The presence of para-aortic lymph node metastases is known to have a significant impact on progression-free and overall survival. Pretreatment knowledge of para-aortic spread could potentially direct treatment in a manner that could improve outcomes. Given the limitations of imaging in reliably detecting para-aortic micrometastases, surgical staging has been used. However, the role of surgical staging for locally advanced cervical cancer remains unclear. Leblanc et al. performed pretreatment laparoscopic nodal staging on 156 patients with stages IB2 to IVA with negative preoperative CT scans (63). The average number of

TABLE 22.1

DEFINITION OF TNM

TNM categories	FIGO stages
PRIMARY TUMOR (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	0 Carcinoma <i>in situ</i>
T1	I Cervical carcinoma confined to uterus (extension to corpus should be disregarded)
T1a ^a	IA Invasive carcinoma diagnosed only by microscopy. Stromal invasion with a maximum depth of 5.0 mm measured from the base of the epithelium and a horizontal spread of 7.0 mm or less. Vascular space involvement, venous or lymphatic, does not affect classification
T1a1	IA1 Measured stromal invasion 3.0 mm or less in depth and 7.0 mm or less in horizontal spread
T1a2	IA2 Measured stromal invasion more than 3.0 mm and not more than 5.0 mm with a horizontal spread 7.0 mm or less
T1b	IB Clinically visible lesion confined to the cervix or microscopic lesion greater than T1a/IA2
T1b1	IB1 Clinically visible lesion 4.0 cm or less in greatest dimension
T1b2	IB2 Clinically visible lesion more than 4.0 cm in greatest dimension
T2	II Cervical carcinoma invades beyond uterus but not to pelvic wall or to lower third of vagina
T2a	IIA Tumor without parametrial invasion
T2b	IIB Tumor with parametrial invasion
T3	III Tumor extends to pelvic wall and/or involves lower third of vagina, and/or causes hydronephrosis or nonfunctioning kidney
T3a	IIIA Tumor involves lower third of vagina, no extension to pelvic wall
T3b	IIIB Tumor extends to pelvic wall and/or causes hydronephrosis or nonfunctioning kidney
T4	IVA Tumor invades mucosa of bladder or rectum, and/or extends beyond true pelvis (bullous edema is not sufficient to classify a tumor as T4)
REGIONAL LYMPH NODES (N)	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Regional lymph node metastasis
DISTANT METASTASIS (M)	
MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	IVB Distant metastasis

Note: The definitions of the T categories correspond to the stages accepted by the Fédération Internationale de Gynécologie et d'Obstétrique (FIGO). Both systems are included for comparison.

^aAll macroscopically visible lesions—even with superficial invasion—are T1b/IB.

Source: American Joint Committee on Cancer (AJCC). Cervix uteri. In: Greene FL, Page DL, Fleming ID, et al. eds. *AJCC Cancer Staging Manual*. 6th ed. New York: Springer; 2002:260.

nodes removed and length of stay were 21 and 1.4 days, respectively. The rate of para-aortic metastasis was 25.4%. Nearly a quarter of patients with stage IB2 required extended field RT due to surgical findings. Survival was not different between patients with microscopic versus resected macroscopic nodal disease.

Leblanc et al. evaluated 184 patients with stages IB2 through IVA with pretreatment extraperitoneal laparoscopic staging of para-aortic nodes (64). They found a 24% incidence of para-aortic nodal involvement and an operative complication rate of 2%. They had a 13% symptomatic lymphocyst rate that decreased to about 3% with modification of techniques. Findings of surgical staging changed the management of 20% of patients who would have only received pelvic RT to extended field RT. Data suggested a survival advantage in patients with resected positive nodes.

Lai et al. compared clinical staging versus surgical staging (laparoscopic or extraperitoneal approach) in 61 patients (65). Para-aortic nodal metastasis was detected in 25% of the surgical group. The study was terminated early as the surgical arm had a significantly worse progression-free and overall survival compared to the nonsurgical arm. The role of surgical staging remains unclear, particularly in the era of metabolic imaging. Gallup et al. described an extraperitoneal approach to dissect and evaluate para-aortic lymph nodes, and Querleu et al. have reported a laparoscopic staging technique (66,67). These approaches can minimize treatment delays and complications compared to the open approach.

Sentinel Lymphatic Mapping in Early Cervical Cancer

The standard surgical treatment for early cervical cancer (stages IA2 to IIA) is radical hysterectomy and pelvic lymphadenectomy (PL). The PL is complete and removes all nodal bearing tissues on the external iliac artery and vein (up to the circumflex iliac vein), internal iliac artery above the obturator nerve, and common iliac artery up to the iliac bifurcation. The procedure carries some risk of injury to vessels and nerves, can lead to lymphedema, and can predispose to a higher complication rate if postoperative RT is needed. Lymphatic mapping (LM) refers to the concept of delineating the path of malignant cells through the lymphatics, identifying the nodes primarily at risk for early spread, and determining if this knowledge will safely allow a limited rather than a complete regional lymphadenectomy.

Thompson and Uren described the sentinel node (SN) as “any lymph node that receives lymphatic drainage directly from primary tumor” (68). In cervical cancer, Medl et al. were the first to report LM with blue dye (69). Dargent et al. reported the laparoscopic identification of the SN (70). In a study of 20 patients, O’Boyle et al. noted a low SN detection rate of 60%, which is lower with larger tumors (71). Levenback et al. reported 39 patients with early cervix cancer who underwent radical hysterectomy (RH) and PL. Preoperative lymphoscintigraphy was performed, revealing at least one SN in 85%. Most SNs were iliac, obturator, and parametrial nodes; however, approximately 20% were in the common iliac and aortic chains. Eight (21%) had nodes involved with tumor, and five of these eight had SN as the only positive node. Sensitivity was 87.5% and negative predictive value (NPV) was 97% (72).

Using a laparoscopic approach to SN identification and dissection, Lambaudie et al. reported a sensitivity of 66%, specificity of 100%, positive predictive value of 100%, and NPV of 90% (73). Plante et al. followed with a larger series of 70 patients using laparoscopy. Bilateral SNs were found in 60% of cases. Using both a gamma probe and blue dye, the SN detection rate was 93%. Eighty-eight percent of SNs were in the external iliac, obturator, and the bifurcation area. Fifty-one percent had two SNs, and 24% had \geq SNs. The NPV was 100% and sensitivity was 93%. The rate of allergy to blue dye was

3% (74). Darai et al. also investigated laparoscopic SN identification and biopsy, finding an SN detection rate of 83%. Consistent with other work, the detection rate was considerably worse in patients with advanced tumors. The positive and negative predictive values were each 80%, and positive SNs tended to be associated with parametrial involvement (75). Use of both blue dye and technetium 99 enhances the detection rate of SN.

Using preoperative lymphoscintigraphy, Frumovitz et al. found that 71% of patients showing a solitary SN actually had multiple SNs during laparotomy, and 52% who had unilateral SNs had bilateral SNs noted during exploration. Given the poor concordance between lymphoscintigraphy and laparotomy findings, the authors questioned the utility of preoperative lymphoscintigraphy (76). Wydra et al. reported their findings on 100 patients and found that the detection rate of SN was 96% in patients with tumors <2 cm compared to 54% in those with tumors >2 cm. The false-negative rate was 3% (77).

PATHOLOGY

Squamous Cell Carcinoma

Squamous carcinoma of the cervix includes both microinvasive squamous carcinoma and more deeply invasive carcinoma. Variants of invasive squamous carcinoma, which may be associated with differences in biologic behavior, include verrucous carcinoma, papillary squamous and transitional carcinoma, warty carcinoma, and lymphoepithelioma-like carcinoma.

Preinvasive Disease

Squamous carcinoma *in situ* is a precursor lesion of invasive squamous carcinoma. Squamous carcinoma *in situ* is characterized by full-thickness atypia of the cervical epithelium. Endocervical glands may also be involved. The normal maturation of squamous epithelium is absent. The epithelium is replaced by atypical cells that often have enlarged, oval nuclei and increased nuclear-to-cytoplasmic ratios. Mitotic figures are present. There is no breach of the underlying basement membrane (Fig. 22.1). A recent study of cervical biopsies found excellent interpathologist and intrapathologist agreement in the diagnosis of cervical biopsy specimens (78).

FIGURE 22.1. Squamous carcinoma *in situ*. The epithelium displays full thickness atypia. Cells have enlarged, hyperchromatic nuclei, and there is no evidence of maturation.

FIGURE 22.2. Microinvasive squamous carcinoma. There is an area of squamous carcinoma *in situ* (lower left). A nest of invasive carcinoma cells (center) has broken through the basement membrane. The invasive cells are larger, with more abundant cytoplasm and larger, more pleomorphic nuclei. A desmoplastic stroma response is present (right).

Microinvasive Carcinoma

Microinvasive squamous carcinoma is associated with squamous intraepithelial neoplasia, and may arise from either the surface epithelium or from endocervical glands involved by dysplasia. It is characterized by small nests of cells that have escaped the basement membrane of the surface or glandular epithelium. Microinvasive carcinoma often displays cells that are larger, with more abundant eosinophilic cytoplasm than cells in the adjacent dysplasia (Fig. 22.2). A desmoplastic stromal reaction is usually present. The nests of microinvasive tumor are irregular and haphazardly arranged. These features are useful in distinguishing microinvasion from rounded, well-circumscribed endocervical glands involved by squamous dysplasia.

Depth of invasion should be measured from the basement membrane of the site of origin. If the tumor arises from surface epithelium, depth is the distance from the basement membrane of the surface epithelium to the deepest nest of invasive neoplasm. If the tumor arises from an endocervical gland, depth is measured from the basement membrane of the gland. If the site of origin is not clear, depth is measured from the basement membrane of the surface epithelium.

Nests of superficial invasion seen in small biopsies should be reported as such, with dimensions of the tumor. A diagnosis of microinvasive squamous carcinoma of the cervix requires a LEEP or conization biopsy that encompasses the entire lesion and has negative margins.

Invasive Squamous Cell Carcinoma

Invasive cervical carcinoma arises from high-grade dysplasia, which may be detected up to 10 years before invasive carcinoma develops. Untreated squamous carcinoma *in situ* results in invasive carcinoma in about one third of cases over a period of 10 years. Invasive carcinoma occurs most often after the age of 40 years (15), although it may be seen in young women. It is associated with human papillomavirus infection in more than 99% of cases. These tumors may consist of firm, indurated masses, or they may be ulcerated or polypoid. Microscopic examination reveals irregular, haphazardly infiltrating nests of cells with eosinophilic cytoplasm and enlarged, atypical, hyperchromatic nuclei (Fig. 22.3).

Mitoses may be numerous, and atypical forms may be present. There is typically a desmoplastic stromal response around

FIGURE 22.3. Invasive squamous carcinoma. Small, irregular nests of cells with markedly atypical nuclei are present. They are surrounded by desmoplastic stroma, containing inflammatory cells.

the nests of invasive neoplasm. Lymphatic and vascular space invasion may be present, especially in more deeply invasive tumors. Invasive squamous carcinomas are classified as keratinizing or nonkeratinizing, although this classification has no prognostic significance. Keratinizing squamous carcinomas display at least some keratin pearl formation. Nonkeratinizing squamous carcinomas are composed of irregular nests of cells that may display abundant eosinophilic cytoplasm and intercellular bridges but do not contain keratin pearls. Some squamous carcinomas are composed of smaller cells without evidence of neuroendocrine differentiation; these neoplasms should be classified as nonkeratinizing squamous carcinomas.

Invasive squamous carcinomas are also graded (79), although treatment protocols do not depend on grade, and the histologic grade may not correlate with prognosis. Grade 1 (well-differentiated) tumors are not very common in the cervix. They display keratin pearls and large numbers of keratinized cells. Nuclei display only mild to moderate atypia, and mitoses are typically not numerous. Grade 2 (moderately differentiated) tumors represent the majority of invasive squamous carcinomas of the uterine cervix, and are usually nonkeratinizing squamous carcinomas with nuclear pleomorphism, numerous mitoses, and an infiltrative pattern. Grade 3 (poorly differentiated) tumors either have smaller cells without neuroendocrine differentiation, or are pleomorphic with anaplastic nuclei and sometimes a tendency to form spindle cells that must be distinguished from sarcoma by positive cytokeratin stains.

Variants of Squamous Cell Carcinoma

Basaloid Squamous Cell Carcinoma. Basaloid squamous carcinoma is an invasive, highly aggressive tumor composed of basaloid cells resembling those seen in squamous carcinoma *in situ* (80).

Verrucous Carcinoma

Verrucous carcinoma occurs rarely in the uterine cervix (81). Examination of the cervix reveals a papillary excrescence that may resemble condyloma acuminatum. In fact, lesions termed “giant condyloma of Buschke and Lowenstein” in the past probably represent verrucous carcinomas. Microscopic examination displays papillary fronds of squamous epithelium not containing connective tissue cores. The fronds are often pointed and have a “church spire” appearance. Underlying connective

FIGURE 22.4. Papillary squamous carcinoma. Papillary fronds of tumor contain connective tissue cores, and are covered with multiple layers of atypical epithelial cells.

tissue displays bulbous nests of squamous epithelium that invade the stroma with a pushing margin but display little cytologic atypia. Any lesion displaying significantly atypical nuclei does not represent verrucous carcinoma. The distinction between verrucous carcinoma and regular squamous carcinoma is important because verrucous carcinoma invades locally but does not metastasize. In order to diagnose verrucous carcinoma, it is necessary to see the invasive portion of the neoplasm. Superficial biopsies are usually not diagnostic.

Papillary Squamous and Transitional Carcinoma

Some cervical neoplasms are characterized by papillary superficial architecture with substantial nuclear atypia not seen in verrucous carcinomas (82,83). The most common presenting symptoms are vaginal bleeding and abnormal Pap smears. Papillary, polypoid, or granular lesions are often evident upon examination of the cervix.

These tumors may have thin or thick papillae that contain a connective tissue core (Fig. 22.4). The papillary processes may be covered by highly atypical epithelium displaying keratinization, or the epithelium may consist of multiple layers of cells with oval, hyperchromatic nuclei that do not show keratinization, and resemble transitional cell epithelium. Nuclear grooves may be present. Some tumors display epithelium with mixed features. Immunohistochemical studies have shown that most of these tumors are cytokeratin 7 positive and cytokeratin 20 negative; these results are consistent with squamous differentiation (83). HPV-16 has been identified in these neoplasms (82). A recent study demonstrated that these tumors all have the same immunophenotype (uroplakin III negative, p63 positive, and p16^{INK4a} positive) regardless of light microscopic features (84). The authors concluded that these neoplasms lack true transitional cell differentiation and share features with squamous carcinoma.

Many papillary squamous and transitional carcinomas are associated with an underlying invasive carcinoma. The invasive neoplasm is often typical squamous carcinoma, but some cases of invasive transitional carcinoma have been described. Superficial biopsies display only the papillary portion of the neoplasm. LEEP or conization biopsy should be performed to evaluate the possibility of underlying invasive carcinoma.

The invasive form of this neoplasm may be associated with local recurrence and metastasis. These tumors must be distinguished from verrucous carcinomas, which display little atypia and have a much more indolent clinical course.

FIGURE 22.5. Human papillomavirus changes. This squamous epithelium displays cells with large halos surrounding atypical nuclei (“koilocytotic atypia”).

Warty Carcinoma

Warty carcinoma of the cervix is a rare papillary neoplasm that displays marked condylomatous change but has features typical of routine invasive squamous carcinoma at its deep margin (85). These tumors are associated with HPV and may behave less aggressively than the usual type of invasive squamous carcinoma. Cellular change consistent with HPV infection (“koilocytotic atypia”) is shown in Figure 22.5.

Lymphoepithelioma-Like Carcinoma

Lymphoepithelioma-like carcinoma, more commonly seen in the nasopharynx, also occurs in the uterine cervix. Some patients may present with abnormal bleeding and have cervical masses, whereas others may have abnormal Pap smears and no visible cervical lesions. Lymphoepithelioma-like carcinoma of the cervix is seen most often in Asian women, and it has been associated with Epstein-Barr virus infection in those patients (86). In contrast, studies from Europe have not demonstrated Epstein-Barr virus DNA (87,88), but some have suggested a role for HPV in the etiology of this neoplasm (88–90).

Microscopically, this tumor is characterized by nests of cells with lightly eosinophilic cytoplasm and large vesicular nuclei with prominent eosinophilic nucleoli. Cell borders are indistinct, giving the tumor cell nests a syncytial appearance. Aggregates of tumor cells are surrounded by a prominent inflammatory infiltrate that includes lymphocytes, plasma cells, and varying numbers of eosinophils. This neoplasm can be distinguished from glassy cell carcinoma (which is also accompanied by prominent inflammation) by the lack of prominent cell borders and granular eosinophilic cytoplasm in

lymphoepithelioma-like carcinoma. The lymphocytic infiltrate in lymphoepithelioma-like carcinoma of the uterine cervix is predominantly T cell in nature, and most of the T cells are suppressor/cytotoxic CD8 cells (87).

Adenocarcinoma

While the incidence of squamous carcinoma of the cervix has decreased in past decades owing to cytologic screening, the number of cases of cervical adenocarcinoma has increased (91–93). Adenocarcinoma of various types accounts for 20% to 25% of cervical carcinomas (92).

Adenocarcinoma *in situ* is a precursor of invasive adenocarcinoma. It is found adjacent to many invasive adenocarcinomas, often accompanied by squamous dysplasia. Both adenocarcinoma *in situ* and invasive adenocarcinoma of the cervix are associated with HPV (usually type 18, but sometimes type 16).

Adenocarcinoma *in situ* is characterized by preservation of the overall endocervical gland architecture. However, endocervical glands and surface epithelium are replaced to varying degrees by cells displaying atypia, including nuclear enlargement and stratification, nuclear hyperchromasia, and mitotic figures (Fig. 22.6). Most adenocarcinomas *in situ* occur near the transformation zone, and skip lesions are unusual (93).

Early Invasive Adenocarcinoma

Early invasive adenocarcinoma of the uterine cervix displays an alteration from the normal endocervical gland architecture. This abnormality may take the form of solid or cribriform nests of cells, architecturally irregular or incomplete glands lined by malignant cells, or small buds of highly atypical cells arising from glands involved by adenocarcinoma *in situ*. A desmoplastic stroma may be present. Diagnosis of early invasive adenocarcinoma may be difficult because endocervical glands normally have a complex pattern. Wheeler and Kurman (94) have reported that close proximity of glands to thick-walled blood vessels is suggestive of an invasive neoplasm.

Technically, the definitions of microinvasive carcinoma, according to both SGO and FIGO, apply to all types of carcinoma. Application of this term to glandular lesions of the cervix has not been generally accepted. Some gynecologic pathologists

FIGURE 22.6. Adenocarcinoma *in situ*. Part of this endocervical gland is normal (upper left corner). The remainder of the gland has been replaced by stratified cells with atypical, large nuclei and mitotic figures.

believe that these lesions should be classified as early invasive adenocarcinomas, with a best possible measurement of the depth of invasion (91,93), because an increased incidence of metastatic disease correlates with increasing depth of invasive disease. One author has suggested that depth of invasion should be measured from the luminal surface to the deepest invasive tumor nest so that, as in malignant melanomas, tumor thickness rather than depth of invasion is measured (93).

Mucinous Adenocarcinoma

There are several variants of mucinous adenocarcinoma of the cervix, including endocervical, intestinal, signet ring cell, minimal deviation, and villoglandular variants. HPV DNA has been detected in more than 90% of mucinous adenocarcinomas of the cervix, including endocervical, intestinal, and endometrial subtypes (95).

Mucinous Adenocarcinoma, Endocervical Variant

The endocervical variant of mucinous adenocarcinoma is the most common type of cervical adenocarcinoma. It is composed of irregular, haphazardly arranged tubuloracemose glands lined by cells resembling those seen in normal endocervical glands, although they may sometimes have limited amounts of cytoplasmic mucin. Nuclei are basally located, stratified, and atypical (Fig. 22.7). Mitoses are present. Grade 1 (well-differentiated) tumors have uniform nuclei with minimal stratification and few mitotic figures. Grade 2 (moderately differentiated) adenocarcinomas have more marked cytologic atypia with frequent mitoses. They may also have solid areas accounting for less than half of the neoplasm. Grade 3 (poorly differentiated) adenocarcinomas contain more prominent solid areas, pleomorphic nuclei, and many mitoses. Desmoplastic stromal response is variable in this type of cervical adenocarcinoma.

Mucinous Adenocarcinoma, Intestinal Type, Signet Ring, and Colloid Variants

Rare endocervical adenocarcinomas have glands containing goblet cells; these tumors display intestinal differentiation. Signet ring cell carcinomas and colloid carcinomas are extremely rare and must be distinguished from metastatic tumors from the gastrointestinal tract.

FIGURE 22.7. Invasive adenocarcinoma. There is a haphazard invasion of the cervix by irregular glands lined by multiple layers of atypical cells.

Mucinous Adenocarcinoma, Minimal Deviation Variant (Adenoma Malignum)

The term *adenoma malignum* was originally proposed by McKelvey and Goodlin (96) to describe a form of cervical adenocarcinoma that is so well differentiated that it may be difficult to recognize as a malignant lesion. The term *minimal deviation adenocarcinoma* is a more appropriate designation for this lesion. There is also a tendency for benign lesions of the uterine cervix to be overdiagnosed as minimal deviation adenocarcinoma (97), further emphasizing the difficulty of diagnosing this neoplasm.

This tumor is uncommon, and represents only about 1.3% of cervical adenocarcinomas (98). Patients range in age from 25 to 72 years. They may present with abnormal bleeding or a mucoid discharge. The cervix may appear normal, or it may display a firm area or a mass. The neoplasm is very difficult to diagnose on small biopsies because the infiltrative gland pattern cannot be appreciated. Conization specimens are more conducive to accurate diagnosis in this lesion, but some cases have been diagnosed only after hysterectomy. In contrast to most other types of cervical adenocarcinomas, minimal deviation adenocarcinomas are not associated with HPV infection (99).

Gross examination of hysterectomy specimens displays firm, tan-yellow neoplasms. Most cases contain mucinous glands, but some display endometrioid glands. Microscopically, glands infiltrate the cervical stroma in a haphazard manner; they do not conform to the normal endocervical gland pattern. They may display budding contours, and they typically have angular, sharply pointed outlines, in contrast to the rounded contours of benign endocervical glands. The glands of minimal deviation adenocarcinoma appear deceptively benign on low power. Lack of substantial cytologic atypia is a prerequisite for this diagnosis. However, high-power examination reveals at least some areas with mild to moderate atypia, in which some nuclear enlargement, stratification, and rare mitotic figures may be identified (Fig. 22.8). The infiltrating glands may be devoid of any surrounding desmoplastic reaction. Some authors (97) have described the utility of positive cytoplasmic staining for carcinoembryonic antigen (CEA) in these neoplasms after the possibility of squamous metaplasia has been excluded.

Minimal deviation adenocarcinoma may occur as a sporadic neoplasm, although patients with Peutz-Jeghers syndrome are at risk of developing this cervical tumor.

FIGURE 22.8. Minimal deviation adenocarcinoma. This gland has some very bland cytologic features (left side), but enlarged, atypical nuclei are evident in other areas.

Mucinous Adenocarcinoma, Well-Differentiated Villoglandular Variant

Well-differentiated villoglandular adenocarcinoma is a type of low-grade adenocarcinoma that displays similarities to villous adenomas of the intestine. Patients may present with polypoid or papillary endocervical masses upon pelvic examination, abnormal bleeding, or abnormal Pap smears. The age range has been 23 to 57 years, with most cases occurring in patients younger than 40 years of age (100,101).

Microscopic examination of these neoplasms reveals villous, papillary structures that may be either long and slender, or short and broad. These processes contain a connective tissue core that often displays inflammatory cells. The covering epithelium is a single layer of stratified cells with endocervical, endometrial, or intestinal differentiation. Nuclei display only mild to moderate atypia, and mitotic figures are infrequent (Fig. 22.9). Only tumors with low-grade cytologic atypia should receive this diagnosis, since other endocervical carcinomas may have papillary features. Invasive adenocarcinoma may be seen deep to the papillary areas, and is characterized by branching glands lined by atypical cells and surrounded by desmoplastic stroma. These neoplasms do not display the marked nuclear atypia and epithelial tufting seen in the much more aggressive papillary serous carcinoma of the cervix. They may be associated with typical adenocarcinoma *in situ* of the cervix.

Some authors have found an association between well-differentiated villoglandular adenocarcinoma of the cervix and oral contraceptive use (100). More recently, these tumors have been shown to contain high-risk types of HPV (types 16 and 18) (99,100). Neither oncogene amplification nor tumor suppressor gene loss was identified (101).

Well-differentiated villoglandular carcinoma has not metastasized unless it was associated with more aggressive types of carcinoma. A few cases have recurred (100). Some cases have been successfully treated by conization if the tumor is completely excised and the patient wishes to retain fertility. Generally, this diagnosis should not be suggested on the basis of small biopsy specimens; definitive diagnosis should be made only in tumors seen on conization or hysterectomy specimens. Diagnosis of this type of neoplasm on the basis of only a small biopsy specimen could result in undertreatment of a potentially more aggressive neoplasm (92). Villoglandular tumors associated with a high-grade cytologic component or

FIGURE 22.9. Well-differentiated villoglandular adenocarcinoma. Long, slender villous processes are covered with epithelium, displaying mild atypia. Nuclei are crowded, but they retain an oval shape, and are uniform in size.

an underlying obvious invasive adenocarcinoma may be associated with lymphovascular invasion, recurrences, and lymph node metastases (102,103).

Endometrioid Adenocarcinoma

Endometrioid carcinomas of the uterine cervix are rare, and have probably been overdiagnosed. These tumors make up about 7% of all cervical adenocarcinomas. These neoplasms display histologic features identical to endometrial carcinoma. Therefore, the possibility of a primary endometrial adenocarcinoma with endocervical extension or drop metastasis must be excluded before the diagnosis of a primary endocervical endometrioid adenocarcinoma is established. A rare case has arisen from endocervical endometriosis (104). In difficult cases, immunohistochemical stains may be helpful since a combination of CEA positivity, ER negativity, and vimentin negativity is most often seen in endocervical primary tumors, while the reverse is more often characteristic of endometrial primary tumors. Evidence of association with HPV also supports an endocervical primary neoplasm.

Other Adenocarcinomas

Clear Cell Adenocarcinoma

Clear cell carcinoma of the cervix has been associated with intrauterine diethylstilbestrol (DES) exposure; however, it also occurs in the absence of DES exposure. Patients usually have a cervical mass. The solid pattern of tumor displays sheets of cells containing abundant glycogen-rich clear cytoplasm, atypical nuclei, and mitoses. The tubulocystic pattern contains tubules and cystic spaces lined by oxyphilic, hobnail, or clear cells. The papillary pattern is the least common variant and often coexists with solid or tubulocystic areas. Clear cell carcinomas of the cervix are not associated with HPV DNA (99).

Serous Adenocarcinoma

Papillary serous carcinoma of the uterine cervix (105,106) has a bimodal age distribution, occurring in patients younger than 40 years and patients older than 65 years. This age distribution has also been seen in well-differentiated villoglandular carcinoma but differs from the typical mid-life age of patients with cervical adenocarcinomas in general. Serous carcinomas of the cervix are not associated with HPV DNA (99).

Gross examination may reveal a nodular mass, an indurated cervix, or no visible abnormality. Microscopically, these tumors are identical to serous tumors of the ovary, endometrium, and primary peritoneal serous carcinomas. Considering the rarity with which this type of neoplasm is seen in the cervix, the diagnosis of primary serous carcinoma of the uterine cervix should be made only after excluding metastasis or extension of disease from another site, especially the endometrium.

Histologic examination of serous carcinoma of the uterine cervix reveals fibrous papillae lined by atypical epithelial cells; secondary papillae and tufts of neoplastic epithelial cells are often present (Fig. 22.10). Glandular structures have irregular luminal borders due to tufting of tumor cells. Nuclei usually show high-grade atypia, and numerous mitoses are present.

These are aggressive tumors (106) that may metastasize to pelvic, periaortic, and inguinal lymph nodes. Larger tumors (>2 cm diameter) and tumors invading more than 10 mm are associated with a worse prognosis.

