muscle differentiation in these tumors.

Leiomyosarcoma is the most common vaginal sarcoma in adults (85). The frequency and behavior are uncertain because of the variable histologic criteria used to distinguish benign and malignant smooth muscle tumors. Smooth muscle tumors 3 cm or greater in diameter have an increased risk of recurrence. It is currently recommended that neoplasms with five or greater mitoses per ten high-power fields (HPFs), moderate or marked cytologic atypia, and/or infiltrating margins be classified as leiomyosarcoma (86). Although they may originate in any part of the vagina, most are submucosal. The macroscopic appearance varies greatly depending on cellularity, type, and extent of degenerative change and the amount of necrosis and hemorrhage (86). On histologic examination, leiomyosarcoma is typically composed of interlacing bundles of spindle-shaped cells with blunt-ended nuclei and fibrillar cytoplasm. An epithelioid pattern or extensive myxoid change occurs uncommonly (86,87). Because smooth muscle tumors vary from area to area, adequate sampling (one block, 1 to 2 cm of tumor diameter) is essential for accurate diagnosis. Rarely, cases of extragastrointestinal stromal tumors present as a vulvovaginal or rectovaginal septal mass (88). Histologically, they can be confused with benign or malignant smooth muscle tumors. Misdiagnosis can lead to inappropriate treatment, whereas specific therapy is available.

Other sarcomas that may occur in the vagina include *endometrioid stromal sarcoma*, which may arise in endometriosis (89–91); *alveolar soft part sarcoma* (92); *malignant fibrous histiocytoma* (93), a biphasic tumor interpreted as resembling synovial sarcoma (94) or *malignant mixed tumor* (95); angiosarcoma (38); *malignant peripheral nerve sheath tumor*; and *hemangiopericytoma* (96).

Malignant Lymphoma and Leukemia

Malignant lymphoma may be localized to the female genital tract or occur there as part of a widespread disease process (97,98). Approximately 6% of female genital tract lymphomas occur in the vagina and over 80% were primary in one study (99). The majority of primary lymphomas involving the vagina are of the diffuse large B-cell type, but lymphoplasmacytic, Burkitt lymphoma, and mucosa-associated lymphoid tissue (MALT) lymphoma also occur (100). The histologic diagnosis depends on the identification of monomorphic, cytologically atypical, mitotically active lymphoid cells deeply penetrating the stroma. Characteristically, the mucosa is intact. The tumors typically express CD20. Patients with vaginal lymphomas characteristically present with vaginal bleeding. Those with primary lymphomas also have a mass on clinical examination. Leukemic infiltrates, especially granulocytic sarcoma, can be histologically impossible to distinguish from lymphoma. Chloracetate esterase or myeloperoxidase stains may be helpful in some cases.

Uncommon Vaginal Tumors

Neuroendocrine small cell carcinoma may occur in the vagina either in pure form or associated with squamous or glandular elements (101,102). A high proportion of these tumors show immunohistochemical or ultrastructural evidence of neuroendocrine differentiation (103). Rarely, primary neuroendocrine carcinoma of the vagina has a Merkel cell carcinoma phenotype (104).

Adenosquamous carcinoma is an uncommon neoplasm of the vagina composed of an admixture of glandular and squamous elements (105). Tumors diagnosed as *carcinosarcoma* (malignant mixed müllerian tumor) of the female genital tract appear to be metaplastic carcinomas, and should be treated as epithelial neoplasms, although the prognosis is poor. This tumor is rare in the vagina, and typically occurs in postmenopausal women (106). Uncommonly, *yolk sac tumor* (endodermal sinus tumor) has been reported in the vagina of infants and young children (107,108). Rare cases of mesonephric adenocarcinoma or malignant mixed mesonephric tumor have been described (109). Rare cases of primary vaginal Ewing's sarcoma—primitive neuroectodermal tumor occur in younger women (110).

PROGNOSTIC FACTORS INFLUENCING CHOICE OF TREATMENT

Invasive Squamous Cell Carcinoma

As with most primaries, stage of disease is the dominant prognostic factor in terms of ultimate outcome (14,16,18,19,42, 111–118). In a report by Creasman et al., the 5-year survival rate was 96% for patients with stage 0, 73% for stage I, 58% for stage II, and 36% for those with stage III–IV disease, respectively (4). In the Perez et al. series including 165 patients

with primary vaginal carcinomas treated with definitive RT, the 10-year actuarial disease-free survival (DFS) was 94% for stage 0, 75% for stage I, 55% for stage IIA, 43% for stage IIB, 32% for stage III, and 0% for those with stage IV disease (19).

The impact of lesion location has been controversial. Tarraza et al. (119) reported that upper-third lesions develop local recurrences more frequently, and lower-third lesions develop a disproportionate number of sidewall and distant recurrences. Chyle et al. (14) observed a 17% rate of pelvic relapse in patients with upper vaginal tumors, 36% in those with middle or lower vaginal tumors, and 42% with whole-vaginal involvement. However, a larger series failed to note any difference in site of recurrence based on primary lesion location (19). Several investigators (14,23,120,121) have shown better survival and decreased recurrence rates for patients with cancers involving the proximal half of the vagina when compared with those in the distal half or those involving the entire length of the vagina. In addition, lesions of the posterior wall have a worse prognosis than those involving other vaginal walls (10-year recurrence rates of 32% and 19%, respectively) (14), which probably reflects the greater difficulty of performing adequate brachytherapy procedures in this location.

The prognostic importance of lesion size has been controversial, with an adverse impact being noted by Tjalma et al. (45) and Chyle et al. (14), which is contrary to the findings of Perez et al. (42). In the Chyle et al. series (14), lesions measuring less than 5 cm in maximum diameter had a 20% 10-year local recurrence rate compared to 40% for those lesions larger than 5 cm. Similarly, in the Princess Margaret Hospital experience, tumors larger than 4 cm in diameter fared significantly worse than smaller lesions (16). In the Perez et al. series (42), stage was an important predictor of pelvic tumor control and 5-year disease-free survival, but the size of the tumor in stage I patients was not a significant prognostic factor. However, in stage IIA disease, lower pelvic tumor control and survival were noted with tumors larger than 4 cm. In stages IIB and III, tumor size was not a significant prognostic factor, probably related to the difficulty in assessing size and the fact that higher doses of RT were delivered for larger tumors. Stock et al. (21) reported that disease volume, a likely surrogate for stage or lesion size, adversely impacted survival as well as local control.

Age was a significant prognostic factor in the Urbanski et al. series (23), with 5-year survival of 63.2% for patients below the age of 60 years compared with 25% for those over 60 years of age ($p < 0.001$). Similar findings were reported by Eddy et al. (115). However, most of these series do not correct for death secondary to intercurrent disease in the elderly population. No statistical significance of age to survival was found in the series of Dixit et al. (116) and Perez et al. (42).

With regard to the histologic type and grade, several series (16,23,121) have shown the histologic grade to be an independent, significant predictor of survival. Chyle et al. (14) noted a higher incidence of local recurrence in patients with adenocarcinoma compared with squamous cell carcinoma (52% and 20%, respectively, at 10 years), as well as a higher incidence of distant metastases (48% and 10%, respectively), and lower 10-year survival rate (20% vs 50%). Overexpression of *HER2/neu* oncogenes in squamous cancer of the lower genital tract is a rare event that may be associated with aggressive biologic behavior (122). Waggoner et al. (123), in a group of 21 women with CCA of the vagina and cervix, observed a more favorable prognosis in gynecologic tumors with an overexpression of wild-type p53 protein than in tumors containing mutated *TP53* genes.

Other Histologies

An increased propensity for distant metastases to the lung and supraclavicular nodes has been reported in patients with CCA

(43). Stage, tubulocystic pattern, size less than 3 cm, and depth of invasion less than 3 mm were all noted to be associated with superior survival (47).

Vaginal melanoma has a higher propensity for development of distant metastases, and affected patients do more poorly than patients with SCC. A review by Reid et al. of 115 vaginal melanoma patients noted that depth of invasion and size of lesion (>3 cm) adversely impacted survival, but stage did not, perhaps because it was known for only 42 of the 115 patients in the series (36).

Patients with malignant mesenchymal tumors of the vagina do less well than those with invasive SCC. Specific, adverse prognostic factors for vaginal sarcoma identified by Tavassoli and Norris (86) included infiltrative versus pushing borders, high mitotic rate of five or more mitoses per ten HPFs, size >3 cm in diameter, and cytologic atypia.

GENERAL MANAGEMENT: TREATMENT OPTIONS AND OUTCOME BY FIGO STAGES

Owing to its rarity, data concerning the natural history, prognostic factors, and treatment of vaginal carcinoma derive from small, retrospective studies. Most of the currently available literature in terms of radiotherapeutic and surgical techniques refers to primary SCC of the vagina. It is important to recognize the complexity of the management of patients with carcinoma of the vagina and the need for an individualized approach after careful assessment by the gynecologic oncologist and radiation oncologist. In most patients, the primary treatment modality is RT, as reported by the Society of Gynecologist Oncologists in practice guidelines published in 1998 (4). RT provides excellent tumor control in early and superficial lesions and with satisfactory functional results.

Local excision and partial and complete vaginectomy have given way to a more individualized approach that takes into consideration the patient's age, the extent of the lesion, and whether it is localized or multicentric. There is evidence that patients with CIS-VAIN and early stage I, primarily with a lesion located in the upper or distal third of the vagina, and highly selected young women with stage II vaginal cancers can be successfully treated with surgery alone (13,21,24,45,124,125). In addition, surgery could be considered in younger patients with a desire to preserve ovarian function (126) and/or a functional vagina (21), patients with verrucous carcinoma (58), those with nonepithelial tumors, and patients with localized pelvic failures after radiation. For the most part, surgical resection often requires a radical approach resulting in urinary and fecal diversion in order to secure adequate margins. Given the potentially devastating functional results often associated with radical surgery, definitive RT has largely replaced surgery as primary therapeutic modality in patients with vaginal cancer, in order to maximize cure and improve quality of life. Furthermore, most patients are elderly, and a radical surgical approach is often not feasible.

Despite the acceptance of RT as the treatment of choice for this disease, the optimal therapy for each stage is not well defined in the literature. A combination of limited surgery and RT has been suggested to improve outcome, although the complication rates may increase (127). Intracavitary and interstitial irradiation is used in small superficial stage I disease. External beam RT (EBRT) in combination with intracavitary (ICB), and/or interstitial (ITB) brachytherapy is generally used for more extensive stage I-II disease. Data regarding the use of cytotoxic therapy in vaginal carcinomas are based on underpowered phase II trials of various monotherapies or extrapolated from SCC of the cervix, which has a similar biology.

FIGO Stage 0: Vaginal Intraepithelial Neoplasia—Carcinoma *In Situ*

VAIN has been approached both surgically and medically by multiple investigators. Treatment options range from partial or complete vaginectomy to more conservative approaches such as local excision, electro-coagulation, laser vaporization, topical 5% fluorouracil (5-FU) administration, or ICB. For patients in whom invasive disease cannot be ruled out, as well as for those who fail conservative therapy, surgical resection remains the treatment of choice. Overall, the reported control rates are very similar among the different approaches, ranging from 48% to 100% for laser, 52% to 100% for colectomy, 75% to 100% for topical 5-FU, and 83% to 100% for RT (Table 21.3) (4,14,16,42,124,125,128–134). The degree of VAIN and the age and general health of the patient are important treatment considerations. A therapy appropriate for CIS in a woman with good performance status and many anticipated years of life expectancy may not be appropriate for a woman with multiple comorbid conditions who may succumb to one of her other illnesses before the CIS would be expected to progress to invasive carcinoma.

The anatomic constraints posed by the location of the vagina with the close proximity of the bladder and rectum led to the use of the CO₂ laser as a relatively noninvasive surgical approach (59,128). Data published by Hoffman et al. (124), who performed upper colectomy in 32 patients, of whom 31

had undergone prior hysterectomy and 14 prior therapy for VAIN, and found a 28% risk of invasive disease, in addition to reports of invasive disease in the laser failures, and in patients who had undergone upper colectomy for presumed VAIN, prompted some to begin to use the laser to effect colectomy (128). Later series have used novel approaches with the Cavitron ultrasonic aspirator (CUSA) (133) to effect partial colectomy with satisfactory results, at least in the reporting investigator's hands. In a series of 52 patients reported by Diakomanolis et al., in which 28 underwent laser and 24 had partial colectomy, results were found to be operator dependent, but they favored partial colectomy for unifocal disease and laser ablation for multifocal disease (135). Overall, the control rates following laser vaporization range from 58% to 100% (59,128). Patients most likely to fail after vaporization are those with anatomic distortion caused by scarring (124). In general, patient acceptance is high and scarring minimal (136).

Even though partial colectomy has many advocates for focal VAIN without any prior history of pelvic RT, patients who had received prior pelvic RT for other gynecologic malignancies, wherein partial colectomy would have high risk of fistula formation, may benefit from a medical approach with topical application of 5-FU. This acts by inciting a desquamation of the vaginal squamous epithelium, which later re-epithelializes with presumably normal cells. Multiple schedules have been suggested since the first use of 5-FU, including monthly, daily, twice a day, and weekly administrations, with control rates

TABLE 21.3

VAIN—CARCINOMA *IN SITU*: TREATMENT APPROACH AND RESULTS

Treatment modality, author(s)	No. of patients	Comments	Outcome—control
LASER THERAPY			
Julian et al. (128)	10	Used to effect colectomy	80%
Hoffman et al. (59)	26	3 of 11 failures had invasive disease Recommended excision. Not ideal	58%
TOPICAL 5-FU			
Woodruff et al. (129)	9	1% to 2% 5-FU q month	88%
Piver et al. (130)	8	20% 5-FU bid × 5 days Could use 5% or 10%	75%
Petrilli et al. (131)	15	5% 5-FU bid × 5 days Repeat in 12 weeks	80%
Krebbs (132)	31	One-third applicator q week × 10 weeks	81%
SURGICAL EXCISION			
Creasman et al. (NCDB) (4)	23		96%

ranging from 75% to 88% (129,130,132,137). However, we prefer the schedule suggested by Krebs et al. of one-third applicator weekly for 10 weeks (132). It is important that the perineal skin be protected with a topical ointment such as zinc oxide to prevent painful vulvar erosions regardless of which 5-FU application schedule is chosen. More recently, investigators have demonstrated the feasibility and likely efficacy of imiquimod in the treatment of VAIN, although large series remain to be performed (138). In the study by Haidopoulos et al., six out of seven patients with high-grade dysplasia (VIN 2-3) regressed to either no evidence of dysplasia or VIN 1 following imiquimod treatment (138). Application of 0.25 g of imiquimod 5% intravaginally once weekly for 3 weeks was effective and well tolerated. Larger studies are required, but this regimen appears to be promising, with a simpler dosing regimen, and lower toxicity when compared to 5-FU (138).

Partial or total vaginectomy has been considered by many to be an acceptable treatment for VAIN (139). However, one of its main drawbacks is shortening or stenosis of the vagina, frequently with poor functional results. Hoffman et al. (124) reported a 17% recurrence rate in a series of 32 patients with CIS of the vagina who underwent upper vaginectomy. In this series, 44% had received prior therapy, including laser vaporization, or topical 5-FU and local excision. Nine patients (28%) were found to have invasive cancer upon final pathologic examination. Four of nine patients with invasive carcinoma showing more than 3.5-mm infiltration were treated subsequently with RT, three of whom remained free of disease. Of the five patients with less than 2 mm invasion, one received RT for local recurrence, and the remaining four patients were without disease after surgery alone. Overall, five of nine patients with microinvasive carcinoma required RT in addition to surgery, and only 72% of all patients treated with surgery remained free of disease at last follow-up. Of 23 patients with VAIN 3, 19 (83%) remained without evidence of recurrence at a mean follow-up of 38 months. Hoffman et al. (124) advocated upper vaginectomy with 1 cm margins when there were concerns about possible invasion, and when the lesion was confined to the upper one third or one half of the vagina. To minimize postoperative stenosis, Hoffman et al. (124) recommended not closing the mucosa, using a dilator with estrogenic vaginal cream, and consideration of a skin graft. Prior RT is probably a contraindication to vaginectomy owing to significantly increased morbidity. Control rates of 66% to 100% following partial colectomy effected either with a traditional surgical approach (124,139), with CUSA (133), or with the loop electrosurgical excision procedure (LEEP) (125) have been achieved.

RT has a long history of documented efficacy with control rates ranging between 80% and 100%, and a significantly better therapeutic ratio than other modalities (14,16,42,56). Using conventional low-dose-rate (LDR) ICB techniques, the entire vaginal mucosa should receive between 50 and 60 Gy, given the high incidence of multicentricity; the area of involvement should receive 70 to 80 Gy, in one or two implants, prescribed to the mucosal surface (134). Higher doses may cause significant vaginal fibrosis and stenosis. Perez et al. reported only one distal local failure in the 20 patients treated for CIS (134). Pelvic recurrences or distant failures have not been observed in the absence of invasive component, after ICB.

There have been some reports in the literature regarding the use of high-dose-rate (HDR) ICB for patients with VAIN 3. Ogino et al. (140) reported six patients treated with HDR to a mean dose of 23.3 Gy (range, 15 to 30 Gy), none of whom developed recurrent disease. Limited rectal bleeding and moderate to severe vaginal mucosa reactions were noted in patients treated to the entire length of the vagina. MacLeod et al. (141) reported on 14 patients with VAIN 3 treated with HDR-ICB to a dose of 34 to 45 Gy in 4.5- to 8.5-Gy fractions.

With a median duration of follow-up of 46 months, one patient had persistent tumor and another showed progression of tumor with an overall local control of 78.5%; two patients developed grade 3 vaginal toxicity. Mock et al. (142) reported 100% recurrence-free survival in six patients with CIS treated with HDR-ICB. At the present time, no definite conclusions can be drawn from the limited data published in the literature regarding the use of HDR-ICB. Based on the excellent local control and functional results obtained with LDR-ICB, this remains, in our opinion, the treatment of choice when definitive RT is used.

Estrogen therapy should be considered in women who are postmenopausal or have undergone RT, provided the possibility of invasive disease has been eliminated. The effect of irradiation on ovarian function, as well as occasional fibrosis of the vaginal vault, makes this treatment currently unacceptable except in cases resistant to conservative therapy.

Invasive Squamous Cell Carcinoma

Surgical Approach and Outcomes

In general, SCC of the vagina has been treated with RT. However, several surgical series have reported acceptable to excellent outcomes in well-selected patients, with survival rates after radical surgery for stage I disease ranging from 75% to 100% (4,13,21,24,40,45). Cases in which surgery may be the preferred treatment include selected stage I-II patients, with lesions at the apex and upper third of the posterior or lateral vagina that could be approached with radical hysterectomy, upper vaginectomy, and pelvic lymphadenectomy providing adequate margins (13,15,21,24,40) and very superficial lesions that may be removed with wide local excision. Lesions in the lower third of the vagina would require vulvovaginectomy in addition to dissection of inguinofemoral node exenteration to achieve negative margins (13,15,21,40). If the margins are found to be close or positive after resection, adjuvant RT is recommended. However, for lesions at other sites, and those cases requiring more extensive resection, definitive RT is the treatment of choice since it offers excellent results (19), with isolated central failures post-radiation being offered exenteration (40).

Creasman et al. noted superior survival in those undergoing surgery (4). However, they and Tjalma et al. (45) recognized that there may be bias in surgical series, such that younger, healthier patients with better performance status are more likely to be offered radical surgery, whereas older patients with multiple comorbid medical conditions are offered RT.

Ball and Berman's series (13) included 58 patients: 27 stage I and 18 stage II disease. Twenty-seven patients were managed primarily with surgery, with an overall 78% 5-year survival rate, 84% in patients with stage I, and a 63% rate in those with stage II disease, which is comparable to the results reported by Perez et al. in their RT series (19). Rubin et al. (40) reported 75 cases of vaginal cancer: 14 patients with stage I and 35 patients with stage II. RT was the primary modality used in this series; however, eight patients (five with stage I and three with stage II) underwent primary surgery with curative intent. Six of these eight patients survived 5 years, and the local control rate for stage I patients was 80%. However, only one patient with stage II was a long-term survivor. This surgical outcome compares unfavorably with the remaining patients in whom RT was the primary modality. In general, patients with lesions that could be encompassed by radical vulvovaginectomy with or without hysterectomy did better than those requiring exenteration. Rubin et al. (40) advocated that exenteration should be reserved for those with central failure after RT, or as primary therapy in those with

disease not fixed to the bone. Davis et al. (24) reported on 52 patients with cancer of the vagina treated with surgery alone in a series that included 89 cases. In this nonrandomized series, an 85% 5-year survival rate was achieved in stage I patients compared to 65% in those treated with RT (24). Of 45 patients with stage II disease, 49% survived after surgery, 50% after RT, and 69% after surgery and RT.

The Peters et al. series (112) included 86 vaginal carcinomas, with an overall survival rate of 56%. Most were treated with RT. However, 12 highly selected patients had surgery, with a 75% survival rate. The investigators suggested that vaginectomy with radical hysterectomy, if the uterus was still in place, should be limited to those with superficial disease because the closeness of the bladder and rectum limited the true radicality of surgical approaches. Gallup et al. (15) reported 28 cases, of which 57% were stage I-II lesions (only three patients had stage II), and of these, 83% survived. Most patients in this series received RT; however, all three patients with stage I disease who were treated with surgery survived. Extent of surgery and median follow-up were not stated.

In the largest single-institution series reported to date by Stock et al. (21), of 100 patients with carcinoma of the vagina (including 85 with SCC), a 47% 5-year survival rate was achieved. In this series, 40 patients were treated with surgery alone, 47 with radiation alone, and 13 with combination therapy. Overall, 5-year survival was 47%. Survival for stage I patients was 56% when treated with surgery versus 80% for those who received RT, whereas for stage II patients, a 68% survival was seen versus a 31% survival in those who underwent RT (21). The investigators acknowledged that the apparent surgical superiority for stage II patients may have been due to selection bias in that those treated with RT alone were more likely to have had stage IIB disease with extensive paracolpos involvement, and those with lesser involvement were preferentially offered surgery. Stock advocated RT for stage II patients with extensive paracolpos. Stock et al. concluded that for upper-third vault lesions, radical hysterectomy and pelvic lymphadenectomy with upper vaginectomy should be offered to those with stage I lesions, with a consideration for wide local excisions, and postoperative RT for patients with small lesions. If there was extension to the paracolpos, RT should be recommended; however, in very well-selected patients, there might be a role for surgery (21).

Tjalma et al. reported on 55 cases of SCC of the vagina, including 27 cases with stage I and 12 with stage II disease, with a median follow-up of 45 months (45). Of the 27 cases with stage I disease, 26 underwent surgery, and 4 of them received some form of postoperative RT. A 91% 5-year survival rate was achieved for stage I disease. Surgery was a part of the primary management for 6 of the 12 patients with stage II disease. In the multivariate analysis, age and lesion size were the only prognostic factors. Tjalma et al. concluded that surgery should be considered part of the therapeutic approach for stage I and minimal stage II disease (45). However, as Stock et al. suggested (21), and later Creasman et al. (4) and Tjalma et al. (45) concurred, such apparent improvement in small surgical series may be secondary to a selection bias such as patients with better performance status and smaller lesions are selected for surgery, whereas older patients with more comorbid medical conditions and larger stage I-II lesions undergo RT.

While several series have reported on primary surgical approaches, including exenterations for patients with advanced stage III-IV SCC, achieving control rates as high as 50% for highly selected patients (13,15,21,40), the number of patients treated in any single series is so small that in modern practice, primary exenteration for advanced disease would not be recommended as the preferred approach (127). Therefore, advanced-stage patients should receive definitive RT, probably in combination with concurrent chemotherapy, although the role of combined modality therapy is unknown.

With regard to the surgical technique, if a complete vaginectomy is to be undertaken, most experts have suggested a combined abdominoperineal approach, with the perineal incision in the pubocervicovesical fascia made beneath the urethra and above the rectum so as to avoid the hemorrhoidal plexus. Some have suggested that the perineal incision can be made before or after the abdominal incision to perform the radical abdominal resection. However, we would favor performing the abdominal incision, first mobilizing the bladder, urethra, and rectum down to the perineum, and dividing the paracolpos at the side wall, mobilizing the ureters, and harvesting the nodes such that if unresectable disease is found, the patient would be spared a perineal incision. Given the large defect that is left after surgical resection, placement of a gracilis myocutaneous flap allows not only coverage of the defect, but may serve as a neovagina in the sexually active woman (143,144). Alternatively, two new techniques have been described with excellent results. Vaginal reconstruction can be performed with the use of vicryl mesh combined with a pedicled omental graftor with a deep inferior epigastric perforator flap. Both techniques have been shown to be effective, and when performed at the time of pelvic exenteration, carry the additional benefit of avoiding an additional surgical incision, as required for creation of a gracilis flap. Long-term follow-up has been favorable for the former, while only preliminary data is available for the latter (145,146).

Radiation Therapy Techniques and Outcome

Stage I. In patients with stage I lesions, usually 0.5 to 1 cm thick, that may involve one or more vaginal walls, it is important to individualize radiation therapy techniques to obtain optimal functional results. Most investigators emphasize that brachytherapy alone is adequate for superficial stage I patients. Superficial lesions can be adequately treated with ICB alone using afterloading vaginal cylinders. The entire length of the vagina is generally treated to a mucosal dose of 60 Gy, and an additional mucosal dose of 20 to 30 Gy is delivered to the area of tumor involvement (134). For lesions thicker than 0.5 cm at the time of implantation, it is advisable to combine ICB and ITB with a single-plane implant to increase the depth dose and limit excessive irradiation to the vaginal mucosa. With LDR-ICB a dose of 60 to 65 Gy is delivered to the entire vaginal mucosa; the dose to 0.5 cm depth from the ICB should be calculated; an additional 15 to 20 Gy at a depth of 0.5 cm beyond the plane of the implant will be delivered with the ITB such that the base of the tumor receives between 65 and 70 Gy, with the involved vaginal mucosa receiving an estimated 80 to 100 Gy. The proximal and distal vaginal mucosal doses should be limited to 140 and 100 Gy, respectively (134).

There are no well-established criteria regarding the use of external beam RT (EBRT) in patients with stage I disease. Perez et al. (19,42) did not find a significant correlation between the technique of irradiation used and the probability of local or pelvic recurrence, probably since the treatment technique varied based on tumor-related factors. There is general consensus that EBRT is advisable for larger, more infiltrating or poorly differentiated tumors that may have a higher risk of lymph node metastasis. The whole pelvis is treated with 10 to 20 Gy; an additional parametrial dose should be delivered with a midline block (five half-value layer [HVL]) to give a total of 45 to 50 Gy to the parametria and pelvic side walls. Chyle et al. (14) recommended EBRT in addition to brachytherapy for stage I disease to cover at least the paravaginal nodes, and, in larger lesions, to cover the external and internal iliac nodes. Ninety-five percent to 100% local control has been achieved with intracavitary and interstitial techniques, with 5-year survival for patients with stage I disease treated with RT alone ranging from 70% to 95% (Table 21.4) (18,19,21,23,121,147).

^aFour patients received adjuvant irradiation.

Stage II. Patients with stage IIA tumors have more advanced paravaginal disease without extensive parametrial infiltration. These patients are uniformly treated with EBRT followed by ICB and/or ITB. Generally, the whole pelvis receives 20 Gy followed by an additional parametrial dose with a midline 2- to 4-cm-wide (five HVL) block, depending on the width of the implant, to deliver a total of 45 to 50 Gy to the pelvic side walls. A combination of LDR-ICB or LDR-ITB may be used to deliver a minimum of 50 to 60 Gy 0.5 cm beyond the deep margin of the tumor (in addition to the whole pelvis dose, to a total tumor dose of 70 to 80 Gy). Double-plane or volume implants may be necessary for more extensive disease. Perez et al. (42) showed that in stage IIA, the local tumor control was 70% (37 of 53) in patients receiving brachytherapy combined with EBRT, compared with 40% (4 of 10) in patients treated with either brachytherapy or EBRT alone. The superiority of the combination of EBRT and brachytherapy over EBRT or brachytherapy alone has been shown as well in other series (14,21,120).

Patients with stage IIB, with more extensive parametrial infiltration, will receive 40 to 50 Gy whole pelvis and 55 to

60 Gy total parametrial dose (with midline shielding). An additional boost of 30 to 35 Gy will be given with LDR interstitial and intracavitary brachytherapy, to deliver a total tumor dose of 75 to 80 Gy to the vaginal tumor (14,20,42,120) and 65 Gy to parametrial and paravaginal extensions. The pelvic side wall dose should be kept below 60 Gy (including the contributions of EBRT and brachytherapy). Patients with lesions limited to the upper third of the vagina can be treated with an intrauterine tandem and vaginal ovoids or cylinders. The local-regional control in patients with stage IIB in the Perez et al. series (42) was also superior with combined EBRT and brachytherapy (61% vs 50%, respectively).

The 5-year survival for patients with stage II disease treated with RT alone ranges between 35% and 70% for stage IIA, and 35% and 60% for stage IIB. The results of several series published in the literature using different treatment approaches for stage I and II vaginal cancer are shown in Table 21.4 (4,13,14,16,21,23,24,40,45,121,147).

Stage III-IVA. Generally, patients with stage III and IVA disease will receive 45 to 50 Gy EBRT to the pelvis, and in some cases, additional parametrial dose with midline shielding

to deliver up to 60 Gy to the pelvic side walls. Ideally, ITB brachytherapy boost is performed, if technically feasible, to deliver a minimum tumor dose of 75 to 80 Gy. If brachytherapy is not feasible, a shrinking-field technique can be used, with fields defined using the three-dimensional treatment planning capabilities to deliver a tumor dose around 65 to 70 Gy. An alternative approach is intensity modulated RT (IMRT) using multiple beams of varying intensity that conform the high-dose region to the shape of the target tissues, with more adequate sparing of the surrounding normal tissues, primarily the bladder, rectum, and small bowel (148,149).

Boronow et al. (127) proposed an alternative to exenterative procedure for locally advanced vulvovaginal carcinoma, using RT to treat the pelvic disease and a radical vulvectomy with bilateral inguinal node dissection to treat the vulvar extension of the tumor. External irradiation to the pelvis and inguinal nodes consisted of 45 to 50 Gy, combined with LDR intracavitary insertions to deliver maximal doses of 80 to 85 Gy to the vaginal mucosa with both modalities.

The overall cure rate for patients with stage III disease is 30% to 50%. Stage IVA includes patients with rectal or bladder mucosa involvement, or in most series, positive inguinal nodes. Although some patients with stage IVA disease are curable, many patients are treated palliatively with EBRT only. Pelvic exenteration can also be curative in highly selected stage IV patients with small-volume central disease. Table 21.5 (4,13,14,16,21,23,40,42,121,147) shows the treatment results with different therapeutic modalities, including four series that reported the use of primary surgery in highly selected patients with advanced disease. However, each of these series reported a far greater number of patients with similar stage disease treated with RT, which represents the preferred approach in contemporary practice (19,56).

External Beam Radiotherapy

EBRT is advisable in patients with deeply infiltrating or poorly differentiated stage I lesions and in all patients with

stages II to IVA disease. The treatment is generally delivered using opposed anterior and posterior fields (AP/PA). The pelvis receives between 20 and 45 Gy depending on the stage of the disease. This will be followed, in some cases, by bilateral pelvic sidewall boosts to 50 to 55 Gy. High-energy photons (≥ 10 MV) are usually preferred. CT simulation is highly encouraged since it allows a more accurate delineation of the regional lymph node areas, rather than relying on pelvic bony anatomy (150). Treatment portals cover at least the true pelvis with 1.5- to 2.0-cm margin beyond the pelvic rim. Superiorly, the field extends to either L4-5 or L5-S1 to cover the pelvic lymph nodes up to the common iliacs, and extends distally to the introitus to include the entire vagina. Lateral fields, if used, should extend anteriorly to adequately include the external iliac nodes, anterior to the pubic symphysis, and at least to the junction of S2-3 posteriorly.

In patients with tumors involving the middle and lower vagina with clinically negative groins, the bilateral inguofemoral lymph node regions should be treated electively to 45 to 50 Gy (42). Planning CT is recommended to adequately determine the depth of the inguofemoral nodes. A number of techniques have been used to treat the areas at risk without overtreating the femoral necks. Some of the most commonly used techniques include the use of unequal loading (2:1, AP/PA), a combination of low- and high-energy photons (4 to 6 MV, AP; and 15 to 18 MV, PA), or equally weighted beams with a transmission block in the central AP field, utilizing small AP photon or electron beams to deliver a daily boost to the inguofemoral nodes (151). A technique has been developed and implemented at Indiana University that uses a narrow PA field to treat the pelvis and a wider AP field encompassing the pelvis and inguofemoral nodes, with daily AP photon boost to the inguinal nodes being delivered using the asymmetric collimator jaws (152). Advantages of this technique include simplicity of setup and treatment (single isocenter, no need for transmission block), dose homogeneity, reduced dose to the femoral necks, low potential risk of nodal underdose, and elimination of dosimetric difficulties inherent in electron boosts (Fig. 21.5).

FIGURE 21.5. (See color plate section.) Vaginal cancer with distal-third vaginal involvement—squamous cell carcinoma. Technique for pelvic and inguino-femoral nodal irradiation. **A:** Digital reconstructed radiographs (DRRs) AP/PA and daily right and left inguino-femoral photon boost. **B:** Axial, sagittal, and coronal isodose distributions.

For patients with positive pelvic nodes or those patients with advanced disease not amenable to interstitial implant, additional boost to the areas of gross disease, as defined by CT scan, should be given using conformal therapy to deliver a total dose between 65 and 70 Gy, when feasible, with high-energy photons. Boost to the areas of gross nodal disease, as defined by CT scan, should be given using small fields (similar to the parametrial boost with midline shielding) to deliver a total dose between 60 and 65 Gy with high-energy photons. In patients with clinically palpable inguinal nodes, additional doses of 15 to 20 Gy (calculated at a depth determined by CT scan) are necessary with reduced portals. This is generally achieved by using low-energy photons or electron beam (12 to 18 MeV). IMRT techniques are now available to deliver

higher doses to the gross disease while reducing the dose to the bladder and rectum (Fig. 21.6) (148,149).

Overall treatment time (7 to 9 weeks) has been found to be a significant treatment factor predicting tumor control (111,153), although this has not been universally recognized (42).