Mesonephric Adenocarcinoma

Remnants of the mesonephric ducts persist and can be seen in the lateral aspects of the cervix. They are often not identified because uteri are traditionally bivalved along their lateral aspects, and

FIGURE 22.10. Papillary serous adenocarcinoma. The papillary structures have a connective tissue core. There is marked tufting and stratification, and the nuclei are markedly atypical.

most microscopic sections are taken from the anterior and posterior portions of the cervix. Mesonephric duct remnants are seen as lobules of small, round, glandular structures lined by flattened cuboidal epithelium and containing intraluminal periodic acid-Schiff stain (PAS)-positive material. The cells of mesonephric duct remnants do not contain intracytoplasmic mucin, unlike the cells lining endocervical glands. Mesonephric duct hyperplasia may occur in the cervix. Mesonephric adenocarcinomas are thought to arise from mesonephric duct remnants. Only about two dozen cases have been documented (107,108). Early reports of lesions termed mesonephric carcinoma are now known to represent clear cell carcinoma, with no relationship to the mesonephric duct remnants.

Patients have ranged in age from 52 to 55 years (98). Some patients have not had grossly apparent lesions, but most present with abnormal bleeding and have visible cervical masses. These neoplasms occur deep in the lateral cervical wall. Microscopically, most mesonephric carcinomas are adenocarcinomas (108), although some with a concomitant spindle cell component have been termed “malignant mesonephric mixed tumors” (107). Mesonephric carcinomas display a variety of histologic appearances, including ductal, tubular, retiform, solid, and sex cord-like patterns (107). Mesonephric hyperplasia may be associated with the carcinoma. Like mesonephric remnants, mesonephric carcinoma tumor cells contain no intracytoplasmic mucin; however, glandular structures may display luminal PAS-positive material. Recent studies suggest that CD10 staining is useful in diagnosing mesonephric-type adenocarcinomas (97,109).

Microcystic Endocervical Adenocarcinomas

Eight cases of this type of endocervical adenocarcinoma have been described (110). Most patients presented with either abnormal Pap smears or vaginal bleeding. Abnormalities of the endocervix were visible in three patients. These tumors are characterized by numerous cystically dilated glands simulating the appearance of a benign lesion at low power. However, higher power examination reveals areas of significant cytologic atypia and mitotic activity. Areas of more typical mucinous or intestinal endocervical adenocarcinoma may also be present. These lesions may be deeply invasive. Three patients had significant follow-up data. One patient died after a debulking procedure for a pelvic recurrence 2 years after her initial diagnosis, and two other patients are alive without evidence of tumor at 1 and 6.5 years after diagnosis.

Other Epithelial Tumors

Adenosquamous Carcinoma

Adenosquamous carcinoma is a tumor composed of admixed malignant glandular and squamous elements. This term should not be used for poorly differentiated squamous carcinomas, in which mucicarmine stains show only scattered mucin vacuoles. Likewise, it is different from collision tumors, which display adjacent adenocarcinoma and squamous carcinoma. A recent multi-institutional study found that adenosquamous carcinomas are more commonly associated with higher tumor grade ($p < 0.001$) and vascular invasion ($p = 0.002$) than are adenocarcinomas (111). Adenosquamous carcinomas appear to be either histologically more aggressive or diagnosed at a later stage than adenocarcinomas of the uterine cervix.

Glassy Cell Carcinoma

Glassy cell carcinoma is a rare form of poorly differentiated adenosquamous carcinoma that displays cells with eosinophilic cytoplasm, well-defined cell borders, prominent nucleoli, and a prominent infiltrate of eosinophils and plasma cells. Occasionally, this morphology may be seen in recurrences of adenocarcinomas or adenosquamous carcinomas that have been treated with radiation therapy (RT) (92).

Adenoid Cystic Carcinoma

Adenoid cystic carcinoma of the cervix is a rare but aggressive malignant neoplasm. These lesions are typically seen in elderly patients, many of whom present with postmenopausal bleeding. Examination of the cervix typically shows a lesion.

Microscopic examination of these tumors reveals a cribriform gland pattern. The glands may contain hyaline or mucinous material. Nuclei are larger and more pleomorphic than those seen in adenoid basal epithelioma, and numerous mitoses as well as areas of necrosis are present in adenoid cystic carcinoma. Electron microscopy has shown basement membrane-like material around the nests of tumor cells as well as in some gland lumina. The tumor cells stain with cytokeratin. In contrast to adenoid cystic carcinoma of the salivary glands, this neoplasm in the cervix has not displayed unequivocal evidence of myoepithelial cells, either by immunohistochemical staining for S100 protein or by electron microscopy.

Adenoid cystic carcinoma of the cervix often recurs, and may metastasize. In the largest series reported, the only patients who were free of tumor at last follow-up had stage IB tumor. No patient with higher stage disease was alive and well.

Adenoid Basal Epithelioma (Carcinoma)

Adenoid basal epithelioma is a rare cervical neoplasm. It was originally called adenoid basal carcinoma. The indolent behavior of most of these neoplasms led to the term “adenoid basal epithelioma.” More recently, Parwani et al. reported ten tumors that had low-grade adenoid basal epitheliomas admixed or associated with invasive carcinomas of various types, including adenoid basal/squamous carcinoma, pure squamous carcinoma, adenoid cystic carcinoma, or small cell neuroendocrine carcinoma. Most adenoid basal epitheliomas and associated invasive carcinomas contain HPV-16 DNA. It now appears that adenoid basal epitheliomas may be precursor lesions that may give rise to carcinomas of various types. These tumors should now be subclassified as adenoid basal epitheliomas and carcinomas (112).

The age of patients with adenoid basal epithelioma ranges from 30 to 91 years (98,113). This neoplasm is often seen in postmenopausal women who are asymptomatic, with normal appearing cervixes. These lesions are usually incidental findings

in specimens obtained for the purpose of evaluating squamous intraepithelial neoplasia. A neoplastic squamous component is often an associated feature (98).

Microscopically, adenoid basal epithelioma is characterized by nests of cells that have a basaloid appearance, and may display peripheral palisading. Some gland lumina are present in the basaloid cell nests, although the number of glands is variable. Squamous metaplasia may also be seen. Mitotic figures are typically rare.

Adenoid basal epithelioma, in the absence of a coexisting invasive carcinoma, is a benign lesion with no reported cases of metastatic behavior (98). It must be distinguished from adenoid cystic carcinoma, which is an aggressive malignant neoplasm. Adenoid basal tumors with carcinomatous components should be reported as carcinomas.

Neuroendocrine Tumors

The College of American Pathologists and the National Cancer Institute (114) have proposed standard terminology for neuroendocrine tumors of the uterine cervix. The previous lack of uniform nomenclature and diagnostic criteria for these neoplasms made it difficult to study their incidence and biologic behavior. Immunohistochemical or electron microscopic evidence of neuroendocrine differentiation is necessary for diagnosis of all neuroendocrine tumors except small cell carcinoma. Chromogranin or synaptophysin stains are recommended for documentation of neuroendocrine differentiation. Chromogranin works best when cells contain numerous neuroendocrine granules; synaptophysin stains cells with fewer granules. Neuron-specific enolase is nonspecific by itself, but may be useful in conjunction with one of the other stains. Many cases of small cell carcinoma will also stain for these markers. CD56 (neural cell adhesion molecule) has recently been reported to be the most sensitive marker for the diagnosis of small cell carcinoma of the uterine cervix (115). Neuroendocrine granules can also be seen by electron microscopy if fresh tumor tissue is available.

Neuroendocrine Tumors

Typical Carcinoid Tumors

Typical carcinoids of the cervix are rare neoplasms. This diagnosis should be made with caution, because most cervical neuroendocrine tumors are aggressive neoplasms. They display organoid architecture without nuclear atypia, mitotic figures, or necrosis. Immunohistochemical stains for chromogranin and synaptophysin demonstrate neuroendocrine differentiation. There are not enough documented cases of this neoplasm to permit assessment of biologic behavior.

Atypical Carcinoid Tumors

Atypical carcinoid tumors also display organoid nests of cells, but the cells display nuclear atypia and a mitotic rate of 5 to 10 MF/10 HPF. Necrosis may be present. These tumors are also rare, precluding evaluation of biologic behavior. However, they may metastasize. Immunohistochemical evidence of neuroendocrine differentiation is required for diagnosis (116).

Large Cell Neuroendocrine Carcinoma

Large cell neuroendocrine carcinomas (Fig. 22.11) display organoid nests of cells with peripheral palisading of nuclei, prominent nucleoli, variable amounts of necrosis, eosinophilic cytoplasmic granules, and numerous mitotic figures (> 0 MF/10 HPF). Vascular/lymphatic space involvement is often seen, and many are associated with coexisting adenocarcinoma

FIGURE 22.11. Large cell neuroendocrine carcinoma. This tumor displays organoid architecture. The tumor cells are much larger than those seen in small cell carcinoma. They have abundant eosinophilic cytoplasm, and there are numerous mitotic figures. Areas of necrosis were present elsewhere in the tumor.

in situ or adenocarcinoma of the cervix (117). These tumors are highly aggressive neoplasms (118). Evidence of neuroendocrine differentiation is necessary for diagnosis and is most easily obtained with immunohistochemical stains for chromogranin and synaptophysin.

Small Cell Carcinoma

Most neuroendocrine tumors seen in the uterine cervix represent small cell carcinomas. A recent study found that 1.3% of cervical cancers contain a small cell carcinoma component, and that even a small component of small cell carcinoma in a tumor of mixed type is associated with adverse outcome (118). Small cell carcinoma is characterized by cells with scant cytoplasm, inconspicuous nuclei with finely stippled chromatin, nuclear molding, extensive necrosis, crush artifact, and numerous mitotic figures (Fig. 22.12). Single cell infiltration of the stroma is common. Vascular/lymphatic space invasion is often seen. These tumors have morphology identical to that seen in small cell carcinoma of the lung. They are aneuploid tumors that show a strong

FIGURE 22.12. Small cell neuroendocrine carcinoma. This tumor displays cells that are smaller than those of squamous carcinoma. Nuclei are large and atypical with molding of adjacent nuclei. There is a very high mitotic rate.

association with type 18 HPV (116). Immunohistochemical stains for neuroendocrine markers such as chromogranin and synaptophysin may be helpful in the diagnosis (119). CD56 (neural cell adhesion molecule) is a sensitive marker for the diagnosis of small cell cancer in the cervix. A panel of antibodies should be used when this diagnosis is a possibility (120).

Mixed Epithelial and Mesenchymal Tumors

Müllerian adenosarcomas occur in the cervix (121). Patients range in age from 13 to 67 years, with a mean age of 37 years. They may present with abnormal bleeding. These neoplasms consist of polypoid or papillary masses. Microscopically, they display benign glands and sarcomatous stroma with a periglandular cuff of condensed stroma. The sarcomatous component contains variable numbers of mitotic figures, and some cases display heterologous elements including cartilage and striated muscle. These tumors generally have a favorable prognosis, but deep invasion and sarcomatous overgrowth are adverse prognostic factors (121).

Malignant mixed müllerian tumors may involve the cervix, although only about 40 cases have been reported (122,123). Patients have ranged in age from 23 to 87 years; the mean age is 65 years. Patients have presented with abnormal bleeding or abnormal Pap smears, and all have had cervical masses. Various types of carcinoma can be seen in these tumors, including squamous carcinoma, basaloid carcinoma, adenocarcinoma, or adenoid cystic carcinoma (122). The sarcomatous component may be homologous or heterologous. Some have suggested that malignant mixed müllerian tumors arising in the cervix have a better prognosis than those arising in the uterine corpus (122). HPV DNA was detected by polymerase chain reaction in all cases of cervical malignant mixed müllerian tumors reported in one study (124).

Other Malignant Tumors

Various sarcomas have been reported in the uterine cervix, although they are uncommon. A recent review of 1,583 cervical malignant tumors revealed eight cervical sarcomas (125). Five were carcinosarcomas, and the remainder were unclassified sarcomas, leiomyosarcomas, or endometrial stromal sarcomas. Primary cervical malignant melanoma is rare (126). About a dozen cases of granulocytic sarcoma involving the uterine cervix have been reported in the past decade (127,128). Some represented the initial disease presentation, and others were identified during the course of acute myeloid leukemia (127). Primary extranodal lymphomas (129) of the uterine cervix are usually diffuse B-cell neoplasms. Primitive neuroectodermal tumors (130,131), desmoplastic small round cell tumors (132), and primary germ cell tumors of the cervix have also been described (133).

Secondary tumors of the cervix include those invading from contiguous organs and metastases from other sites. The former include tumors arising in the uterine corpus, urinary bladder, or rectum. Metastases can originate from many sites, including the ovary, uterus, and more distant primary tumors.

PROGNOSTIC FACTORS

Tumor Size, Volume, Margin Status

In a Gynecologic Oncology Group (GOG) study, Delgado et al. (134) described 3-year disease-free survival rates of 94.8%, 88.1%, and 67.6%, respectively, for occult, ≥ 3 cm, and >3 cm stage I squamous cell carcinomas of the cervix treated by

radical operation. Survival strongly correlated with depth of tumor invasion of the stroma: 86% to 94% for less than 10 mm, 71% to 75% for 11 to 20 mm, and 60% for 21 mm or greater. In patients without parametrial involvement, the survival rate was 84.9%, but it was 69.6% for those with parametrial tumor extension. More recently, these findings were validated by Van de Putte et al. (135). Rutledge et al. compared patients with FIGO stage IB1 cancers with IB2 cancers treated with radical hysterectomy, finding that lymphovascular space invasion and depth of cervical stromal invasion were more significantly associated with poor prognosis in a multivariate analysis (136). In all these series, there was frequent use of postoperative RT with or without chemotherapy. The use of adjuvant treatment was preferentially given in higher risk patients, narrowing the differences in outcomes and affecting the analysis. In patients treated with curative intent RT, Perez et al. analyzed 1,499 patients treated curatively with RT, finding 10-year actuarial pelvic failure rates of 5%, 15%, and 35% for tumors <2 cm, 2 to 5 cm, and >5 cm, respectively, with the stage IB group. In stage IIB patients, medial parametrial involvement was significantly favorable compared to lateral parametrial extension, and in stage IIIB disease unilateral sidewall extension was significantly favorable to bilateral extension (137). Similarly, Eifel et al. (138) noted a strong correlation between central and pelvic tumor control, disease-specific survival, and tumor size. Pelvic tumor control was 97% with tumors less than 5 cm, and 84% with tumors 5 to 7.9 cm.

In a multivariate analysis of prognostic factors related to nodal or distant metastases in 128 patients, Pitson et al. found that tumor size and tumor hypoxia were both independently predictive, whereas stage and hemoglobin concentration were not (139).

In patients with stage IB cervical cancer treated surgically, with or without RT, positive margin status conveyed a hazard ratio of 3.92 compared to negative margins. Also, margin status (distance in millimeters in patients with close margins) was significantly associated with an increased recurrence rate. In this series, postoperative RT eliminated local recurrences in patients with close margins and halved the recurrence rate in patients with positive margins (140).

Stage

The FIGO stage is universally accepted for its prognostic significance. For example, Fyles et al. (141), in 965 patients with invasive carcinoma of the cervix, identified FIGO stage as the most significant prognostic factor. Stehman et al., reporting for the GOG on 626 patients treated in phase 3 trials (142), confirmed the prognostic significance of tumor burden, whether measured by FIGO stage, centimeter size, or bilateral disease. Para-aortic node metastases conferred a much greater risk than any of the measures of volume of tumor, however. This emphasizes the fact that FIGO staging does not take into account important prognostic information such as nodal status. While some clinicians would place patients with known para-aortic nodal disease in the stage IV category, others would choose to stage according to approved clinical staging procedures, mainly pelvic examination. Furthermore, stage is only indirectly related to tumor volume, since there can be significant variability in this important prognostic factor within a given stage, resulting in substantial overlap within stage groupings.

Nodal Status

Lymph node involvement is, in most studies, the most significant negative prognostic factor. Reports emphasize higher 5-year survival rates (90% or higher) among surgically treated patients with no evidence of metastasis in the regional nodes, compared

to patients with positive pelvic (50% to 60%) or para-aortic nodes (20% to 45%). Delgado et al. (134) reported a 3-year disease-free survival of 85.6% for 545 patients with negative pelvic lymph nodes, compared with 74.4% for patients with one or more positive nodes. In an extensive review of the literature, Creasman and Kohler found that lymph node involvement was reported as an independent risk factor for survival in 88% of series reporting multivariate analyses, versus tumor size/depth of invasion in 61% of series (143). Decreasing 5-year survival rates have been associated with increasing numbers of positive pelvic nodes.

Even micrometastases appear to negatively impact prognosis. Marchiole et al. reported that recurrence was tenfold more likely in an early-stage population of patients treated with radical surgery compared to those without micrometastases (144). Similarly, in a retrospective study from Stanford, a much higher rate of recurrence was seen in early-stage surgically treated patients in whom lymph node micrometastases were detected immunochemically (145).

Lymphovascular Space Invasion

Lymphovascular space invasion (LVSI) proved to be a significant prognostic factor in a surgical-pathologic study of 542 patients completed by the GOG (134). Disease-free survivals were 77% and 89%, respectively, in patients with and without LVSI. Furthermore, LVSI was shown to correlate strongly with pelvic adenopathy. In a case-control study, Marchiole et al. established a relative risk of recurrence of 2.64 in patients with LVSI compared to those without (144). Chernofsky et al. quantitated the amount of LVSI in 101 consecutive patients who underwent surgery for stages IA2-IIA cervical cancer, showing that amount of LVSI was an independent prognostic factor for time to recurrence (146). In a similar but smaller study, Sykes et al. evaluated the density of lymphovascular space invasion, finding that it offered no useful information in addition to presence versus absence (147). Milam et al. showed a very strong correlation between LVSI on preoperative biopsy specimen and nodal metastases in surgically treated early-stage cervical cancer (148).

Hypoxia and Anemia

Fyles et al. published an excellent review of the basic, translational, and clinical data regarding anemia and its potential impact on radiosensitivity and radiocurability (149). Clearly, the interactions are much more complex than previously believed. For example, in the presence of anemia, adaptive mechanisms come into play that shift the oxyhemoglobin dissociation curve to the right, providing a compensatory increase in oxygen released into the tissues. There is also an increase in tissue perfusion and oxygenation as hemoglobin decreases due to reduced blood viscosity. However, these effects are potentially less effective in patients with diabetes, smokers, or patients who are vasoconstricting in the presence of marginal cardiac output.

Furthermore, the work of Fyles et al. shows that the relationship between pretreatment hemoglobin levels and direct measurements of oxygen tension in cervical cancers is tenuous. Interestingly, there was a positive correlation between hemoglobin and tumor oxygenation in nonsmokers, but the correlation was negative in smokers. Fyles et al. suggested that the negative prognostic impact of tumor hypoxia might be present only in subgroups of patients. Specifically, they observed worse outcomes with tumor hypoxia only in node-negative patients, manifested by an increase in distant metastases rather than poorer pelvic tumor control (150).

Fuso et al. looked at the impact of pretreatment serum hemoglobin as a predictive factor of response to neoadjuvant

chemotherapy in patients with locally advanced cervical cancer, finding hemoglobin level to be the most powerful predictor of response. A threshold of 12 mg/dL served to discriminate between optimal and nonoptimal response. However, the authors recognized that a lower hemoglobin level could also be simply a marker for more aggressive disease as opposed to a physiologic variable that could be manipulated for therapeutic benefit (151). The Southwest Oncology Group conducted a phase 2 study in 53 patients to determine whether erythropoietin along with oral iron therapy could safely correct anemia during chemoradiotherapy for cervical cancer. This study did show such an effect, at the cost of a higher than expected incidence of deep vein thrombosis (152).

A more important question therapeutically is whether correction of the anemia will improve oxygenation status and treatment outcomes. Human data from Sundfor et al. show that only 50% of transfused patients will show an increase in tumor oxygenation (153), similar to data from Fyles et al. (149). Furthermore, the significant association between tumor hypoxia and tumor size suggests that improving oxygen delivery is unlikely to improve outcomes owing to factors unrelated to oxygenation, such as number of clonogens, suboptimal brachytherapy dose distributions, and greater risk of metastatic disease.

In spite of the lack of a clear relationship between serum hemoglobin and tumor oxygenation status, various efforts have been directed to the correction of anemia as a therapeutic target. A common approach in cervical cancer and other malignancies has been the use of poietic proteins such as erythropoietin. However, two randomized studies (one in head and neck and one in breast cancer) showed a decrease in survival in the erythropoietic stimulation arm (154,155). A meta-analysis of randomized trials between 1985 and 2001, although not including the studies just mentioned, suggested the possibility of a small but difficult to measure improvement in survival (156).

Santin et al. investigated the effect of blood transfusion on immune function in patients receiving radiotherapy for cervical cancer. These investigators measured significant changes in percentages of lymphocyte populations that differed in transfused and nontransfused populations. Furthermore, interleukin-10, a potential dysregulator of lymphocyte function, was only observed in transfused patients. These findings provide a basis for implicating blood transfusion as a possible factor in diminished immune function (157). Additional basic and clinical research will be helpful in determining the reliability of these findings and the potential utility of altered hemoglobin and tumor oxygenation status on tumor sensitivity and treatment outcomes.

Another approach that has been used to potentially address tumor hypoxia is the application of hypoxic cytotoxins. Tirapazamine is one such agent that has shown promise in lung cancer and is currently under study (158).

A concern possibly related to the risk of decreased survival with poietic protein use is the associated risk of thromboembolic events. This topic is reviewed later in the chapter in the context of treatment complications. In addition, De Los Santos and Thomas have published an excellent review of the literature regarding the potential cellular and tissue responses to hypoxia (including angiogenesis), the potential advantages and disadvantages of anemia correction in the management of malignancies, and a review of the clinical data regarding the incremental increase in thromboembolism with the administration of hemopoietic factors (159).

Biomarkers and Bio-imaging

Multiple biomarkers with potential prognostic value have been evaluated in cervical cancer, often with conflicting results and conclusions (160). For example, measures of tumor proliferation parameters (e.g., potential doubling time, S phase fraction,

labeling indices), apoptosis, and other cellular characteristics often correlate with clinical outcomes. What is less clear is how to use this information in a way that improves therapy in the individual patient. Gaffney et al. performed immunohistochemical staining for epidermal growth factor receptor (EGFR), vascular endothelial growth factor (VEGF), topoisomerase-II alpha (TOPO-II), and cyclooxygenase-2 (COX-2) on specimens from 55 patients, and evaluated potential correlations between expression and outcome (161). On multivariate analysis, increased staining for VEGF and COX-2 correlated with an increased risk of death.

More recently, metabolic bio-imaging has been explored as a possible prognostic marker. Using F-18 fluorodeoxyglucose (FDG) positron emission tomography (PET), Xue et al. found a significant correlation between the standardized uptake value and disease-free survival (162). As suggested by the authors, high FDG uptake could be useful in identifying patients requiring alternate or more aggressive initial treatment. Similarly, Grigsby et al. used PET scanning to show that patients who are node-negative by PET scan might not benefit from concurrent chemoradiation as compared to RT alone (163). In terms of prognostic information, the same group performed pre- and post-treatment PET scanning in 152 patients. Those whose PET scans became or remained negative had an 80% 5-year cause-specific survival estimate compared to only 32% for those patients who showed persistent abnormal uptake (164).

Histopathology

There have been several reports of similar survival rates for comparable stages of adenocarcinoma and squamous cell carcinoma. Look et al. found no additional risk associated with adenocarcinoma compared to squamous carcinoma among stage IB patients (165). Similar observations were reported by Eifel et al. (166) for 334 patients with adenocarcinoma of the cervix. The 5-year relapse-free survival and locoregional control rates were 88% and 94%, respectively, for 91 patients with normal-sized cervix, 64% and 82%, respectively, for 102 patients with lesions 3 to 5.9 cm in diameter, but only 45% and 81%, respectively, for 22 patients with tumors greater than 6 cm in diameter. In a surgical series, Ayhan et al. reviewed 67 patients with IB adenocarcinomas and compared them to a concurrent series of 454 squamous carcinomas. Although the percentage of patients with metastases to three or more nodes was significantly greater in the adenocarcinoma group, there were no differences in overall or disease-free survival (167).

However, Kleine et al. performed a matched-pair analysis of squamous carcinomas (268 patients) and adenocarcinomas (144 patients) of the cervix, finding significantly lower 5- and 10-year survival in stages I-II adenocarcinomas (168). Baalbergen et al. reported 5-year survival rates of 79% and 37% for stages I and II adenocarcinoma of the cervix and less than 9% for stages III and IV, results that would be generally considered inferior to those typically obtained in squamous lesions (169).

A study of 505 patients with non-squamous cell carcinoma of the cervix examined histologic features for prognostic significance (170). In comparison with tumor limited to the cervix, tumor extension to the uterine corpus was correlated with twice the risk of dying of tumor. The grade and specific type of adenocarcinoma were not of prognostic significance in this study, although well-differentiated villoglandular adenocarcinoma and minimal deviation adenocarcinoma were not evaluated. There is no prognostic significance in the distinction between mucinous and endometrioid adenocarcinoma of the cervix. There is evidence that adenosquamous carcinoma is either a histologically more aggressive tumor than cervical adenocarcinoma or it is diagnosed later in the disease course (111).

Higher tumor grade and vascular invasion are statistically more common in adenosquamous carcinoma than adenocarcinoma

of the cervix. The presence of small cell neuroendocrine carcinoma in any amount, even when associated with other types of neoplasm, is an independent prognostic factor associated with aggressive tumor behavior.

GENERAL MANAGEMENT AND RESULTS OF TREATMENT

Prevention: HPV Vaccination

HPV is composed of a major capsid protein, L1, and a minor capsid protein, L2. L1's protein coat is transcribed at the superficial epithelial level and is capable of spontaneously assembling into an isometric capsid composed of 360 L1 molecules arranged in 72 pentameric capsomers. It is therefore capable of self-assembly into a virus-like particle (VLP) when expressed in recombinant systems. VLPs elicit strong adaptive immune responses, both B-cell and T-cell mediated, that are capable of protecting against subsequent type-specific infections (171).

L2 plays a critical role in incorporating the viral genome into the nucleus during the active phase of HPV infection and encapsulates the viral genome during the later stages of HPV replication. The underlying target and major site of the prophylactic vaccine against HPV is the L1-based VLPs. L1-based VLP vaccines are highly HPV type specific; evidence suggests that antibody responses to L2 may confer some protection against other oncogenic HPV types (172).

It is believed that most antibodies produced after exposure to HPV are type specific and do not necessarily cross react or protect against other types, although some data suggest some cross protection. HPV evades the reticuloendothelial system and does not undergo cytolysis; therefore, there is no release of immune modulators (173).

The efficacy of the HPV vaccine has been established in randomized clinical trials (172,174). A quadrivalent vaccine (QVV) targets HPV types 16, 18, 6, and 11, and bivalent vaccine (BVV) targets types 16 and 18.

Villa et al. (172) reported a double-blind, placebo-controlled, randomized trial evaluating the QVV in 277 young women (mean age of 20.2 years). Vaccine was given intramuscularly on day 1 and at 2 months and 6 months. The primary end point was combined incidence of infection with the types of HPV in the vaccine, cervical or external genital disease, HPV infection recorded, external warts, CIN, and invasive cancer. The combined incidence of persistent infection or disease with the HPV types in the vaccine was reduced by 90%.

Villa et al. (175) also reported highly sustained efficacy of the QVV in 552 women ages 16 to 23. The rate of persistent HPV-6, -11, -16, and -18 infection was reduced by 96% in the treated group. There were two cases of HPV infection in the vaccination arm versus 46 in the placebo arm. Protection against types 6, 16, and 18 was 100%, 86%, and 89%, respectively. No case of infection with HPV-11 was noted. The vaccine was 100% efficacious against CIN caused by all types 16 and 18. There was no case of genital warts in the vaccinated group. The seroconversion rate was high for all types (type 6, 94%; type 11, 96%; type 16, 100%; and type 18, 76%) at 3 years. Villa et al. (176) demonstrated a 12- to 26-fold higher antibody response following vaccination compared to that of a natural immune response after exposure to HPV.

Garland et al. reported a phase 3 study of the QVV in 5,455 women ages 16 to 24 years. The vaccine was 100% effective in preventing type-specific HPV-related genital warts, vulvar intraepithelial neoplasia (VIN), vaginal intraepithelial neoplasia (VAIN), CIN, AIS, and invasive cancers of the cervix, vulva, and vagina (177).

Olsson et al. evaluated the phenomenon of immune memory following the QVV in a randomized, placebo-controlled

trial (178). This study confirmed the finding of high immunity from initial vaccination and a robust immune memory response following a subsequent challenge dose, suggesting long-lasting efficacy of the vaccine.

Harper et al. reported a randomized, double-blind, placebo-controlled trial of the BVV in 1,113 women ages 15 to 25 years (174). Vaccine efficacy was 91.6% against incident infection and 100% against persistent infection for HPV types 16 and 18. In an intent to treat analysis, the vaccine efficacy was 95.1% against persistent cervical infection and 92.9% against cytologic abnormalities. These authors subsequently reported sustained efficacy of the BVV (179).

In these trials the vaccine was generally very well tolerated with very few side effects. The most common adverse effect was pain at the injection site. The vaccine has not been fully tested in women with HIV, and the immune response is unknown in that population.

The Advisory Committee on Immunization Practices (ACIP), an arm of the Centers for Disease Control and Prevention (CDC), and the American College of Obstetrics and Gynecology have recommended the QVV for all women ages 9 to 26 years. As the vaccine does not contain live virus, it is classified as category B for pregnant women. Its use and implementation in that population are not recommended as not enough safety data are available. Lactating women can receive the vaccine safely (180).

All women who receive the vaccine are recommended to be followed according to guidelines already set for cytologic smears as discussed previously. This is a potential pitfall as women may have a false sense of security that the vaccine is effective against all strains. However, up to 30% of CIN and invasive cancers are caused by strains not in the vaccine.

The vaccine is given at 0, 2, and 6 months. The vaccine is not effective in women with active HPV infection and abnormal cytology. HPV testing is not recommended before initiating HPV vaccination (181).

Goldie et al. reviewed the cost effectiveness and projected clinical benefits of HPV vaccination. They reported that the most cost-effective strategy is combining vaccination at age 12 with triennial conventional cytologic screening beginning at age 25. This would reduce the absolute lifetime risk of cervical cancer by 94% compared with no intervention (182). Sanders et al. estimated that if all girls at 12 years of age were vaccinated in the United States, over 1,300 deaths from cervical cancer would be prevented (183).

Block et al. reported the use of the QVV in men ages 16 to 23 years. They reported a seroconversion rate of 99% and antibody titers that were similar to vaccinated females (184).

It is recognized that psychosocial factors could negatively impact efforts to implement HPV vaccination programs. Parents might not accept vaccinations of their young daughters or sons because this could imply early sexual activity. Furthermore, the male child is not at risk for cervical cancer. Because the general population is relatively naïve about HPV and cervical cancer, mass education is needed to inform the public and health professionals about the HPV vaccine and follow-up after inoculation.

The HPV vaccine has the potential of significantly reducing the burden of cervical cancer worldwide, and particularly in less developed countries where screening and treatment programs are scarce. The impact of HPV vaccine on rates of invasive cervical cancer has not been established.

Severe Dysplasia and Carcinoma *In Situ*

Patients with severe dysplasia/CIN and carcinoma *in situ* (CIS) have essentially no risk of lymphatic involvement and are often treated with local therapies such as conization, laser ablation, cryotherapy, or a simple hysterectomy. These various techniques

have comparable efficacy. The more conservative approaches are preferentially used when a patient wishes to have more children. Patients with HIV infection, high HPV viral load, positive margins, older age, and residual high-risk infection following conservative management have a higher recurrence rate (185–187). Detection of residual high-risk HPV infection following conservative management predicts for a higher recurrence rate after conservative treatment (186,187). In 1976, Kolstad reported results of conization in treatment of CIS. Therapeutic conization was performed in 795 patients; 2.3% had recurrent CIS, and 0.9% developed invasive cancer (188). Two hundred thirty-eight patients were treated with hysterectomy and the corresponding rates were 1.2% and 2.1%, respectively. Luesley et al. reported a 91% success in over 600 patients treated with LEEP (189). Martin-Hirsch et al. in a review of the Cochrane Gynecologic Cancer Group registry, evaluated 23 trials in treatment of CIN. They concluded that there was no clearly superior surgical technique for treating CIN (190).

Instances in which conization might be preferred to ablative procedures such as laser or cryotherapy include presence of a positive endocervical curettage (ECC), treatment of adenocarcinoma *in situ* (AIS), and inadequate colposcopy due to the advantage of having a pathologic specimen. If the patient is not desirous of childbearing, a hysterectomy would also be a viable option. All uterus-sparing procedures have potential adverse effects including cervical stenosis, predisposition to preterm labor in subsequent pregnancies, persistent vaginal discharge, and possible infertility.

Temkin et al. reviewed 146 patients who had undergone cold knife conization after having been treated with LEEP for CIS (191). Of 146 patients, 133 had residual CIN on cone biopsy, and 15.8% had invasive carcinoma. Patients with residual CIN 3, ectocervical and endocervical margins with CIN, and positive endocervical curettages after conization were more likely to harbor or develop invasive disease. Lu et al. evaluated 449 patients with CIN 3 treated with conization (192). They found that a positive post-cone ECC was the most significant factor predicting persistent-disease-associated (65.5%) versus 7.6% with a negative post-conization ECC. Positive endocervical margins and multiquadrant disease had an odds ratio of 2.97 for persistent disease. The only preoperative indicator of persistent disease was age >50. Given these data, patients with positive ECC after conization or positive endocervical margins on a cone specimen for CIS should have repeat conization prior to hysterectomy to avoid inappropriate treatment for invasive disease.

Of interest is recent data reported by Case et al. evaluating CIN in adolescent women in which 192 patients with CIN 2,3 underwent conization. On follow-up, 55% had abnormal cytology but no invasive cancer was found (193). This may reflect a high infection rate and point prevalence with HPV in adolescents rather than true recurrence.

Since patients with CIS have virtually no risk of pelvic adenopathy, it is also appropriate to treat with only intracavitary RT. Tumor control rates of 100% have been reported. Grigsby and Perez successfully treated 21 such patients with a single intracavitary implant, delivering a mean point A dose of 46.12 Gy; no treatment sequelae were observed (194). Others might choose to use two separate low-dose-rate implants and slightly higher point A doses.

Stage IA

The concept of “microinvasion” (equating to FIGO stage IA) should define tumors that penetrate the basement membrane but have little or no risk of nodal involvement or dissemination. Elliott et al. reported a 0.8% rate of lymph node metastasis in stage IA1. All macroscopically visible lesions are considered stage IB tumors (195).

Controversies remain in regard to the clinically relevant definition of microinvasive squamous carcinoma of the cervix, particularly as conservative treatment options, including fertility sparing, have become more common. Takeshima et al. performed a clinico-pathologic analysis of 402 patients with invasive squamous carcinoma of the cervix whose tumors demonstrated no more than 5 mm of stromal invasion (196). Although the incidence of nodal metastasis was only 1% among 82 patients with invasion limited to 3 mm, it was nearly 7% in 73 patients with 3 to 5 mm of invasion. Nevertheless, recurrences were rare and were nearly exclusively limited to tumors with more than 7 mm of horizontal spread. In an accompanying editorial, Creasman noted that this work validated the FIGO definition of microinvasion and potentially opens up the IA2 patients for consideration of more conservative surgical approaches (197).

Stage IA1 carcinoma is usually treated with conization or hysterectomy. The control rate approaches 100% (188). Morris et al. demonstrated the efficacy and safety of cervical conization as definitive treatment for these patients (198). Absence of LVSI plays a key role in opting for conservative management of patients with MID as its presence may herald a higher incidence of lymphatic involvement. Buckley et al. found that tumor recurrence was greater in positive LVSI tumors as compared to those with no LVSI (9.7% vs. 3.2%) (199). Roman et al. found that LVSI was a significant factor in pelvic nodal metastasis (200). If fertility is not a consideration and prognostic factors for recurrence such as positive post-cone ECC or involved margins are present, a hysterectomy is the standard option for definitive treatment of stage IA1 (188).

Management of stage IA2 disease is more controversial. Patients with FIGO IA2 disease with LVSI are not candidates for conservative surgical approaches in most circumstances. The average pelvic lymphatic metastasis rate from reported data is 5% to 13% (199,201).

Presence and greater extent of LVSI are poor prognostic signs and predict a higher recurrence rate (199). The recommended treatment for stage IA2 squamous cell carcinoma is a modified (type II) radical hysterectomy and pelvic lymphadenectomy, although curative intent RT is an equivalent option. However, the role of radical hysterectomy and the need for parametrial resection have been challenged in this population. Covens et al. evaluated 842 patients (202). Six percent had positive pelvic nodes, and 4% had parametrial involvement. Parametrial invasion was associated with LVSI, tumor size >2 cm, higher tumor grade, greater depth of invasion (DOI), and pelvic node metastasis. The incidence of parametrial involvement in patients with tumors <2 cm, negative pelvic nodes, and DOI <10 mm was 0.6%. They concluded that because most patients with positive nodes and deep invasion will likely receive adjuvant pelvic RT, resection of the parametrium may not be necessary. Kodama et al. found that simple or modified radical hysterectomy alone may be sufficient in IA2 lesions with no LVSI (203). Gadducci et al. validated the role of conization in stage IA1 and found that simple hysterectomy with pelvic lymphadenectomy may be sufficient for stage IA2 (204). Some have advocated for conization and pelvic lymphadenectomy in stage IA2. Greer et al. evaluated 50 patients with stage IA2 treated with cone biopsy followed by radical hysterectomy, finding histologically positive margins in 66% of patients after conization. The rate of residual invasive disease discovered after radical hysterectomy was 24% in patients who had negative margins after conization (205). It is difficult to justify conization alone as definitive therapy for stage IA2 disease.

Nam et al. reported a comparative study of laparoscopic-vaginal radical hysterectomy and abdominal radical hysterectomy in patients with IA1 to IB cancers less than 2 cm in maximum dimension (206). These authors found excellent survival in both groups but higher recurrence rates among the larger lesions in the laparoscopic group.

In the absence of a clear consensus on the type of hysterectomy (simple vs. abdominal modified radical vs. laparoscopically assisted vaginal) in stage IA2 disease, a modified radical hysterectomy with pelvic lymphadenectomy is most easily supported until clearer data is presented.

In patients who are medically inoperable, intracavitary RT may be used successfully. Hamberger et al. studied 151 patients with stage I treated with intracavitary radium. None of the patients with stage IA recurred (207). Grigsby et al. treated 34 patients with stage IA with 13 receiving intracavitary RT only and the remaining 21 treated with pelvic RT. Only one patient with stage IA recurred. The overall complication rate was about 6% (194).

Adenocarcinoma—Early Disease

The incidence of cervical adenocarcinoma has increased in the past 40 years. Adenocarcinoma *in situ* (AIS) presents a potential diagnostic and therapeutic challenge. The term “microinvasion” is controversial in describing glandular lesions as accurate measurement of depth of invasion in glands may be difficult. Schorge et al. provided some parameters for defining stage IA1 adenocarcinoma in 1999 (208). Almost all AIS lesions are associated with HPV, with 18 being the predominant type. Management of AIS is controversial. Schorge et al. reported on five women who were treated with conization for stage IA1 adenocarcinoma (209). All had negative margins and no LVSI. No recurrence was seen in follow-up of 6 to 20 months. Schorge et al. also reported on ten patients with AIS treated with conization with negative margins and no LVSI; of seven evaluable patients, none had recurrence within 2 years (210). Shin et al. reported on 92 patients with AIS treated with conization with negative margins (211). During a 30-month follow-up, none had recurrent AIS. Sixty-two percent of those with positive margins after conization had residual disease on hysterectomy specimens. Wolf et al. reported their experience in which, out of 55 patients treated with conization, 80% had subsequent hysterectomy (212). Seven out of 21 (33%) patients with negative margins on conization had residual disease in the hysterectomy specimens, and three had invasive cancer. Of 19 with positive margins after conization, 10 (53%) had residual disease on hysterectomy specimen, and 5 had invasive cancer. The overall rate of residual disease in hysterectomy specimens after conization with negative margins is 25% and with positive margins around 50%. Lea et al. highlighted the importance of post-conization endocervical curettage, demonstrating a positive predictive value of 100% for detecting residual disease (213). Widrich et al. evaluated margin status of AIS lesions following cold knife conization and LEEP (214). The rates of positive margins were 33% and 50%, respectively. Given the critical role of margin status post-conization, a cold knife technique may be preferred in patients with AIS. The recommended surveillance after conization for AIS includes cytology and ECC every 4 months. The most successful conservative management protocols require negative margins and no LVSI. Therefore, careful counseling and follow-up are warranted.

Stage IB-IIA (Non-bulky)

Stage IB is divided into IB1 (lesions less than 4 cm) and IB2 (lesions confined to cervix >4 cm). IB1 lesions and selected IIA lesions without extensive vaginal involvement can be treated with either RH and pelvic lymph node dissection (PLD) (followed by tailored chemoradiation as indicated by surgical findings) or primary chemoradiation. The preference of one over the other depends on the institution, the oncologists involved, the general condition of the patient, and tumor characteristics. Surgery is the preferred option in younger women as ovarian function and

vaginal length, and thus sexual function, can generally be maintained. Transposition of the ovaries to the abdominal wall or the gutters away from the field of RT may prevent radiation-induced ovarian failure. Chambers et al. reported that 71% of patients maintained ovarian function after ovarian transposition (OT) and pelvic RT (215). The preservation of function correlated with the estimated scatter dose to the ovaries. The rate of ovarian failure was 11% with doses ≤ 300 cGy, compared to 50% if the estimated dose was >300 cGy. Others have reported that up to a quarter of patients with OT had symptomatic ovarian cysts requiring operative interventions, and only 53% retained ovarian function (216).

Radical hysterectomy can be performed through an abdominal, vaginal, or minimally invasive approach (traditional laparoscopy and robotic assisted). As salpingo-oophorectomy is not part of RH, ovarian removal should be based on the patient's age or other factors. The rate of ovarian metastasis is very low, about 0.9% (217). The two most common types of RH used in treatment are classes II and III, described elsewhere in the chapter. Landoni et al. compared these two approaches in a prospective, randomized trial in 238 patients (218). Type II had a significantly decreased mean operative time (135 minutes vs. 180 minutes), and the rate of blood loss and transfusions was comparable. Immediate postoperative complications and length of hospital stay were also similar. The long-term complication rate was significantly less in type II versus type III (13% vs. 28%). The use of postoperative RT, recurrence rate, and death rate due to disease were similar in both arms. The overall survival was 81% and 77%, respectively.

Nam et al. performed a retrospective analysis of outcomes with laparoscopic radical hysterectomy with or without pelvic lymph node dissection with conventional radical hysterectomy (206). Operating time, complication rate, and number of lymph nodes obtained were similar with the two approaches. Hospital stay was shorter with the laparoscopic technique. Overall, recurrences were lower with the standard operative route, leading the authors to recommend limiting the laparoscopic approach to patients with tumor diameters less than 2 cm.

Radical operation will shorten the functional length of the vagina, but pliability and transudative lubrication are usually preserved. Jensen et al. documented a substantial negative impact on sexual function that is persistent following radical hysterectomy (219). Radiation therapy can reduce length, caliber, and lubrication of the vagina; however, these symptoms can be alleviated in some patients with hormonal replacement and vaginal dilatation. The evidence to differentiate between surgery and radiation based on sexual function is poor. A strong predictor of post-therapy sexual function is the level of activity prior to therapy. The postmenopausal patient who is not sexually active may have complete obliteration of the vagina, precluding follow-up examination. Combined modalities appear to have a more pronounced effect than either radiation or operation alone (220).

In terms of outcome, radical surgery and definitive chemoradiation have similar good outcomes. Typically, 5-year survival for stage IB patients is 85% to 90% and 65% to 75% for stage IIA. Landoni et al. reported a prospective study of RH versus RT (221). In the RH arm, patients with parametrial involvement, deep stromal invasion, and/or positive nodes received postoperative RT. Fifty-four percent (62 out of 114) and 84% (40 out of 55) of stages IB1 and IB2 received postoperative RT, respectively. Severe morbidity was seen (28%) in the surgical arm (mostly combined surgery and RT) compared to 12% in the RT arm. No difference was seen in disease-related outcomes.

Results of therapy comparing modalities should include all patients evaluated for each therapeutic modality. This applies particularly to surgical series. Findings revealed at operation may change the treatment plan, excluding some high-risk patients. This is exemplified by a report by Delgado et al. (222)

for the GOG. Member institutions entered 1,125 patients prior to operation. There were 80 ineligible patients after pathology review. An additional 129 patients were explored, but the hysterectomy was abandoned because of intraoperative complications in 49 patients, or because of extent of disease beyond the uterus in 80. Failure to account for these patients in other series overestimates the efficacy of the operative procedure.

It is best to select patients who can have a high chance of being adequately treated with only one modality, assuming equal oncologic outcomes.

Fertility-Sparing Surgery/Radical Vaginal and Abdominal Trachelectomy

Almost 30% of women diagnosed with cervical cancer will be less than 40 and 40% will have early stage I disease. Preservation of fertility can be a major consideration in treatment if an acceptable oncologic outcome can be obtained. Recently, there have been major advances in fertility-sparing surgery (FSS) in women with stage IA2 to IB1 cervical cancer. Dargent pioneered the procedure of transvaginal resection of cervical and paracervical tissue (vaginal radical trachelectomy, VRT) and proximal vaginal, placement of a permanent cerclage at the cervico-uterine junction, and a laparoscopic pelvic lymphadenectomy (LPL) (223).

Plante et al. reported on 72 patients treated with VRT and LPL (224). Median age was 32, with 74% being nulligravid. Fifty pregnancies occurred in 31 women. Miscarriage rates in the first and second trimester were 16% and 4%, respectively, and 72% of pregnancies reached the third trimester. The overall prematurity was rate was 16% to 19% versus 12% in the general population.

The overall recurrence rate in the literature is about 4%, comparing favorably with standard treatment (224). Bader et al. reported an isolated recurrence on residual uterine cervix in 6 months, and Bali et al. reported a central recurrence 7 years post VRT (225,226). In a review, Boss et al. reported that of patients electing FSS, 43% attempt conception, 70% conceive, 49% deliver at term, and 15% have cervical stenosis causing infertility (227).

Marchiole et al. compared VRT with LPL to radical vaginal hysterectomy (RVH) with LPL in patients with lesions <2 cm (228). They reported similar intraoperative complication rates (2.5% vs. 5.8%, respectively) and postoperative complication rates of 21.2% and 19.4%, respectively. The recurrence rates were also similar, 5.2% and 8.5%, respectively. Ungar et al., among others, have reported an abdominal approach to radical trachelectomy (ART) (229).

In terms of patient selection, appropriate lesions include FIGO stage IA1 without extensive LVSI and IA2 or IB1 lesions less than 2 cm with limited endocervical involvement. Although early data is encouraging, no level I evidence exists to adequately compare safety and efficacy between conservative and radical surgical approaches. Whether adenocarcinomas are appropriately managed in this fashion is subject to debate; however, in the literature, close to 40% of cases were of glandular histology.

Bulky IB Carcinoma of the Cervix

Bulky endocervical tumors and the so-called barrel-shaped cervical cancers have a higher incidence of central recurrence, pelvic and para-aortic lymph node metastasis, and distant dissemination. Historically, adjuvant extrafascial hysterectomy following preoperative RT was an accepted treatment approach.

The GOG performed a randomized trial in which 256 eligible patients with carcinomas of the cervix ≥ 4 cm were treated with external beam and intracavitary irradiation, or with a

slightly lower dose of intracavitary irradiation and the same external beam pelvic irradiation followed by an extrafascial hysterectomy (230). The 3-year disease-free survival and overall survival rates were 79% and 83%, respectively, and were virtually identical in the irradiation alone and the combined irradiation and surgery groups. The incidence of progression was somewhat higher in the irradiation alone group (46%) compared to the combined therapy group (37%) ($p = 0.07$). However, it appears that surgery does not contribute to increased survival compared to RT alone in patients with "bulky" stage IB disease. A favorable impact on the local recurrence rate with adjuvant hysterectomy is likely, and an improvement in survival for patients with tumors 4 to 6 cm in diameter is suggested. Nevertheless, conventional management typically involves chemoradiation (231).

Boronow reported a survival rate of 71.3% in patients with tumors greater than 6 cm who were treated initially with radical hysterectomy and postoperative RT and chemotherapy in all cases (232). Complications were reported to be minimal. Havrilesky et al. reported an analysis of 72 patients who underwent radical hysterectomy and lymph node dissection for stage IB2 cervical cancer, followed by adjuvant RT for high-risk features (233). The 5-year survival was 72%, and the 5-year progression-free survival was 63%. Survival was particularly poor for high-risk patients. Yessian et al. also reported their experience with initial radical surgery and tailored postoperative RT in stage IB2 patients (234). As postoperative RT was used less frequently than suggested by currently reported randomized trials, the recurrence rate was 38%, and the estimated 5-year survival was only 62%. Interestingly, out of 21 recurrences, 11 were on the pelvic sidewall.

Kamelle et al. retrospectively analyzed 86 patients with IB2 tumors treated with radical hysterectomy (235). Over half the patients received postoperative RT. This study identified presence of LVSI as the only independent predictor of recurrence and argued for the utility of radical hysterectomy up front in the management of patients with intermediate-risk IB2 cervical cancers when there is no evidence of LVSI. Two accompanying editorials questioned several aspects of the analysis, including the diagnostic accuracy of a cervical biopsy in determining LVSI, the small numbers of patients and wide confidence intervals, the possible inferiority of radical hysterectomy compared to modern chemoradiation, and the wisdom of relying on a single variable to determine therapy when there are a number of other recognized considerations for prognosis and treatment selection (236,237).

Stages IIB, IIIB, and IVA

Most patients in the United States with stage IIB disease are treated with curative intent chemoradiation. With RT alone, the 5-year survival rate has historically been 60% to 65%, and the pelvic failure rate 18% to 39%. Similarly, most patients with stage III and IVA tumors are best treated with concurrent chemoradiation. Leung et al. reported long-term outcomes in 91 patients with stages IIIB ($n = 84$) and IVA ($n = 7$) tumors treated curatively with RT. With a median follow-up of 8.8 years, the 5- and 10-year local control rates were 53% and 53%, respectively, and 5- and 10-year survival rates were 29% and 21%, respectively (238). The severe complication rate was 13%.

Based on multiple randomized clinical trials, concurrent cisplatin is a standard agent to combine with RT. Other chemotherapy agents that have been used successfully include 5-fluorouracil (5-FU), mitomycin, carboplatin, paclitaxel, and epirubicin. This data is nicely summarized in an article by Eifel (Table 22.2) (231). As acute effects are increased when conventional chemotherapy is added to RT, the clinician must always

weigh the risk of acute side effects and the threat posed by them with the potential benefit in patients with significant comorbid illnesses and poor performance status.

Chemoradiation should result in outcomes that compare favorably to these older series. Considering all eligible patients with stages IIB-IVA carcinomas enrolled in GOG #85, a 55% survival rate with platinum-based chemotherapy with RT was demonstrated after a median follow-up of 8.7 years (239). In this same group of patients, GOG #120 found a 66% to 67% survival rate with platinum-based chemoradiation (240).

External Irradiation Alone

Rarely, brachytherapy procedures cannot be performed because of medical reasons or unusual anatomic configuration of the pelvis or the tumor (e.g., extensive lesion and inability to identify the cervical canal, presence of a fistula). These patients may be treated with higher doses of external irradiation alone, although the results are inferior to those obtained with combined external beam and intracavitary irradiation.

Although speculative, results of external RT alone could be improved over historical results with the utilization of intensity-modulated RT (IMRT), which could allow higher doses to be delivered to the tumor volume while respecting normal tissue tolerances.

UNUSUAL CLINICAL SITUATIONS

Node-Positive Early-Stage (Operable) Cervical Carcinoma

Approximately 15% of patients with surgically amenable cervical carcinomas (FIGO stages I-IIA) will have positive pelvic nodes. Of these, a percentage less than 50% will have grossly positive nodes recognized intraoperatively. When this occurs, the dilemma becomes whether to proceed with the radical hysterectomy or to abandon the surgery and opt for curative intent chemoradiation. Whitney and Stehman reviewed the GOG #49 database and found that, in 98 of 1,127 patients with clinical stage IB tumors, the surgeon abandoned the operation. Sixty-eight of these were patients with squamous carcinomas whose surgery was abandoned due to tumor extension beyond the uterus rather than for medical reasons, forming the basis of their report (241). Of these, 17 (1.5% of the total group, 25% of the study group) patients had grossly positive pelvic lymph nodes, and 12 (1.1% of the total group, 17.6% of the study group) had this finding as the only manifestation of extrauterine disease. Most patients received curative intent RT when feasible. Patients with positive pelvic nodes did poorly, with 8 of 12 failing, including 3 with distant disease. The median recurrence-free interval was only 10 months, and the median survival was 17 months. The main conclusion from this study was that it is invalid to directly compare results of surgical treatment with results from RT, since surgical series typically exclude the patients with a poor prognosis in whom the operation is abandoned, while these patients would be included in the RT series.

Should the Hysterectomy Be Completed?

Leath et al. reviewed 23 patients with early-stage cervical cancer who had the radical hysterectomy aborted because of pelvic extension (11 patients) or positive nodes (12 patients) (242). All received RT as definitive treatment. The 5-year overall survival was 83%, suggesting that the aborted radical hysterectomy did not negatively impact outcome.

Bremer et al. reported considerably better outcomes in a series of 26 patients in whom the operation was aborted after the intraoperative finding of positive pelvic nodes. Five-year survival was 61% in this patient group (243). Morbidity was limited. Suprasert et al. compared 23 patients in whom the radical hysterectomy was aborted due to the intraoperative finding of grossly positive nodes with 35 patients whose positive nodes were detected after completion of the operation. Although the outcome was substantially better in the group completing surgical treatment, the authors recognized that the surgical group had much better prognostic factors (244).

Although older, probably the best data regarding whether to complete the hysterectomy come from Potter et al., who did a matched-pair analysis of 30 patients with positive pelvic nodes. Patients undergoing hysterectomy also received pelvic RT (245). There was no survival or local control advantage conferred by completing the radical hysterectomy; however, local control data suggested a trend favoring definitive RT.

In patients with positive nodes, the use of concurrent chemotherapy would be advised based on the possibility of distant spread and the need to optimize pelvic control. Randomized data support the addition of chemotherapy to postoperative RT in these patients (245).

Based on available data, it is difficult to conclude that completing the hysterectomy improves the outcome. Possible disadvantages of surgery include delaying the initiation of RT, adding surgical morbidity, and utilizing two treatment modalities when one (RT) would likely suffice. Furthermore, leaving the uterus in place provides an appropriate conduit for intracavitary RT and probably lessens the risk of complications. Clinicians who believe that completing the radical hysterectomy improves outcome, even with positive nodes, will point to data suggesting that patients who undergo radical hysterectomy, as a group, have a better outcome than the patients in whom the procedure is aborted (241,243). Others will point out that the groups are not prognostically similar and suggest that a reasonable approach is to have the surgeon resect or debulk grossly positive nodes and surgically stage the para-aortics but abort the radical hysterectomy. RT with chemotherapy would then become the primary therapy.

Should the Lymphadenopathy Be Debulked?

Data suggests an advantage for surgically resecting grossly positive lymph nodes prior to RT, although others have questioned the benefit in the vast majority of patients (247). Kupets et al. calculated that only 7 out of 300 patients undergoing surgical debulking of positive nodes could benefit in terms of survival. These calculations are based on assumptions suggested to be faulty by Tammela et al. (248), who calculated that 43 patients out of 300 would benefit.

Invasive Carcinoma Treated by Simple Hysterectomy

Given the frequency of simple hysterectomy or total abdominal hysterectomy (type I), it is not surprising that occasionally a patient is found to have an invasive cervical cancer unrecognized prior to surgery. Although this occurs uncommonly in an era of cytologic screening, it can occur in patients operated on for what is felt to be carcinoma *in situ*, "microinvasive" disease, or for "benign" indications.

If only microinvasive carcinoma is found, with no evidence of LVSI, no additional therapy is necessary. However, in patients with more advanced disease, simple extrafascial abdominal hysterectomy is not curative, because the paravaginal/paracervical soft tissue, vaginal cuff, and pelvic lymph nodes are not removed.