Low-Dose-Rate Intracavitary Brachytherapy

VAIN and small T1 lesions with less than a 0.5-cm depth can be adequately treated with intracavitary brachytherapy (ICB) alone. Low-dose-rate (LDR)-ICB is performed using vaginal cylinders such as Burnett, Bloedorn, Delclos (154), or MIRALVA (Nucletron Veenendaal, the Netherlands) (155,156) loaded with cesium 137 (^{137}Cs) radioactive sources. Choo et al. (157)

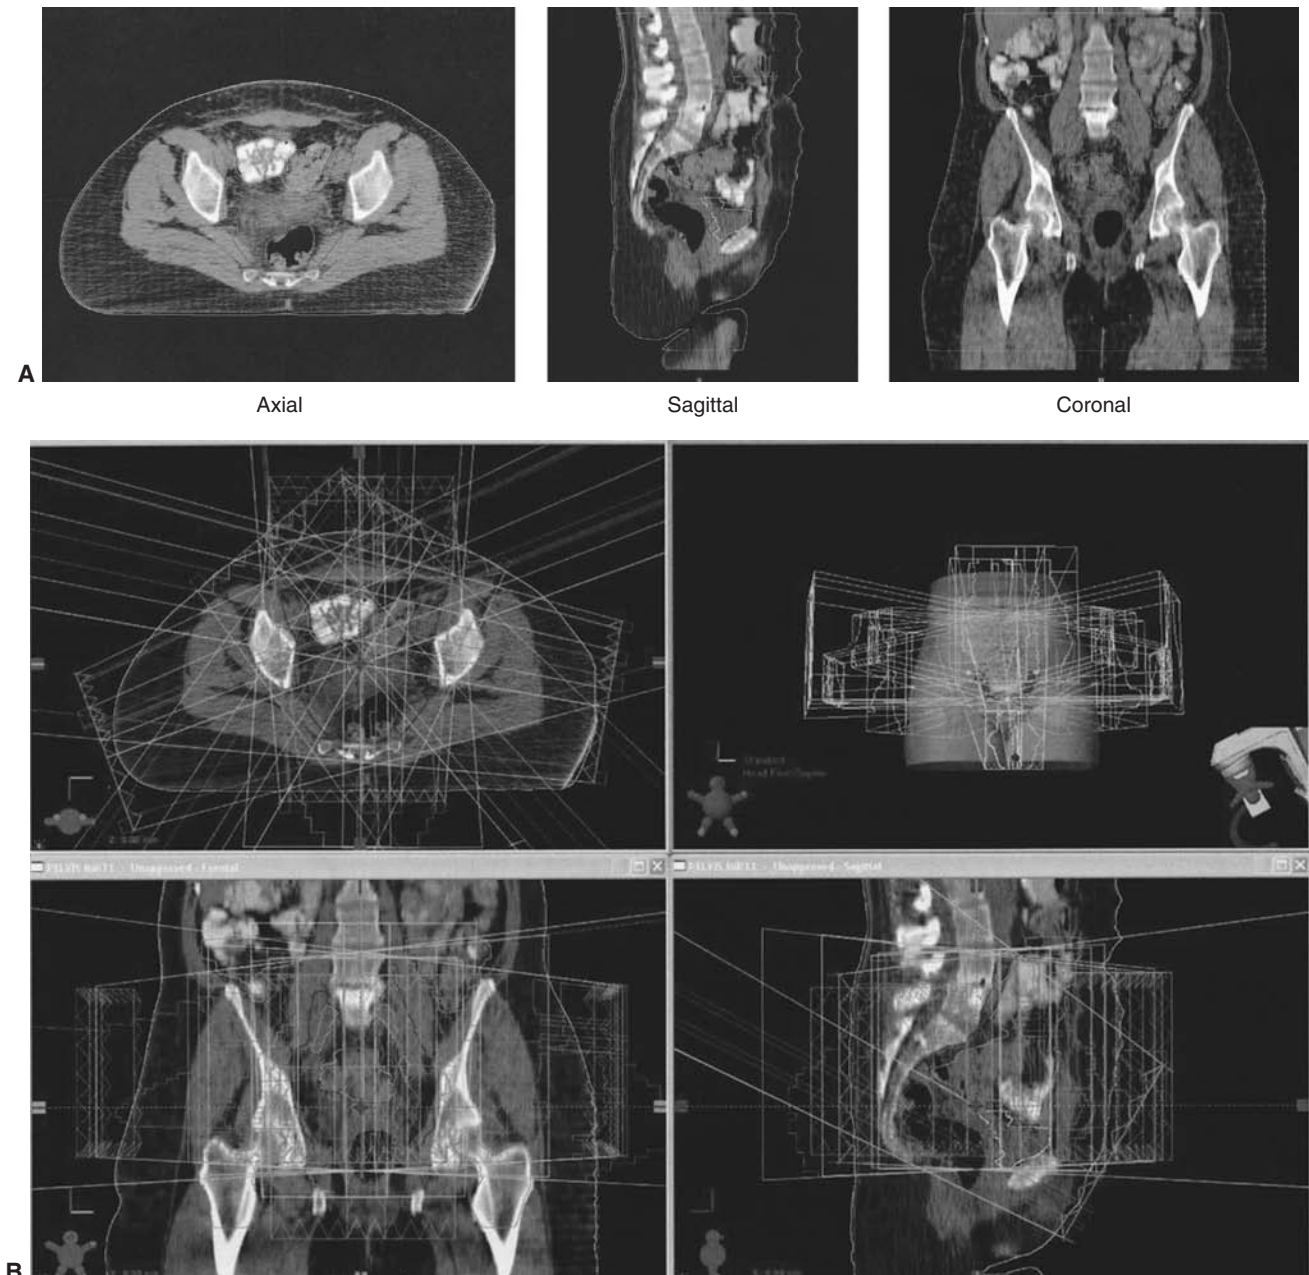

FIGURE 21.6. (See color plate section.) Intensity modulated radiotherapy (IMRT) in vaginal cancer. A: Axial, sagittal, and coronal reconstructions of the gross tumor volume (GTV). B: Beam arrangement, IMRT plan. (Continued.)

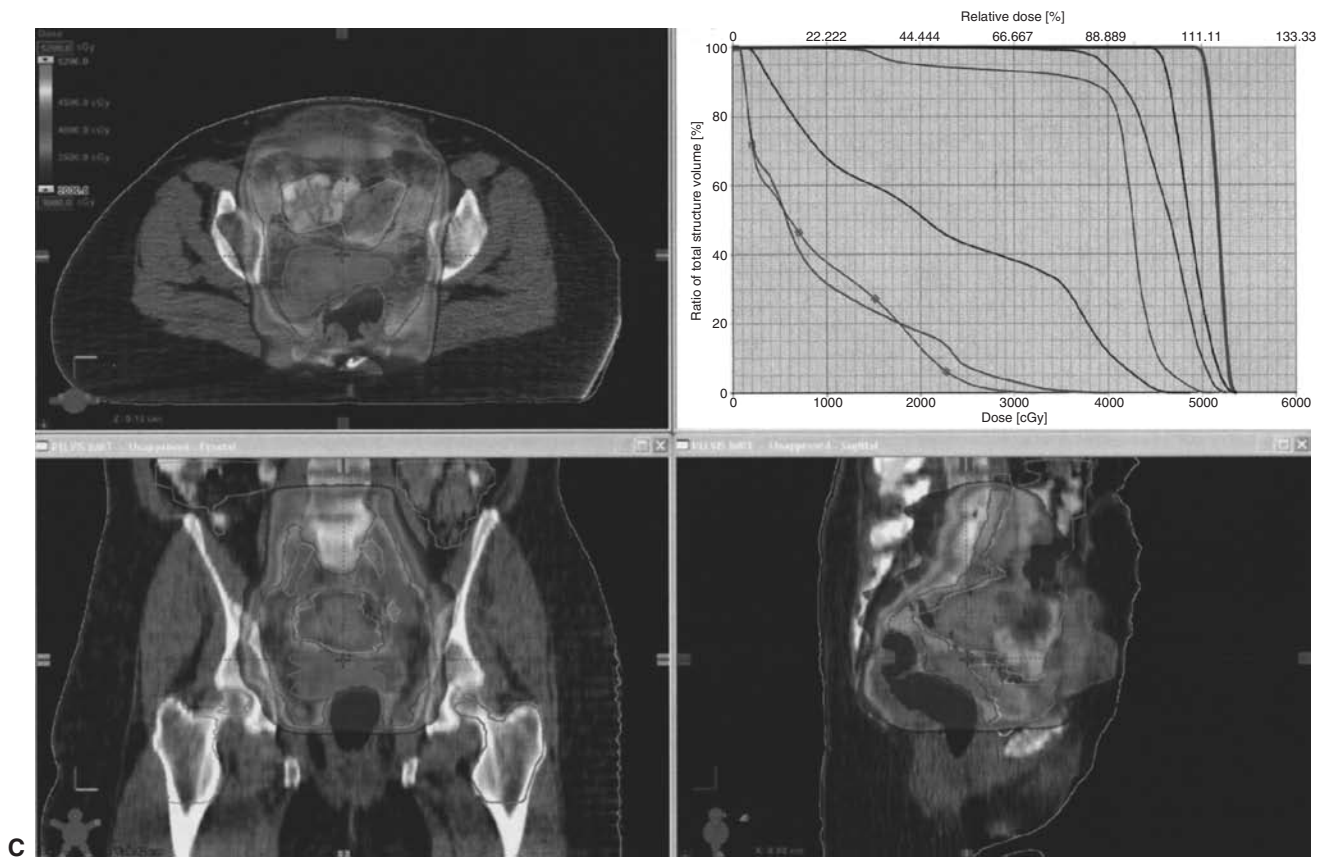

FIGURE 21.6. C: (See color plate section.) Isodose distribution, IMRT plan.

evaluated the depth distribution of lymphatics lying beneath the mucosal surface of the vagina in 31 patients who underwent full-thickness vaginal biopsy or resection for benign or malignant lesions. In their series, 95% of vaginal lymphatic channels were located within a 3 mm depth from the vaginal surface, confirming the adequacy of prescribing the dose to a depth of 5 mm for superficially invasive lesions (157).

It is recommended that the largest possible diameter that can be comfortably accommodated by the patient should be used to improve the ratio of mucosa to tumor dose, and eliminate vaginal rugations. In general, the vulva is sutured closed for the duration of the implant in order to secure the position of the applicators. Perez et al. (155,156) designed and constructed a vaginal applicator, MIRALVA, that incorporates two ovoid sources and a central tandem that can be used to treat the entire vagina (alone or in combination with the uterine cervix).

In patients with upper vagina lesions with less than a 0.5 cm depth of invasion, vaginal colpostats alone (after hysterectomy) or in combination with intrauterine tandem, loaded with ^{137}Cs sources similar to that used in treatment of cervical cancer, can be used to treat the proximal vagina to a minimum dose of 65 to 70 Gy, estimated to 0.5 cm depth, including the contribution of EBRT if given. When indicated, the remainder of the vagina can be treated by performing a subsequent implant using vaginal cylinders (generally 50 to 60 Gy prescribed to the vaginal surface). It is important to avoid the placement of a protruding source over the vulva, with the subsequent increased risk of complications. When appropriate dose specification points are chosen, a very uniform dose distribution over the entire length of the vagina can be obtained.

The use of LDR remote control afterloading technology allows the reduction of radiation exposure to hospital personnel and optimization of the isodose distribution.

High-Dose-Rate Intracavitary Brachytherapy

The International Commission of Radiation Units (ICRU) defines HDR brachytherapy as exceeding 12 Gy/h (42). High-dose-rate intracavitary brachytherapy (HDR-ICB) is typically performed with a 10 Ci single iridium-192 (^{192}Ir) source (Micro-Selectron HDR, Nucletron). The applicators are similar to those described for LDR. Little information regarding HDR-ICB in the treatment of primary carcinoma of the vagina is available (22,158). Fewer patients have been treated compared with LDR-ICB, follow-up for most series is short, publication bias is likely, and there is no agreement on treatment regimen. Generally, the number of insertions ranges from one to six (median three), with the dose per fraction ranging from 300 to 800 cGy (median 700 cGy).

Nanavati et al. (158) reported 13 patients with primary vaginal cancer treated with external beam RT (45 Gy) and HDR-ICB. All 13 patients had a complete response, and local control was achieved in 92% of the patients with a median follow-up of only 2.6 years (range 0.7 to 5.2 years). The investigators did not observe any acute or chronic intestinal or bladder grade 3 or 4 toxicity. However, moderate to severe vaginal stenosis occurred in 46% of the patients. They recognize that "late-occurring toxicity could be missed at a medium follow-up of 2.6 years." Kucera et al. (159) reported on 190 patients with invasive carcinoma of the vagina. Eighty were

treated with intracavitary HDR-ICB with or without EBRT. These patients are compared with a historical group of 110 patients treated with intracavitary LDR brachytherapy with or without EBRT. No significant differences were found for stages, tumor grade, or location between the two groups. The crude 5-year survival rates for all patients were 41% in the LDR group, 81% in stage I, and 43% in stage II. Overall actuarial 3-year survival and disease-specific survival rates for all patients in the HDR series were 51% and 66%, respectively. Disease-specific 3-year survival rates were 83% in stage I and 66% in stage II. There were no significant differences in local and distant recurrences between the treatment modalities. Complications analysis showed no significant differences between the HDR and LDR series. Similar results were published by Mock et al. (142) in 86 patients treated with HDR-ICB alone or in combination with EBRT with fairly good toxicity profile. However, Kushner et al. (160) reported on 19 patients with vaginal cancer treated with different combinations of EBRT and intracavitary and interstitial HDR brachytherapy, with a low 39.3% 2-year progression-free survival and 15.8% serious late complications including ureteral stenosis, painful vaginal necrosis, and small bowel obstruction.

Many aspects remain unknown or not well understood in the use of HDR-ICB in vaginal cancer treatment. These include the radiobiologic equivalency of HDR to LDR, fractionation schedule, total dose, specification of dose prescription, and how to combine HDR with EBRT and/or LDR brachytherapy. In addition, optimization approaches and methods of dose calculation, such as the inclusion of anisotropic corrections, are not well described in the sparse literature available to date (161,162). These factors could result in an increased incidence of severe complications, such as vaginal necrosis and rectovaginal or vesicovaginal fistulas (160,163,164). In our opinion, until further data are available with longer follow-up, as well as a better understanding of the physical and radiobiologic principles involved in HDR-ICB, its use should be cautiously considered in the radiotherapeutic management of primary vaginal carcinoma.

Interstitial Brachytherapy

Interstitial brachytherapy (ITB) is an important component in the treatment of more advanced primary vaginal carcinomas, typically in combination with EBRT and/or ICB. In the first place, a careful definition of the “target volume,” which is the gross tumor volume (based on clinical, radiologic, and operative findings) and a margin of adjoining normal tissue, is required. Other considerations include whether a permanent (^{198}Au or ^{125}I) or temporary implant (^{192}Ir) is optimal, the geometry of the implant (e.g., single or double plane or volume implant), source distribution, dose rate, and total dose, based upon tumor size, location, local extent, and proximity of normal structures (165). The principal advantages of temporary implants are readily controlled distribution of the radioactive sources and easier modification of the dose distribution. The main advantages of a permanent seed implant include relative safety/simplicity, easy applicability, cost-effectiveness, and ability, in most cases, to be performed using local anesthesia. As a general rule, temporary implants are more commonly used in the curative treatment of larger gynecologic malignancies, whereas permanent implants are usually performed for smaller volume disease. When performing an interstitial procedure, freehand implants or template systems designed to assist in preplanning and to guide and secure the position of the needles in the target volume can be employed. Commercially available templates include the Syed-Neblett device (SNIT) (Alpha Omega Services, Bellflower, California, USA) (166), the modified Syed-Neblett (167), and the “MUPIT” (Martinez Universal Perineal Interstitial Template) (168). These templates generally consist of a perineal template, vaginal obturator, and 17-gauge

hollow guides of various lengths that can be afterloaded with ^{192}Ir sources. The vaginal obturator is centrally drilled so that it can allow the placement of a tandem to be loaded with ^{137}Cs sources. This makes it possible to combine an interstitial and intracavitary application simultaneously (Fig. 21.7). The major advantage of these systems is greater control of the placement of the sources relative to tumor volume and critical structures owing to the fixed geometry provided by the template. In addition, improved dose-rate distributions are obtained by means of computer-assisted optimization of the source placement and strength during the planning and loading phase.

Owing to the inaccuracies of pelvic examination and close proximity of the rectum and bladder to the target volume, there exists a serious risk of either underdosing the target volume or causing bladder and rectal morbidity. In order to improve the accuracy of target localization and needle placement, several investigators have explored performing ITB under transrectal ultrasound (TRUS) (169), CT, MRI-planned implants with endorectal coil (170), laparotomy, and laparoscopic guidance (167–173). An open retropubic approach allows direct visualization of the bladder and urethra during interstitial implantation of anterior vaginal malignancies and facilitates negotiation of the pubic arch. Paley et al. (173) described a technique using an open retropubic approach for Syed template interstitial implants in anterior vaginal tumors under direct visualization.

Tewari et al. (174) described results in 71 patients who underwent ITB with (61 patients) or without (10 patients) EBRT. Patients included those with stage I (10 patients), Perez modification stage IIA (14 patients), Perez modification stage IIB (25 patients), stage III (15 patients), and stage IV (7 patients) disease. Each implant delivered a total tumor dose reaching 80 Gy integrated with EBRT. Local control was achieved in 53 patients (75%). With a median follow-up of 66 months the 5- and 10-year actuarial disease-free survival rates were both 58%. By stage, 5-year disease-free survival rates included stage I, 100%; stage IIA, 60%; stage IIB, 61%; stage III, 30%; and stage IV, 0%. Stage and primary lesion size independently influenced the survival rates. Significant complications occurred in nine patients (13%) including necrosis ($n = 4$), fistulas ($n = 4$), and small bowel obstruction ($n = 1$).