It may be technically difficult to perform an adequate radical operation after previous simple hysterectomy, but this alternative deserves consideration for selected patients. In 23 stage

FIGURE 22.13. The influence of type of treatment on disease-free survival in patients undergoing radical hysterectomy with and without RT and those who had simple hysterectomy followed by adjuvant RT. (Kaplan-Meier analysis, $p =$ not significant). *Source:* From Munstedt K, Johnson P, von Georgi R, et al. Consequences of inadvertent, suboptimal primary surgery in carcinoma of the uterine cervix. *Gynecol Oncol* 2004;94:515–520.

IA2 and IB1 patients, Leath et al. reported good results with a radical surgical approach, although three patients also received postoperative RT. The operative complication rate was 30% (249). Another approach favored by some is the use of adjuvant pelvic RT in patients with invasive disease of severity greater than microinvasive. A large series of 90 patients, including 18 stage II patients, treated with RT following inadvertent hysterectomy was reported by Hsu et al. (250). Overall 5- and 10-year survival rates were 85.5% and 74.1%, respectively. Long-term complications were rare. Munstedt et al. reviewed their experience with 80 patients who had inappropriate simple hysterectomies followed by postoperative RT and compared outcomes with those undergoing radical hysterectomy, with or without postoperative RT (251). These authors found that patients who had inadvertent hysterectomies followed by postoperative RT had outcomes at least equivalent to those who had radical hysterectomies up front (Fig. 22.13). In an exhaustive review of the literature comparing series of patients having reoperation with radical parametrectomy and lymph node dissection (LND) versus those having postoperative RT, the weighted average 5-year survival favored RT (68.7% vs. 49.2%) (Table 22.3)

If the postoperative RT approach is chosen, postoperative irradiation should be administered immediately after recovery from operation, as prognosis is much worse if therapy is delayed. When there is gross tumor present in the vaginal vault, external irradiation to the whole pelvis (40 to 45 Gy) is required. In some cases, a small external beam boost might be advisable for an additional 10 to 15 Gy. An intracavitary insertion, as outlined previously, should be performed (35 to 60 Gy mucosal dose). If there is residual tumor, an interstitial implant, when feasible, should be carried out to increase the dose to this volume. The brachytherapist should note the possibility that small bowel is adherent to the vaginal cuff in the hysterectomized patient, representing a risk factor for complications with interstitial implants. Laparotomy or laparoscopy can be helpful in guiding the implant in these circumstances.

The potential contribution of concurrent platinum-based chemotherapy must be considered, particularly in view of the

randomized study of patients treated after radical hysterectomy with high-risk features (246). Although not directly comparable, it is reasonable to extrapolate these results favoring concurrent chemotherapy to patients treated after simple hysterectomy for invasive disease, particularly in patients with gross residual, positive margins, positive nodes, lymphovascular space invasion, and, possibly, adenocarcinoma.

Stage IIIA Carcinoma of the Cervix

Cervical carcinomas extending to the lower third of the vagina without pelvic sidewall extension or hydronephrosis are uncommon, representing less than 2% of patients with cervical cancer. As a result, these patients are often not reported separately, although management presents a significant challenge to the radiation oncologist. In general, these patients have a better prognosis than stage IIIB patients, especially when there is limited parametrial extension and the vaginal involvement is continuous with the cervix.

Kavadi and Eifel (252) found a local control rate of 72% in 44 patients, but 5- and 10-year actuarial survival rates were 37% and 34%, respectively, reflecting the impact of distant failure seen in 13 patients. In this series, patients with no parametrial extension and direct extension from the cervix (as opposed to “skip” lesions in the lower vagina) had a 5-year survival of 73%.

The inguinal lymph node areas must be assessed clinically and radiographically. When this assessment is negative, RT is

FIGURE 22.14. (See color plate section.) This coronal dose plot shows how IMRT can be used to deliver adequate radiation dose to inguinal areas while limiting dose to femoral heads, as might be necessary in a cervical cancer extending to the lower third of the vagina. *Source:* From Jhingran A. Potential advantages of intensity-modulated radiation therapy in gynecologic malignancies. *Semin Radiat Oncol* 2006;16:144–151.

given to the inguinofemoral nodes prophylactically. When the lymph node assessment suggests gross disease, it might be appropriate to confirm this with needle biopsy or consider the role of inguinal lymph node dissection following RT. Alternatively, RT doses can be escalated to reflect the presence of gross tumor.

Treating the inguinal nodes adequately while limiting the dose to the underlying femoral heads is a challenge. Understanding the location of the inguinal nodes is best accomplished by measuring the depth of the femoral vessels by a cross-sectional imaging technique. The depth of these nodes averages 6 cm and can vary substantially and be beyond the range of typical electron energies. Dittmer and Randall have reported a photon-only technique that provides good coverage of inguinal nodes at depth, minimizes “hot” and “cold” spots, and respects the tolerance of the femoral heads in most cases (Fig. 21.5A and B, previous chapter) (253). Intensity-modulated techniques are also possible (Fig. 22.14).

More difficult is the challenge of delivering tumoricidal doses of radiation to the entire vagina while respecting tolerances of the normal tissues, in particular the rectum. Given that virtually the entire length of rectum will be treated with an intracavitary approach encompassing the entire vagina, the tolerance will be lessened, and the risk of complications will increase. In addition, because of the typical “slope,” or decrease, in patient thickness in the superior-inferior direction, there will be a dose gradient that can result in “hot” spots of 120% to 125%. This is potentially remediable with intensity-modulation techniques, although another approach is simply to measure the dose gradient and take it into account by raising the lower border accordingly, and/or taking the gradient into account during the brachytherapy portion of the treatment.

A general approach is to give external beam RT to the pelvis and entire vagina of approximately 40 to 44 Gy over 5 weeks (delivering 50 Gy to the inguinal areas at depth), and follow this with one or two intracavitary implants. An intrauterine tandem combined with Delclos rings permits delivery of a controlled, measurable dose to the vagina. One should aim for a total dose of approximately 65 Gy to the entire vagina, combining the external and intracavitary doses. One can consider a second implant that does not treat the entire vagina, typically with a Fletcher-Suit applicator, particularly when there is parametrial extension. Ideally, one will deliver 80 to 85 Gy to point A in this fashion, but if the maximum rectal dose is limited to 60 to 65 Gy

some compromise in point A dose may be required. These doses are appropriate only for low-dose-rate techniques, which are to be preferred when treating the entire vagina.

It is appropriate to administer cisplatin-based chemotherapy with the external RT with the hope of improving survival. However, concurrent chemotherapy will likely increase acute toxicities, particularly given the increased volume encompassed by the RT port and the sensitivity of the vulva to RT. Considerable individualization of therapy is required.

Small Cell Carcinoma of the Cervix

The term “small cell” should be limited to those rare tumors with counterparts in the lung and other anatomic locations noted for a high proliferation rate, marked propensity to regional lymph node and distant metastases, and positive staining with neuroendocrine markers (116). These tumors account for less than 3% of cervical neoplasms.

Small cell carcinomas are not often confined to the cervix and surrounding tissues at diagnosis. Therefore, workup may include bone marrow aspiration and other tests to detect the metastatic spread characteristic of this histology. Lymph node involvement is present in over 50%, and vascular invasion is frequently present. Viswanathan et al. reviewed 21 patients meeting stringent criteria for neuroendocrine type small cell cervical carcinomas (254). Ten patients had IB1 disease (although 2 of these had radiographic evidence of nodal metastases), and 11 patients had IB2-IIIb disease. Six patients underwent radical hysterectomy (5 of these were IB1), and 15 patients had RT as curative intent treatment. Cisplatin-based chemotherapy was given to 62%, either neoadjuvantly and/or following surgery or RT. No patient with greater than stage IB1 survived, and even for stage IB1 patients, the survival was much worse than would be expected in more common histologies. In-field RT failures were uncommon, but metastatic failures were not. Given the propensity to distant metastasis, the use of combination chemotherapy has been widely accepted in these patients (255). Prophylactic cranial RT has also been given following this chemoradiation in the absence of progression. However, its role remains unclear.

Cervical Lymphoma

Lymphomas primarily arising and confined to the cervix are quite rare. Patients often present with signs and symptoms including vaginal bleeding, discharge, and pelvic pain. Cervical lymphomas typically develop and grow submucosally; therefore, Pap smears often do not detect these neoplasms. Generous punch biopsies or conizations are often required for diagnosis. Histologically, these lymphomas are typically of the diffuse, large B-cell variety (256,257).

Due to the rarity of this diagnosis, reports of management approaches are anecdotal and there is no clear consensus. However, general guidelines can be suggested. Clearly, treatment with systemic therapy using combination chemotherapy regimens is indicated in the majority of cases (256–259). The CHOP regimen (cyclophosphamide, doxorubicin, vincristine, prednisone) is commonly used. Surgery has been used as an adjunct to chemotherapy, either before or after chemotherapy, especially in patients with stage I or II disease. Radiation therapy following chemotherapy should be considered, particularly for larger tumors, tumors that do not completely respond to chemotherapy, and in patients with early-stage disease who are not candidates for or refuse hysterectomy (258,259).

Young patients who wish to preserve fertility can be counseled about the possibility of conization followed by fertility-preserving chemotherapy and close follow-up. Conception has

been reported in patients treated in this fashion, although the outcome of these pregnancies is unclear due to their overall rarity (256,260).

Cervical Sarcomas

Primary sarcomas arising in the cervix are exceedingly rare. In a tumor registry of 1,583 patients with cervical malignancies conducted at Washington University, only eight sarcomas were identified. Five of these were carcinosarcomas. All six patients treated with curative intent remained alive with a mean follow-up of 2.5 years, although two patients had developed pulmonary metastases. Radical surgery and chemoradiation were both effective in curing patients with localized pelvic disease (125).

Granulocytic sarcoma can present as a cervical neoplasm. It is important to distinguish this lesion from primary cervical lymphoma, as this is a manifestation of acute myelocytic leukemia and the chemotherapy regimens are quite different. Outcomes for these patients are generally dismal (261).

Carcinoma of the Cervical Stump

Historically, in patients who have undergone subtotal or supracervical hysterectomy, carcinoma of the cervical stump made up nearly 4% of cases treated with RT. Although the incidence has greatly declined, these increasingly rare patients remain at risk of developing cervical carcinoma. The natural history and patterns of spread of these cancers are similar to those of the cervix in the intact uterus. The diagnostic workup, clinical staging, and basic principles of therapy are the same. However, there are potentially important differences in treatment.

Radical operation for stage I cervical stump carcinomas (trachelectomy) is made more difficult by the previous procedure. Barillot et al. prospectively accrued 213 cases of cervical stump carcinoma (262) and reported that stage for stage, local control and survival were equivalent among the surgically treated and the RT-treated patients. However, lethal complications were much more likely in the surgically treated patients. Patients receiving RT including brachytherapy had significantly better results than those having only external RT. Severe complications with RT were similar to those observed among patients with intact uteri.

The higher complication rate probably relates to the lack of adequate uterine cavity length to accommodate a tandem containing two or three sources. However, some patients with a history of supracervical hysterectomy retain enough lower uterine segment to insert two standard cesium-137 sources. As many sources as technically feasible should be inserted in the remaining cervical canal without protruding active source length through the cervical os. Comparably higher activity sources should be used in the tandem, allowing a greater contribution from these sources to the point A dose and a correspondingly lower vaginal mucosal dose.

In early-stage tumors, it is critical to maximize the brachytherapy portion of the treatment, because this allows higher doses to be delivered to the tumor while limiting dose to normal structures. Early midline shields (e.g., at 20 to 30 Gy) are desirable. Limiting the total external beam dose to 40 Gy, optimizing the intracavitary RT with proper packing and distribution of activity, and respecting the tolerances of the rectum and bladder will keep complication rates reasonably low. Limiting the maximum rectal dose to 65 or 66 Gy and the bladder dose to around 80 Gy is desirable, even if the point A dose is somewhat compromised (<80 Gy). More advanced stages should be treated with 40 Gy to the pelvis, combined with the maximum intracavitary doses permitted within tolerance. Platinum-based chemotherapy will be indicated in most cases.

Limited sidewall boosts may be necessary, depending on the dose to the sidewalls from the brachytherapy and the radiographic evaluation of the nodes. When there is no opportunity to insert any sources in the cervical canal, the whole pelvis dose should be increased to 45 Gy, and the primary tumor boosted to around 60 to 65 Gy with shrinking fields. Stereotactic and intensity-modulated RT techniques can be used to escalate doses to the primary tumor.

The 5-year survival for carcinoma of the cervical stump treated with irradiation is similar to that reported for patients with carcinoma of the intact uterus.

MANAGEMENT OF CERVICAL CANCER DURING PREGNANCY

Of all patients with cervical cancer, about 1% are pregnant at diagnosis (263). Most will present with abnormal cytology or abnormal vaginal bleeding. Overall incidence of abnormal cytology in pregnancy is about 5% (264). The availability of cervical cytology in developed countries affords an opportunity to diagnose early dysplastic changes during pregnancy, which may contribute to a higher incidence (3:1) of stage I cervix cancer diagnosed during pregnancy compared to the nonpregnant state (263). Either conventional or liquid-based cytology is effective in pregnancy. The use of an endocervical brush is safe and can enhance the rate of optimal smears. Endocervical curettage is not recommended due to predisposition to premature rupture of membranes and bleeding.

Hopkins and Morley published their experience with cervical cancer during pregnancy and outcomes compared to those in nonpregnant state (265). They found similar survival rates when controlled for confounding factors such as age and stage.

Diagnosis

All abnormal cervical lesions during pregnancy require a biopsy. Colposcopy in pregnancy is used to rule out invasive disease. Colposcopic evaluation and directed biopsies are safe in pregnancy. In a series of 612 women with abnormal smears during pregnancy reported by Economos et al., 449 colposcopies were performed (239). All patients had satisfactory colposcopy by the 20th week of gestation, as the squamo-columnar junction (SCJ) everts during pregnancy. They reported a 95% concordance rate between colposcopic impression and directed biopsies within one degree of severity. No complications were noted. Failure to visualize the entire SCJ is not an indication to proceed to conization during pregnancy as most repeat colposcopies will be satisfactory due to eversion of the SCJ as the pregnancy progresses.

A diagnosis of cervical cancer during pregnancy requires a multidisciplinary approach involving gynecologic and radiation oncologists, perinatologist, neonatologist, and psychologic counselors.

Management of Dysplasia

Woodrow et al. reported only a 7% progression rate from dysplasia in pregnancy to higher-grade dysplasia in the postpartum period in 811 women (266). Given these data it is reasonable to manage abnormal cytology in pregnancy according to guidelines in nonpregnant states. Given the low rate of progression and high reliability and safety of colposcopy, a conservative approach is likely to be safe for the patient and the unborn child. Dysplasia diagnosed by colposcopy and biopsies in pregnancy should be followed conservatively with serial colposcopic examinations every 8 weeks and managed definitively in the postpartum period.

Conization During Pregnancy

In a series of 180 conizations during pregnancy, Averette et al. reported a first trimester fetal loss rate of 24% (267). Second trimester fetal loss was less than 10%. Hannigan et al. reported 13 conizations during the first trimester and no fetal loss. The rate of severe bleeding was 9%. Fetal loss rate in second trimester was less than 10% (268).

In a small series of 17 patients, Goldberg et al. reported a novel approach to conization in pregnancy. The cervix was injected with vasopressin, and lateral hemostatic sutures and a cerclage were placed following the conization. The mean gestational age was 18.8 weeks (10–32). There was no major bleeding or other complications and no second trimester loss (269). An argument against the use of a cerclage is that the majority of post-conization fetal deaths are delayed and presumably due to chorioamnionitis and not necessarily a function of cervical incompetence. The cerclage may also act as a nidus for infection.

Robinson et al. reported their experience with loop electrocautery excisional procedure (LEEP) excision during pregnancy in 20 patients with gestational ages ranging from 8 to 34 weeks (270). They found that 57% had involved margins and 47% had residual disease after LEEP. There were three preterm deliveries, two patients requiring blood transfusions, and one intrauterine fetal demise 4 weeks after LEEP excision (chorioamnionitis was found on autopsy). They concluded that LEEP excision during pregnancy does not yield consistent diagnostic specimens and is associated with a high complication rate. If conization is indicated during pregnancy, a cold knife technique may be the preferred method. The optimum timing would be sometime in the second trimester.

Treatment of Adenocarcinoma *In Situ* and Microinvasive Disease

Diagnosis of glandular abnormalities in pregnancy can be difficult as glandular hyperplasia and decidual and glandular cells may exhibit benign Arias-Stella reaction, which may appear ominous to someone who is not experienced with these conditions during pregnancy. An expert evaluation is mandated for accurate diagnosis of glandular disease in pregnancy.

There is a paucity of data on management of adenocarcinoma *in situ* (AIS) in pregnancy. Lacour et al. reported the safety of conization in the second trimester as treatment of AIS in pregnancy in five patients. All patients delivered at term and only one required radical hysterectomy for stage IB disease after delivery (271).

It is believed that there is no significant difference in outcome in squamous MID versus AIS. It is difficult to know how to best treat these lesions in pregnancy. It is recommended that similar guidelines be adopted as in nonpregnant patients.

Most patients with MID in pregnancy can be safely followed even if margins are involved with dysplasia (not invasive disease). Vaginal delivery should be safe in women with microscopic disease, and definitive management may be delayed safely until the postpartum period.

Management of Invasive Cancers During Pregnancy

Surgery

Over 70% of cervical cancers in pregnancy present with stage I disease and have an excellent survival rate. Key elements in therapeutic decision making include stage, tumor size, gestational age, and the patient's desire to maintain the pregnancy.

Treatment options can be separated according to gestational age of <20 or >20 weeks.

Invasive disease diagnosed in a pregnant patient of less than 20 weeks gestation should generally be managed immediately, resulting in loss of the fetus. However, there are reports of delaying treatment until fetal maturity without harm to the mother or the fetus. Most of the reported cases of delay in treatment were stage I disease. The delay of treatment ranged from 3 to 32 weeks. The overall mortality is about 5% to 6% with a similar recurrence rate. These data are limited by small numbers of patients but are reassuring when considering a delay in treatment. This approach is only appropriate in selected well-counseled patients with early-stage, small volume disease.

Sood et al. published a case-control study of 30 pregnant women with cervical cancer with matched nonpregnant controls (272). Surgical treatment included either radical or simple hysterectomy. Eleven patients underwent surgical treatment in the third trimester after a mean delay in treatment of 16 weeks, and none developed recurrent disease. Radical hysterectomy in pregnancy was associated with increased blood loss but with no increased rate of blood transfusion. No difference was noted in postoperative complication rates.

Monk and Montz evaluated the safety and efficacy of radical hysterectomy with pelvic lymphadenectomy in 13 patients with fetus *in situ* and 8 with cesarean delivery followed by radical hysterectomy. No perioperative deaths were reported. The most common postoperative morbidity was febrile illness. The overall survival was 95% with over 40 months median follow-up (273).

For stage I disease, radical hysterectomy and pelvic lymphadenectomy can be safely performed prior to 20 weeks with fetus *in situ* or as a planned procedure after cesarean section in the third trimester after documentation of fetal lung maturity. Excellent oncologic outcomes are generally obtained.

Radiotherapy

Radiotherapy and platinum-based chemosensitization has become the standard of care for advanced cervical cancer (274), and it is an equivalent option to radical hysterectomy in stage I disease. Most reports of chemoradiation for cervical cancer during pregnancy are in patients with locally advanced disease.

Benham et al. reported the use of chemoradiation in two patients (275). The first patient was diagnosed with stage IVA squamous carcinoma at 12 weeks gestation. She was treated with RT and weekly cisplatin with the fetus *in situ*. Spontaneous miscarriage occurred at about 40 Gy, which is consistent with other reports in the literature. The patient died of metastatic disease 20 months after treatment. The second patient was diagnosed with stage IIB squamous cancer at 12 weeks gestation and received the same treatment regimen. Spontaneous miscarriage occurred 3 weeks after beginning RT. The patient remained disease-free at 29 months follow-up. Ostrom et al. reported two cases of stage IB2 disease diagnosed at 15 weeks gestational age. Fetal losses occurred 3 to 4 weeks after initiation of RT. Both patients were disease-free 12 months after completing treatment (276). Although experience is limited with chemoradiation in pregnancy, it seems to be feasible and safe. If RT is used in the postpartum setting, it should begin within 3 weeks after uterine involution.

Neoadjuvant Chemotherapy in Pregnancy

Use of neoadjuvant chemotherapy (NACT) has been reported in eight pregnant women with cervical cancer. Chemotherapeutic agents used included cisplatin, bleomycin, and vincristine. Gestational age ranged from 12 to 21 weeks at diagnosis and stages were IB1 to IIA. Seven of eight had clinical response including one complete response. Surgical treatment was delayed for a median of 16.5 weeks. Three of seven received

adjuvant treatment after surgical resection. With a follow-up range of 5 to 80 months, four were alive disease-free and four were dead of disease. All children appeared to be normal (277,278). Although data are very limited, they do suggest that NACT could be cautiously considered and discussed with patients who have advanced-stage cervical cancer diagnosed during pregnancy when a delay in treatment is desired to allow fetal lung maturation.

Radical Trachelectomy During Pregnancy

Vaginal or abdominal trachelectomy and cerclage placement along with laparoscopic or pelvic lymphadenectomy is an option for treatment of stage I cervical cancers less than 2 cm in women interested in preserving pregnancy and fertility (224). Ungar et al. reported birth of two healthy term infants to two of five pregnant patients with stage IB disease who were so treated (229). Gestational age ranged from 13 to 18 weeks. Fetal losses were reported on postoperative days 1 and 16. All patients remained disease-free with follow-up ranging from 10 to 54 months.

Route of Delivery

Sood et al. studied outcomes of women diagnosed with cervical cancer during pregnancy or within 6 months after delivery. One of 7 women who had cesarean sections developed local and distant metastasis compared to 10 of 17 (59%) of those who delivered vaginally. In multivariate analysis, vaginal delivery was the strongest predictor of recurrence. They concluded that pregnant women with cervical cancer should deliver by cesarean section (279).

Except in stage IA1 where vaginal delivery is reasonable, a cesarean section should be performed in the presence of cervical cancer. This should be done through a classical uterine incision to avoid encroaching into the lower uterine segment or cervix. In addition, cesarean section can be followed by radical hysterectomy as definitive treatment or to allow surgical exploration to delineate extent of disease. Performing oophorectomy during the procedure may assist in preserving ovarian function after pelvic RT.

HUMAN IMMUNODEFICIENCY VIRUS/ACQUIRED IMMUNODEFICIENCY SYNDROME AND CERVICAL NEOPLASIA

About 2.1 million people live with HIV in North America of whom approximately 1.2 million are in the United States. Heterosexual transmission accounted for 34% of cases. The proportion of women among new HIV and AIDS diagnoses has increased greatly in the United States. Over 50% of HIV-positive women are infected with HPV. In 1993, the CDC designated high-grade dysplasia as a marker for early HIV infection and cervical cancer as an AIDS-defining illness (280).

Prevalence

Ahdieh et al. reported that the HPV point prevalence in HIV-positive women is as high as 60%, compared to about 30% in HIV-negative women (281). The relative risk (RR) of HPV-associated cancers in patients with HIV/AIDS is significantly increased with relative risks of 5.4 and 5.8 for cervical and vulvar/vaginal cancers, respectively (282,283). The clearance of HPV in an HIV-positive individual correlates directly with the CD4 count. HPV DNA prevalence is as high as 85% in those with CD4 counts of 0 to 500 and as high as 70% in those with

CD4 counts over 500. This is compared to a range of 30% to 50% in HIV-negative women. Even with a normal CD4 count, HIV-positive women still have a twofold increase in incidence of HPV compared to HIV-negative women (281,282,284).

Pathophysiology

In HIV-infected women with no evidence of CIN on Pap smear and colposcopy and negative HPV testing, a prospective study found that the probability of developing CIN was much greater than women who were HIV negative (20% vs. 5%). The strongest predictor of development of CIN in HIV-positive women is the degree of immunosuppression delineated by CD4 counts (284). Ellerbrock et al., in a prospective study of HIV-positive and -negative women with normal cytology at onset, found a significantly higher rate of CIN development in HIV-positive patients over a 3-year interval (20% vs. 5%) (285). When matched for sexual behavior, HIV-positive women have a one- to twofold increase in HPV sero-prevalence compared to HIV-negative women. When controlled for exposure to HPV, the persistence and detection of HPV is much greater in HIV-positive women compared to HIV-negative women (286–288). In immunocompetent women, the rate of HPV clearance within 2 to 4 years is 80% to 90%. This is affected by multiple factors such as smoking, re-exposure, prolonged oral contraceptive use, and other sexually transmitted infections (e.g., *Chlamydia trachomatis*, herpes simplex virus). The clearance rate of HPV is twofold greater in HIV-negative women as compared to those infected with the virus, despite adequate CD4 counts and low HIV viremia (286,288,289). There are emerging data evaluating the effects of HIV and HPV coinfection and its effect on local immunity in the cervix and vagina. Infection of vaginal Langerhans cells (LC) by HIV is a primary mode of entry and propagation into systemic infection. LCs constitute an important local defense against HPV infection. The numbers of LCs are lowered significantly in patients with AIDS with a resultant decrease in their immunologic response to HPV (290).

HPV Genotype Distribution in HIV-Positive Women

Most HIV-positive women are infected with multiple types of high-risk HPV including 11, 16, 18, 33, 51, 52, 53, 58, and 61. Clifford et al. found HPV-16 to be the most common HPV subtype in HIV-positive women; however, when compared to HIV-negative women the rate of type 16 infection is lower (291). HIV-positive women showed a higher proportion of multiple and HPV types other than 16 as compared to HIV-negative women.

Screening

Despite conflicting reports in the literature regarding the reliability of cervical smears as a screening tool for CIN in HIV-infected patients, it remains an important tool in primary screening. In a study of 189 HIV-infected women versus 95 controls, Anderson et al. found that the incidence of biopsy-proven CIN, despite normal cytology, was greater for HIV-infected women (14.3% vs. 1.2%, $p < 0.01$) (292). However, in the small number of HIV-infected women with normal cytology and biopsy-proven CIN, 95% had an abnormal cytologic smear within the preceding 12 months, most commonly ASCUS. The authors concluded that these data did not support routine colposcopy in all HIV-infected women. These data also highlight the importance of vigilance in follow-up and colposcopic examination of even low-grade cytology including ASCUS in

HIV-infected women, especially those with low CD4 counts. A finding of ASCUS on cervical smears of HIV-infected women is more common than in uninfected women. The probability of development of CIN in those with ASCUS was greater in the infected group compared to controls (60% vs. 25%) (293). According to U.S. Preventive Services Task Force recommendations, women with HIV infection should undergo semiannual screening in the first 12 months after diagnosis and then annually if the results are normal. If any abnormality is detected, then closer follow-up and colposcopic examination are warranted.

In a low resource setting where cervical cytology and adequate follow-up is problematic, a new approach has been devised and tested called the "see and treat" or visual inspection with acetic acid (VIA) or visual inspection with Lugol's iodine (VILI). In this approach, health care extenders are trained to use immediate visual inspection to detect dysplastic changes on the cervix. If detected, immediate treatment of the area with cryotherapy is offered. Multiple studies addressing the accuracy of VIA demonstrated a sensitivity of 66% to 96% with median of 84% and a specificity of 64% to 98% with median of 82%. The positive predictive value was 10% to 20% with a negative predictive value of 92% to 97%. Overall VIA is found to be more sensitive but less specific than cytology. The overall sensitivity and specificity of VIA and VILI are 92% and 85%, respectively. Although these methods can be helpful in a low resource setting, debate continues on its use in HIV-positive women (294).

HPV Subtype Testing

Given the high prevalence of HPV in HIV-infected women, the value of HPV testing is unclear. Goldie et al. evaluated the cost effectiveness of HPV testing in this population, concluding that adding HPV testing to the initial two cervical cytologies in the first year after diagnosis of HIV may modify subsequent cytology screening intervals and may be cost effective (295). This would be true in patients with CD4 counts >500 with normal cytology whose risk would be equivalent to women without HIV infection. There is no consensus regarding its use, and the best recommendation is to individualize to the patient and specific risk factors.

Vaginal Cytology After Hysterectomy

There is a paucity of data regarding cytologic screening of the vaginal vault in women infected with HIV. Paramsothy et al. evaluated 102 HIV-infected women after hysterectomy for varying indications (296). Among those with a history of CIN prior to hysterectomy, 63% were found to have vaginal intraepithelial neoplasia (VAIN) in follow-up. CD4 count of <200 and HIV viral load of >10,000 copies/mL at time of hysterectomy were highly predictive of subsequent VAIN. Overall, out of 102 women, 16% developed VAIN in follow-up. The authors concluded that close follow-up with vaginal cytology is warranted in HIV-infected women after hysterectomy, particularly in those with severe immunodeficiency and a previous history of CIN.

Effects of Highly Active Antiretroviral Therapy on HPV

The introduction of highly active antiretroviral therapy (HAART) has made significant impact on the prognosis of patients with HIV but has not been shown to affect the rate of HPV detection, and data regarding its effect on cervical

dysplasia are mixed. The close relationship of low CD4 count and cervical dysplasia makes HAART attractive in halting progression of HPV infection. Ahdieh-Grant et al. studied 2,059 HIV-infected women receiving HAART (297). In 312 women with CIN, 141 had regression of CIN to normal with a median time to regression of 2.7 years. After HAART, elevated CD4 counts were associated with greater regression of CIN. However, there are no clear data to support HAART's role in regression of high-grade dysplasias. Therefore, the recommendation remains active surveillance and aggressive treatment for HPV in HIV-positive women who have responded well to HAART with low viral loads and adequate CD4 levels.

HPV Vaccination and Its Effect on HIV-Positive Women

In phase 3 clinical trials, HPV vaccination has been shown to be effective in reducing the rate of HPV infection by over 90% by inducing a much higher antibody titer for almost 5 years compared to the natural immune response (172,174). None of these trials included women known to have HIV infection, and there are no data demonstrating the efficacy of HPV vaccines in HIV-positive women. A pilot study to evaluate the safety and immunogenicity of HPV vaccine is under way in HIV-positive women.

Treatment of Dysplasia

The indolent nature of low-grade CIN in HIV-positive women allows for a conservative treatment approach. These patients have a low rate of progression to high-grade CIN, especially if CD4 counts are above 500. Delmas et al., in a large study of the natural history of CIN in HIV-positive women, demonstrated that almost 30% of low-grade CIN lesions would regress (298). Close follow-up with cytology or colposcopy every 4 months will help in detecting progression. It is important to collaborate with other health care professionals caring for the patient, particularly to determine the CD4 count status. As mentioned, HAART therapy may also contribute to regression of low-grade CIN.

For high-grade CIN, cervical conization by cautery or cold knife technique, or ablative techniques such as cryotherapy or laser vaporization are adequate, provided that invasive disease has been ruled out and that a satisfactory colposcopy is documented.

Although these techniques are effective in treatment of CIN in patients with HIV, the rate of recurrence is higher than in HIV-negative women. Wright et al. reported outcomes from LEEP procedures, finding a recurrence rate of 56% in patients with HIV versus 10% in non-HIV patients (185). The quality and size of the LEEP was an issue as all HIV-positive patients had positive margins compared to only 32% of controls. However, even when controlling for margin status, the rate of recurrence was higher among HIV-positive women, highlighting other risk factors for disease recurrence, e.g., CD4 counts.

Role of Medical Therapy

Maiman et al. evaluated 5-fluorouracil (5-FU) as maintenance therapy in HIV-positive women after treatment for high-grade dysplasia (299). Women received either biweekly 5-FU (2 g) or no further therapy. The recurrence rate was 28% in the treatment arm compared to 47% in the observation arm. Those with CD4 counts <200 had a 46% recurrence rate versus 33% in patients with CD4 counts >200. There was no grade 3 or 4 toxicity.

Robinson et al. studied the effects of isotretinoin for low-grade dysplasia in women infected with HIV and found no significant effect on time to progression (300).

Treatment of Invasive Cancer

The age at which HIV-infected women present with cervical cancer is, on average, 15 years younger than HIV-negative cohorts. Lomalisa et al. found that CD4 <200 was an independent risk factor for advanced stage of presentation (301). The treatment of invasive cervical cancer in HIV-infected women differs little from that used in HIV-negative women. There is little data on the role and long-term follow-up of radical hysterectomy for early-stage disease. Gichangi et al. evaluated the impact of HIV status on morbidity and pelvic tumor control following pelvic RT and found that 53% had acute radiation-related grade 3 to 4 toxicity (302). HIV infection was associated with a sevenfold higher risk of multisystem toxicity, was found to be a major factor in treatment interruption, and was associated with a sixfold increased risk of residual tumor 4 to 7 months after treatment. Mugambe and Kavuma compared outcomes of HIV-infected women with cervical cancer treated with RT, finding that 4-year survival was significantly lower for sero-positive patients as compared with sero-negative (303).

SURGERY

A generally accepted classification of types of hysterectomy is given in Table 22.4 and described below.

Class I Extrafascial Hysterectomy

This is the most common hysterectomy performed for a variety of gynecologic disorders. It consists of removing the uterus by separating it from the adnexal structures and round ligaments, dissecting the bladder off of the vesicouterine fold past the level of the cervix, ligation of the uterine vessels at their insertion close to the cervicouterine junction, serial application of surgical

clamps next to the uterine and cervical wall as the parametrial tissues are separated from these walls, and completed by removal of the cervix off the upper vaginal vault with very little removal of vaginal mucosa. The pubovesicocervical fascia is removed with the uterus. The opened vaginal cuff is usually closed with simple running or interrupted sutures. This hysterectomy is adequate for treatment of stage IA1 and advocated by some for stage IA2. This procedure can be accomplished abdominally, vaginally, or laparoscopically.

Class II or Modified Radical Hysterectomy

The modified radical hysterectomy (MRH) has gained popularity as the operation of choice for treatment of early-stage cervical cancer, depending on extent of the lesion. MRH involves opening the paravesical and pararectal spaces to determine resectability by palpating the parametrial tissues and surrounding structures. The pelvic nodal tissues are examined for gross involvement. Once resectability is established, the rest of the operation is carried forward.

Modified radical hysterectomy involves dissection of the uterine artery at its junction with the ureter. The ureters are partially dissected off the parametrial tissue and tunneled to their insertions into the bladder. The bladder is dissected off the lower uterine segment past the cervix. The parametrial tissue is resected medial to the ureter. The ureterosacral ligaments are isolated, and the proximal portions medial to the ureter are resected. A 1- to 2-cm vaginal margin is resected along with the cervix. A pelvic lymphadenectomy is typically performed along with MRH. Type II MRH is reserved for microscopic or smaller tumors depending on the surgeon's experience and preference.

Class III or Radical Abdominal Hysterectomy

The radical hysterectomy (RH) differs from the MRH in the amount of dissection and resection. The paravesical and pararectal spaces are opened. The uterine artery is ligated at its origin from the internal iliac artery. The ureters are dissected

TABLE 22.4

TYPES OF ABDOMINAL HYSTERECTOMY

Type of surgery	Intrafascial	Extrafascial type I	Modified radical type II	Radical type III
Cervical fascia	Partially removed	Completely removed	→	→
Vaginal cuff removal	None	Small rim removed	Proximal 1 to 2 cm removed	Upper one third to one half removed
Bladder	Partially mobilized	→	→	Mobilized
Rectum	Not mobilized	R-V septum partially mobilized	→	Mobilized
Ureters	Not mobilized	→	Unroofed in ureteral tunnel	Completely dissected to bladder entry
Cardinal ligaments	Resected medial to ureters	→	Resected at level of ureter	Resected at pelvic sidewall
Uterosacral ligaments	Resected at level of cervix	→	Partially resected	Resected at post-pelvic insertion
Uterus	Removed	→	→	→
Cervix	Partially removed	Completely removed	→	→

Note: Type IV, extended radical hysterectomy (partial removal of bladder or ureter), in addition to type III. (Source: Perez CA. Uterine cervix. In: Perez CA, Brady LW, eds. *Principles and Practice of Radiation Oncology*. 3rd ed. Philadelphia: Lippincott-Raven; 1998.)

Source: From Stehman FB, Perez CA, Kurman RJ, et al. Uterine cervix. In: Hoskins WJ, Perez CA, Young RC, eds. *Principles and Practice of Gynecologic Oncology*. 3rd ed. Philadelphia: Lippincott Williams & Wilkins; 2000:864.

with complete tunneling to their insertion into the bladder trigone. The uterosacral ligaments are isolated after the rectovaginal space is developed. The bladder is dissected off the cervix anteriorly. The cardinal ligaments are resected to the pelvic sidewall. Complete resection of the uterosacral ligaments to their attachment may not be necessary in all cases. An alternative is resection of the uterosacral ligaments midway and resection of 2 to 3 cm of proximal vagina, but the operation can be tailored according to tumor size and patient anatomy.

The choice of abdominal incision for RH depends on body habitus. A Maylard incision keeps the fascia on the rectus muscles. The epigastric vessels are ligated and the muscle is transected in the middle to have greater access to the sidewall and to facilitate pelvic lymphadenectomy. The other option is a Cherney's incision, which involves detachment of the rectus muscle from its tendinous insertion, allowing for greater access to the pelvis and common iliac and lower para-aortic nodes. The muscle is reattached at the end of the procedure. The peritoneum is closed in both of these approaches. In properly selected patients, these incisions provide excellent exposure compared to a vertical incision with better cosmetic outcome and perhaps less discomfort to the patient.

Class IV or Extended Radical Hysterectomy

There is little indication for extended radical hysterectomy (ERH) with availability of modern RT and chemosensitization for locally advanced tumors. As distinct from type III RH, ERH involves complete dissection of the ureter off the vesicouterine ligament, sacrifice of the superior vesical artery, and resection of three fourths of the vagina. The risk of bladder dysfunction and fistula formation is greatly increased compared to types I-III hysterectomy.

Class V Hysterectomy

A rarely performed operation, a type V hysterectomy involves resection of the distal ureter or bladder with reimplantation of ureter if needed.

Nerve-Sparing Radical Hysterectomy

Radical hysterectomy can disrupt the hypogastric plexus, which contains sympathetic fibers that fuse with parasympathetic fibers located in the parametrium to control bladder contraction and compliance. Bladder dysfunction occurs in about 5% of patients, which may require continuous or intermittent drainage for several weeks. Some patients may also experience some rectal dysfunction depending on the extent of the dissection and resection. Nerve-sparing radical hysterectomy (NSRH) has been proposed as a possible technique to identify and spare nerves and preserve good oncologic outcomes (304,305).

Trimbos et al. described NSRH as identification of the hypogastric nerve beneath the ureteral sheath lateral to the uterosacral ligament, identification of the inferior hypogastric plexus during resection of the cardinal ligament, and preservation of the distal inferior hypogastric plexus during dissection of the posterior aspect of the vesicouterine ligament (304).

Although intriguing, large studies to clearly define the benefit of NSRH are lacking. Charoenkwan et al. reported on post-void residual (PVR) of patients with NSRH versus standard RH (306). At 7 days, 36% and 27% of NSRH patients had PVRs <100 and <50 cc, respectively, increasing to 82% and 77% by day 14. Raspagliesi et al. reported that type III

NSRH had a similar rate of bladder dysfunction as MRH, and both were lower than standard RH III (307). Papp et al. reported their experience with NSRH in 501 patients with stages IA2 to IIB and found no decrement in outcome (305).

Pelvic Exenteration

Total pelvic exenteration (TPE) is mainly used for patients with limited central recurrences and no metastatic disease following treatment with primary RT or combined surgery and RT. It involves *en bloc* removal of bladder, uterus, rectum, vagina, and at times vulva, depending on the exact site and extent of recurrence. The procedure can be tailored to remove only the anterior or posterior structures including the bladder (anterior exenteration) or rectum (posterior exenteration). In treatment of central recurrence of cervix cancer, TPE is the most common approach. Reported 5-year survival is approximately 40%, ranging from 18% to 70% in the literature (308,309). TPE has been employed in selected patients with stage IVA cervix cancer, although with modern chemoradiotherapy this is unusual.

As part of TPE, reconstruction can involve diversion of the urine through a conduit utilizing a segment of the bowel (ileum, transverse and sigmoid colon) and/or vaginal and pelvic reconstruction with placement of flaps using either transposed muscle (rectus or gracilis), segments of colon (rarely), or omentum. Depending on the location of tumor and the extent of resection, the colon may be reanastomosed with the rectal stump (suprlevator) or a permanent colostomy placed (310).

TPE is a morbid operation that should only be undertaken in selected patients with limited recurrences. Sidewall extension, metastatic disease, and, usually, hydronephrosis are possible contraindications to the procedure. Even with appropriate workup and evaluation, 25% to 50% of candidates will have the procedure aborted due to intraoperative findings of metastatic or locally advanced disease. Equally important are evaluations of patients' overall health status and a careful psychological and social evaluation and counseling to ensure that the patient realizes the sequelae of TPE. Perioperative complications can include bleeding, infection, cardiac and pulmonary complications, gastrointestinal and urinary leaks, fistulas, bowel obstruction, and reconstruction flap failure. Sexual dysfunction and psychosocial effects are often longer-term sequelae that can be permanent. The mortality rate from TPE is about 5%, even with careful patient selection (308,309).

RADIATION THERAPY

External Irradiation

Standard Fields (Non-IMRT)

Treatment of invasive carcinoma of the uterine cervix requires delivery of adequate doses of irradiation to the pelvic lymph nodes. Greer et al. (311) reported on intraoperative retroperitoneal measurements carried out in 100 patients at the time of radical surgery. Both common iliac bifurcations were cephalad to the level of the lumbosacral prominence in 87% of patients. Therefore, the superior border of the pelvic portal should be at the L4-5 interspace to include the external iliac and hypogastric lymph nodes. This margin should generally be extended to the L3-4 or even the L2-3 interspace if common iliac nodal coverage is indicated. The width of the pelvis at the level of the obturator fossae averaged 12.3 cm, and the distance between the femoral arteries at the level of the inguinal rings averaged 14.6 cm. Posterior extension of the cardinal ligaments in their attachment to the pelvic wall was consistently posterior to the rectum

FIGURE 22.15. **A:** Anteroposterior simulation film of the pelvis illustrating portals used for external irradiation. The 15×15 cm portals at SSD (source-skin distance) are used for stage IB (broken line), and 18×15 cm portals are used for more advanced disease (solid line). This allows better coverage of the common iliac lymph nodes. The distal margin is usually placed at the bottom of the obturator foramina. **B:** Lateral simulation film of the pelvis illustrating portals used for external irradiation. *Source:* From Stehman FB, Perez CA, Kurman RJ, et al. Uterine cervix. In: Hoskins WJ, Perez CA, Young RC, et al., eds. *Principles and Practice of Radiation Oncology*. 3rd ed. Philadelphia: Lippincott-Raven; 2000:867.

and extended to the sacral hollow. The uterosacral ligaments also extended posteriorly to the sacrum. These anatomic landmarks must be kept in mind in the correct design of lateral pelvic portals. The upper margins of the portals in patients with small stage IB tumors can be placed at the L5-S1 interspace, and for more advanced stages at the L4-5, L3-4, or even L2-3 interspace (Fig. 22.15A and B). A 2-cm margin lateral to the bony pelvis is adequate. If there is no vaginal extension, the lower margin of the portal is at the midportion to inferior border of the obturator foramen. When there is vaginal involvement, the field should extend distally beyond the tumor a minimum of 4 cm, although some contend that the entire length of vagina should be treated down to the introitus. It is important to identify the distal extension of the tumor in some manner at the time of initial simulation, for example, by inserting a small rod with a radiopaque marker in the vagina. Often, vaginal extension will not be clearly defined by CT scan. For stage IB disease, 15×15 cm portals at the surface (about 16.5 cm at isocenter) usually will be sufficient. For patients with stage IIA, IIB, III, or IVA carcinoma, somewhat larger portals (18×15 cm at surface, 20.5×16.5 cm at isocenter) may be required to cover all of the common iliac nodes, in addition to the cephalad half of the vagina (312). Using placement of intraoperative clips to determine the extremes of nodal locations, McAlpine et al. essentially confirmed the findings of Greer et al. (313).

In patients with involvement of the distal third of the vagina, portals should cover the inguinal lymph nodes because of the increased probability of metastases. Dittmer and Randall have published a convenient method of treating inguinal-femoral nodes using anteroposterior-posteroanterior (AP-PA) photons only while limiting the dose to femoral heads and avoiding some of the problems with junctioning fields, e.g., electrons (Figure 21.5A and B, previous chapter) (253). Alternatively, IMRT approaches can be used (Fig. 22.14) (314).

The lateral portal anterior margin is placed anterior to the pubic symphysis to include the anterior extent of the external iliac nodes. A margin at the anterior edge of the symphysis pubis may not suffice for adequate coverage of primary tumor as well. The posterior margin usually covers at least 50% of the rectum in stage IB tumors, and will often extend to the sacral hollow in patients with more advanced tumors (Fig. 22.15B).

Routinely placing the posterior border at the S2-3 interspace frequently results in inadequate coverage of the planning target volume. Ideally, three-dimensional imaging with CT, MRI, or both will be used to ensure adequate coverage (315).

The use of lateral fields allows significant protection of small bowel. With a four-field technique, some radiation oncologists choose to weight the AP-PA beams in relation to the lateral fields, e.g., 60:40. While this increases small bowel dose slightly, it can avoid giving very high doses laterally, particularly in larger patients.

Use of Midline Shield

Although common practice, the use of midline shields (MLSs) during external beam RT for cervical cancer has not been well described, and there is no consensus regarding their use. There is variability in opinions and practice patterns. The purpose of the MLS is to limit dose to the bladder and rectum in order to permit maximization of the intracavitary dose while still delivering sufficient doses to gross parametrial disease and microscopic or gross pelvic sidewall disease (nodal or tumor extension). In general terms, patients with earlier disease (stages I-IIA, or perhaps early IIB) benefit from earlier introduction of an MLS (20 to 30 Gy); patients with more advanced disease should not have an MLS placed before 40 Gy, and possibly not at all. By performing pelvic examinations on a weekly basis in patients receiving primary RT for cervical cancer, the physician might note an early favorable response that might permit earlier use of the MLS. Keeping in mind the purpose of the MLS, a frequent practice is to use a standard-width shield (4 cm), and place it in midline position. Generally, the pelvic dose delivered with the MLS is not added to the point A dose, but this dose is added to the nodal (sidewall, point B, point P) dose calculation. Unilateral sidewall boosts should be considered in patients who have only unilateral parametrial or sidewall involvement. Increasing parametrial doses correlate with risk of complications, particularly radiation proctitis (316).

Small Field RT

In patients treated postoperatively, a sensible approach to limiting complications in selected patients was piloted by Kridelka

et al. (317). Pelvic failure is by far the most frequent site of failure in early-stage cervical cancer patients, regardless of the initial treatment. However, in node-negative patients, the risk factors that indicate adjuvant RT following radical surgery are overwhelmingly related to a risk of failure in the central pelvis, including the vaginal vault and paravaginal soft tissues. Given the well-known relationship between radiation volume and complication risk, Kridelka et al. limited the adjuvant pelvic RT to fields smaller than “standard.” In 25 patients with a risk of recurrence of at least 40%, as suggested by the GOG study (222), only one recurrence was noted, with a median follow-up of 32 months. As predicted, morbidity was very limited in quantity and grade. The authors compared disease-free survival curves of their experience and that of the observation arm in the GOG trial by Sedlis et al. (318), finding small field pelvic RT to be significantly superior ($p = 0.005$).

A similar experience with small field pelvic RT was reported by Ohara et al. in 42 patients with stages I-II node-negative squamous carcinoma of the cervix at significant risk of local recurrence (319). All patients so treated had deep cervical stromal invasion, parametrial extension, and/or positive or close (<5 mm) surgical margins. Only three patients treated with small field RT suffered recurrences, all in the pelvis. Serious toxicity was rare. The analysis of Chen et al. supports the concept of treating only the lower pelvis with adjuvant RT in appropriately selected patients as a means of limiting non-rectal radiation-induced intestinal injury (320).

An alternative approach to limit small bowel dose in the postoperative RT situation is to utilize intensity-modulated RT (IMRT) approaches. D’Souza et al. compared IMRT plans to conventional four-field plans, finding that the mean volume of small bowel was 33% lower with the IMRT plans. However, the authors noted that these calculations did not account for interfraction organ motion and recognized the lack of data regarding safety and efficacy (312).

Intensity-Modulated External Radiation Therapy

IMRT refers to the delivery of radiation beams that have varying intensity patterns that, when summed inside a patient, create a dose distribution in which the target receives near to the prescribed dose while tissues that are to be avoided receive much less radiation. Treatment planning is based on three-dimensional imaging utilizing CT, most commonly. MRI and PET images can also be incorporated into the determination of treatment volume.

Specially configured linear accelerators with multi-leaf collimators (MLCs) are used to create highly contoured dose distributions utilizing various techniques. “Step and shoot” IMRT uses multiple static fields, typically five to nine, with specific dose maps entering the patient from multiple beam angles. “Sliding window” IMRT utilizes an arcing motion of the radiation source along with movements of the MLC leaves. Helical TomoTherapy is a variation of the sliding window technique in which the radiation source is constantly moving around a patient and the patient is translated through the path of the beam while the MLCs rapidly open and close to create the desired dose distribution.

Potential benefits of IMRT include the ability to preferentially limit the dose of radiation to normal tissues, safely deliver higher tumor doses, and enable treatment and retreatment of tumors that are not otherwise treatable (Fig. 22.16A and B). Roeske et al. were the first to propose and test the hypothesis that IMRT could be used to lower small bowel dose in patients receiving pelvic RT (321). Subsequently, this approach has been popularized by Mundt et al. (322).

Dose-volume histograms (DVHs) plot the percent of a certain organ or volume of interest versus the dose received (Fig. 22.17). By looking at a DVH, the radiation oncologist can quickly and

FIGURE 22.16. (See color plate section.) **A:** Dose distribution from a standard four-field box showing some volume of small bowel receiving full dose. **B:** IMRT approach in which the small bowel is almost excluded from the full dose region. *Source:* From Jhingran A. Potential advantages of intensity-modulated radiation therapy in gynecologic malignancies. *Semin Radiat Oncol* 2006;16:144-151.

quantitatively assess whether the dose delivered to critical structures and tumor volumes is adequate for safety and efficacy of treatment. Furthermore, DVH analysis provides an objective method of comparing different treatment plans. The increasing use of IMRT requires a better understanding of radiation dose-volume relationships than has existed in the past. For the most part, consensus remains to be generated regarding proper dose-volume constraints for most normal tissues.

Jhingran has published an extensive review of IMRT use in gynecologic malignancies (314). Early data supports the ability

FIGURE 22.17. This dose-volume histogram from an extended field RT plan plots the volume of various organs or structures versus the dose received. It shows excellent coverage of tumor and nodal regions while the normal structures, e.g., kidneys, spinal cord, etc., receive limited dose. This provides quantitative measures of dose distribution for use in evaluating and comparing treatment plans.

of IMRT to reduce dose to normal tissues and thereby reduce acute and late toxicities. It can also facilitate treatment of recurrences in or near previous RT fields, dose escalation to grossly involved lymph nodes, and treatment of patients with vesico- or rectovaginal fistulae. There is active debate regarding the ability of IMRT techniques to replace intracavitary brachytherapy for treatment of cervical cancer (323–325). To date, the weight of opinion does not support this latter indication.

Randall and Ibbott have presented a discussion of possible pitfalls and hazards from implementation of IMRT for gynecologic cancers (326). Chief among these concerns is the problem of organ and tissue motion. In addition to respiratory motion, in the pelvis there is considerable motion with varying amounts of distention of the bladder and rectum (327). Ahamad et al. performed a systematic analysis of 10 patients with gynecologic cancers planned with both IMRT and four-field approaches. When IMRT margins were expanded to take into account internal motion and setup variation, the dosimetric advantage of IMRT largely disappeared (328). Han et al. completed a similar study, noting that significant differences in the small bowel dose-volume histogram can result, making strict protocols for bladder distention, margins, and image guidance necessary for IMRT implementation (329).

In addition, patient and tumor geometry often changes during treatment. Beadle et al. performed serial CTs during treatment of 16 patients with cervical cancer to assess tumor regression and organ motion. These authors found that the location of the tumor volume varied markedly during treatment from both these factors, and proper treatment would require large volumes initially, as is done with conventional treatment. As a result, it was felt that the potential value of

IMRT was diminished and the risk of missing tumor was increased (330).

In general, there is lack of agreement regarding scanning parameters, necessity of intravenous contrast enhancement, appropriate volumes to contour, and dose-volume constraints. Taylor et al. have presented guidelines for contouring pelvic lymph nodes for patients undergoing RT, suggesting that a 7-mm margin around iliac vessels presents a reasonable trade-off in terms of maximizing nodal coverage while limiting small bowel dose (331). Other concerns include an increase in the incidence of secondary radiation-induced malignancies (332–335), limitations of imaging in accurately defining pelvic disease, increased dose heterogeneity, and problems with quality assurance (326). In addition there are concerns regarding deleterious effects of prolonged treatment times on the radiation-induced cell killing (336,337). Finally, many technical issues are of concern, including the fact that dose distributions are less reproducible and the fact that calculated dosimetry might not reflect what is actually delivered to the patient for many reasons (326).

Extended Field RT

The reluctance among some radiation oncologists to utilize extended field radiation therapy (EFRT) either prophylactically or therapeutically in some cases relates to concern over increased acute and late toxicities. This is largely because the para-aortic chain is surrounded by organs of limited radiation tolerance, i.e., spinal cord, kidneys, small intestine. The use of opposed anterior and posterior fields is the easiest technique but delivers to a significant portion of the small bowel a radiation dose that will generally exceed tolerance if an appropriate

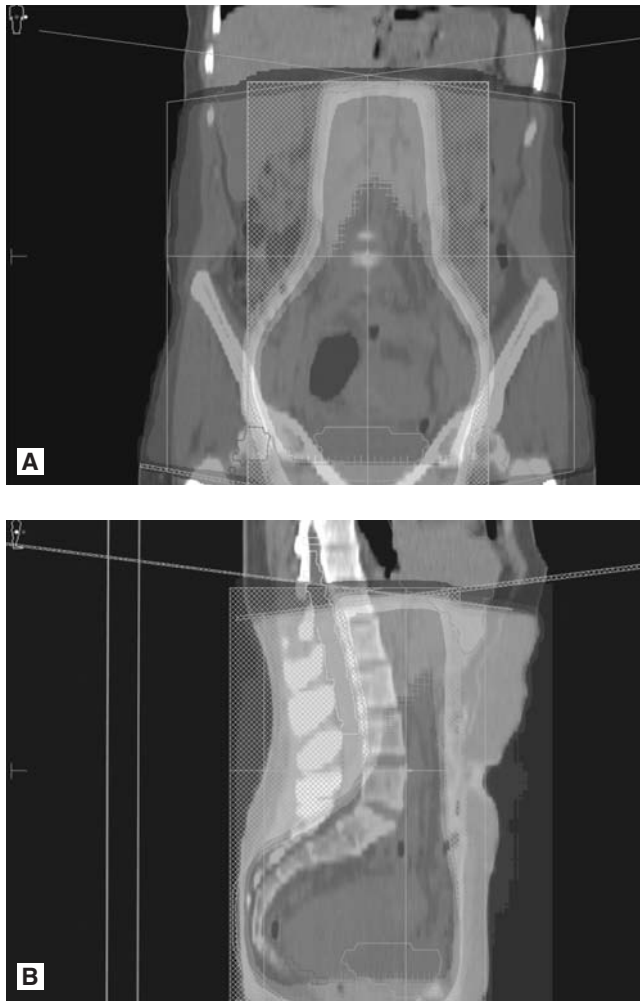

FIGURE 22.18. (See color plate section.) This shows dose distribution from extended field RT given with a four-field isocentric technique with all fields treated in continuity. The AP-PA fields (A) are weighted 70:30 in relation to the lateral fields (B), limiting the dose to kidneys, as shown in the DVH in Figure 22.17. This patient had a large pelvic mass, compromising the ability to spare rectum and bladder.

dose for microscopic disease is delivered. Various techniques have been utilized in an effort to deliver EFRT, all of which have both advantages and disadvantages. A four-field technique permits continuity with and use of a four-field approach in the pelvis, spares much of the small intestine, and shields the spinal cord and the vast majority of the kidneys from half of the beams (Fig. 22.18A and B). It is important to perform an intravenous pyelogram (IVP) or CT to accurately determine the kidneys' location. The dose to the kidneys can be kept within tolerance by preferentially weighting the anterior and posterior beams (e.g., 70:30 AP-PA to laterals). In most cases, this will be adequate to limit kidney doses within tolerance, even when delivering 40 to 45 Gy to the volume. Nevertheless, it is critical to know the kidney doses and the amount of the renal parenchyma receiving this dose when utilizing this technique. A DVH of such a treatment is shown in Figure 22.17.