Stryker (175) treated 40 patients with vaginal carcinoma; 14 had a history of prior hysterectomy. There were four treatment groups: EBRT and intracavitary brachytherapy (group WPIC, $n = 15$), EBRT and interstitial brachytherapy (group WPIS, $n = 10$), EBRT alone (group WP, $n = 7$), and brachytherapy alone (group BA, $n = 2$). The 5-year disease-specific survival rates were 68% for 28 patients with squamous cell carcinoma and 50% for six patients with adenocarcinoma. The 5-year survival rates were 78% for stage I disease, 63% for stage II, 33% for stage III, and 50% for stage IV ($P = 0.2$). Local failure occurred in two patients (13%) in the WPIC group, two (20%) in WPIS, three (43%) in WP, and one (50%) in BA. Nine patients (26%) had late small/large intestine or bladder morbidity. Vaginal morbidity occurred in 15 patients (44%).

Role of Chemotherapy and Radiation

The control rate in the pelvis for stage III-IV patients is relatively low, and about 70% to 80% of the patients have persistent disease or recurrent disease in the pelvis in spite of high doses of EBRT and brachytherapy. Failure in distant sites does occur in about 25% to 30% of the patients with locally advanced tumors, which is much less than pelvic recurrences. Therefore, there is a need for better approaches to the management of advanced disease such as the use of concomitant chemoradiotherapy. Agents such as 5-FU, mitomycin-C, and cisplatin have shown promise when combined with RT, with complete response rates as high as 60% to 85% (176,177),

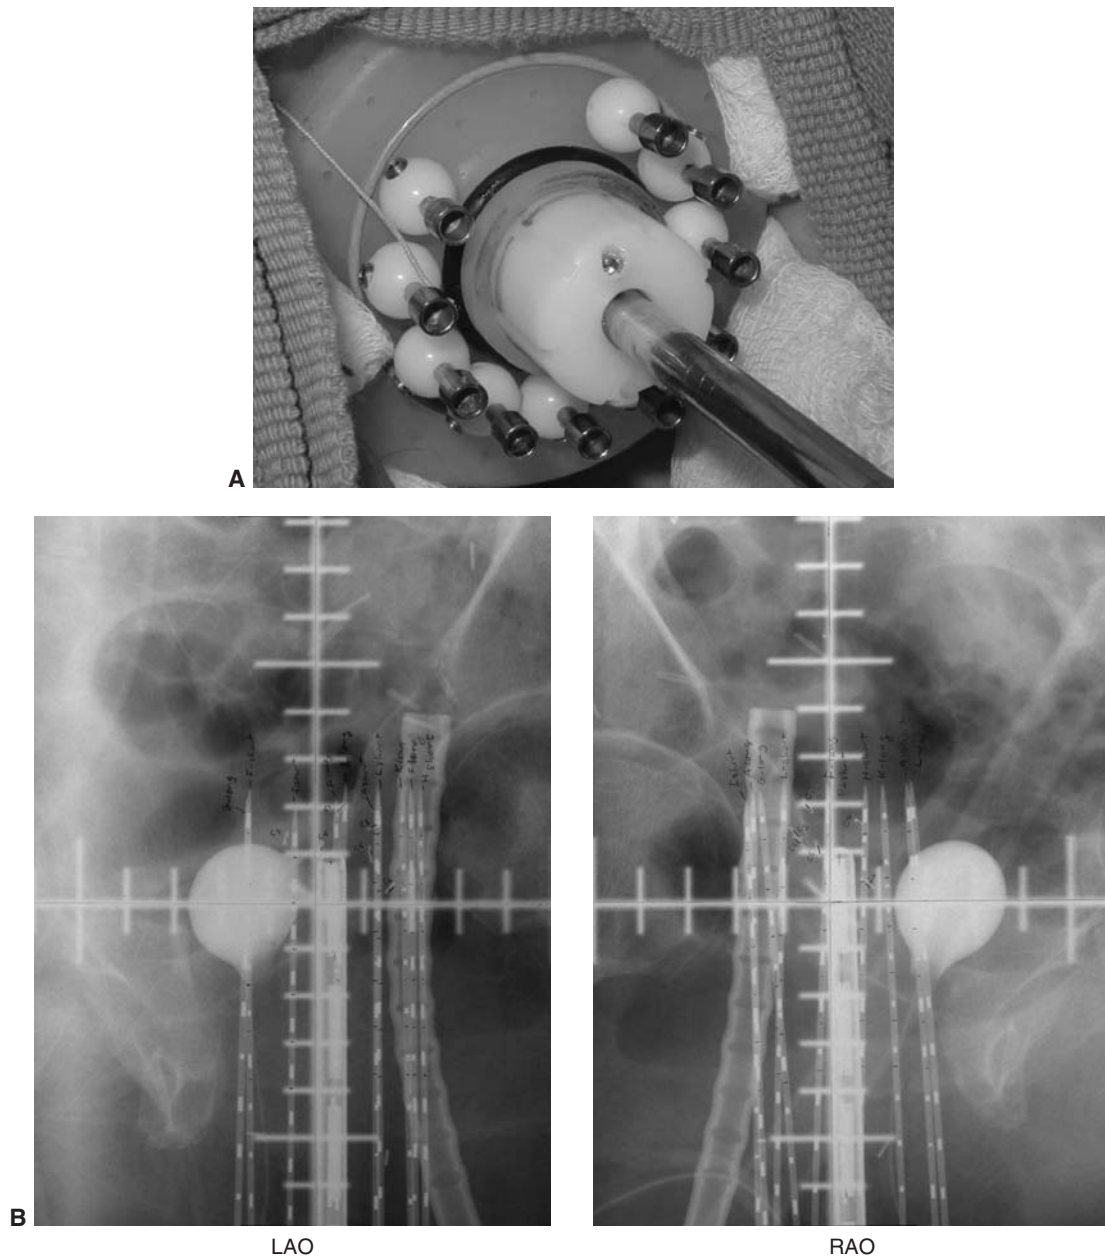

FIGURE 21.7. (See color plate section.) Interstitial plus endocavitary brachytherapy in a patient with vaginal cancer. A. Applicators in place. B. Oblique implant films.

but long-term results of such therapy have been variable. In these small studies, many of the patients had advanced (stage III) disease at the initiation of combined-modality therapy, perhaps explaining the lack of long-term disease control.

Evans et al. (176) found no local recurrences, however, among patients achieving a complete response with RT and 5-FU plus mitomycin C (12 of 25 patients), with a median follow-up period of 28 months, suggesting that local control may be improved with combined-modality therapy since local failure is common with radiation alone in large-volume pelvic disease. The survival for the entire population was 56% (66% for patients with primary vaginal cancer). Only two patients had severe complications, although the investigators recognize that longer follow-up is probably required to assess the true

incidence of late effects. More sobering are the data from Roberts et al. (177), who reported 67 patients with advanced cancers of the vagina, cervix, and vulva treated with concurrent 5-FU, cisplatin, and RT. Although 85% experienced a complete response, 61% of the cancers recurred, with a median time to recurrence of only 6 months and an overall survival at 5 years of 22%. Further, 9 of 67 patients (13%) developed severe late complications, of which 8 required surgeries.

Kersh et al. (178) reported that five of eight vaginal cancer patients achieved local control with combined modality therapy. Dalrymple et al. (179) recently published a small study including 14 patients, primarily stages I and II SCC of the vagina, treated with reduced doses of RT (median 63 Gy)

FIGURE 21.7. C: (See color plate section.) Dose Distribution.

concurrently with different 5-FU-based chemotherapeutic regimens. They reported a 93% control rate (four patients died of intercurrent disease with no evidence of tumor), probably reflecting a more favorable stage distribution. Interestingly, none of the patients required interstitial implants and no patients developed fistulas. The authors indicate that this approach, similar to the one used in the management of anal and vulvar cancer, would allow reducing the RT dose with the subsequent improvement in organ function and late toxicity.

Studies of primary chemoradiation in primary vaginal cancer are small or heterogeneous populations including cervical and vulvar cancers, making it difficult to truly assess the role of combined-modality therapy in the management of locally advanced disease. No randomized trials comparing radiation with or without chemotherapy have been reported. Further investigation is needed to determine the therapeutic efficacy of the concurrent chemoradiotherapeutic and the optimal chemotherapeutic regimen. Recently published data on locally advanced cervical cancer have demonstrated an advantage in locoregional control, overall survival, and disease-free survival for patients receiving cisplatin-based chemotherapy concurrently with RT (180–183). The only drug common to all the studies was cisplatin, suggesting it may be the only agent needed to improve radiation sensitivity. Based on these data, as well as data on locoregionally advanced vulvar cancer (184), consideration should be given to a similar approach in patients with advanced vaginal cancer. Randomized trials comparing radiation therapy alone to chemoradiation therapy, however, are unlikely because of small patient numbers.

PATTERNS OF FAILURE IN SQUAMOUS CELL CARCINOMA

At least 85% of patients who recur will have a component of locoregional failure, and the vast majority of these recurrences will be confined to the pelvis and vagina. The rate of locoregional recurrence in stage I is approximately 10% to 20% versus 30% to 40% in stage II. The pelvic control rate for patients with stage III and stage IV is relatively low and about 50% to 70% of the patients have recurrences or persistence in spite of well-designed RT. The median time to recurrence is 6 to 12 months. Tumor recurrence is associated with a dismal prognosis, with only a few long-term survivors after salvage therapy (185). Failure in distant sites alone or associated with locoregional failure does occur in about 25% to 40% of patients with locally advanced tumors (Table 21.6) (61,62,67, 68,91,101,147,185).

It is important to recognize that analysis of RT doses and techniques and their impact on local/pelvic tumor control are fraught with difficulty since the available data are retrospective and not the result of prospective randomized or dose escalation studies. Andersen (12) has shown that the combination of EBRT and brachytherapy and tumor dose over 70 Gy were associated with improved local control. In the Stanford experience (20), earlier stage and higher RT dose had a positive influence on survival. Nine of 16 patients receiving ≤ 75 Gy had recurrent disease versus 3 of 22 receiving >75 Gy. Larger series have not found a significant impact of the RT dose and

recurrence rate, probably because larger tumors received higher EBRT and brachytherapy doses (14,42). The M. D. Anderson series (147) did not find dose lower than or greater than 75 Gy to be associated with improved pelvic control or disease-specific survival, the only two statistically significant factors being the stage of the disease and the size of the tumor over 4 cm.

Perez et al. (19,42) observed increased tumor control in patients with stages IIA to IVA with EBRT and brachytherapy compared to patients receiving brachytherapy alone. In patients with stage I disease, no correlation was found between the technique of RT used and the incidence of local or pelvic recurrences. In addition, they suggested that doses in the range of 70 to 75 Gy to the primary tumor volume and 55 and 65 Gy to the medial parametria for patients with more advanced disease are necessary to optimize tumor and pelvic control. Furthermore, of 100 patients with primary tumors involving the upper and middle third of the vagina who received no elective irradiation to the groins, none developed metastatic inguinofemoral lymph nodes, which is in contrast to 3 of 29 (10%) patients with lower-third primaries and 1 of 20 patients with tumors involving the entire length of the vagina. Of seven patients with initially palpable inguinal lymph nodes treated with doses to around 60 Gy, only one developed a nodal recurrence. The investigators recommended that elective RT of the inguinal lymph nodes should be carried out only in patients with primary tumors involving the lower third of the vagina. Similar results were published by Stock et al. (21) and Stryker (175). Lee et al. (111) identified overall treatment time as the most significant treatment factor predicting pelvic tumor control in 65 patients with carcinomas of the vagina treated with definitive RT. If the entire course of RT, including EBRT and brachytherapy, was completed within 9 weeks, pelvic tumor control was 97% in contrast to only 57% when treatment time extended beyond 9 weeks ($P < 0.01$). Conversely, Perez et al. (42) did not find a significant impact of prolongation of treatment time on pelvic tumor control. Nevertheless, these investigators advocate completion of treatment within 7 to 9 weeks.

TREATMENT COMPLICATIONS AND THEIR MANAGEMENT

The anatomic location of the vagina places the lower gastrointestinal and genitourinary tracts at greatest risk for complications after surgery or RT. Although in most of the retrospective series, the investigators comment on the nature of the complications encountered, little information is typically given regarding their prevention or management (13,15,21,40,112,124). In modern oncology, survival rate is the primary endpoint in treatment evaluation, but the analysis of treatment complications and quality of life is of crucial importance. The knowledge of common acute and late complications with standard RT and consideration of risk factors may improve the therapeutic ratio of RT for gynecologic malignancies in general, and for vaginal cancer in particular (186).

The acute and chronic pathophysiology of vaginal RT has been well described by Grigsby et al. (187). As an immediate response to high-dose RT, there is loss of most or all of the vaginal epithelium, especially in areas in proximity to brachytherapy sources. Clinically, the severity of the acute effects (edema, erythema, moist desquamation, and confluent mucositis with or without ulceration) varies in intensity and duration depending upon patient age, hormonal status, tumor size, stage, RT dose, and personal hygiene. These effects usually resolve within 2 to 3 months after completion of therapy. In some patients, there is progressive vascular damage with subsequent ulcer formation and mucosal necrosis, which may require up to 8 months for healing. Chemotherapy concurrently with RT enhances the acute mucosal response to both EBRT and brachytherapy. The effects of chemotherapy on the incidence of late complications, if any, are unclear. Over time, most patients will develop some degree of vaginal atrophy, fibrosis, and stenosis. Telangiectasis is commonly seen in the vagina. Vaginal narrowing or shortening, paravaginal fibrosis, loss of elasticity, and reduced lubrication often result in dyspareunia. More severe complications include necrosis with ulceration that can progress to fistula formation (rectovaginal, vesicovaginal, urethrovaginal).

The RT tolerance limits of the entire vagina are ill defined given the variety of techniques employed for the treatment of vaginal cancers. An irradiation tolerance level of the proximal vagina was suggested by Hintz et al. (188) based on a study of 16 patients whom received a maximum surface dose of 140 Gy, none of who developed severe complications or necrosis of the upper vagina. Based on their previous observation of a patient who developed a vesicovaginal fistula after receiving a 150-Gy mucosal dose to the anterior vaginal wall, they recommended a tolerance dose level of 150 Gy (direct summation of EBRT dose and ICB) to the anterior upper vaginal mucosa. They advocated dose rates of <0.8 Gy/h. These authors cautioned against placing radioactive needles on the surface of the vaginal cylinder because this may increase the frequency of vaginal necrosis. They also recommended keeping the total dose to the distal vagina less than 98 Gy. In addition, it was also observed that the posterior wall of the vagina is more prone to radiation injury than the anterior or lateral walls, and that the dose should be kept below 80 Gy in order to minimize the risk of rectovaginal fistula. Rubin and Casarett (189) suggested that the tolerance of the vaginal mucosa (Tolerance dose 5/5: 5% necrosis within 5 years) is approximately 90 Gy for ulceration and more than 100 Gy for fistula formation. This tolerance limit has been specified as a direct summation of dosage given by LDR-ICB and EBRT in the treatment of cervical cancer. Within the low-dose-rate range, whether a correction for the brachytherapy dose rate is necessary remains controversial. In a more recent series from Washington University, the traditional LDR tolerance dose of 150 Gy to the mucosa of the proximal vagina was shown to yield a nominal 11% and 4% grades 1, 2, and 3 sequelae, respectively (190).

The incidence of grade 2 or higher complications has been reported to be 15% to 25%, with the average of severe complications (those requiring surgery for correction or necessitating hospitalization) being approximately 8% to 10%. Table 21.7 (56,61,62,67,79,91,92,101,147) shows the incidence of complications greater than grade 2 in several large series of vaginal cancer patients. Host factors that may increase the risk of complications include prior pelvic surgery, pelvic inflammatory disease, immunosuppression status, collagen vascular disease, low body weight, patient age, significant smoking history, and comorbid illness (e.g., diabetes, hypertension, and cardiovascular disease) (19,42,147).

Perez et al. (19) reported grade 2-3 complications in approximately 5% of patients treated for stage 0 and I disease and in approximately 15% of patients with stage II lesions. No

complications were reported in stage III and IV disease, probably because few patients lived long enough to manifest complications of treatment. The most common major complications were proctitis (two), rectovescovaginal fistula (three), and vesicovaginal fistula (two). The most common minor complications were fibrosis of the vagina and small areas of mucosal necrosis, which were noted in approximately 10% of patients.

Lee et al. (111) showed that the total dose to the primary site was the most significant factor predicting the development of a severe complication (9% in patients receiving ≤ 80 Gy as compared with 25% in those receiving higher doses). Perez et al. (19) reported an increase in the rate of severe complications with higher clinical stage, probably reflecting the higher doses delivered with EBRT and brachytherapy.

Ball and Berman (13) reported on 58 patients with carcinoma of the vagina, including 30 who underwent surgery. There were four rectovaginal fistulae (one following RT and three after exenterative surgery) and two vesicovaginal fistulae (one following radical vaginectomy and the other following a recurrence, being managed with cystectomy and diversion). The single ureterovaginal fistula occurred after radical vaginectomy and partial cystectomy and was managed with ureteroneocystotomy.

In the Peters et al. report (112) of 86 vaginal primaries, there were two fistulae in the 57 patients who received primary RT. However, there was a 44% rate of fistula formation in the nine patients who underwent re-irradiation after having previously received RT for an earlier cancer. Rubin et al. (40) reported a 23% incidence of complications after RT, including a 13% rate of fistula formation and a 10% rate of cystitis/proctitis. Although two patients developed fistulae following combination therapy, the investigators did not think that the rate of complications following combination therapy was greater than that seen following RT alone.

In the Stock et al. series (21) of 100 patients with vaginal carcinoma, there was a 16% actuarial complication rate at 10 years. All patients undergoing vaginectomies or exenterations lost vaginal function. None of the patients was offered vaginal reconstruction in this series. The investigators emphasized that therapeutic options need to be individualized such that surgery is offered only to those most likely to benefit and least likely to suffer complications.