Esthappan et al. used positron emission tomography (PET) data to assess for metastatic disease and to guide planning using IMRT techniques (338). In this fashion, it was feasible to escalate RT doses to 59.4 Gy while maintaining acceptable doses to surrounding tissues. Salama et al. reported the use of IMRT for extended field RT in 13 patients, finding the

approach to be well tolerated (339). With limited follow-up, two patients reported grade 3 or higher toxicity, and the local control rate was high.

Elective Para-aortic Lymph Node Irradiation. Occult involvement of the para-aortic lymph nodes is a potential cause of treatment failure in carcinoma of the cervix. Given the orderly lymphatic spread of cervical carcinoma to pelvic and para-aortic lymph nodes, and its frequency in defined patient groups, adjuvant or EFRT is a logical treatment strategy that seeks to avoid the risks and treatment delays associated with surgical staging. Its use may be considered in patients with early-stage disease who have undergone appropriate surgical treatment and have risk factors arguing for adjuvant postoperative RT and in patients for whom RT is the primary treatment.

Retrospective and prospective data suggest that EFRT can be delivered safely and with reasonable efficacy in high-risk patients. In a large retrospective series from Japan, Horii et al. reported on patients who received adjuvant (in some cases, therapeutic) EFRT based on multiple positive pelvic lymph nodes, and/or radiographic evidence of para-aortic lymph node enlargement (340). The investigators found a significant survival advantage for patients receiving EFRT, compared to similar patients who received only pelvic RT. This survival advantage was particularly noticeable among stage II patients. No serious complications were reported. The European Organization for Research and Treatment of Cancer (EORTC) study reported by Haie et al. (341) included 441 patients with stages I-III disease who did not have surgical staging, but were considered at high risk of undetected para-aortic lymph node involvement. In the study group, the para-aortic area received 40 to 50 Gy with external beam radiation therapy (EBRT). Significant findings included a higher rate of gastrointestinal toxicity, a significantly lower rate of para-aortic failures in the EFRT group, and a significantly lower rate of distant metastases in patients receiving EFRT and achieving pelvic control. There was no statistically significant difference between the two treatment arms with regard to local control, distant metastases, disease-free survival at 4 years, or survival. The incidence of small bowel injury was 0.9% in the pelvic RT and 2.3% in the EFRT groups. A severe complication rate of 9% was observed in patients receiving EFRT, compared with 4.8% in those treated to the pelvis only. Rotman et al. published 10-year results from Radiation Therapy Oncology Group (RTOG) study 79-20 (342). In this study, 367 patients (stage IIB or stages IB-IIA ≥ 4 cm) were randomized to pelvic RT versus EFRT. Overall survival was 67% at 5 years and 55% at 10 years for the patients receiving elective EFRT, compared with 55% and 44%, respectively, for those treated to the pelvis only ($p = 0.02$). Locoregional failures were similar at 10 years for both arms (pelvic only, 35%; EFRT, 31%). When the first disease failure patterns were examined, more patients failed distally when treated only with pelvic RT compared to those receiving EFRT ($p = 0.053$). The EFRT arm was associated with more grade 4 and 5 complications, particularly in patients with prior abdominal surgery (11% vs. 2%).

Gerzten et al. reported the use of concurrent cisplatin with EFRT using IMRT techniques (343). In 22 consecutive patients, the median length of treatment was 39.5 days. Only two patients required short treatment breaks, and there was no acute or subacute grade 3 or 4 gastrointestinal (GI) or genitourinary (GU) toxicity.

Grigsby et al. looked at the ability to control nodal disease with RT in cervical cancer. In patients with subclinical para-aortic disease demonstrated by PET, there were no failures with a median dose of 43.3 Gy (344).

Results from RTOG 90-01 show that pelvic RT combined with platinum-based chemotherapy is superior to adjuvant EFRT in patients with locally advanced disease (274). However, given the apparent ability of EFRT to impact failure rates in the

para-aortic chain and the improving therapeutic ratio, EFRT combined with chemotherapy could offer opportunities for improved outcomes in patients at high risk of metastatic para-aortic disease. Possible indications for its consideration include positive PET scans in the para-aortic region; high pelvic lymph nodes involved, e.g., common iliac; gross nodal metastases in the pelvis; bilateral positive pelvic lymph nodes; adenocarcinoma histology with any number of positive pelvic lymph nodes; and squamous cell histology with four or more positive pelvic lymph nodes. In all cases, the radiation oncologist must determine that the patient is in reasonably good general health, with no limited risk factors for RT injury. Furthermore, there should be an assessment that there is a good chance of pelvic control (in patients receiving primary RT), since the absence of pelvic control will render para-aortic control meaningless.

Therapeutic Para-aortic Lymph Node Irradiation. Data from the GOG suggests that patients with stages IB, II, III, and IVA cervical cancer will have spread to the para-aortic lymph nodes in 5%, 16% to 21%, 25% to 31%, and 13%, respectively (27). Tumor involvement in para-aortic lymph nodes is quite uncommon in the absence of pelvic lymph node metastasis (27). Grigsby et al. have demonstrated that para-aortic RT can control known metastatic nodal disease in a high percentage of patients (344). However, the degree to which RT demonstrates curative potential in this group of patients is quite variable, and is mostly related to selection factors in the patient population so treated.

Kim et al. reviewed 43 patients with known para-aortic lymph node spread who received curative intent RT following surgical staging and removal of gross para-aortic disease, in some cases (345). Pelvic tumor size (<6 cm vs. \geq 6 cm) was a significant factor in survival. It was noted that patients with no residual para-aortic disease following surgery had significantly better outcomes than those patients with gross residual tumor, raising the question of whether surgical excision of bulky para-aortic lymph node disease is advisable in this situation. In contrast, Grigsby et al. did not find that tumor stage (reasonably correlated with pelvic tumor volume) was a significant factor in patients with para-aortic lymph node involvement (346). In a series of 43 patients, the overall survival rate was 32% and the median survival was 2.2 years, although only 20 patients manifested recurrence. The predominant failure pattern was distant spread, suggesting that effective systemic therapy is warranted. Severe toxicity occurred in only two patients.

Based on a retrospective review of 35 patients treated for documented para-aortic lymph node spread, Stryker and Mortel suggested that EFRT can contribute to cure in approximately 30% of these patients (347). Again, patients with only microscopic involvement had considerably better outcomes than those with gross disease (42% vs. 26% 5-year survival). Grade 4 morbidity was seen in 8.6%, although in all cases the morbidity was related to the pelvic portion of the treatment rather than the EFRT.

Varia et al. completed a phase 2 GOG study of EFRT plus chemotherapy (348). The protocol called for cisplatin to be given at 50 mg/m² on day 1, and 5-FU to be given at 1,000 mg/m² over 96 hours during weeks 1 and 5. Eighty-six evaluable patients were accrued, 85 of whom completed EFRT; 90% completed chemotherapy. Grade 3 to 4 gastrointestinal and hematologic toxicities were seen in 19% and 15%, respectively. The actuarial risk of late morbidity was 14% at 4 years, primarily from rectal injury. Three-year overall survival and progression-free survival rates were 39% and 34%, respectively. Overall survival was 50% among stage I patients. Approximately 40% of patients had a distant failure as the first site of relapse.

In terms of toxicity, the RTOG found much greater toxicity compared to the Varia-GOG study when giving extended field RT along with sensitizing chemotherapy. Small et al. observed very high acute and late toxicities. Differences in the treatment regimens included the use of weekly cisplatin at 40 mg/m² and

more frequent boosting of para-aortic nodes in the RTOG study (349).

Therapeutic EFRT in patients with para-aortic metastases appears to be efficacious, resulting in long-term survivals of 25% to 50%. Definable subgroups may have an even higher rate of long-term survival. EFRT can reliably control microscopic disease in the para-aortic chain; however, the curability of the individual patient is more a function of the ability to gain control of the pelvic disease and the likelihood that the patient will develop other metastatic disease.

Chemotherapy can feasibly be added to EFRT in these patients, and it is reasonable to approach patients in this fashion unless comorbid illnesses contraindicate systemic therapy. The optimum chemotherapy agents and schedule remain to be determined, although weekly cisplatin is a reasonable suggestion, based on current knowledge. The potential impact of concurrent chemotherapy on complication rates is unclear.

Proton Beam Radiotherapy

There is increasing interest in and availability of proton beam RT, although the reported experience in cervical cancer is limited. Kagel et al. reported 25 patients, stages IIB-IVA, treated with curative intent by photon pelvic RT followed by a proton boost to the primary tumor. No intracavitary RT was given. Long-term survival and complication rates were considered similar to those of conventional photon RT plus intracavitary brachytherapy (350).

Brachytherapy

Brachytherapy refers to the placement of radioactive sources at a short distance from the intended target. Because the anatomy of cervical cancer typically facilitates brachytherapy, and because brachytherapy permits very high doses to be safely delivered, it has long been a major factor in the ability of RT to cure cervical cancer. Several isotopes are available for cervical cancer brachytherapy, although at the present time ¹³⁷Cs is the most popular for low-dose-rate (LDR) brachytherapy. ¹⁹²Ir is frequently used for high-dose-rate (HDR) brachytherapy because of its high specific activity. It is also frequently used in lower activity in removable LDR interstitial applications. Brachytherapy can be delivered with intracavitary techniques using applicators typically consisting of an intrauterine tandem and vaginal colpostats or, when necessary, vaginal cylinders. All state-of-the-art applicators are afterloading. Interstitial implants are typically done with permanent or removable isotopes, such as ¹⁹⁸Au and ¹⁹²Ir, respectively. Radiographs are obtained using dummy sources, and the active sources can be afterloaded following review of images, if the position of the applicators is judged to be satisfactory.

Intracavitary Implants

Intracavitary brachytherapy is generally used in combination with external beam RT, although it may be used alone in very early disease. LDR has been used since the early 1900s, but starting in the late 1950s, with the Cathetron Cobalt-60, HDR brachytherapy has become increasingly utilized.

Three brachytherapy systems were developed almost simultaneously: the Paris, Stockholm, and Manchester systems. The term "system" denotes a set of established rules, taking into account the source strength and the geometry, method, and duration of the application in order to obtain suitable dose distributions. In each of these systems, a brachytherapy insertion consisted of an intrauterine component (tandem) and a vaginal applicator. Treatment duration and loadings were developed empirically. Intracavitary treatment prescriptions were quantified in terms of milligram-hours, i.e., the product of the total

mass of radium or radium equivalent (e.g., ^{137}Cs) contained in the sources, and the duration of the application in hours.

The classical Manchester system was the first system to use units of radiation exposure (roentgens) rather than milligram-hours to prescribe dose. The dose (in roentgens) was prescribed at specific points, termed A and B. Point A was originally defined as a point 2 cm lateral to the center of the uterine canal and 2 cm from the mucous membrane of the lateral fornix in the plane of the uterus. Point A was intended to represent the average dose to the “paracervical triangle.” Point B was defined as 5 cm from the patient’s midline at the same level as point A, and it was intended to quantify the dose received by the regional (obturator) lymph nodes. The various combinations of Manchester system ovoid dimensions and applicator loadings were designed to provide a reasonably constant point A dose rate of 50 to 55 cGy per hour. This approach heavily influenced intracavitary treatment practice patterns in the United States. The widely used Fletcher-Suit applicator system, Fletcher loadings, and the reference points A and B are all derived from this system.

Computer-generated isodose curves provide the best means of determining the doses to point A, point B, bladder, and rectum (Fig. 22.19A and B). International Commission on Radiation Units and Measurements (ICRU) Report No. 38 (351) defines the dose and volume specifications for reporting intracavitary therapy in gynecologic procedures. ICRU-38 recommended that reference points such as point A not be used, because “such points are located in a region where the dose gradient is high and any inaccuracy in the determination of the distance results in large uncertainties in the absorbed doses evaluated at those points.” Instead, it introduced the concept of reference volume, i.e., the tissue volume encompassed by a reference isodose surface, recommending that the dimensions of the 60-Gy isodose surface be specified, including the contribution of EBRT. They proposed that this pear-shaped reference volume be described in terms of its three dimensions: height (maximum dimension along the intrauterine sources), width (maximum dimension perpendicular to the intrauterine sources), and thickness (maximum dimension perpendicular to the intrauterine sources in the oblique sagittal plane), measured in the oblique, coronal, and sagittal planes containing the intracavitary sources. A number of weaknesses of the ICRU-38 recommendations have been pointed out, including the absence of rationale for the choice of 60 Gy. Widespread adoption is, therefore, lacking (352). However, the ICRU definitions of rectal and bladder points are frequently used.

If the vaginal vault is narrow, making it impossible to insert regular colpostats, miniovoids can be used (usually loaded with 10 mCi RaEq sources). When miniovoids cannot be inserted, an option is to use a protruding source in the vaginal vault, which is inserted in the afterloading tandem (usually 20 to 30 mCi RaEq) with an overlying plastic sleeve (Delclos ring). Afterloaded vaginal cylinders are used in conjunction with an intrauterine tandem to irradiate the vagina when the disease extends from the uterine cervix along the vaginal walls. Cylinders are available in various diameters (1 to 5 cm) and lengths to fit any vaginal width and length.

For LDR implants, the first intracavitary insertion is generally scheduled after 20 to 45 Gy of EBRT if patient and tumor geometry permit an adequate implant (typically early-stage patients, e.g., IB to early IIB). Otherwise, 30 to 45 Gy are delivered before the first application to decrease the size of the lesion and improve the relationship of the applicators to the cervix and vagina. The second application is performed 1 or 2 weeks later. For HDR implants, there is more variability in number of implants used. However, generally, more implants are done, and a common practice is to do one implant each week during external beam RT.

FIGURE 22.19. (A) Anteroposterior and (B) lateral radiographs of an HDR intracavitary insertion. Isodose lines reflect various dose levels, including the point A isodose of 700 cGy. A urinary catheter is in place with contrast material in the balloon, which is used to determine the maximum bladder dose. Radiopaque material in the vaginal packing helps determine the location of the anterior rectal wall to aid in determining the maximum rectal dose. Although not yet in common use, analysis of brachytherapy dose distributions based on cross-sectional imaging reconstructions, e.g., MRI, is an area of interest and research.

Intracavitary therapy, with its rapid dose fall-off with distance, yields a high dose to the uterus and paracervical tissues, but it is inadequate to treat the pelvic lymph nodes; external irradiation is necessary to supplement the dose. Therefore, the parametrial dose is primarily delivered with external irradiation. This combination technique affords a high central dose to the cervix, paracervical tissues, and parametria, as well as a moderate dose to the external iliac lymph nodes, without exceeding the bladder and rectal tolerance doses.

Image-Based Brachytherapy

Although the empiric point A has proven very useful in cervix cancer brachytherapy prescription, it has been suggested that better anatomic understanding of brachytherapy

dose distribution using modern imaging techniques could allow better tumor coverage and lessen dose to normal tissues. The U.S.-based Image-Guided Brachytherapy Working Group and the Europe-based Gynecologic GEC-ESTRO Working Group have proposed similar guidelines for implementation of image-based brachytherapy (353,354). These investigators recommend T2-weighted MRI scans with contrast as the preferred method for imaging implant geometry. Limited availability of MRI-compatible applicators and expense have slowed adoption of this approach. Definitions of gross tumor volume (GTV), clinical tumor volume (CTV), and organs at risk (OAR) are suggested, enabling quantitative analysis of implant geometry through dose-volume histograms (DVHs), similar to external beam RT (355). Viswanathan et al. compared the results of contouring CTVs and OARs according to CT versus MRI images in ten patients following placement of a standard applicator (356). Both CT and MRI were adequate for contouring OARs. However, it was found that CT overestimated tumor width compared to MRI, and this could result in significant differences in dose prescription when compared to MRI contours. These investigators supported the use of MRI as the gold standard for CTV definition in image-based brachytherapy.

Dose Rate Considerations

The rate at which radiation is given is an important variable in the delivery of RT. Conventional EBRT typically uses dose rates of 100 to 300 cGy per minute but is fractionated. Brachytherapy dose rates can be much more variable, the exposure is often continuous, and dose gradients are infinitely greater than with external beam therapy.

The ICRU defines LDR as exposures between 40 and 200 cGy/hr, medium dose rate (MDR) as between 200 and 1,200 cGy/hr, and HDR as >1,200 cGy/hr (351). All agree that clinically significant differences exist between LDR, MDR, and HDR. In general, as the dose rate is lowered, the biologic effect of the radiation is decreased owing to the ability of tissues to repair sublethal radiation damage and to repopulate. While there is probably no inherent difference in these parameters between tumor and normal tissues, there is apparently a substantial difference when one considers acute-responding (rapidly proliferating) versus late-responding (slowly proliferating) tissues. Late-responding tissues have a greater capability for repair than tumor or early-responding tissues, but this repair does not take place as fully with high dose rates. Therein lies the radiobiologic dilemma: higher dose rate or large doses per fraction cause relatively more severe late damage than tumor cell kill during HDR brachytherapy or external beam therapy.

To a large degree, published data documenting the effectiveness of RT has been obtained with continuous LDR intracavitary techniques, which have been used for nearly a century. However, even within the dose-rate range considered LDR (0 to 200 cGy/hr), a strong dose-rate effect is likely (357,358). Using a slightly higher dose rate (in the low MDR range), Patel et al. suggested, based on analysis of their clinical experience, that a dose reduction factor of approximately 30%, in comparison to a typical LDR range of 50 to 55 cGy/hr, would be required when using a dose rate of 220 cGy/hr at point A (359).

Although the dose prescriptions for LDR brachytherapy are reasonably well established and practiced around the world, there remains some disagreement about whether the LDR intracavitary dose should be given in one or two implants (360). Rotman and Aziz have published a nice review of the literature regarding this controversy (361). Most radiation oncologists favor fractionating the intracavitary portion of the treatment (mostly two implants) because of theoretical and practical advantages that include (a) tumor shrinkage between

implants, allowing better dose coverage in the relevant isodose (higher dose to the tumor periphery); (b) repair of normal tissues between fractions, leading to fewer late effects; and (c) limiting the duration of bed rest and potential complications that can result. The clinical data tend to support the superiority of two implants over one implant, but this is not uniformly the case.

Pulsed LDR brachytherapy has also been investigated as a possible means of preserving the radiobiologic advantages of LDR while taking advantage of dose optimization offered by HDR technology. Swift et al. reported their experience in 65 patients, 42 of who had cervical cancer (362). Median follow-up was only 15 months. In these patients with cervical cancer, 23 were alive without known disease at the time of the report. The 2-year actuarial survival rate was 65%, and the 2-year actuarial incidence of late complications was 14%. The authors concluded that pulsed LDR was feasible and produced good local control rates. Bachtiary et al. compared outcomes of patients treated with LDR (109 patients) and pulsed dose rate (PDR) (57 patients). Seventy patients also received concurrent cisplatin. No significant differences were noted in outcomes or toxicities (363).

The use of HDR in the curative management of cervical cancer is becoming more accepted, presumably because the outpatient treatment is more convenient. Other suggested advantages include better stability of the implant and source positions during the short duration of the implant and better ability to optimize dose distributions. The literature reflects considerable inconsistency in terms of whether complication rates are increased with HDR over LDR. Although many retrospective series and a few randomized trials have been reported, results are difficult to interpret. More recent studies include the results of Hareyama et al., who published a randomized trial of 132 patients with stage II or IIIB disease (364). External RT doses were identical, and a conversion factor of 0.588 was used to convert LDR to HDR. The 5-year disease-specific survival rates were 69% and 51% with HDR in stages II and III, respectively. This compared with 87% and 60% with LDR. Pelvic recurrence-free survival with HDR was 89% and 73% for stages II and III, versus 100% and 70%, respectively, in the LDR group. Actuarial complication rates (\geq grade 3) at 5 years were 10% with HDR and 13% with LDR. These differences did not reach statistical significance, although stage II patients had a better survival rate than those treated with HDR.

Ferrigno et al. published a retrospective series of 190 patients treated with LDR from 1989 to 1995 and 118 patients treated with HDR from 1994 to 2001. With median follow-ups of 70 and 33 months in the LDR and HDR groups, respectively, no significant differences were seen in overall survival (OS), disease-free survival (DFS), and local control among stage I-II patients. However, for stage III patients, OS and DFS were significantly better in the LDR group, and local control was also better, although not at a statistically significant level (365).

Falkenberg et al. reported a single institution study comparing outcomes of 103 patients treated with LDR versus 57 patients treated with HDR. No significant differences were seen in any stage in this series (366).

To facilitate multiple insertions, intrauterine stents can be used so that applicators can be placed quickly, without cervical dilatation, using little or no sedation. Treatment planning is performed on the initial insertion, and is duplicated for all fractions by verifying the applicator position with fluoroscopy or radiographs. In addition to fractionation, clinical experience has demonstrated that some method of increasing the distance from the HDR sources to the rectal wall is mandatory to keep rectal doses and subsequent sequelae at acceptable levels. Various techniques, including rectal retractors, vaginal speculums, gauze packing, and intravaginal Foley catheter balloons, are used to achieve this goal.

Interstitial Implants

Interstitial implants are an option when intracavitary implants are impossible (367). Implants are typically planned and facilitated using perineal templates such as the Syed-Neblett Interstitial Template or the Martinez Universal Perineal Template (MUPIT). The use of endorectal magnetic resonance coils and transrectal ultrasound can facilitate needle placement by improving visualization of tumor and normal tissues in relation to needle position. In some cases, this is done in conjunction with open laparotomy or laparoscopy.

Patients are typically selected for interstitial therapy on the basis of practical difficulties that preclude intracavitary therapy; thus, they may not be comparable to patients treated in a more conventional manner. However, until further improvements and better data supporting the efficiency and safety of this technique are available, its use in locally advanced cervical cancer should be only in exceptional circumstances, and by experienced brachytherapists. Furthermore, IMRT is likely to prove to be an effective alternative to interstitial therapy in patients who are not candidates for intracavitary therapy.

Doses of Irradiation

Invasive carcinoma of the cervix is treated with a combination of whole pelvis and intracavitary therapy. Some institutions use lower doses of pelvic RT (10 Gy for stage IB and 20 Gy for stages IIA, IIB, and III), in addition to parametrial doses to complete therapy with an MLS. This brings total doses to 50 Gy in stage IB and IIA, or 60 Gy to the involved parametrial tissues for more advanced stages.

Other institutions prefer higher doses of whole pelvis external irradiation (usually 40 to 45 Gy), delivered by four-field box or IMRT technique. This is usually combined with one or two LDR intracavitary insertions for approximately 40 to 55 Gy to point A, depending on tumor stage (volume). Usual doses to point A from both the external irradiation to the whole pelvis and the LDR intracavitary brachytherapy range from 70 Gy for small (≤ 1 cm) stage IB tumors to 90 to 95 Gy for stage IIB or IIIB tumors. An additional parametrial dose is administered in some patients with IIB, III, or IVA tumors (considering the dose delivered to the side wall by the brachytherapy). In patients with only unilateral parametrial involvement, consideration should be given to boosting only the involved side.

When using HDR brachytherapy, the greatest concern is the potential for increasing complication rates in a patient population in which the majority will be cured. To decrease the likelihood of increased late effects with HDR brachytherapy, it is necessary to use multiple HDR fractions and to decrease, as much as possible, the dose to late-responding tissues. Peterit and Pearcey (368) used 45 Gy/25 fractions of external beam irradiation to the pelvis, combined with five HDR fractions (5.5 to 6 Gy per fraction), or four fractions of HDR brachytherapy (6.5 to 7 Gy in each fraction). The equivalent LDR brachytherapy at point A is 80 Gy, with 67 Gy delivered to the bladder or the rectum, assuming that these tissues receive 70% of the prescribed point A dose. For advanced stages, such as IIB or IIIB, the intracavitary dose may be increased to 7.5 Gy per fraction, to have an LDR equivalent dose of 85 to 90 Gy to point A.

The recommended HDR brachytherapy prescription in GOG cervical cancer protocols is five fractions of 6 Gy (to point A) in addition to EBRT. Toita et al. from Japan have reported good results in their patients using significantly lower HDR doses (369). Whether this observation can be explained by anatomic variation, different tumor biology, or other reasons is not clear at this time. More clinical data with close observation and extended follow-up are needed to establish optimum brachytherapy treatment schedules using nonstandard dose rates.

Altered Fractionation

Conventional RT schedules typically employ fraction sizes of 180 to 200 cGy, given 5 days per week over a number of weeks. Altered fractionation refers to the use of nonstandard dose and fractionation schedules. Radiobiologic research and modeling suggest that these different fractionation schedules could favorably impact control rates, complication rates, or both. Examples include hypofractionation (larger doses per fraction, lower total dose), hyperfractionation (smaller doses per fraction given more frequently, e.g., two to three fractions per day, to a slightly higher total dose), accelerated fractionation (standard fraction sizes given more frequently, e.g., twice daily), and concomitant boost techniques (a larger volume is treated in standard fashion, while part of the volume, typically gross tumor, is treated with an additional smaller fraction on the same day, separated by 4 to 6 hours).

Hyperfractionation has been the most frequently investigated altered fractionation regimen (370). In general, the results have not been sufficiently positive to warrant its adoption.

Use of the concomitant boost technique in cervical cancer was reported by Kavanagh et al., who conducted a prospective trial in 22 patients (371). Pelvic RT of 45 Gy/25 fractions was given, and a concomitant boost of 14.4 Gy/9 fractions was given to gross tumor during weeks 3 to 5. Standard LDR brachytherapy was also given. Although the local control and survival rates were higher than a matched control group, the incidence of late bowel toxicity was sufficient to diminish enthusiasm for this approach until methods of lowering toxicity can be established.

Overall Treatment Time

Owing to the radiobiologic phenomena of tumor cell repopulation and accelerated repopulation, clinicians have long assumed that treatment prolongation, beyond some reasonable point, would likely have a deleterious effect on outcome in patients treated with RT. Several studies have supported this assumption by demonstrating lower pelvic tumor control and survival rates after definitive RT in invasive carcinoma of the uterine cervix when the overall treatment time is prolonged (372–374).

Combining the published results, one can suggest that pelvic control will suffer at an approximate rate of 1% per day that treatment extends beyond 52 to 55 days. This impact will be potentially seen in all stages of localized disease, and survival will be negatively affected. Erridge et al. have pointed out that there is probably a limit to the relationship between treatment time and outcome (375). In a cohort of patients, almost all of whom completed treatment within 7 weeks, no impact of overall treatment time was observed. However, grade 4 toxicities were more common among patients completing treatment on a compact schedule of 29 to 32 days.

Palliative or Emergent Irradiation

The radiation or gynecologic oncologist is often faced with treating a patient who requires palliation of pelvic pain, obstruction, or bleeding. If vaginal bleeding is the main concern, a single intracavitary implant with tandem and colpostats, about 50 to 55 Gy, to point A suffices. Alternatively, bleeding can be controlled by more conservative measures, such as vaginal packing, followed by the immediate institution of EBRT. In this circumstance, it can be appropriate to treat a slightly smaller pelvic volume and use doses per fraction slightly higher than standard, e.g., 250 to 300 cGy, allowing patients

with localized disease to be approached with curative intent, without an excessive risk of complications.

Patients with stage IVB or incurable recurrent carcinoma often require palliation of pelvic pain or bleeding, and their general condition may not warrant a prolonged course of external irradiation. Spanos et al. (376) reported an RTOG phase 3 study of accelerated split-course palliative irradiation in 284 patients. Patients received three courses of 14.8 Gy in four fractions over 2 days, with a rest of 2 to 4 weeks between courses, up to 44.4 Gy total dose. There were 136 patients randomized to rest periods of 2 or 4 weeks. There was a trend toward increased acute toxicity in patients with shorter rest periods (5 of 68, versus 0 of 68; $p = 0.07$). Late toxicity was not significantly different in the two groups, although length of follow-up was not sufficient to accurately assess it. Pelvic tumor response was comparable in both groups (34% vs. 26%). More patients in the 2-week rest period group completed the three courses of therapy, but the most significant predictor for completion of therapy was Karnofsky performance status of 80 or higher. This schedule offers significant logistic benefits and has been shown to result in good tumor regression and excellent palliation of symptoms.

CHEMOTHERAPY

Chemotherapy is increasingly utilized in the management of cervical cancer, both in primary management and for recurrent and metastatic disease. Reviews have indicated that several chemotherapeutic agents from different classes are active in this disease (377). Conventional agents able to induce a response rate of at least 20% in measurable disease include cisplatin, paclitaxel, topotecan, ifosfamide, doxorubicin, epirubicin, and vinorelbine. Doublets that combine these agents with cisplatin result in a doubling of response rate and improved progression-free survival but little or no improvement in overall survival when compared to cisplatin as a single agent. Three and four drug chemotherapy regimens further increase the response rate without improvement in overall survival at the expense of increased toxicity.

COMBINED MODALITY TREATMENT

Adjuvant Hysterectomy after Radiation Therapy

Multiple retrospective series have been reported comparing preoperative RT plus adjuvant hysterectomy post-radiation therapy (AHPRT) with curative intent RT or chemo-RT without AHPRT. Most commonly, no improvement in tumor control or survival is noted (378). Other series report improved pelvic control rates and possibly improved survival (379). Given the retrospective nature of these series, the authors acknowledge likely biases in patient selection, limiting the ability to draw conclusions.

A randomized trial to address this question was performed by the GOG. Keys et al. reported 256 patients with cervix cancers >4 cm in size who were randomized to curative doses of pelvic RT with brachytherapy versus preoperative doses of RT and brachytherapy plus AHPRT. The relapse rate was significantly lower in the AHPRT arm versus RT alone (27% vs. 14%). The incidence of progression was somewhat higher in the RT alone group at 46% versus 37% ($p = 0.07$) in the AHPRT group. However, no overall survival advantage was seen, and the toxicities were similar in both groups. Pathologic evaluation of hysterectomy specimens revealed

48% with no residual disease, 40% with microscopic disease, and 12% with grossly positive tumor. Patients with grossly positive tumors had a death rate seven times higher than those with negative specimens (230).

The main impetus for AHPRT is to decrease the incidence of pelvic recurrence; however, its use remains controversial because overall survival appears to be unaffected. Patients who could potentially benefit include those with bulky endocervical lesions greater than 4 cm in size and patients with difficult anatomy that limits appropriate placement of brachytherapy applicators. Patients with persistent disease after RT may benefit from planned hysterectomy.

Adjuvant Postoperative Pelvic RT

The most common failure pattern following radical surgery for cervical carcinoma is pelvic relapse. Based on an extensive GOG clinico-pathologic study, Delgado et al. proposed separate intermediate- and high-risk groups (134). These definitions have become generally accepted and incorporated into the design of both prospective trials and retrospective reports. Intermediate-risk criteria relate to tumor size, depth of stromal invasion, and lymphovascular space invasion; these are presented in Table 22.5. High-risk criteria include positive pelvic nodes, close or positive margins, and parametrial extension. Retrospective and prospective data suggest that adjuvant pelvic RT significantly improves pelvic control rates and disease-free survival in patients with risk factors for recurrence who have completed radical surgery. The role of chemotherapy, particularly in high-risk patients, has also become established.

Intermediate Risk, Node Negative

The GOG conducted a phase 3 trial comparing radical hysterectomy alone with radical hysterectomy and postoperative pelvic RT in patients with node-negative stage IB cervical carcinomas, with prognostic features correlated with an intermediate risk of recurrence (GOG #92) (317). Eligibility criteria for this study are given in Table 22.5. There were 277 patients randomized after radical hysterectomy: 137 to pelvic RT, and 140 to no further therapy. RT consisted of 46 to 50.4 Gy to a whole pelvic field. No brachytherapy was used. After a median follow-up of 5 years for living patients, recurrence was observed in 28% of the patients in the control group and in 15% of the radiated patients. There was a statistically significant reduction in the risk of recurrence (relative risk = 0.53, $p = 0.008$) in the irradiated group. Cox model analysis adjusting for risk factor combinations indicated that the risk of recurrence was decreased by 44% in the RT arm. A trend toward lower mortality with RT was observed but had not reached statistical significance at the time of publication. Severe or life-threatening adverse effects were observed in 7% of the radiated patients, versus 2.1% of the controls.

TABLE 22.5

GOG 92 ELIGIBILITY CRITERIA

CLS (capillary lymphatic space involvement)	Stromal invasion	Tumor size
Positive	Deep 1/3	Any
Positive	Middle 1/3	≥2 cm
Positive	Superficial 1/3	≥5 cm
Negative	Deep or middle 1/3	≥4 cm

After additional follow-up and data maturation, Rotman et al. presented a final report from GOG #92 (380). It was shown that the RT arm had a 46% reduction in the risk of recurrence compared to the observation arm ($p = 0.007$) and a reduction in the risk of progression or death ($p = 0.009$). Particularly striking was the impact of postoperative RT in patients with adenocarcinoma or adenosquamous histologies: among this subset, only 8.8% recurred in the RT arm, versus 44% in the observation arm. There was a strong trend toward improved survival in the RT arm, but this did not reach statistical significance ($p = 0.074$).

Several reasons have been suggested for the inability of this study to conclusively demonstrate a survival benefit in the presence of such a strong impact on recurrence rate. For example, a number of patients randomized to the RT arm did not receive RT and additional patients had protracted treatment or inadequate doses. However, the strongest factor is probably that the study was powered for its primary end point, which was disease-free interval, and was not sufficiently powered to demonstrate a survival benefit.

A retrospective series from the Netherlands looked at 51 patients with intermediate-risk, node-negative tumors. Of these, 34 received RT and 17 did not. The 5-year disease-free survival was 86% in the group receiving RT, compared to 57% in the observation group (381).

Management of patients with stage IB2 tumors is somewhat controversial, in that some favor initial surgery followed by adjuvant RT, while others recommend curative intent chemoradiation, avoiding the use of two local modalities. This topic is discussed earlier in the chapter.

Node-Positive/High-Risk Patients

Metastatic disease in the pelvic lymph nodes is a poor prognostic sign. Pelvic nodal metastases may be associated with lesion size, deep stromal invasion, and involvement of capillary or lymphatic vascular spaces (134). Postoperative pelvic radiation therapy has been advocated in the presence of these prognostic factors.

An intergroup study was conducted by the Southwest Oncology Group (SWOG), GOG, and RTOG in women with FIGO stages IA2, IB, or IIA carcinoma of the cervix found to have metastatic disease in the pelvic lymph nodes, positive parametrial involvement, or positive surgical margins at time of primary radical hysterectomy, and total pelvic lymphadenectomy with confirmed negative para-aortic lymph nodes (245). One hundred twenty-seven patients were randomized between pelvic external beam radiation therapy with 5-FU infusion and cisplatin, and 116 were treated with pelvic external beam irradiation alone. The median follow-up for survivors was 43 months. The 3-year survival on the adjuvant cisplatin/5-FU and irradiation arm was 87%, compared with 77% on the pelvic irradiation arm. The difference is statistically significant. Chemotherapy appeared to reduce both pelvic and extrapelvic recurrences. Acute toxicities were more common in the chemotherapy arm. Monk et al. reviewed the data from this randomized intergroup trial to assess the benefit of adjuvant therapies in definable subgroups of patients and to better understand histologic and clinical risk factors for recurrence (382). With a median follow-up of 5.2 years, the survival rates were 80% and 66% for the chemo-RT and RT alone groups, respectively. In a univariate analysis, the benefit of chemotherapy was most significant in patients with tumors >2 cm and >1 nodal metastasis.

Although retrospective, a large and well-analyzed series of patients receiving postoperative RT was presented by Kim et al. (383). Death and recurrence rates increased with the number of positive lymph nodes. Five-year disease-free survival was 89% if no nodes were positive, decreasing to 85%,

74%, and 56% in patients with one, two to three, and four or more positive nodes, respectively. Similar data was reported by Uno et al. (384).

Close or Positive Margins/Parametrial Involvement

Eighty-five percent of patients accrued on the SWOG/GOG/RTOG Intergroup study were eligible based on pelvic node involvement. Only 5% of patients accrued to this intergroup study had positive margins, probably because of the reluctance of clinicians to put these patients on a trial that did not allow brachytherapy boosts. Nevertheless, patients with positive or close margins and/or parametrial involvement are considered to be at high risk and, based on this randomized trial, should be considered for adjuvant chemoradiation (245). Other data might suggest that some patients, particularly close or positive margin patients, might be adequately treated with only postoperative RT.

Estape et al. retrospectively analyzed 51 patients with close vaginal surgical margins following radical hysterectomy (defined as ≤ 5 mm) (385). Twenty-three patients with negative nodes and close vaginal margins were studied. Although the 16 patients receiving RT had a preponderance of other risk factors, recurrence rates (12.5% vs. 85.7%) and 5-year survival rates (81.3% vs. 28.6%) significantly favored the group receiving adjuvant pelvic RT.

Kim et al. (386) described results for 38 patients receiving postoperative RT after radical hysterectomy for close surgical margins and/or metastatic pelvic lymph nodes. Patients with close surgical margins were treated with intracavitary vaginal ovoid insertions. Patients with positive margins fell into two groups: those with positive parametrial margins and those with involved vaginal margins. All five patients with involved parametrial margins treated with only cuff brachytherapy suffered local failures, compared with no pelvic failure in similarly treated patients with only vaginal margins positive for tumor.

Uno et al. analyzed 117 patients with parametrial invasion who had undergone radical surgery and received adjuvant RT. Of 51 node-negative patients, only 6 developed extrapelvic recurrence, and the 5-year overall survival and recurrence-free survivals were 89% and 83%, respectively. Patients with positive nodes fared much worse (384). Similarly, Kodama et al. found excellent outcomes among parametrium-positive patients who were treated with RH and adjuvant RT if lymph node metastasis and vaginal invasion were not present (approximately 90% 5-year survival) (387).

Radiation Therapy Dose and Technique

Vaginal intracavitary RT alone can be appropriate for patients with carcinoma *in situ* with minimally invasive carcinoma at the vaginal margin of resection as the only risk factor. Outpatient HDR brachytherapy is commonly employed because it prevents the prolonged immobilization required for LDR brachytherapy. The usual dose per fraction prescribed at 0.5 cm depth is 7 Gy; three weekly fractions are typically given. The upper 3 to 5 cm of the vagina should be targeted.

When external RT is used, patients generally should not receive more than 45 Gy to the whole pelvis. Doses up to 50.4 Gy are acceptable when treating smaller fields that exclude more small bowel. Brachytherapy or small-field external beam boosts can be given, within tolerance, to increase dose to the central pelvis. The impact of concurrent chemotherapy on complication rates appears to be limited, but continued follow-up and research are needed.

The use of IMRT with chemotherapy has been reported to maintain excellent pelvic control rates, with better acute tolerance and fewer chronic toxicities compared to conventional four-field box RT (388).

Chemotherapy in Combinations for Localized Carcinoma of the Cervix

Neoadjuvant Chemotherapy Followed by Radiotherapy

Randomized trials of neoadjuvant chemotherapy (NACT) followed by radiation versus radiation alone in patients with locally advanced cervical cancer (mainly stages III and IV) have been disappointing, in terms of both complete response rates and increase in survival (389–394). In fact, none of the five reported studies showed any survival benefit (Table 22.6). Pelvic failure was more common on the NACT arm in some of these trials, and a negative influence on survival was reported in two trials (392,394). In addition, treatment morbidity was sometimes severe (392). Explanation for these negative results cannot be given with certainty, but it has been suggested that chemotherapy could lead to an accelerated regrowth of surviving clones of cells, thus lessening the effect of subsequent RT (395). Another possibility is the development of cross-resistance

between certain chemotherapeutic agents and radiation (396). A meta-analysis of 18 randomized clinical trials of neoadjuvant chemotherapy including 2,074 patients compared NACT followed by RT to RT alone and demonstrated no advantage of neoadjuvant chemotherapy with regard to progression-free survival, locoregional disease-free survival, metastasis-free survival, or overall survival (397). Whatever the reason, NACT followed by RT for patients with locally advanced cervical cancer does not seem to be an option to follow any further.

Neoadjuvant Chemotherapy Followed by Surgery

Numerous nonrandomized studies reported in the 1990s suggested that NACT followed by surgery might be an attractive approach (398–403). Indeed, some but not all of the randomized trials show a trend in favor of this combined approach (Table 22.7) (404–408). A meta-analysis of five randomized clinical trials and 872 patients who received NACT followed by surgery ± RT were compared to RT alone (397). There was a significant improvement in progression-free survival, locoregional disease-free survival, metastasis-free survival, and overall

survival for those who were resectable following NACT. Results of NACT were best for trials with cisplatin dose intensity greater than 25 mg/m²/wk and dose density with treatment interval less than 14 days. Observations that have been made in the above-mentioned studies include the following: (a) cisplatin-based regimens are well tolerated, induce high response rates (particularly in earlier disease), and have little or no effect on surgical morbidity; (b) with NACT there is a reduced incidence of involved lymph nodes, capillary space involvement, deep invasion, or undiagnosed parametrial disease; and (c) recurrence rates are reduced. Nevertheless, based on the available data, NACT remains investigational.

Preoperative Chemoradiation in Advanced Disease

Houvenaeghel et al. have reported long-term results of neoadjuvant chemoradiation followed by radical surgery in 35 patients with locally advanced cervical cancer. Forty patients initially entered the study; however, five patients did not go on to have surgery following the preoperative regimen. Patients received cisplatin and 5-fluorouracil along with RT, typically 45 Gy. Twelve of 20 stage IB-IIb patients obtained a complete histologic response compared to 4 of 15 patients with stage III-IVA disease, and the pelvic control rate was 88.6%. The 10-year disease-free survival was 66.4%. Serious postoperative complications were seen in five patients (409).

Adjuvant Chemotherapy

Several nonrandomized studies suggest a beneficial effect of adjuvant chemotherapy given after radical surgery in patients at high risk for recurrence (410–412). Two randomized trials with a very limited number of patients have tried to evaluate the effect of adjuvant chemotherapy in patients with high-risk cervical cancer after radical hysterectomy. The first study, with only 71 patients (all with lymph node metastases) compared postoperative RT versus three cycles of postoperative chemotherapy (PVB; cisplatin, vinblastine, bleomycin) followed by RT. In the second study 76 patients (with pelvic lymph node metastases and/or vascular invasion) randomly received either adjuvant chemotherapy (carboplatin plus bleomycin) for six courses at 4-week intervals, standard RT, or no further treatment. The results of both studies are inconclusive, but there was no apparent difference in the recurrence rates and patterns of recurrences or survival between those treated and those not treated with adjuvant chemotherapy.

TREATMENT OF RECURRENT CARCINOMA OF THE CERVIX

General Considerations

The main cause of death among women with cervical cancer is uncontrolled disease in the pelvis. However, a subset of patients with recurrent disease confined to the pelvis following definitive therapy, whether that therapy is surgery or RT, are potentially curable. Treatment selection and the likelihood of success are functions of the primary therapy, extent of disease at presentation, site of recurrence, local extent of the recurrence, disease-free interval, performance status, and comorbidities.

When curative intent salvage treatment is contemplated, the local recurrence should be biopsy proven, and the patient should be evaluated for regional and distant metastasis by physical examination and imaging. A clinical diagnosis of pelvic sidewall involvement can almost always be made in the presence of a triad of sciatic pain, leg edema, and hydronephrosis. PET scanning may be the most accurate test in terms of assessing metastasis prior to embarking on local salvage therapy.

Husain et al. enrolled 27 patients with recurrent cervical or vaginal cancer who were being considered for surgical resection on an imaging protocol consisting of PET with CT and/or MRI (413). Metabolic imaging was found to have a sensitivity of 100% and a specificity of 73% in detecting sites of extra-pelvic metastasis. However, biopsy confirmation of recurrence remains the gold standard for diagnosis.

Generally, patients with pelvic or regional recurrences after definitive surgery alone are managed with RT or chemoradiation, often with brachytherapy. Salvage options for patients with central recurrence after definitive or adjuvant RT are limited to radical, usually exenterative, surgery, and in selected patients, re-irradiation using interstitial radiation implants or highly conformal EBRT or IMRT. Chemotherapy-responsive patients can obtain meaningful palliation in many cases.

Salvage Treatment After Definitive Radiation Therapy: Re-irradiation

Recurrent cervical carcinoma following definitive RT within previously irradiated areas presents a difficult management problem. Although salvage surgery, usually exenterative, can be offered to patients with limited, centrally recurrent lesions if age and general condition permit, radical surgery following RT is accompanied by operative mortality in some, severe morbidity in many, and substantial loss of structure and function in all. Therefore, the applicability of salvage surgery is limited by physician and patient acceptance, as well as by clinical parameters. Even among patients meeting rigorous preoperative criteria, salvage surgery will be aborted in about one fourth of patients.

Previously irradiated tissues do not have the same tolerance as newly irradiated tissues. Therefore, severe late effects have been frequently observed, particularly in older series that predominantly used external beam techniques in poorly selected patients. More recently, evidence has been presented to suggest that re-irradiation can be curative in a significant percentage of patients with small-volume central recurrences, particularly when there has been a long disease-free interval since the earlier diagnosis and treatment.

Randall et al., in a series of 13 patients, observed a 69% complete response rate and a 46% NED (no evidence of disease) rate with a minimum 2-year follow-up, and median follow-up of 59 months (414). Interstitial re-irradiation (IRI) doses of 30 to 55 Gy were employed, with low-dose-rate permanent and temporary implants. Patients with squamous histology did significantly better than patients with adenocarcinoma histology. Other predictors for improved outcomes included smaller tumor volumes, higher implant doses, and vaginal wall/suburethra versus vaginal cuff location. Late morbidity was limited to one rectovaginal fistula in a patient who also had recurrent tumor.

In a series of 73 patients with late recurrences of squamous carcinoma of the cervix in the vaginal canal following radiation therapy, Wang et al. (415) reported a 5-year survival rate of 40%. Sixty-one patients received only RT, mainly with fractionated brachytherapy techniques such as vaginal molds. Doses of 20 to 40 Gy in three to five fractions over 3 to 5 weeks, using both LDR and HDR techniques, were typically employed, sometimes followed by more focused boosts. Favorable prognostic factors included proximal location in the vagina and tumor size <4 cm. Significant complications occurred in nearly 25%, including a 12% fistula rate. Complications were more common among patients with distally located tumors.

Jhingran has described the use of IMRT in the re-irradiation setting (314). In particular, IMRT can treat pelvic recurrences that cannot be treated with brachytherapy, because of size, location, or other factors (Fig. 22.20).

FIGURE 22.20. (See color plate section.) This demonstrates the use of multiple-field IMRT to retreat a painful pelvic sidewall recurrence after previous RT. After 35 Gy at 2.5 Gy per fraction, the patient became asymptomatic and remained stable for 2 years. *Source:* From Jhingran A. Potential advantages of intensity-modulated radiation therapy in gynecologic malignancies. *Semin Radiat Oncol* 2006;16:144–151.

Compared to exenterative surgery, re-irradiation is better tolerated acutely, has little operative mortality, and often preserves structure and function of pelvic organs. When contemplating re-irradiation, it is important to analyze the techniques used in the initial treatment (beam energy, volume, doses delivered with external or intracavitary irradiation). The period of time between the two treatments must be taken into consideration.

Re-irradiation is probably under-utilized in the management of locally recurrent cervical cancer. As chemotherapy does not have curative potential and many patients will not be candidates for exenterative surgery or will refuse such surgery, re-irradiation, in many cases, will be the only feasible curative intent therapy. Patient selection and careful brachytherapy technique are crucial to successful re-irradiation.

Recurrence in the Para-aortic Chain

Although unusual, recurrences limited to the para-aortic nodal region are reported following primary surgery or RT. Grigsby et al. reported 20 patients with recurrent cervical cancer confined to the para-aortic region following definitive RT (346). The median time between the initial diagnosis and the recurrence was 12 months. Although all patients died within 2 years after recurrence, median survivals were longer in patients receiving >45 Gy. A disease-free interval of >24 months was also a positive prognostic factor. However, a subsequent report from this group found a 100% salvage rate in patients with isolated para-aortic recurrences if the recurrences were asymptomatic and discovered by imaging follow-up and received full dose (>45 Gy) salvage RT combined with chemotherapy (416).

This observation was confirmed by the experience reported by Kim et al. (345). These investigators treated 12 patients with isolated para-aortic failures following RT with concurrent chemotherapy (mostly paclitaxel) and hyperfractionated RT. In patients who relapsed within 24 months of their initial treatment, the median survival following attempted salvage was 13 months. In contrast, patients having a disease-free interval >24 months had a median survival of 45 months with this therapy. A much larger series with encouraging results was presented by Hong et al., who reported 46 patients with isolated para-aortic failures, of whom 35 (76%) received salvage chemo-RT. The 3-year and 5-year survival rates were 34% and 27%, respectively. Patients who had supraclavicular relapse, with or without para-aortic relapse, had a 28% 3-year survival with salvage therapy (417).

An IMRT plan demonstrating treatment of gross recurrence and clinically high-risk areas in the para-aortic chain is shown in Figure 22.21.

FIGURE 22.21. IMRT dose distribution in a patient treated for para-aortic lymph node recurrence. The gross nodal disease received 63 Gy at 2.5 Gy per fraction, and the nearby at-risk areas received 50 Gy. IMRT allows the creation of this sort of dose gradient to provide a “field within a field” boost. *Source:* From Jhingran A. Potential advantages of intensity-modulated radiation therapy in gynecologic malignancies. *Semin Radiat Oncol* 2006;16:144–151.

Salvage Treatment After Definitive Radiation Therapy: Radical Surgery

Pelvic Exenteration

Advances in perioperative and postoperative care and better techniques of pelvic, urinary, and GI reconstruction have led to much improved outcomes and enhanced quality of life compared to early experiences with pelvic exenteration (PE). Survival rates have increased from 20% to about 60% with an average of 40% to 50% 5-year survival in reported series of patients completing the procedure (418,419).

Despite these advances, PE is still a very morbid operation with acute and late complications reported as high as 50% to 60% and a mortality rate of 5% to 7%. The procedure is most commonly used in patients with recurrent central pelvic disease after treatment with pelvic RT. In some cases patients with stage IVA disease may be offered primary PE, although modern chemoradiotherapy is probably preferred.

In patients undergoing PE, Marnitz et al. noted the importance of margin status: 5-year survival was 55% with negative margins compared to 10% if margins were positive (420). Given this fact and the potential morbidity and mortality from the procedure, proper patient selection requires that all efforts be made to assure that there is no site of metastatic disease and the isolated central recurrence can be resected with negative margins. Additional negative prognostic factors include disease-free interval <1 year, size of recurrence >3 cm, lymphatic spread, and parametrial and sidewall involvement. Patients with positive nodes have a survival rate of 20% or less. The presence of grossly positive lymph nodes during exploration is a poor indicator for survival and should be considered a contraindication to exenteration.

Historically, 40% to 50% of patients explored for PE will have the procedure abandoned. Husain et al. prospectively evaluated the role of PET scanning in identifying metastatic disease prior to PE. They found that PET scan had a sensitivity of 100% and specificity of 73% in detecting extra-pelvic metastatic sites and may be the most accurate imaging modality prior to PE (413). Other investigators have confirmed these findings (421). Kohler et al. found that laparoscopy was able to accurately identify cases that were eligible for PE, and their laparoscopic findings were not changed with laparotomy (422). Hopefully, better imaging and evaluation techniques will improve patient selection and minimize laparotomies in patients who are not candidates for PE.

Berek et al. reported 75 patients older than 45 years who underwent PE at a single institution. The operative time averaged 7.76 hours, the mean estimated blood loss was 2.5 liters, and the median length of stay was 23 days. Morbidities included intestinal fistulae in 15%, urinary fistulae in 8%, early bowel obstruction in 11%, and late bowel obstruction in 22%. When a J-pouch was used for colonic re-anastomosis, there was no reported fistula. Survival for patients with cervical and vaginal cancers was 73% at 1 year, 57% at year 3, and 54% at 5 years (419).

Goldberg et al. reported a 16-year experience in 103 patients. Complications included ureteral anastomotic leaks (14%, no difference between continent vs. incontinent), ureteral stricture (5%), pouch fistula (3%), pouch stones (2%), wound complications (17%), and GI fistula (11%). Other observations included that 46% of patients with primary low rectal re-anastomosis had pelvic recurrences, continent conduits were unsatisfactory in 54%, and use of mesh for pelvic floor reconstruction increased infection and fistula rates. The overall mortality was low at 1%. The 5-year survival in patients with recurrent cervical cancer was 48% (309).

Pelvic Reconstruction

In 1950, Bricker described a novel approach to diversion of urinary flow that involved isolating a segment of ileum, implanting the ureters into this segment, and bringing an open end to the abdominal wall as a separate urostomy (423). This technique was a major advancement and significantly reduced complications compared to the wet colostomy (reimplantation of ureters in the colostomy that diverts the fecal stream). This form of urinary conduit is incontinent, where the urine drains continuously to an external reservoir. The other option is to create an internal reservoir using bowel wall with a continent mechanism that allows for self-catheterization, which negates the need for an ostomy bag and affords more control to a motivated patient (423,424). The most common complications of continent reservoirs are acute and chronic pyelonephritis, ureteral stricture, urinary leak, fistula, stone formation, and, rarely, renal failure (424,425).

Segreti et al. reported their experience with transverse colon conduits and found no advantage for incontinent pouches (426). The choice depends most heavily on the surgeon's preference and the status of the distal ileum after RT. Penalver et al. reported complications in a series of patients undergoing construction of a Miami pouch. The early complication rate in 66 patients was 53% and included ten ureteral stricture/obstructions, four anastomotic leaks, and four fistulae. An additional five had difficulty with catheterization, and ten had pyelonephritis. Most complications were managed conservatively with antibiotics, percutaneous drainage, and nephrostomies. The operative mortality was 9%. The late complication rate was 37%. Out of 25 patients, 6 had strictures, 8 were incontinent, 7 had difficulty with catheterization, and 4 developed urinary stones. Again, most complications were managed conservatively (427). In a similar

series from M. D. Anderson Cancer Center, 65% had postoperative complications related to the Miami pouch. Most complications were managed conservatively, and 90% retained normal continent conduit function (428).

Ungar and Palfalvi reported 29 patients who underwent orthotopic urinary reconstruction using ileocecal ascending colon reservoirs (the Budapest pouch). Although 77% of patients were able to void voluntarily without the need for self-catheterization, 23% to 47% had some incontinence (429). This is an attractive option as patients can potentially be free of any ostomies. However, only a select group of patients are candidates for these procedures.

The other component of pelvic reconstruction following PE is creation of a neovagina. Formation of a neovagina is an important component of reconstruction in several respects. For example, it fills the pelvis with well-perfused tissue and can significantly decrease the rate of pelvic infection and fistula formation (430). It also may restore some sense of normalcy in patients who are able to resume sexual activity after PE.

Many options are available for construction of a neovagina. These include the following flaps: gracilis myocutaneous, anterolateral thigh fasciocutaneous, bulbocavernosus myocutaneous, transverse rectus abdominis musculoperitoneal (TRAMP) or myocutaneous (TRAM), vertical rectus abdominis musculocutaneous (VRAM), femoris myocutaneous, tensor fasciae latae myocutaneous, inferior gluteal, and omental J flap. Portions of sigmoid colon have also been used. Myocutaneous flaps are favored due to better blood supply, ease of procedure, and functionality.

McCraw et al. first described the use of gracilis muscle for vaginal reconstruction (431). Burke et al. described perineal reconstruction using a single gracilis muscle, and 3 out of 17 had flap necrosis (432). Ratliff et al. evaluated sexual adjustment in these patients and found that 52.5% never resumed sexual activity even though 70% were thought to have adequate and functional neovagina length on examination. Self-consciousness about urostomy and colostomy was the most common reason cited for avoiding sexual activity (433). Soper et al. reported on a "short gracilis" flap based on the terminal branches of the obturator artery and found no difference between the traditional and "short gracilis" flaps (434).

O'Connell et al. reported a 100% success rate with no fistula formation, bowel obstruction, or pelvic infection using VRAM flaps. Almost 50% of women reported sexual activity after VRAM (435). Soper et al. reported that 62% of women reported sexual activity within 12 months after VRAM or TRAM flap reconstruction, concluding that both techniques give similar results and complication rates (436). Previous ligation of the inferior epigastric artery is an absolute contraindication of use of rectus flaps.