Chyle et al. (14) in 301 patients noted that 39 (13%) had 48 grade 2 or greater sequelae, including rectal ulceration or proctitis in 10 (3 requiring colostomy), small bowel obstruction in 7, rectovaginal fistula in 6, vesicovaginal fistula in 4,

TABLE 21.7

COMPLICATIONS OF THERAPY (\geq GRADE 2)

Frank et al. (147)	193	5 years, actuarial St I, 4% St II, 9% III-IVA, 21%

Note: St, stage.

vaginoperitoneal/cutaneous fistula in 2, and vaginal ulceration or necrosis in 8 patients. Fewer complications developed in patients with stage 0 or I tumors (8% to 9%) than with more advanced stages (14% to 40%). Vaginal ulceration occurred in 8 of 206 patients (4%) treated with brachytherapy, but in none of 95 patients who received no brachytherapy ($p = 0.06$).

Frank et al. (147) reported 10% and 17% 5- and 10-year cumulative rates of major (greater than grade 2) complications in a series of 193 patients treated with definitive RT with or without chemotherapy. They found FIGO stage and history of smoking to be the two factors significantly correlated with subsequent complications. Other clinical, dosimetric factors or the addition of chemotherapy did not correlate with the likelihood of complications. However, 73% of patients with major complications had tumors involving the posterior vaginal wall.

Treatment options for acute radiation vaginitis include daily vaginal douching with a diluted hydrogen peroxide/water mixture (187). This should continue for 2 to 3 months or until the mucosal reactions have subsided. Patients are then advised to continue douching once or twice per week for several months. Regular vaginal dilation is recommended as a way for patients to maintain vaginal health and good sexual function, although the compliance rate is low. The lack of resolution of vaginal ulceration or necrosis after several months of adequate therapy must be appropriately evaluated, considering the possibility of recurrent tumor. The use of topical estrogens following completion of RT appears to stimulate epithelial regeneration more than systemic estrogens. Some patients with severe radiation sequelae, such as fistula formation, will respond to conservative treatment with antibiotics and periodic limited debridement of necrotic tissue. More recently, Delanian et al. (191) published a randomized trial demonstrating the effectiveness of the combination of pentoxifyllin and vitamin E in the regression of radiation-induced fibrosis.

Patients with more severe gastrointestinal or urinary late effects will require urinary or fecal diversion with possible delayed re-anastomosis. Occasionally, repair of the fistula may be attempted by employing a myocutaneous graft in which the skin, subcutaneous fat, and muscle are mobilized using a vascular pedicle to maintain the blood supply to the pedicled graft (Martius flap), or by excision of the necrotic tissue with re-establishment of organ continuity (such as in the treatment of high rectovaginal fistula). A detailed review of the pathogenesis and management of potential late effects of treatment is not within the scope of this chapter, and may be found in the chapter on management of complications of gynecologic cancer treatment (see Chapter 31).

It is likely that improvements in modern practice such as advancements in surgical techniques (such as more generous use of myocutaneous flaps) (104,134), improved supportive care during the immediate postoperative stay, the use of more sophisticated RT field setting (three-dimensional conformal therapy and IMRT) and treatment delivery, more accurate brachytherapy techniques, and dose calculations have the potential to lessen complication rates posttherapy, regardless of which modality is used.

CLEAR CELL CARCINOMA OF THE VAGINA

Since Herbst and Scully's first report (192) of seven adenocarcinomas arising in the vagina of adolescent females after *in utero* exposure to DES, there have been several reports limited to DES-related vaginal CCA (28,29,47,193). In 1979, Herbst et al. (194) reported 142 cases of stage I CCA of the vagina. An 8% risk of recurrence was seen after radical surgery (N = 117),

and an 87% survival was achieved. There was a 36% risk of recurrence after RT for stage I lesions; however, the investigators acknowledged that, in general, RT was reserved for large stage I lesions that involved more of the vault and were less amenable to surgical resection. Surgery for stage I CCA may have the advantage of ovarian preservation and, after skin graft, better vaginal function. As the majority of CCAs occur in the upper third of the vault, the largest series addressing the surgical approach to these lesions have advocated radical hysterectomy, pelvic and paraaortic lymphadenectomy, and sufficient colpectomy to achieve negative margins. Senekjian et al. have also reported a series of exenterations done for CCA (195). However, there have also been efforts to attempt fertility-sparing radical resections (196) or more limited wide local excisions followed by some form of RT (197). Wharton et al. (198) advocate intracavitary or transvaginal irradiation for the treatment of small tumors because this may yield excellent tumor control with a functional vagina and preservation of ovarian function.

Senekjian et al. (197) reported a series of 219 stage I CCA cases of which 176 had conventional therapy and 43 underwent local therapy. The two groups appear to be similar with respect to symptoms, stage, location of the lesion in the vagina, greatest tumor diameter, depth of invasion, predominant histologic pattern, grade, and number of mitoses. Actuarial survival rates at 5 and 10 years for the local therapy group (92% and 88%, respectively) were essentially equivalent to those for the conventional therapy group (92% and 90%, respectively). However, the recurrence experience after local therapy was less favorable; at 10 years, the actuarial recurrence rate for the local excision subgroup was 45%, in comparison with only 13% for patients treated with more radical surgery. Local therapy consisted of vaginectomy in 9 cases, local excision alone in 17 cases, and local irradiation (with or without local excision) in 17 cases. The subgroup of patients receiving local irradiation had a recurrence rate of 27%, similar to that of the conventional therapy group and more favorable than that of either the subgroup treated with vaginectomy or local excision alone. Recurrences were more frequently noted in patients with tumors >2 cm, with invasion of ≥ 3 mm, and with a predominant histologic pattern other than tubulocystic. Pelvic lymph node metastases were noted at death in 12% of patients. They advocated a combination of wide local excision and extraperitoneal node dissection followed by brachytherapy for patients desirous of fertility preservation (197).

In a subsequent report, Senekjian et al. (199) reviewed the experience with 76 cases with stage II CCA from the Registry for Research on Hormonal Transplacental Carcinogenesis. The overall 5- and 10-year survival rates were 83% and 65%, respectively. Of the 76 patients, 22 received surgery exclusively (either radical hysterectomy with vaginectomy, 13 patients, or exenterative type procedure, 9 patients), 38 received RT alone, 12 received combination therapy, and 4 underwent other approaches. Patients treated with primary RT achieved an 87% 5-year survival rate versus 80% for those treated with surgery and 85% for those receiving both treatments. The investigators concluded that most patients with stage II vaginal CCA should be treated with combination EBRT and brachytherapy; however, small, easily resectable lesions in the upper fornix might undergo resection, allowing better preservation of coital and ovarian function (199).

In 1989, Senekjian et al. (195) reported their experience of 20 pelvic exenterations for CCA of the vagina, including 13 for primary lesions and 7 for recurrent disease. The 9 patients with stage II disease treated with primary exenteration were compared with the 67 who had other modalities of therapy; no significant difference in the survival experience was noted between the two groups. They reported a 72% success rate if

the exenterations were done as part of primary therapy. They advocated reserving exenterative approaches for those who have failed RT in order to maximize quality of life for the greatest number of patients (195).

There are few published reports regarding the use of systemic therapy for CCA. Fowler et al. (200) reported one complete and one partial response after treatment with melphalan (1 mg/kg qd \times 5 days). Robboy et al. (43) reported responses in recurrent disease to both 5-FU and vinblastine.

NONEPITHELIAL TUMORS OF THE VAGINA

Melanoma of the Vagina

Vaginal melanoma is an exceedingly rare entity. It accounts for 2% to 3% of all primary tumors of the vagina and approximately 0.5% of all malignant melanomas in females. Therefore, the number of patients with vaginal melanoma is too small to permit prospective controlled trials. Melanoma of the vagina, with its propensity to develop distant metastases and its lack of a recognized precursor lesion, has presented therapeutic challenges for surgeons. Investigators have reported small series with generally disappointing results irrespective of treatment modality (34,201–206). Because of the reputation of melanoma as a radioresistant tumor, it is not surprising that radical surgery has been considered to be the treatment of choice in operable patients. However, limited data are available that validate its efficacy. Although 75% 2-year survival has been achieved after radical excision in small series (206), most series report 5-year survival rates of 5% to 30% regardless of radicality of surgery (34–36,201–206).

Morrow and DiSaia, in their review of all genital melanomas, noted no long-term survivors after isolated wide local excision for vaginal melanoma; however, 3 of 19 patients survived following exenteration (35). In the Chung et al. series of 19 patients, 7 were treated with radical surgery, including one exenteration and 6 radical vaginectomies, with or without hysterectomy, with an overall survival of 21%. All patients treated with wide local excision developed recurrences (34). On the other hand, Levitan et al. (205), in their review of the literature, argued that although the 2-year survival following radical surgery was better (20% to 40%) than with any other therapy, the 5-year survival rates were equally poor (average 8%) regardless of type of therapy. Furthermore, the incidence of distant recurrence was not influenced by the extent of surgical resection. Geisler et al. (203) published the Indiana University experience using pelvic exenteration for malignant melanomas of the vagina or urethra with more than 3 mm of invasion. None of the four patients included in this study had recurrences, and three patients remained alive with a minimum follow-up of 31 months. Conversely, Bonner et al. (201) reported nine cases of vaginal melanoma: Three received wide local excisions and six underwent radical surgery (including exenterations and radical vaginectomies with or without hysterectomies), with a 29% actuarial 5-year survival rate. All nine patients suffered locoregional recurrence. The investigators advocated that surgery alone was ineffective in obtaining local control, and that preoperative RT should be considered (201).

Reid et al. (36) reported an overall 17% 5-year survival rate in a report of 15 patients, including 13 who underwent surgery. In addition, they reviewed the literature, summarizing the results achieved in 115 patients with vaginal melanoma, and compared outcomes for the 55 patients who underwent some form of surgery, including the 24 treated conservatively

with wide local excision or partial vaginectomy, to the 31 treated with more radical excisions. No difference in survival or disease-free survival was found among the different surgical procedures (36). In a meta-analysis of essentially the same patient population (n = 119 patients), Van Nostrand et al. (206), after adding eight of their own cases, reached different conclusions. They stated that radical surgery is recommended for patients with primary vaginal melanomas of less than 10 cm². In the Van Nostrand et al. series of their own eight patients with vaginal melanoma, including four treated conservatively and four undergoing radical surgery, the only long-term survivor was in the radical surgery group. In their review of the literature, comprising a total of 119 patients, there was 48% 2-year survival rate if treated with radical surgery (50 patients) versus only 20% if treated conservatively (69 patients) ($P < 0.005$). Therefore, Van Nostrand et al. advocated radical excision for those vaginal melanomas less than 10 cm² in area (206).

Not all authors support a radical resection approach. Buchanan et al. (202) performed a literature review of 66 cases reported since the publication of Reid et al. (36). Survival was influenced by tumor size, with a median survival time of 41 months of those with lesions <3 cm and 21 months in those with larger lesions. However, there was no statistically significant difference in median survival or 2- and 5-year survival among the various surgical strategies. Hence, many investigators have adopted the suggestion of Irvin et al. (204) that if distant failure and death are expected, quality of life should be optimized by wide excision followed by RT to affect local control, while obviating the need for disfiguring radical surgery (162). In the Irvin et al. series (204), all patients treated with wide local excision or brachytherapy alone developed recurrent disease locally, whereas those patients treated with radical surgical resection or with wide local excision followed by high-dose-per-fraction EBRT maintained locoregional control until death.

Recent retrospective data suggest that vaginal melanoma is reasonably radioresponsive and possibly radiocurable (204,207). Volumes and doses of irradiation are similar to those used for epithelial tumors, ranging from 50 Gy for subclinical disease to 75 Gy for gross tumors. Retrospective analysis suggested a dose-response curve of melanoma to external beam irradiation as the dose per fraction is increased and fractions of 3.5 Gy three times weekly to 5 Gy twice weekly have been used to treat melanoma because of a large D_{90} observed in *in vitro* studies (208,209). However, the Radiation Therapy Oncology Group conducted a prospective randomized study (RTOG 83-05) (210) evaluating the effectiveness of high-dose-per-fraction irradiation in the treatment of melanoma. Patients with measurable lesions were randomized to 4 \times 8.0 Gy in 21 days once weekly to 20 \times 2.5 Gy in 26 to 28 days, 5 days a week. One hundred thirty-seven patients were randomized and 126 patients were evaluable; stratification was performed on lesions <5 cm or \geq 5 cm. There was no difference between the two arms in terms of response rate (complete responses 24.2% and 23.4% in the 4 \times 8.0 Gy and in the 20 \times 2.5 Gy arms, respectively) (210).

Chung et al. (34) reported on 19 cases of primary vaginal melanoma. Local tumor control was obtained by primary radical surgery in five of seven patients, three of whom later died of disseminated disease. Six of eight patients treated primarily with radiation therapy died with metastatic melanoma; another died after pelvic exenteration for persistent local disease. The overall 5-year survival rate for these 16 patients was 21%. Harwood and Cummings (211) described a complete response in four patients with vaginal melanoma treated with irradiation, although two subsequently relapsed; complete response to irradiation was seen in one patient who was alive and well 10 months after treatment. Harrison et al. (212)

reported that one of three patients with vaginal melanoma treated with irradiation survived 7.5 years; the other two died with distant metastases but had local tumor control. Rogo et al. (213) reported on 22 cases of vulvovaginal melanoma treated with conservation surgery or irradiation, or both. Eight patients (36%) were alive 5 years and four 10 years after treatment. Inguinal lymph node recurrences and distant metastases were the most common modes of failure. Results were comparable with those obtained with radical surgery.

In the Petru et al. series (207) of 14 patients, the three long-term survivors received either primary RT after biopsy only, or adjuvantly after local excision. Tumor size was found to be prognostically important, with 43% of patients with tumors ≤ 3 cm surviving longer than 5 years, compared with 0% of patients with tumors > 3 cm. The median overall survival was 10 months, and the 5-year DFS and overall survival rates were 14% and 21%, respectively. The authors concluded that prolonged local control could be obtained with RT as an adjunct to more limited surgery, or even with RT alone, primarily in patients with lesions ≤ 3 cm in diameter.

In summary, given that the high incidence of distant metastasis remains a major factor in limiting curability, a more conservative treatment approach might be more reasonable in selected patients. Patients with vaginal melanoma should probably be managed in a manner similar to that recommended for cutaneous lesions (214). Wide local excision with 1- to 2-cm margins should be the surgical treatment of choice for most primary vaginal melanomas since radical surgery has failed to improve long-term survival. The role of adjuvant RT is unclear, but it appears to improve survival in some series. The use of systemic chemotherapy and/or immunotherapy has been very disappointing in the limited published data (215).

Sarcomas of the Vagina

Sarcomas represent 3% of vaginal primaries (4) with leiomyosarcoma representing 50% to 65% of vaginal sarcomas. Unfortunately, most of the sarcomas are diagnosed at an advanced stage. Histopathologic grade appears to be the most important predictor of outcome (39). Most vaginal leiomyosarcomas arise from the posterior wall of the vagina. Radical surgical resection, such as posterior pelvic exenteration, offers the best chance for cure for vaginal leiomyosarcomas (4,216). The largest series on vaginal sarcomas reported to date included 17 cases, of which 35% had received prior RT. This series, which included ten leiomyosarcomas, four malignant mixed müllerian tumors (MMMTs), and three other sarcoma types, noted that all were resistant to chemotherapy, and all of the failures were first noted as pelvic recurrences. There were only three survivors seen, and all had undergone exenterative surgery. The 5-year survival rate was 36% in patients with leiomyosarcoma and 17% in those with MMMT (85).

Vaginal MMMTs occur more commonly in postmenopausal women. In approximately half of the cases there is a history of prior pelvic RT (85,217). Despite surgery and adjuvant RT, patients usually do poorly, with a high incidence of local and distant recurrences. The treatment of choice is complete surgical resection, followed by EBRT and ICB in an attempt to decrease the local recurrence rate.

The roles of adjuvant chemotherapy and RT in vaginal sarcomas have not been clearly defined, primarily owing to limited patient numbers and even fewer data where chemotherapy was used as the primary treatment rather than as salvage therapy at recurrence. Adjuvant RT seems to be indicated in patients with high-grade tumors and locally recurrent

low-grade sarcomas. According to Peters et al. (85) the most common site of failure is the pelvis. In 50% of patients with recurrence, it is the only site of failure. Extrapolating data from the Gynecologic Oncology Group (218) for uterine sarcomas and considering patterns of failure, patients with localized MMMTs would be appropriately treated with pelvic exenteration, or with more limited surgical resection followed by postoperative RT, unless the patient has received prior pelvic RT. Since patterns of failure suggest that local therapies only reduce the local recurrence rate and do not improve survival, consideration should be given to adjuvant treatments with agents that are active in similar tumors arising in the uterus. Agents found to be active in MMMT of the uterus include ifosfamide, cisplatin, and paclitaxel, although it remains unclear whether any combination of these agents is better than ifosfamide alone, which has produced the highest response rate among these agents (219,220). Doxorubicin remains the standard therapy for leiomyosarcoma (221).

Embryonal rhabdomyosarcoma (RMS) of the vagina, the most common pediatric vaginal tumor, is such a rare lesion that no single institution has sufficient experience to identify superior therapeutic strategies. Rather, cooperative efforts through the Intergroup Rhabdomyosarcoma Study Group (IRSG) through numerous clinical trials have demonstrated that the use of multimodality therapy with wide local excision and cytotoxic chemotherapy with or without RT makes it possible to avoid exenterative surgery and optimize quality of life for these young patients (50,222–224). Prior to the modern era of multimodality therapy, Hilgers reported that only 20% to 30% 5-year survival rates were achieved with the use of exenterative-type surgery alone (225). Later, several small series noted that 70% survival could be achieved if RT and combination cytotoxic chemotherapy including vincristine, actinomycin D, and cyclophosphamide (VAC) were given in addition to radical surgery (84,225,226). After complete resection, irradiation of the entire pelvis is not required, thus avoiding its adverse effects.

In a series of reports from the IRSG, survival rates in excess of 85% have been achieved utilizing VAC chemotherapy and wide excision with or without adjuvant RT, sparing the great majority of patients from exenterative surgery (222–224, 227,228). In a subsequent report, Andrassy et al. (229) from the IRSG summarized the outcome of 72 patients with embryonal RMS of the vagina treated on four IRSG trials. Over the course of the four IRSG trials, the need for radical resection decreased from 100% to 13%, with continued improvement in disease-free survival (229). Andrassy et al. suggested that after biopsy to document RMS, multiagent induction chemotherapy with doxorubicin, cisplatin, vincristine, actinomycin D, and cyclophosphamide should be utilized, then local resection undertaken, with radical resection being reserved for those with persistent or recurrent disease (229). In addition, several non-IRSG series have shown that combination chemotherapy with or without RT leads to sufficient tumor shrinkage, and that less radical resections can become feasible (227,228), allowing preservation of anatomy and function.

Flamant et al. (227) reported 11 cases of vaginal RMS (8 stage I, 2 stage II, 1 stage III) in whom 100% survival was achieved with multimodality therapy. Eight patients received neoadjuvant chemotherapy, generally a VAC regimen, and all patients underwent brachytherapy (doses of 26 to 75 Gy), followed by maintenance chemotherapy and VAC alternating with VAD (vincristine, doxorubicin, dacarbazine). Seven patients underwent ovarian transposition in an attempt to preserve function. The investigators noted partial ovarian insufficiency in one patient without ovarian transposition. They recommended brachytherapy at a total dose of approximately 50 to 60 Gy (227).

Lymphomas and the Vagina

Lymphomatous involvement of the vagina most often represents metastatic spread from another primary site. Although surgery including radical hysterectomy, pelvic lymphadenectomy, vaginectomy, and exenteration has been performed in the past, more recent reports suggest that combination RT and chemotherapy can achieve excellent results. Radical surgery in such patients then should be avoided, as lymphoma represents a systemic disease. Following biopsy, patients with lymphoma should be managed with chemotherapy alone or combined chemoradiation. Extrapolation from patients with similar tumors arising in extranodal sites would suggest that RT has its primary role in preventing local recurrence in patients who present with bulky disease. In some patients who have a rapid and complete response to multiagent chemotherapy, RT may not be indicated since the combination of both modalities increases the risk of second malignancies. Harris and Scully noted in a clinicopathologic series of 25 lower genital tract lymphomas, including four vaginal lymphomas, that definitive local therapy prevented relapse (98). Prevot et al. (230) and Perren et al. (231) also advocated the use of less extensive surgery, with RT plus cytotoxic multiagent chemotherapy such as CHOP (cyclophosphamide, hydroxydaunomycin [doxorubicin], Oncovin [vincristine], prednisone) or BACOP (bleomycin, Adriamycin [doxorubicin], cyclophosphamide, Oncovin [vincristine], prednisone) for four to six cycles to affect local control with better preservation of fertility in patients with stage IE and nonbulky tumors of low and intermediate grade.

Yolk Sac (Endodermal Sinus) Tumors of the Vagina

Prior to the use of multiagent cytotoxic chemotherapy, less than 25% of patients with yolk sac tumor (YST), or endodermal sinus tumor (EST), of the vagina survived. However, Young and Scully noted 100% survival in a small series of six patients who had received chemotherapy (232). The VAC regimen in conjunction with surgery or RT was advocated by Copeland et al. (233). Collins et al. (234) reported on the use of combination bleomycin, vinblastine, and platinum (BVP) for patients with EST of the vagina. Aartsen et al. (235) reported a successful pregnancy following surgery and chemotherapy. Most recently, Hwang et al. have reported two cases, one of which did well with partial vaginectomy followed by 2 years of VAC; however, the second one developed a central persistence following wide local excision and VAC, but was salvaged with bleomycin, etoposide, and platinum (BEP) (236). Given the excellent results that three to four cycles of BEP have achieved in malignant germ-cell neoplasms of the ovary (237), it is likely that BEP will become the preferred regimen for EST of the vagina used in conjunction with parital vaginectomy, as it requires less prolonged administration and is less oophorotoxic than VAC. It appears that routine use of combination chemotherapy in the management of endodermal sinus tumor allows conservative surgery with preservation of sexual function in young patients, with excellent prospects for long-term survival.

The role of radiation in this disease is limited because of the younger age at presentation, and preservation of ovarian function is desired; in addition, RT would potentially increase the risk for secondary malignancies (238,239), which may be even more significant with the use of IMRT as the volume of irradiation receiving lower doses is generally larger (240). Brachytherapy may occasionally be used, and in one instance, preservation of hormonal function and subsequent pregnancy were reported (235).

OTHER UNCOMMON VAGINAL CANCERS

Squamous Cell Carcinoma of the Neovagina

In situ and invasive carcinomas arising in the neovagina are rare, and this type of malignancy seems to be related to the transplanted tissue. A few cases of squamous cell carcinoma have been described after split-thickness skin graft vaginoplasty in patients with vaginal agenesis (241–243), as well as after radical vulvo-vaginal resection for known malignancy (244). Mucinous adenocarcinoma has been described arising in the sigmoid colon used for the reconstruction of the neovagina (76). Neovaginal malignant melanoma following surgery and radiation therapy for vulvo-vaginal malignancies, although extremely rare, has been reported (245), suggesting the potential role of radiation-induced melanoma in non-sun-exposed areas such as the genital tract.

Malignant transformation occurs in the neovaginal epithelium, in relation with local carcinogenic environmental factors as well as possible viral infection, with the subsequent risk of malignancy. Therefore, it is important to emphasize the need for regular follow-up visits with Pap smears. The elapsed time between the construction of the neovagina and the development of malignancy ranges between 10 and 30 years. The optimal treatment is not well defined. Radical surgery resection when possible should be the treatment of choice, since definitive RT seems to be associated with higher failure rates (241). Adjuvant RT could be considered in patients with positive margins or positive nodes (76).

Carcinoma in Episiotomy Scar

Episiotomy scar tumor implantation from a cervical or vulvar carcinoma is a very rare event. Van Dam et al. (246) reported on three cases of primary or metastatic carcinoma in an episiotomy scar. One patient had a primary squamous cell carcinoma of the vulva in an episiotomy scar; a second patient was diagnosed with cervical carcinoma 6 months postpartum and was found to have a metastatic deposit in the episiotomy scar during the staging of her disease; the third patient developed adenocarcinoma metastatic from an endocervical primary in an episiotomy scar that presented as a small nodule at the introitus. These cases exemplify the need for careful inspection and biopsy of any nodular lesions in episiotomy scars as part of the initial assessment and follow-up of patients with premalignant or malignant lesions of the lower genital tract. Early initial stage, small size lesion, and early therapy appear to improve prognosis. Treatment needs to be individualized given the rarity of this entity. Patients with limited recurrent disease at the episiotomy site without any other evidence of locoregional recurrence could be treated with surgical resection followed by tailored radiation therapy. Patients with more advanced disease may be offered radiation with or without chemotherapy followed by surgical resection when feasible (247,248).

SALVAGE THERAPY

In general, the patient with recurrent cancer of the lower female genital tract presents a difficult clinical dilemma. Optimal therapy for patients with recurrent gynecologic cancer after potentially curative therapy has not been completely defined, partly owing to the difficulty of conducting prospective, randomized trials in this heterogeneous population. It must

be determined if the disease is amenable to curative salvage therapy, implying some reasonable chance of cure, or whether palliation is the primary goal. Treatment selection factors include primary therapy, extent of the disease at presentation, site of recurrence, extent of the recurrence, disease-free interval, evidence of metastatic disease, patient age, performance status, and coexisting medical conditions. The presence of distant metastasis portends a poor prognosis, and although chemotherapy may result in objective responses and improvements in short-term survival, the current lack of curative systemic treatments focuses therapeutic attempts on symptom palliation and quality of life. In most cases, only patients with small volume local recurrences and no metastatic disease are curable. Therefore, careful workup to establish extent of disease is crucial. When salvage therapies are contemplated, local recurrences should be confirmed by biopsy, and, when possible, parametrial recurrences should be documented pathologically. Pelvic sidewall involvement can almost always be diagnosed in the presence of a symptom triad of sciatic pain, leg edema, and hydronephrosis. It is important to evaluate for regional and/or distant metastasis by physical examination and imaging studies such as CT or MRI scans. More recently, the positron emission tomography (PET) scan has been used to document the extent of recurrent disease (249), but both false-positive and false-negative results have been reported.

Generally, patients with isolated pelvic or regional recurrences after definitive surgery who have not received prior RT are managed with EBRT, often in conjunction with brachytherapy. Concurrent cisplatin-based chemotherapy may also be recommended. Salvage options for patients with central recurrence after definitive or adjuvant RT are limited to radical surgery, usually exenterative, or, in selected patients with small volume disease, reirradiation using interstitial radiation implants or highly conformal three-dimensional EBRT. Response rates with chemotherapy are low and the impact on survival is limited. Further, response to chemotherapy in central pelvic recurrences following RT tends to be less common than response at distant sites. Additionally, prior high-dose radiation therapy compromises bone marrow tolerance of many agents that are active in this tumor (e.g., ifosfamide and doxorubicin). However, chemotherapy-responsive patients can obtain meaningful palliation in many cases.

Surgical Considerations

Despite thorough clinical evaluation of patients considered to be excellent candidates for salvage surgery, this will be aborted in over 25% of the cases because of advanced disease found at the time of the exploratory laparotomy (250). Pelvic exenteration results in long-term functional and psychologic changes that have not been adequately studied (251). Surgical refinements have done much to improve body image changes associated with pelvic exenteration. The purposes of vaginal and perineal reconstruction following radical pelvic surgery for recurrent gynecologic cancer are primarily twofold: to restore or create vulvovaginal function, and thereby minimize the effects of surgical treatment on body image and normal sexual activity, and to minimize postoperative complications by transferring to the pelvic defect healthy tissue with a good blood supply (143,144). A detailed review of urinary diversion and pelvic reconstruction techniques is not within the scope of this chapter.

Radiation Therapy Considerations

Those patients who have not received prior RT should receive whole-pelvis EBRT followed, when feasible, by brachytherapy.

Generally, the whole pelvis receives a dose of 40 to 50 Gy. Inguinofemoral lymph node regions should be included in patients with involvement of the distal third of the vagina or with vulvar recurrences. The gross tumor volume in the vagina, paravaginal tissues, and/or parametrium should receive an additional boost, preferably with an interstitial implant, to bring the total tumor dose to 75 to 80 Gy. The role of combined chemoradiotherapy in the management of patients with recurrent disease is unknown. Given the rarity of vaginal carcinoma and the heterogeneity within the population with recurrent disease, large randomized studies intended to answer this question will probably never be conducted. However, by extrapolation from the available data for locally advanced cervical and vulvar cancer (181–184), it seems that a combined modality approach may improve the locoregional control and survival in patients with isolated pelvic recurrences.

Reirradiation in previously irradiated patients must be undertaken with extreme caution. However, selected patients who are medically inoperable, technically unresectable, or refuse to undergo exenterative surgery are appropriately considered for reirradiation to limited volumes. A variety of techniques is available, and the choice is based on patient and tumor-related factors, as well as the experience of the radiation oncologist. When using EBRT, multiple-beam arrangements utilizing three-dimensional treatment planning are favored. Only limited doses are possible, and the physician might consider a hyperfractionated regimen in an attempt to decrease the incidence of late toxicity. In patients with small, well-defined vulvovaginal or pelvic recurrences, reirradiation using primarily interstitial techniques has been attempted with control rates between 50% and 75% and grade 3 or higher complication rates between 7% and 15% (252–256). The rationale, logistics, and selection of implant technique when performing an interstitial implant (ITI) were reviewed earlier in the chapter. Permanent radioactive seed implants (e.g., ¹⁹⁸Au) in patients with small vaginal recurrences often provide long-lasting tumor control in elderly or medically debilitated patients previously treated with definitive doses of RT (253).

Other potential treatment options include the use of surgery and intraoperative RT (IORT) with intraoperative electron beam (257,258), laparotomy, or laparoscopically guided placement of HDR catheters (172,257,259,260), which allows direct visualization of the target volume and displacement and/or shielding of the surrounding normal tissues. However, the published series are generally small, including a wide spectrum of patients with different gynecologic malignancies, varying amounts of residual disease, and disparate initial therapies. The locoregional recurrence and distant metastasis rates after IORT vary between 20% and 60% and 20% and 58%, respectively. The 3- to 5-year actuarial survival is poor, ranging from 8% to 25%. Grade 3 or higher toxicity has been reported in about 35% of patients (257,258). In the Memorial Sloan-Kettering Cancer Center experience using radical surgical resection and HDR-IORT, patients with complete gross resection had a 3-year local control rate of 83% compared to 25% in patients with gross residual disease. Interestingly, most of the failures in the microscopic group were distant, perhaps indicating a potential role for adjuvant chemotherapy (259).

Hockel et al. (260) described a combined operative and radiotherapeutic treatment (CORT) for the treatment of recurrent gynecologic malignancies infiltrating the pelvic sidewall. The procedure involves gross complete resection of the tumor and a single plane interstitial implant. In order to improve the therapeutic index, well-vascularized tissue is transposed to the pelvis to protect the hollow organs and reduce the late effects of RT. Reconstruction of pelvic organs is performed as with exenteration. The tumor bed is irradiated postoperatively, days 10 to 14, using HDR brachytherapy. In a

total of 48 patients treated with this technique, the overall severe complication rate was 33% at 5 years. The 5-year survival rate was 44%, and the absolute local control rate was 60% for the first 20 patients and 85% for the last 28 treated patients (260).

Stereotactic body radiotherapy (SBRT), also known as extracranial stereotactic radioablation (ESR), is a novel treatment paradigm that delivers a small number of high-dose fractions to extracranial targets using a linear accelerator with highly precise, accurate, and reproducible target localization based on the same principle as that of gamma-knife therapy. By means of better target localization and patient immobilization, smaller margins of normal tissue surrounding the gross tumor volume are required, which allows treatment complications to be minimized. Blomgren et al. (261) reported on 15 patients with 19 extrahepatic abdominal tumors who had a mean survival of 17.7 months. The toxicity was more often self-limited except for four patients with gastrointestinal bleeding. They concluded that this treatment, which is noninvasive, painless, rapid, and does not require hospitalization, does not impair the quality of life of the patients when used properly.

PALLIATIVE THERAPY

Radiation Therapy

At the present time, there is no curative option for patients who present with stage IVB disease. Many of these patients suffer from severe pelvic pain or bleeding. If vaginal bleeding is the main concern, ICB, if feasible, often offers good symptom control with relatively low morbidity. For patients who have received prior RT, intracavitary doses in the range of 35 to 40 Gy to point A should be prescribed. A short course of EBRT using high-dose fractionation schedules has been used, including single doses of 10 Gy per fraction, times three, with an interval of 4 to 6 weeks between courses, combined with misonidazole (RTOG clinical trial 79-05), resulting in significant palliation in selected patients with advanced gynecologic malignancies. The overall response rate was 41% for patients completing the three courses; however, the actuarial 45% incidence of grades 3 and 4 late gastrointestinal toxicity was unacceptable (262).

Spanos et al. (263) reported on a phase 2 study (RTOG 85-02) of daily multifraction split-course EBRT in patients with recurrent or metastatic disease. The regimen consisted of 3.7 Gy per fraction given twice daily for 2 consecutive days and repeated at 3- to 6-week intervals for a total of three courses (tumor dose 44.4 Gy). Occasionally, this regimen was combined with an intracavitary implant (ICI) (4,500 mgh), with a midline block in the last 14.4 Gy. Complete tumor response was noted in 15 patients (10.5%) and partial response in 32 (22.5%). In patients completing three courses of irradiation (59%), the rate of complete or partial response was 45%. Twenty-seven patients survived longer than 1 year. Late complications were significantly fewer, with a projected actuarial rate of 5% at 12 months. In a subsequent phase 3 study (210), 136 patients were randomized between rest intervals of 2 versus 4 weeks between the split courses of RT. Decreasing the interval between courses did not result in a significant improvement in tumor response (34% vs 26%). More patients in the 2-week rest group completed the three courses of therapy, and not surprisingly, patients completing all three courses had a higher overall response rate than patients completing less than three courses (42% vs 5%) and a higher complete response rate (17% vs 1%). This schedule offers significant logistic benefits, and has been shown to result in good

tumor regression and excellent palliation of symptoms (264). Spanos et al. (265) reported a trend toward increased acute toxicity in patients with shorter rest periods, but late toxicity was not significantly different in the two groups.

Chemotherapy in Advanced and Recurrent Vaginal Cancer

Given its rarity, most chemotherapy reports for treatment of metastatic disease in vaginal cancer are anecdotal or combined with reports of treatment of advanced or recurrent cervical cancer. Concurrent chemoradiation is frequently employed in clinical practice in the treatment of unresectable, locoregionally advanced disease. Various chemotherapeutic agents have been used with limited success (176,177). Evans et al. (176) reported on seven patients with vaginal cancers who were treated with a combination of 5-FU 1,000 mg/m²/d for 4 days, mitomycin C 10 mg/m² day 1, and primary irradiation, receiving 2,000 to 6,500 cGy. All of the vaginal cancer patients responded, and 66% were alive with a median follow-up of 28 months. Treatment of recurrent or metastatic disease is confined to a handful of phase 2 clinical trials and anecdotal reports. In general, regimens that are active in cervical cancer are usually active in vaginal cancer. Thigpen et al. (220) reported the results of a phase 2 trial of cisplatin 50 mg/m² every 3 weeks in 26 patients with advanced or recurrent vaginal cancer. There were 22 evaluable patients, 16 with SCC, two adenocarcinomas, one clear cell carcinoma (CCC), one leiomyosarcoma, and two unspecified. Of the 16 SCC patients, there was one complete response (6.2%). It should be noted that these patients, for the most part, had received prior surgery and RT. Muss et al. (266) reported no responses in 19 evaluable patients who were treated with mitoxantrone 12 mg/m² every 3 weeks. Median survival of patients with vaginal cancer was 2.7 months. Other anecdotal reports of responses in trials that included advanced cervical cancer include a report by Long et al. (267) in which three patients with advanced vaginal SCC received treatment with methotrexate, vinblastine, doxorubicin, and cisplatin (MVAC). All three patients achieved a complete response of short duration. Patton et al. (268) reported the results of intra-arterial chemotherapy with mitomycin C, bleomycin, cisplatin, and vincristine, including six patients with primary vaginal cancer and 40 patients with cervical cancer. Seventy-six percent responded to intra-arterial chemotherapy and subsequently received primary RT. The report did not give details as to site of relapse, impact on disease-free survival, or overall survival.

At the present time, data on systemic treatment of advanced vaginal cancer outside of a clinical trial is purely anecdotal, although it might be reasonable to extrapolate from the experience reported with SCC of the cervix and vulva (180-184). Although published response rates are low, standard therapy should include cisplatin alone or in conjunction with RT in patients with locoregionally advanced vaginal cancer.

SUMMARY AND CONCLUSIONS

The malignant histologies of the vagina are so rare that randomized clinical trials have not been undertaken. It is difficult to establish strong, evidence-based recommendations in such a rare disease as cancer of the vagina. Therefore, future progress will likely come from reports from single institutions. Most of the available data refer to the treatment of primary invasive SCC of the vagina, since this represents the most common histology. The following management recommendations are made based on the available data.

Vaginal Intraepithelial Neoplasia

In patients with unifocal disease, partial colpectomy has come to be favored over laser vaporization, since there is an approximately 25% risk that there can be underlying invasive disease, and one quarter to one third of patients will require a second laser vaporization to effect long-term control. However, for patients who develop VAIN following radiation wherein colpectomy would be associated with a higher risk of fistulae development, there may be a role for laser vaporization and/or topical 5-FU application. Intracavitary brachytherapy alone has provided satisfactory functional and local control results as well.

Invasive Squamous Cell Carcinoma

Although RT can control many cases of vaginal cancer, local control remains a problem. The treatment of invasive SCC with RT should include the use of brachytherapy, with particular attention to technique that ensures that the treatment volume is adequately covered. In larger tumors, the dose that is needed to achieve local control may well exceed the tolerance of surrounding normal tissues. Although not specifically proven for patients with vaginal primaries, the addition of chemotherapy (i.e., weekly cisplatin) as a radiosensitizing agent may help to improve these results if the strong evidence in locally advanced cervical cancer can be extrapolated to vaginal cancer. Although there are multiple series that demonstrate excellent results with radical surgery for well-selected early-stage patients, RT will continue to be the primary modality even for early-stage disease and for those elderly patients with multiple comorbid conditions.

Clear Cell Adenocarcinoma

It has been suggested that patients with early-stage disease may be offered fertility-sparing combined modality local therapy with extraperitoneal node dissection and wide local excision followed by brachytherapy with acceptable local failure rates. However, advanced-stage disease would require primary RT. Patients who have completed childbearing would be best served by radical hysterectomy, colpectomy, and lymphadenectomy. Exenteration should be reserved for those patients who have isolated central failures following definitive RT.

Melanoma

The risk of distant metastases is high enough that most modern investigators have suggested that ultra-radical surgery, although it might improve 2-year survival rates, has not led to an increase in long-term survival. Wide excision followed by RT to effect local control may obviate the need of disfiguring surgery in those likely destined to develop distant metastases.

Sarcoma

The trials conducted by the IRSG and others have demonstrated that pediatric embryonal RMS of the vagina is best approached with induction multiagent-combination therapy, e.g., VAC, followed by local resection with or without brachytherapy, with radical surgery being reserved for those with persistent or recurrent disease. Patients with adult-onset vaginal sarcoma do not respond as well to chemotherapy, and the only long-term survivors are those who have been offered exenterative surgery.

CHAPTER 22 ■ UTERINE CERVIX

MARCUS E. RANDALL, HELEN MICHAEL, HARRY LONG III, AND SEAN TEDJARATI

EPIDEMIOLOGY

Worldwide, cervical cancer is the third most common malignancy, and the second most common cancer (after breast cancer) in women. Nearly one-half million new cases occur each year (1). The majority of cases occur in developing countries without availability of routine Papanicolaou (Pap) smear screening. Cervical cancer is the leading cause of death of women from cancer in developing countries (1). The highest incidence of the disease is seen in Central and South America, southern and eastern Africa, and the Caribbean (2). There is a correlation between incidence and mortality in a given area, but Africa appears to have a disproportionately higher mortality (2). The incidence and mortality of this disease in North America have declined during the last half-century owing to both increased availability of Pap smear screening and a decrease in fertility rate. These declines in incidence have slowed in recent years, and there is a trend toward increasing incidence in some populations of white women in the United States (2). Cervical carcinoma is the 12th most common malignant tumor in women in the United States (3), but black and Hispanic women are disproportionately affected (4).

RISK FACTORS AND ETIOLOGY

Cervical cancer is a sexually transmitted disease associated with chronic infection by oncogenic types of human papillomavirus (HPV). Therefore, risk factors for cervical cancer are the same as those for sexually transmitted disease, including early age at onset of sexual activity, multiple pregnancies, long duration of oral contraceptive use, other sexually transmitted infections including chlamydia and herpes simplex virus, immunosuppressed states such as renal transplant, and multiple sexual partners. Tobacco smoking is also a risk factor for cervical cancer (5). Cigarette smoking may be a cofactor for development of high-grade cervical dysplasia in women who have chronic HPV infections (6). Patients infected with human immunodeficiency virus (HIV) are often also infected with HPV, and they have higher rates of cervical dysplasia and progression to invasive carcinoma than HIV-negative women (7).

Human Papillomavirus

Human papillomavirus is a double-stranded DNA virus of approximately 8 kd, and contains eight open reading frames and a non-coding region that contains transcriptional regulatory sequences (8). Over 30 recognized oncogenic strains of

HPV and over 70 nononcogenic strains of HPV have been described to date (9,10). Oncogenic strains in order of decreasing prevalence include HPV-16, -18, -45, -31, -33, -58, -52, -35, -59, -56, -6, -51, -68, -39, -82, -73, -66, and -70. In the United States, HPV-16 and -18 account for approximately 70% of cervix cancers. The HPV genomes code for six early (E) and two late (L) open reading frame proteins (11). High-risk HPV genotypes code for three early proteins (E5, E6, and E7) with cellular growth-stimulating and transforming properties. The E5 protein is expressed during active HPV infection, and the open reading frame is often deleted in cervical carcinoma (11). It has weak transforming activity and can activate membrane-associated protein kinases. The E6 protein binds to p53, results in chromosomal instability, activates telomerase, inhibits apoptosis, and results in cellular immortalization (11). The E7 protein binds to retinoblastoma protein (Rb), inactivating the Rb protein-related pocket proteins, activates cyclins E and A, inhibits cyclin-dependent kinase inhibitors, and also results in cellular immortalization (11). In cells with p53 mutations, E7 exerts an antiapoptotic effect (11). HPV E6 and E7 have numerous other functions, and together with those outlined above, lead to dysplasia and malignant transformation of cervical epithelium. High-risk HPV types are identified in a high percentage of patients with adenocarcinoma of the cervix (12) and small cell carcinoma of the cervix (13) in addition to the more common squamous carcinoma of the cervix.

Cellular and humoral immune responses are likely to be involved in the resolution of HPV infection, and deficiencies may result in more rapid progression to dysplasia and carcinoma. CD4⁺ T-lymphocytes have been described with increased prevalence in the stroma and epithelium of regressing early cervical intraepithelial neoplasia (CIN) (14) compared to progressed CIN, CIN 3, and squamous cell carcinoma (SCC). Histologically determined CD4⁺/CD8⁺ ratios declined as HPV⁺ patients progressed from CIN 1 to SCC. (8).

Almost 50% of women will be infected with the HPV virus within 4 years after onset of sexual activity. Despite a high prevalence of HPV, only 5% to 15% will develop cervical dysplasia (15,16). HPV attaches to basal epithelial cells and remains elusive to the reticuloendothelial system. It can amplify to more than 1,000 genomes per cell without cell lysis, enhancing its ability to escape a host immune response.

The age-specific HPV prevalence peaks between 25 to 35 years of age when exposure is at its greatest. In a large cohort study, Ho et al. evaluated over 600 female college students and found a cumulative incidence of new HPV infection of 43%. The two-year clearance rate of HPV was over 90% and only 5% developed cytologic abnormality (15).

Concurrent Infection With HPV and HIV

HIV is a sexually transmitted virus that results in a decline in circulating CD4+ cells over time. It is not surprising, therefore, that concurrent HIV and HPV infections are commonly seen in sexually active patients, and that the HPV infection may more rapidly progress from chronic infection to dysplasia and cancer. Reports of abnormal cervical cytology as high as 78% have been reported in HIV+ patients compared to 38% of HIV- patients who are also HPV+ (17). HIV-infected women with low CD4+ lymphocyte counts (<200 cells/ μ L) were nearly twice as likely to have squamous intraepithelial lesion (SIL) than women with high CD4+ counts. This was confirmed in another report that noted no association with duration of HIV infection, antiretroviral therapy, or HIV viral load (18). HIV+ patients with concurrent HPV infection must be followed closely and should be aggressively treated for SIL. This combination is a particular problem in Equatorial Africa where the combination of HIV and HPV infections is prevalent. Antiretroviral therapy does not affect HPV-related disease in HIV-infected patients (7).

ANATOMY

The uterus, situated in the center of the pelvis, is composed of a muscular layer (myometrium) and mucosal layer (endometrium), which lines a hollow cavity extending from the top of the uterus (fundus) through the lower uterine segment connecting to the endocervical canal. The endometrial cavity is surrounded by the myometrium. The three segments of the uterus include the fundus, body, and isthmus (lower uterine segment). Anteriorly, the lower uterine segment is attached to the bladder peritoneum (vesicouterine pouch), which requires dissection and separation to expose the cervix. This compartment between the bladder and uterus is the anterior cul-de-sac. Posteriorly the peritoneum lines and separates the lower uterine segment and cervix from the rectum, creating the posterior cul-de-sac (pouch of Douglas). The cervix is an extension of the lower uterine segment and can be divided into vaginal and supra-vaginal components. The cervix varies in length, averaging 3 to 4 cm. Centrally in the vaginal portion is the external cervical os, which connects to the endocervical canal, the internal cervical os, and the endometrial canal.

The cervix is a fibrous organ lined by squamous and columnar cells. The transition from columnar cells to squamous cells occurs in the region of the cervical os in the transformation zone. Most cervical dysplasias and invasive cancers arise from this area. The endocervix contains mostly mucinous glandular epithelium.

The uterus has five ligamentous attachments. Specifically these include the round, broad, utero-ovarian, cardinal, and uterosacral ligaments. The round ligaments run from both sides of the fundus anterolaterally on top of the broad ligaments to the pelvic sidewall where they are closely related to the inferior epigastric vessels and continue on their path to leave the pelvis through the inguinal ring and canal. They contain a vessel known as Sampson's artery as well as other small vessels and nerves.

The broad ligaments attach to the lateral margin of the uterus on either side and extend underneath the round ligaments from above the cervicouterine junction and to the pelvic sidewall. These ligaments are covered by peritoneum anteriorly and posteriorly, and are relatively thinner above the cervicouterine junction. Within the leaves of the broad ligament are extraperitoneal connective tissues known as the parametrium.

The utero-ovarian ligaments originate just below the fallopian tubes and directly connect to the ovaries. The cardinal ligaments, also known as Mackenrodt's ligaments, are thickened extensions of the broad ligaments attaching laterally from the lower uterine

segment (isthmus) and the cervix. They course to the lateral vaginal wall and rectal pillars and extend to the pelvic sidewalls.

Each cardinal ligament helps create and define two important anatomical spaces, the pararectal and paravesical spaces, which are important in the surgical treatment of early cervical cancer. The cardinal ligament covers a portion of the pelvic ureter, which lies underneath the uterine artery and above the uterine vein about 2 cm away from the isthmus. It contains uterine, vaginal, middle rectal, and inferior vesical arteries and veins as well as lymphatic tissue and channels.

The uterosacral ligaments connect laterally to the cervix and lower uterine segment medial to the ureters. They run from the posteriolateral segment of the cervix over the top of the anterolateral portion of the rectum and attach to the rectal wall and the sacrum. The cardinal and uterosacral ligaments provide the bulk of support for the uterus and cervix.

The blood supply of the uterus is mainly through the uterine artery, originating from the anterior division of the hypogastric artery. An important landmark during a radical hysterectomy, the uterine artery spawns cervical and vaginal branches that supply the cervix, and then extends superiorly to the fundus where its tributaries supply the fundus and the body of the uterus. The uterine artery also descends toward the vagina and gives off a vaginal branch. The ovarian vessels originating from the aorta also contribute to the blood supply of the uterus. There is a rich anastomosis between the uterine and ovarian arteries. Other potential collateral blood supply to the uterus may be from the branches of the posterior division of the hypogastric, the ilio-lumbar artery, or other vessels supplying the pelvis such as middle sacral artery, and pudendal and obturator arteries. The venous drainage follows the arterial supply.

The lymphatic drainage of the cervix is rich and complex. Laterally from the cervix, the lymphatics drain into the paracervical and parametrial lymph nodes and to the internal, external, and common iliac chains. The obturator lymph nodes are the most medial portion of the external iliac nodal region. Other lymphatic drainage routes include the inferior and superior gluteal lymph nodes and the superior rectal, presacral, and para-aortic lymph nodes. The innervations of the cervix are from the sacral roots (S2-4) crossing through the hypogastric plexuses.

Two important anatomical landmarks during radical hysterectomy for treatment of early cervical cancer are the paravesical and pararectal spaces. The paravesical space is lateral to the bladder and can be opened by dissection underneath the insertion of the round ligament into the pelvic wall. The anterior wall is bounded by the superior pubic ramus, the medial wall is the bladder and vagina, the lateral wall is composed of the external iliac vessels and parts of the obturator fossa, and the posterior wall is formed by the cardinal ligament, separating this space from the pararectal space. This space can be continuous with the space between the bladder and the pubic bone, known as the space of Retzius.

The pararectal space is found between the ureter laterally and the origin of the hypogastric artery medially and follows the curve of the sacrum. Anteriorly it is bounded by the cardinal ligament. The lateral wall is formed by the hypogastric vessels. Medially it is bounded by the ureter, and the floor is composed of the curve of the sacrum down to the levator muscles.

NATURAL HISTORY

Preinvasive Disease

Cervical cancer is preceded by an interval of epithelial dysplastic changes, typically in the transformation zone, known as cervical intraepithelial neoplasia (CIN), which may progress to

invasive cancer. Low-grade dysplasia (CIN 1) is confined to the basal one third of the epithelium, whereas high-grade dysplasia (CIN 2-3) involves two thirds or greater of the epithelial thickness. Full thickness involvement is known as carcinoma *in situ* (CIS). Cytologic screening has helped in decreasing the incidence of cervical cancer in the United States and other developed nations by over 90%. Of approximately 50 million Pap smears performed in the United States annually, 5% to 7% are abnormal, and the majority of these are atypical squamous cells of undetermined significance (ASCUS) (19,20). The majority of the disease burden is in developing nations where screening and treatment programs are scarce (21).

Many studies have evaluated the natural history of cervical dysplasia. Holowaty et al. evaluated cervical dysplasia in about 17,000 women with mild, moderate, and severe dysplasia (22). The reported risk of progression from mild to severe dysplasia was 2% and 6% at years 2 and 5, respectively. However, progression from moderate to severe dysplasia was 16% and 25% at 2 and 5 years, respectively. The relative risks of progression from severe dysplasia to CIS and invasive cancer were 4.2 and 2.5, respectively, 2 years after diagnosis of dysplasia. The majority of mild dysplasias (CIN 1) regressed to normal within 2 years.

In a meta-analysis of 15 studies of 27,929 women, Melnikow et al. found 2-year progression rates to high-grade dysplasia to be 7% and 21% from ASCUS and low-grade dysplasia, respectively (23). The rate of progression to invasive cancer for ASCUS was 0.25%, as compared to low-grade dysplasia (0.15%) and high-grade dysplasia (1.4%). The regression rates to normal for ASCUS, low-grade, and high-grade dysplasias were 68%, 47%, and 35%, respectively.

The incidence of progression from CIS to invasive cancer in patients with persistent abnormal cytology after initial treatment was 24.8 times greater than in those who had normal cytology after initial treatment (24). Overall the reported rate of progression of CIS to invasive cancer ranges from 12% to 22% (24).

Most low-grade dysplasia will regress to normal in about 24 months. Therefore, only careful follow-up is warranted. However, women with high-grade disease or CIS should be more closely evaluated and treated aggressively as the risk of progression is higher (24).

Patterns of Spread

Cervical cancer can spread through direct extension to the endocervix, lower uterine segment, parametrium, vagina, and, less often, to the bladder and/or rectum. It can also spread lymphatically to the parametrial, obturator, and internal, external, and common iliac lymph nodes. Inferior and superior gluteal, superior rectal, presacral, and para-aortic lymph nodes can also become involved. The pattern of spread is usually predictable and orderly as the rate of para-aortic lymph node metastasis is very rare if the pelvic nodes were spared. The overall risk of pelvic lymph node metastasis in stage IB is about 17% (25,26). The risk of para-aortic nodal metastasis is higher with advanced stage with rates of 16% and 25% for stage II and III, respectively (27). Scalene nodal involvement is reported to be between 10% and 23% (28).

Girardi et al. reported data in 163 patients who had undergone radical hysterectomy, finding that when the parametrial nodes were not involved, the rate of pelvic nodal involvement was 26% (29). However, when the parametrial nodes were involved, the incidence of pelvic lymphatic spread was over 80%.

The most common sites of hematogenous spread include lung, mediastinum, bone, and liver. Other less common sites are spleen, brain, and adrenal. Most recurrences occur in the first 24 months with a median of 17 months (30).

CLINICAL PRESENTATION AND DIAGNOSTIC EVALUATION

Preclinical Invasive Disease

Screening and Cytology

In 2007, 11,150 women were expected to be diagnosed with invasive cervical cancer in the United States, and about 3,670 of them were expected to succumb to the disease (31). These statistics represent a dramatic reduction from statistics prior to introduction of cervical cytology screening programs in the 1950s. However, in developing nations it is one of the leading causes of cancer death (32). This disparity is essentially due to availability of cytologic screening programs in developed nations.

The effectiveness of screening cytology is related to the ease of obtaining specimens, the sensitivity of the test, and a long dysplastic phase that can be detected via cytology and effectively treated with high success rates. There are currently two primary means of obtaining and diagnosing cervical dysplasia. One is the conventional Pap smear and the other is liquid-based thin layer preparation.

Using classification as low-grade squamous intraepithelial lesion (LSIL) as the threshold, Nanda et al. reported a large variation in the sensitivity of conventional smears with published data ranging from 30% to 87%; specificity was much higher at 86% to almost 100% (33). Cytologic screening is a continuum in which sensitivity is increased through sequential testing. The most common reasons for false-negative smears are errors in sampling and preparation. In 1996, liquid-based cytology was introduced in the United States. Cells are obtained by a Cytobrush and transferred into a buffered alcohol medium. The suspended cells are then plated in a thin, evenly distributed layer, improving the clarity of the slide for evaluation. Another benefit is that the specimen can be tested for HPV, gonorrhea, and chlamydia. Although the data is conflicting, it appears that liquid-based cytology may be superior to conventional cytology in minimizing the number of unsatisfactory smears and increasing detection rates of low- and high-grade abnormalities (34). Sulik et al. reported no difference between the two methods in a large systematic review (35). The American Cancer Society (ACS) and U.S. Preventive Services Task Force (USPSTF) have concluded that, although liquid-based technology may be more sensitive than conventional cytology, there was insufficient evidence to recommend universal adoption. The American College of Obstetricians and Gynecologists (ACOG) does not support changing screening intervals based on the method of screening (36).

The current recommendation is to start cytologic screening within 3 years after onset of sexual activity or when a woman reaches the age of 21. The ACS recommends annual screening until age 30 with conventional Pap smear or every other year if liquid-based cytology is used. If a woman has two to three normal smears, the screening interval can be lengthened to every 2 to 3 years (37). The ACOG recommends annual testing and does not specify any testing methodology until age 30. Patients over 30 with no history of CIN 2 or 3, no immunocompromised state, and no diethylstilbestrol (DES) exposure who have three negative cytologies may be screened every 2 to 3 years. In women over 30 years of age with negative testing using both cytology and HPV screening, testing is recommended every 3 years (36,38). The USPSTF recommends that screening intervals be lengthened to every 3 years regardless of age in patients who have had two negative smears. Liquid-based cytologic screening and testing has not been adopted by the USPSTF due to insufficient data. High-risk women should be screened annually.

The upper age of screening is set at 65 by the USPSTF if there are previous normal smears and the woman is not at high risk. The ACS recommends stopping at age 70 if there have been three consecutive negative smears in the prior 10 years. The ACOG recommends individual assessment of risk factors and examination (36). Women who have undergone hysterectomy should be screened according to risk factors such as prior history of CIN 2 and 3 and others.

To provide a standard terminology when reporting cytologic findings, the Bethesda system set forth guidelines in 1988 with revisions in 2001 (39). This system describes the adequacy of the specimen, a general categorization of whether it falls within normal limits or not, and a description of the dysplastic cytologic abnormalities detected in three categories: ASCUS or atypical squamous cells—cannot rule out high-grade squamous intraepithelial lesion (ASC-H), LSIL (the same as CIN 1), and high-grade squamous intraepithelial lesion (HSIL), which is the same as CIN 2 or 3. It can also report squamous cell carcinoma directly. For glandular lesions, categories include atypical glandular cells (AGS), denoting origin if possible (endocervix, endometrial, or not otherwise specified), AGS favoring neoplastic, adenocarcinoma *in situ* (AIS), or frank adenocarcinoma.

It is estimated that approximately 10% to 20% of women with ASCUS or ASC-H have underlying CIN 2 or 3 and that 1 in 1,000 may have underlying invasive cancer. ASC-H is expected to be diagnosed in about 5% to 10% of all ASCUS readings. AGS is associated with a much higher percentage of high-grade disease when compared to ASCUS—as high as 39%.

The ASCUS/LSIL Triage Study (ALTS), a multicenter randomized trial of 3,488 women, compared immediate colposcopy versus triage to colposcopy based on HPV testing, and liquid-based cytology with a threshold of HSIL versus conservative management with triage based on repeat cytology with a threshold of HSIL (40,41). ASCUS was reproducible in repeat liquid-based cytology in only 32% of cases with an overall CIN 2 and 3 diagnosis of 15% when ASCUS cytology was further investigated. HPV testing was able to identify 92% of women who would ultimately have a diagnosis of CIN 3. Only 1.4% of women with negative HPV testing developed CIN 3 over 2 years. Repeat cytology for ASCUS would have referred almost 67% of women to colposcopy as compared to HPV testing, which referred about half the number of women for colposcopy. The American Society of Colposcopy and Cervical Pathology (ASCCP) endorsed HPV testing as the preferred method of triage for ASCUS smears detected by liquid-based cytology (42).

HPV Testing

HPV testing has been gaining more popularity in recent years. Methods of detecting HPV include hybrid capture II and polymerase chain reaction. Both tests have similar sensitivity and specificity, but the former is easier to perform technically, especially in a large screening program setting. Sherman et al. studied over 20,000 women, evaluating the role of conventional Pap smear and concurrent HPV testing to determine the risk of developing CIN 3 (43). In this study, 72% of women who developed CIN 3 had baseline abnormal cytology and positive HPV testing with a cumulative incidence of developing CIN 3 or invasive cancer of 4.5% in approximately 45 months of follow-up. This was compared with women with negative smears and HPV testing whose cumulative incidence of developing CIN 3 or invasive cancer was only 0.16%. The combination of negative cytology and HPV testing carries a high negative predictive value of over 95% regarding the development of CIN 3 or invasive cancer, providing great reassurance for low-risk women and lengthening

the interval of screening in that population. The ACS and ACOG agreed that it would be reasonable to offer this combined modality screening to low-risk women aged 30 or greater and allow for screening intervals of 3 years (36).

Clavel et al. studied the role of HPV testing as a primary screening tool in almost 8,000 women (44). They reported 100% sensitivity of HPV testing in detecting histologically proven high-grade dysplasia compared to conventional smear (68%) and liquid-based cytology (87%). The specificity of HPV testing was 93% in women over 30, compared to conventional and liquid-based technologies with specificities of 86% and 95%, respectively. Overall it was found that HPV testing is much more sensitive in detecting high-grade disease compared to conventional smears but with a lower specificity rate. This approach requires further study; screening women younger than 30 may lead to unnecessary testing as many HPV infections are transient, and most women will not develop dysplasia with HPV infection. In LSIL, more than 85% of cases test positive for HPV. Therefore, HPV testing is not encouraged. CIN 2 and 3 require immediate referral for colposcopic evaluation. The overall 2-year cumulative risk of developing CIN 2 and 3 for LSIL and ASCUS with positive HPV testing was essentially the same (27.6% and 26.7%). The authors suggested that repeat HPV testing 12 months after diagnosis of LSIL and ASCUS with positive HPV yielded the highest sensitivity and lowest rate of referral for colposcopy. Repeat cytology with HPV testing did not significantly increase sensitivity and increased referral for colposcopy. HPV testing appears to be useful in triage of ASCUS smears, possibly reducing colposcopic referrals by almost 50% (40,41).

Colposcopy

Colposcopy examines the lower genital tract including the vulva, vagina, and epithelium of the cervix and opening of the endocervix. The use of acetic acid and Lugol's solution assists in highlighting abnormal and dysplastic changes. Changes such as aceto-white plaques and vascular abnormalities such as punctations, mosaicism, and abnormal branching may signify high-grade disease. Indications for colposcopy include an abnormal appearing cervix, persistent post-coital bleeding or discharge, persistent CIN 1, 2, or 3 on cytology, *in utero* exposure to DES, and ASCUS smears with positive high-risk HPV testing. In order to have an adequate colposcopic examination the entire transformation zone must be fully visualized. Endocervical curettage is recommended in all colposcopic evaluations.

Conization Biopsy

Cervical conization refers to the surgical removal of the squamo-columnar junction. This may be done in the operating suite through a classical cold knife conization technique or as an outpatient using thermal cautery with loop excision. Indications for conization include inadequate colposcopy, positive endocervical curettage, persistent CIN 1 (usually >1 year), CIN 2,3 or CIS, and discrepancy between cytologic, colposcopic, or pathologic findings.

Loop Electrosurgical Excision Procedure

Loop diathermy, an alternative to cold knife conization, is usually performed on an outpatient basis. Trials have demonstrated loop electrosurgical excision procedure (LEEP) to be as effective as cold knife conization with advantages in terms of cost, anesthesia, and ease of use (45). A disadvantage is that significant thermal artifact can hamper evaluation of margin status, which can be minimized with careful technique avoiding prolonged contact with the tissue.

Clinical Disease

Symptoms and Complaints

The most common presentations of invasive cervical cancer are abnormal vaginal bleeding, post-coital bleeding, and vaginal discharge. However, many women are asymptomatic and are found to have disease upon pelvic examination or cytologic evaluation. As the tumor enlarges it can cause local symptoms such as pelvic pain and difficulty with urination or defecation. As the disease metastasizes to regional lymph nodes, back pain, leg swelling (especially unilateral), and neuropathic pain may occur.

Physical Findings

The most common finding on physical examination is an abnormal lesion on the cervix, at times necrotic and friable. Possible extension onto the vaginal wall should be assessed. Determination of parametrial, sidewall, and uterosacral ligament involvement must be done through a rectovaginal examination. Other areas of concern are the superficial groin and femoral lymph nodes and the supraclavicular region.

Diagnostic Biopsy

Suspicious lesions on the cervix and surrounding areas should be biopsied with enough depth to assure adequate non-necrotic tissue to render diagnosis. Biopsy on the margin tends to yield better results.

Staging

Clinical Staging Procedures

The most critical component of staging is a thorough pelvic examination, including a rectovaginal exam. If necessary, an exam under anesthesia allows for a careful visual and digital examination as well as cystoscopy and proctoscopy.

Laboratory Studies

A complete peripheral blood count is indicated to evaluate for anemia, which might warrant correction. Thrombocytosis is found in up to 30% of patients with locally advanced disease and has been associated with larger tumor size, parametrial involvement, and poorer survival. Serum chemistries with attention to serum creatinine are essential to evaluate for renal failure or assess renal function in patients who will receive cisplatin-based chemoradiotherapy. Additional tests should include liver function and urinalysis.

Serum Tumor Markers

The most commonly studied markers are squamous cell carcinoma antigen (SCCA), carcinoembryonic antigen (CEA), CA-125, and CYFRA 21-1. Molina et al. evaluated SCCA, CEA, and CYFRA 21-1 in 156 patients with invasive cervical cancer. They found a sensitivity at diagnosis of 43%, 25%, and 26%, respectively, and found that in squamous cell cancers the latter two did not add to SCCA alone (46). Reesink-Peters et al. studied preoperative SCCA levels in early-stage cervical cancer and found that patients with elevated SCCA had a higher chance of requiring postoperative radiation therapy (RT) (57% vs. 16%) and a higher relapse rate in those with elevated SCCA as compared to those with normal levels (15% vs. 1.6%) (47). In any case, most clinicians will use parameters for postoperative RT such as margin status, lymph node and parametrial involvement, depth of invasion, size of

tumor, and lymph vascular involvement, irrespective of SCCA levels, to assess the need for adjuvant RT. In one study CA-125 was a poor marker as only up to 21% of patients had elevated levels (48). In general, tumor markers currently have no role in management of advanced cervical cancer.

Radiographic Studies

Cervical cancer is clinically staged by physical examination and limited radiographic evaluation. Computed tomography (CT) and magnetic resonance imaging (MRI) are used extensively to delineate disease extent and improve treatment planning but do not change the assigned staging. Mitchell et al. compared CT versus MRI for measurement of tumor diameter in early-stage disease in 208 patients and found that MRI was superior to CT in preoperative evaluation of tumor size and uterine body involvement (49). Hirack et al. evaluated MRI in evaluating extent of disease in correlation with surgical findings. They reported an accuracy of 91% for detection of tumor location, 70% in determining tumor size, 93% for vaginal extension, and 88% for parametrial involvement (50). In a meta-analysis, Bipat et al. reported sensitivity of 74% for parametrial involvement with MRI as compared to 55% for CT; lymph node involvement was 60% versus 43%, respectively, and MRI was superior in detecting bladder and rectum invasion (51).

Narayan et al. studied International Federation of Gynecology and Obstetrics (FIGO) staging, tumor volume, and lymphatic metastasis using MRI and positron emission tomography (PET) scanning (52). They found that tumor invasion of the uterine body was a strong predictor of lymphatic invasion; uterine body invasion was present in 58%, 73%, 88%, and 100% of stages I, II, III, and IV, respectively. Node positivity was noted in 11% of patients with PET scanning without uterine body involvement on MRI versus 75% of those with uterine body involvement.

Choi et al. reported a preoperative accuracy of MRI in tumor staging of 77% and a sensitivity of 97% for pelvic node metastasis (53). Park et al. evaluated 36 patients with MRI and PET, reporting an accuracy of FIGO and MRI staging of 67% and 84%, respectively. PET was superior to MRI in detecting pelvic nodal metastasis (78% vs. 67%) (54).

Hricak et al. reported a multicenter trial of 172 patients. They found that surgico-pathologic findings correlated with FIGO staging in 76% of cases in stages IA to IIA and in 21% in stage IIB. Sensitivity for detecting advanced stage (>IIB) for FIGO staging, CT, and MRI were 29%, 42%, and 53%, respectively, with specificities of 99%, 82%, and 74%, respectively (55).

In comparing MRI to CT, Subak et al. reported that MRI was superior to CT in evaluating stage of disease, with an accuracy of 90% versus 65%, respectively (56). MRI was superior to CT in detecting parametrial invasion (94% vs. 76%). In evaluating pelvic adenopathy, both were equal. Contrast-enhanced T1-weighted images are superior to nonenhanced T2-weighted images.

Modern imaging techniques such as CT and MRI have low sensitivities for detecting disease in the para-aortic nodes less than 1 cm (57). PET has emerged as a superior method of imaging nodal disease in cervical cancer. The reported sensitivity is about 84% (58,59). Loft et al. completed a prospective study of PET/CT scanning in 120 patients with cervical cancer. There were several false negatives, resulting in a positive predictive value of only 63%. However, negative predictive value, sensitivity, and specificity were 100%, 100%, and 94%, respectively (60).

FIGO and American Joint Committee on Cancer Staging

The staging system used for cervical cancer is based on the 1995 FIGO staging system (61,62). Stage IA1 is defined as stromal

invasion to <3 mm in depth and no wider than 7 mm, stage IA2 is defined as stromal invasion of 3 to 5 mm with width of no >7 mm. The Society of Gynecologic Oncologists (SGO) also considers negative lymphovascular space invasion (LVSI) and margin status as criteria for microinvasive disease (MID). The horizontal spread must be 7 mm or less to be considered MID according to FIGO, but SGO does not include lateral spread in defining MID. The diagnosis of MID must be made on a conization or hysterectomy specimen. Punch biopsies are not adequate. Stage IB is divided into IB1, which includes all lesions greater than IA2 and no more than 4 cm in greatest dimension, and stage IB2, a lesion limited to the cervix measuring greater than 4 cm.

Surgical findings and radiographically guided biopsies of suspected lesions cannot be used to change or modify clinical FIGO staging. Stage IVA requires biopsy confirmation of bladder or rectal mucosal involvement. For example, bullous edema of bladder mucosa is not sufficient to render staging as FIGO IVA. Stage IIIB indicates pelvic sidewall involvement or demonstration of a nonfunctioning kidney or hydronephrosis, irrespective of clinical detection of sidewall involvement, as long as there is no alternative explanation for the kidney abnormality.

A tumor-node-metastasis (TNM) staging system is proposed by the American Joint Committee on Cancer (AJCC) that corresponds well to the FIGO clinical staging. The current criteria for the various stages are defined in Table 22.1. TNM is mainly used in documenting findings on surgical and pathologic evaluations as the pathologic stage of the disease, and FIGO is used for clinical staging. All histologic types are included. If there is ambiguity regarding the correct stage, the lower stage is assigned.

Pretreatment Nodal Staging