Sood et al. reported a modification to the VRAM using a smaller flap size anteriorly with a full thickness skin graft placed posteriorly. One of 18 had a partial flap loss that resolved with conservative management, and 8 of 18 remained sexually active (437). This technique allows for a smaller abdominal wall defect with minimal compromise of the neovagina. Goldberg et al. reported that gracilis flaps had a failure rate of 11% to 37%. As a group, VRAMs resulted in better outcomes with a vaginal stenosis rate of 11% and the majority of women remaining sexually active (309,310). Soper et al. compared gracilis muscle versus rectus abdominis flaps for vaginal reconstruction. Flap-specific complications and flap loss were significantly greater in gracilis muscle flaps. The authors have adopted rectus abdominis flaps as their preferred choice for vaginal reconstruction (438).

Re-anastomosis following rectosigmoid resection depends on many factors and is an option in patients undergoing supralevator PE. Factors associated with anastomotic integrity include the length of remaining rectum/anus (<4 cm having a higher

incidence of leaks versus >7 cm), blood supply to the region, and tension on the anastomosis. The use of low rectal anastomosis is controversial. Mirhashemi et al. found a 35% versus 7.5% rate of fistula formation or anastomotic breakdown in patients with previous RT compared to those who were radiation naïve. Protective colostomy was not associated with an improved outcome (439). Husain et al. reported a 54% anastomotic leak after low rectal anastomosis (440). This may be decreased by using a J pouch instead of an end-to-end re-anastomosis (419). However, some patients have difficulty emptying the pouch, particularly with shorter pouch lengths.

Wheless described good results from neovaginal construction combining an omental J flap and a split thickness skin graft, an approach that may be considered in patients who are not candidates for rectus or gracilis flaps (441). No method of pelvic reconstruction is clearly superior to others or appropriate in all cases. The surgeon has many choices and should individualize according to each patient.

Radical Hysterectomy

Patients with very small central recurrences (less than 2 cm) after RT may be candidates for a less radical approach than PE, specifically RH. Maneo et al. evaluated the role of RH in patients with persistent or recurrent disease in 34 patients. They reported grade 3 to 4 toxicities in 44%, including five who developed fistulae. The overall 5-year survival was 49%, and 59% recurred with an average time to recurrence of 37 months. Patients with smaller tumors and lack of involvement of parametrium or vagina had better outcomes (442). Coleman et al. studied 50 patients treated with RH for persistent or recurrent central disease after RT. All patients with positive nodes died within 13 months. Severe toxicities occurred in 42%, and 28% developed either a GI or GU fistula. An additional 22% had ureteral injuries with 20% having severe long-term bladder dysfunction. The 5- and 10-year survival rates were 72% and 60%, respectively. Tumor size less than 2 cm was associated with a significantly greater survival compared to larger tumors. Overall recurrence rate was 48% (443).

RH may be a reasonable option for selected patients with persistent or recurrent central disease less than 2 cm with no extension to the parametrium or vagina. However, significant morbidity rates are relatively high (442–444).

Salvage Treatment After Previous Surgery— Definitive RT or Chemoradiation

Monk et al. (445) utilized EBRT followed by laparotomy and “open” interstitial implant for recurrent cancer in the upper vagina following hysterectomy. This approach provided the ability to accurately assess the extent of the disease and to separate bowel and bladder adhesions from the area of the implant, facilitated placement of the interstitial brachytherapy needles, and allowed the placement of an omental pedicle graft to separate the bladder and rectum from the implant volume. In 28 patients, local control was 71%, and the long-term complication rate was 11%. Long-term NED survival was 36%. Lesions <6 cm in patients with no previous RT had high control rates.

Ito et al. (446) reported on 90 patients with central recurrences from cervical cancer after surgery treated with HDR intracavitary brachytherapy (ICB), with or without EBRT. The 10-year survival for the entire series was 52%. They found survival to be greatly influenced by tumor size—72%, 48%, and 0% 10-year survival rates respectively, for small or no palpable tumor, medium (<3 cm), and large (≥ 3 cm). In addition, patients who achieved a complete response after RT had a 10-year survival of 63% versus 10% for those with residual disease.

Ijaz et al. (447) reported a 5-year survival of 39% in 43 patients with isolated locoregional recurrences treated with external RT and brachytherapy. In 16 patients with limited recurrences to the vagina and paravaginal tissues, the 5-year survival was 69% after radical RT.

Concurrent chemotherapy with RT has proven beneficial in locally advanced cervical cancer. Several studies also suggest a possible benefit in patients with recurrent disease (413,448). Grigsby reported a prospective trial of 22 patients with pelvic recurrences of cervical cancer following hysterectomy who received concurrent RT with 5-FU and cisplatin chemotherapy (449). None had received prior RT. The 10- and 15-year overall survival rates were 35%. Acute toxicity was limited; however, late toxicity was significant in some survivors, leading the author to recommend consideration of other chemotherapy regimens or RT alone.

In RT-naïve patients, pelvic RT of 40 to 50 Gy to the primary tumor and regional lymphatics is indicated. Inguino-femoral lymph node regions should be included in patients with involvement of the distal third of the vagina. The entire vagina should be treated in most patients with vaginal recurrences following hysterectomy. A vaginal dose of 60 to 65 Gy from external RT, with or without brachytherapy, is desirable. The gross tumor volume should receive additional radiation; doses of 15 to 30 Gy are administered with single, double-plane, or volume implants, or with intensity-modulated external RT. High-dose-rate brachytherapy techniques are also possible with appropriate dose modifications.

Salvage Treatment—Intraoperative Radiation Therapy

Patients with microscopically positive or close margins have a poor prognosis after salvage surgery. Intraoperative RT (IORT) has been used in this situation to potentially sterilize residual disease after tumor debulking. IORT allows direct visualization of the target volume, and displacement and/or shielding of the surrounding normal tissues. The IORT dose is generally limited because of prior RT, proximity of critical normal structures, and the single fraction nature of the treatment.

IORT has been used for treatment of locally advanced and recurrent carcinoma of the cervix. Most of this experience is based on the treatment of isolated central and nodal recurrences, generally amenable to surgical excision. Limitations in evaluating IORT include small patient numbers, short follow-up, and widely varying patient selection criteria. The available data seem to indicate that IORT, although feasible, does not dramatically improve prognosis and is associated with significant incidences of long-term complications. Patients with limited central recurrences who are candidates for pelvic exenteration but are found to have unfavorable prognostic factors for local recurrence, such as close positive margins, LVSI, or perineural invasion, may benefit from IORT or intraoperative interstitial brachytherapy (450).

Salvage Treatment—Role of Chemotherapy

Cisplatin, at present, is considered the single most active cytotoxic agent, and its preferred schedule of administration in metastatic or recurrent disease is 50 to 100 mg/m², given intravenously every 3 weeks. Overall, the duration of the objective responses to cisplatin in patients with metastatic or recurrent disease remains disappointing (4 to 6 months) and survival in such patients is only approximately 7 months. There is a suggestion of a dose-response relationship; in one trial comparing 50 mg/m² and 100 mg/m², the overall response rate increased

TABLE 22.8**RANDOMIZED STUDIES OF CISPLATIN-BASED COMBINATIONS VERSUS SINGLE-AGENT CISPLATIN IN PATIENTS WITH CERVICAL CANCER**

^d*p* < 0.01

from 21% to 31% (451). However, there was only a minimal increase in the complete response rate (from 10% to 13%) and no improvement in response duration, progression-free interval, or survival. A small study performed at the Memorial Sloan-Kettering Cancer Center using 200 mg/m² of cisplatin (and sodium thiosulfate nephroprotection) suggested no further increase in response rate with these higher dosages, and toxicity was unacceptably high (452).

Response rates with combination chemotherapy have varied from 0% to nearly 100% in individual reports, reflecting sample size, differences in response assessment criteria, and patient characteristics. However, cumulative data indicate that a response rate of about 40% can be expected in well-selected patients. Randomized clinical trials that compared combination chemotherapy regimens to single-agent cisplatin have demonstrated improved objective response rates and progression-free survival without improvement in overall survival (Table 22.8) (453–455). A recent randomized clinical trial (456) was the first to demonstrate an overall survival advantage for combination chemotherapy over single-agent cisplatin. Topotecan (0.75 mg/m²) days 1 to 3 with cisplatin (50 mg/m²) day 1, repeated every 21 days demonstrated a significant improvement in objective response rate (27% vs. 13%; *p* = 0.004), progression-free survival (4.6 vs. 2.9 months; *p* = 0.014), and overall survival (9.4 vs. 6.5 months; *p* = 0.017). The figures for single-agent cisplatin were considerably lower than in previous trials with cisplatin, suggesting that the advantage for the combination could represent reduced efficacy of cisplatin in this patient population due to prior platin exposure during concurrent chemoradiation for primary treatment (57%). For those with no prior platin exposure the progression-free survival was 6.9 versus 3.2 months and overall survival 15.4 versus 8.8 months favoring the combination. Nevertheless, this was the first randomized clinical trial to demonstrate a

survival advantage for combination chemotherapy over single-agent cisplatin in this patient population. Despite increased hematologic toxicity of this combination, a concurrent quality of life study failed to demonstrate any reduction in the quality of life of treated patients for the combination compared to the single agent (457). An individual approach to these patients is warranted. Identification of a subset of patients who might benefit from chemotherapy would be a major advance. Any decision for treatment of cervical cancer patients in the palliative setting should be assessed against the benefit of best supportive care, which may provide the best option for some of these patients.

COMPLICATIONS AND SEQUELAE OF TREATMENT

Surgery Related

The most common complications with conization include infection, bleeding, damage to surrounding structures (bladder, rectum, vagina), and cervical incompetence with predisposition to preterm labor in future pregnancies. Radical hysterectomy and lymphadenectomy may result in additional and somewhat unique complications. Urologic complications such as ureteral injuries and vesicovaginal or ureterovaginal fistulas are reported in 1% to 2% of cases, and this can be increased in patients requiring postoperative RT (318). Most vesicovaginal fistulas can be diagnosed with a voiding cystogram or clinically by infusion of a diluted methylene blue solution into the bladder and observation of leakage into the vaginal vault commonly known as the “tampon test.” The majority will heal spontaneously with continuous bladder drainage for 6 to 8 weeks and treatment of

any underlying infection. Ureterovaginal fistulas may be more difficult to diagnose. An intravenous pyelogram or CT scan may be indicated and demonstrate such a fistula in a patient with symptoms suggestive of a urinary fistula with a negative clinical exam or cystogram. Conservative management can include ureteral stenting and drainage of the urinary system via percutaneous nephrostomy, which may lead to healing of the fistula. Repeat imaging should be done prior to removal of the stent to assure ureteral healing. Repair of a persistent vesicovaginal fistula can be attempted vaginally, depending on the site of injury. The fistulous tract is excised and repaired in multiple layers, followed by continuous bladder drainage and repeat cystogram to ensure surgical success. Ureteral fistulas that do not resolve with conservative management may require reimplantation of the ureter into the bladder (ureteroneocystostomy). Fistulas that occur following pelvic RT are less likely to heal with conservative management and may require earlier surgical treatment. As surgical repair after RT has a lower success rate, urinary diversion may be required as definitive treatment.

Averette et al. published their experience with RH in 978 patients over 25 years. The surgical mortality was 1.4%, and the urinary fistula rate was 1.4% (458). Artman et al. published their experience with RH in 275 patients over 21 years. The average blood loss was 1,800 cc. The urinary fistula rate was 2.6%, and the surgical mortality rate was 0.7% (459). Lee et al. reported a fistula rate of 2.4% and an operative mortality of 0.4% in a series of 954 patients. Lymphocyst formation is about 1.6% and the lymphedema rate is about 3.6% following pelvic lymph node dissection (LND) (460).

Located over the sacral promontory, the hypogastric plexus contains sympathetic fibers that fuse with parasympathetic fibers located in the parametrium and allows for bladder contraction and compliance. Surgical disruption of this plexus results in bladder atony and dysfunction in about 5% of patients, possibly requiring continuous or intermittent drainage for a few weeks (461). Efforts have been made to incorporate nerve-sparing techniques into the radical hysterectomy procedure, and these efforts continue (462).

Farquharson et al. compared bladder function after RH versus RH plus RT. They found that bladder compliance was significantly reduced when RT was added to RH (463). Ralph et al. performed urologic evaluations in 40 patients at 2 weeks, 6 months, and 1 year after RH. At 2 weeks all had impaired bladder sensation and 68% had residual urine after voiding. At 1 year, 63% had impaired bladder sensation. Bladder capacity was lowest at 2 weeks (180 mL) and returned to baseline between 6 to 12 months. By 1 year, patients had residual urine after voiding. However, 62% had abnormal compliance and 85% used abdominal straining to void (464).

Rectal function can also be impacted by RH. Schreuder et al. used a questionnaire to evaluate rectal function after RH in 48 patients; 18% had constipation, 33% required chronic straining, and 60% required laxative or manual assistance with defecation. The incidence of chronic constipation was >20% (465). Barnes et al. used manometric studies to demonstrate that all patients had normal manometric studies preoperatively, and all had abnormal manometric studies postoperatively. Changes included altered relaxation of the internal sphincter, increased distention required to trigger relaxation, and decreased rectal sensation. Twelve of 15 patients reported rectal dysfunction (466).

It has been suggested that inflammatory change induced by conization increases the risk of complications from subsequent RH. A waiting period of 6 weeks between procedures has been advocated on this basis. Orr et al. reviewed 122 patients who had undergone conization followed by RH. The interval between conization and RH ranged from 48 hours to 6 weeks (467). Similarly, Samlal et al. evaluated 68 patients with conization followed by RH (468). Both reported no difference

in complications related to differing intervals of time from conization to RH.

Levrant et al. evaluated the effects of obesity and age on RH outcomes. They reported no difference in survival or complications in obese versus nonobese patients. Similarly, age did not affect long-term complications and survival. However, patients older than 65 did have a higher incidence of postoperative ileus (469). Cohn et al. reported on 48 obese women (median body mass index [BMI] of 36 kg/m²) who underwent RH. Median blood loss was 800 cc, and the median number of lymph nodes obtained was 26. Margins were uninvolved in 98%. This study also confirmed the safety and efficacy of RH in selected obese patients (470).

Methods to decrease postoperative complications following RH have been suggested. Franchi et al. evaluated the role of pelvic drains following RH with LND in a randomized trial of pelvic drainage versus none. No difference was noted in lymphocyst formation or postoperative complications, suggesting that drains can be safely omitted following RH (471). The omental J flap has been used in gynecologic oncology for pelvic reconstruction. Patsner and Hackett evaluated 140 patients who had an omental J flap placed following RH. No urinary complications or infections were noted, even in patients who received postoperative RT (472). These data suggest that an omental J flap may decrease postoperative complication rate, although there was no control arm for comparison.

Radiation Therapy Related

Acute effects during external pelvic RT most typically include diarrhea and bladder irritation. These are usually self-limited and can be managed effectively with conservative measures. Most late gastrointestinal and urologic complications occur within the first 3 years after RT, with an overall fistula rate of about 2%. Post-radiation fistulae can be difficult to manage as most will not heal spontaneously and local corrective procedures may prove unsuccessful. Patients with large fistulas may require diversion. Factors that may increase the rate of fistula are combined treatment (surgery and RT), smoking, thin habitus, inflammatory bowel diseases, and diabetes and other vasculopathies.

Late sequelae are often permanent or require some intervention to improve. Commonly reported late sequelae of pelvic RT involve the rectosigmoid, the small intestine, the genitourinary tract, the vagina, and other sites or organs, resulting, for example, in lymphedema, lumbosacral plexopathy, and pelvic insufficiency fractures. Rectosigmoid complications include chronic proctosigmoiditis, rectal stricture, and rectal ulcer. Complications involving the small intestine include obstruction and malabsorption syndrome. It is accepted that predisposing factors for injury, particularly to small bowel, include a history of abdominopelvic surgery and pelvic inflammatory disease. Furthermore, it appears that radiation enteritis is not a single disease entity, but rather a variety of diagnoses that manifest with similar symptoms. Accurate diagnosis is essential to proper management. It does not appear that specific symptoms have a reliable relationship to the underlying process (473). Genitourinary toxicity includes chronic cystitis, bladder contracture, urethral stricture, and incontinence. Late sequelae involving the vagina include vaginal stenosis/fibrosis, dyspareunia, vault necrosis, and rectovaginal or vesicovaginal fistulae.

There is approximately a 5% rate of major late sequelae in patients with stage I cervical carcinoma treated with RT, and approximately 10% in patients with stages II-IVA disease. Grade 2 complications are seen in 10% to 15% of patients with all stages treated with RT alone (474,475). However, the risk is related to a number of factors, mainly dose and volume treated.

Perez et al. reported a <2% risk of severe small bowel toxicity when the pelvic sidewall dose was <50 Gy, and a 5% incidence with doses >60 Gy (474). In a multivariate analysis, Perez et al. found only total doses to rectal and bladder points to significantly impact morbidity (475). Many investigators have found a significant relationship between radiation dose and complications. A greater incidence of pelvic complications has been consistently observed in patients treated with higher doses to the whole pelvis (above 40 to 50 Gy). Intracavitary dose from radium or cesium does not correlate closely with severe complications. Injury to the gastrointestinal tract is the most frequent late complication of RT for cervical cancer. The rate of chronic bowel injury is 5% to 15% in most series of patients treated with pelvic RT (476). Although these injuries may take years to manifest, I raha et al. reported a median latency period of 10 months (476). A report by Eifel et al. (477) on 1,784 patients with stage IB carcinoma of the cervix indicates that the greatest risk is in the first 3 years after therapy. The risk of rectal complications declined after the first 2 years of follow-up to 0.06% per year. Major complications include intestinal obstruction, fistula formation, severe bleeding, and intractable diarrhea. Fortunately, these sequelae are relatively infrequent. These injuries generally result from fibrosis and ischemia secondary to the effect of RT on the small blood vessels and connective tissue. Conservative management might include a low residue diet, antidiarrheal medications, and steroid or sucralfate enemas. Some cases of partial small bowel obstruction can be managed by bowel rest, decompression, and diet modification. Obstruction refractory to conservative management may require surgery involving intestinal resection, and/or end-to-end anastomoses.

Chronic urinary symptoms (urgency, incontinence, and frequency) are frequently seen following RT. Parkin et al. (478) reported a 26% incidence of these symptoms in patients treated with RT alone for cervical carcinoma. The authors found that the mean volume of full bladder sensation was significantly lower in the post-RT group than in the pretreatment group, as was the mean maximum cystometric capacity.

Severe genitourinary toxicities secondary to RT include hemorrhagic cystitis and fistula in 2% to 3% (474,475). The latency period between RT and symptom onset is considerably longer than for gastrointestinal sequelae. In the longitudinal study by Eifel et al. (477), the risk of major urinary tract complications for survivors continued at 0.3% per year beyond 20 years. At 20 years, the actuarial risk of major complications was 14.4%. Lajer et al. prospectively gathered data regarding urologic morbidity in 177 consecutive patients treated curatively with RT (479). The 5-year actuarial incidences of grades 1 + 2 + 3, 2 + 3, and 3 were 62%, 32%, and 5%, respectively. In the long-term recurrence-free survivors, there was evidence of some reversibility of grade 1 and 2 morbidities.

Vaginal function can be affected by both radical surgery and RT. Surgery will shorten the functional length of the vagina, but pliability and transudative lubrication are often preserved. Radiation therapy can reduce length, caliber, and lubrication of the vagina; however, these symptoms can be alleviated in some patients with hormonal replacement and vaginal dilatation. Although some gynecologists feel that radical pelvic surgery may affect vaginal function to a lesser degree than RT, a large Swedish study found that the type of treatment had virtually no effect on the prevalence of vaginal changes and sexual distress (480).

Although extremely rare, lumbosacral plexopathy has been occasionally reported in patients treated for pelvic tumors with doses of 60 to 68 Gy. Characteristically, these patients have lower motor neuron weakness of the legs combined with loss of deep reflexes and muscular fasciculation. The differential diagnosis of lumbosacral plexopathy with recurrent tumors is sometimes difficult. Generally, weakness is more

prominent in radiation-related plexopathy, and pain is more frequently seen in tumor-related cases. Muscular weakness, numbness, and paresthesias are common in both groups.

Insufficiency fracture occurs with normal stress in bone with diminished elastic flexibility, a condition that can exist in irradiated bones. The usual presenting symptom is moderate to severe pelvic pain. Huh et al. reported that 8 out of 463 patients (1.7%) developed this complication (481). All patients were postmenopausal, and seven of eight were treated with curative intent. Differential diagnosis can include metastatic disease, tumor recurrence, second malignancy, and benign causes. Because symptoms can resolve with conservative management, proper diagnosis is important.

High doses of RT can cause obliterative endarteritis, reactive fibrosis, and decreased vascularity and oxygenation. As a result, soft-tissue injury can occur, and this can be particularly problematic in the treatment of cervical cancer extending to the distal vagina. Careful attention to radiation planning and dosimetry, careful blocking, and avoidance of unnecessary dose to the perineum during brachytherapy will make these complications less common. Although these injuries can cause pain that can be difficult to distinguish clinically from recurrent disease, the possibility of radiation injury should be kept in mind, because it is advisable to try to avoid deep biopsies or other trauma to tissues in which perfusion is compromised. For refractory radiation-related ulceration and necrosis of the vagina, vulva, and soft tissues, hyperbaric oxygen therapy has been used with some success (482).

Low-dose-rate (and pulsed LDR) implants require hospitalization and bed rest. At typical dose rates of 50 to 60 cGy per hour, implants typically last 2 or 3 days. During this time, there is the potential for acute problems related to or during the hospital stay. However, Jhingran and Eifel reviewed 7,662 implants in 4,043 patients, finding fatal or life-threatening complications to be exceptionally rare (483).

Combined Modality Related

Irradiation Followed by Surgery

Eifel et al. reported a series of patients with stage IB cervical carcinoma treated with RT. At 3 and 5 years, 7.7% and 9.3% experienced major complications; the actuarial risk of major complications was 14.4% at 20 years. The rate of fistula formation was doubled in those who underwent adjuvant hysterectomy (5.3% vs. 2.6%) (477).

In a GOG study reported by Keys et al., 256 patients with stage IB carcinomas of the cervix ≥ 4 cm confined to the cervix were treated with either external RT and intracavitary irradiation, or with external RT and a lower dose of intracavitary irradiation followed by an extrafascial hysterectomy. The toxicities were similar in both groups with grade 3 and 4 toxicities of about 10% in each arm (230). Meticulous, sharp dissection is recommended in the performance of extrafascial hysterectomy following preoperative RT.

Coleman et al. studied 50 patients managed with RH for persistent or recurrent disease limited to the cervix after pelvic RT. Severe toxicities occurred in 42%, and 28% developed GI or GU fistulas (443).

Surgery Followed by Irradiation

Radical operation commonly results in intestinal adhesions to denuded surfaces in the pelvis. When postoperative RT is given, complications are more likely. The GOG demonstrated a significant increase in grade 2 to 4 late complications among patients undergoing pre-RT surgical staging, particularly with a transperitoneal approach compared with a retroperitoneal

FIGURE 22.22. (A and B): Lateral radiographs with and without bladder distention in a patient with contrast in small intestine.

approach (484). Pretreatment laparotomy also increased the rate of fistula formation (5.2% vs. 2.9%) as well as small bowel obstruction (14.5% vs. 3.7%) (477). An extraperitoneal approach to lymph node staging purposes lessens these complications (67).

In a randomized study of postoperative RT versus no further treatment (NFT) after RH, Sedlis et al. found that grade 3 to 4 GU toxicities occurred in 3.1% in the RT versus 1.4% in the NFT arm. Grade 3 to 4 GI toxicities were 3.1% versus 0.8%, respectively. The overall grade 3 to 4 toxicity was 6% in the RT group versus 2.1% in the NFT arm (318).

Kim et al. presented an analysis of 800 patients with stages IB-IIIB cervical cancer who received postoperative RT following RH and bilateral salpingo-oophorectomy (BSO). With a median follow-up of 100 months, the incidences of late injuries (grade 3 to 4) were 1.6%, 1.4%, and 1.0% for rectum, bladder, and small bowel, respectively (383).

Methods to decrease the volume of small bowel irradiated will further lessen enteric morbidity. Figures 22.22 and 22.23

show the effect of treating patients in the prone position with a full bladder as a means of limiting the volume of small bowel irradiated. Similarly, IMRT techniques can also be used to limit doses to normal tissues (Figs. 22.14 and 22.16A and B) (314).

Concurrent Chemoradiation

As concurrent chemoradiation has become standard management for most patients treated nonsurgically for cervical cancer, it is not surprising that additional hematologic toxicity has been seen. A major concern has been the possible need to delay treatment, thus potentially compromising outcomes. Typical RT fields radiate some pelvic bone marrow, and Mell et al. have shown that as the volume of marrow receiving ≥ 10 Gy (V_{10}) increases, the incidence of grade 2 or worse leucopenia and neutropenia increases (485). No association of V_{30} and V_{40} with hematologic toxicity was observed. A role for IMRT to limit hematologic toxicity in some patients was suggested but not proven in this study. On the contrary, Chen et al. reported 68 patients who received

FIGURE 22.23. (A and B): Anterior-posterior radiographs with and without bladder distention in a patient with contrast in small intestine.

pelvic IMRT with concurrent chemotherapy. Compared to non-IMRT historic controls, patients receiving IMRT had significantly lower acute and late GI and GU effects (486). A possible role for single photon emission computed tomography (SPECT) in individualizing dose distribution to optimize functional marrow sparing has been suggested (484).

Although some early series suggested that concurrent chemotherapy increased late complications in patients receiving curative intent RT, most studies suggest no significant impact (487). However, some unusual complications have been reported that are rarely if ever seen with RT alone. Subacute neurologic toxicity including radiation myelitis can occur with extended field RT combined with chemotherapy. In a case reported by Bloss et al., this devastating complication was seen with only 45 Gy in 30 fractions given to the para-aortic chain along with cisplatin (50 mg/m²) and 5-FU continuous infusion at 300 mg/m² per day during RT (488). A latent period of 4 months was observed in this case. Coulombe et al. reported an additional two patients who developed lower extremity weakness and paresthesia that began 1 and 4 months following extended field RT of 45 Gy in 25 fractions concurrent with weekly cisplatin at 40 mg/m² (489). Clinical and electromyography (EMG) findings were consistent with neuropathy, and potential causes other than chemoradiation were felt to be ruled out. One patient showed spontaneous improvement beginning at 10 months. A case of complete uterine necrosis following chemoradiation has also been reported (490).

Early studies suggest that amifostine, a cytoprotectant and radioprotectant, is reasonably well tolerated when combined with RT and cisplatin. Data is limited regarding its ability to decrease complications; however, clinical trials are ongoing (349).

Thromboembolic Complications

Clarke-Pearson et al. (491) reported the experience of thromboembolic complications in 281 consecutive patients who underwent radical surgery for cervical and uterine malignancies. Postoperative thromboembolic complications were experienced in 7.8% of patients despite regular use of low-dose heparin and antiembolism stockings during the postoperative hospitalization. Preoperative risk factors included weight in excess of 85.5 kg, clinical stage II malignancy, and preoperative RT within 6 weeks of the surgical procedure. Jacobson et al. (492) reported a 16.7% incidence of thromboembolic complications in 48 patients who received chemoradiation therapy without surgery. Brachytherapy alone is associated with a very low rate of thromboembolic complications, 0.3% in one series (483).

Erythropoietin has been utilized to maintain normal hemoglobin levels during chemoradiation. Reports of increased incidence of thromboembolic complications have been noted in patients who receive erythropoietin during RT. Wun et al. reported thromboembolic complications in 17 of 75 (23%) patients who received erythropoietin during chemoradiation compared to 2 of 72 (3%) who did not receive erythropoietin (493). A survey of the literature regarding this phenomenon has been presented (159). The routine use of erythropoietin to maintain normal hemoglobin levels during chemoradiation should be discouraged.

CHAPTER 23 ■ CORPUS: EPITHELIAL TUMORS

D. SCOTT McMEEKIN, KALED M. ALEKTIAR, PAUL J. SABBATINI,
AND RICHARD J. ZAINO

Endometrial cancer accounts for nearly 50% of all new gynecologic cancers diagnosed in the United States. It is the fourth most common malignancy in women, and the eighth most common cause of cancer death. The American Cancer Society (ACS) estimated that there were 39,000 new cases of endometrial carcinoma and 7,400 deaths from advanced or recurrent disease in 2007 (1). The death rate per 100,000 women from all malignancies in the United States was 160.49, with uterine cancers contributing at a rate of 4.13 (1). Worldwide, endometrial cancer is only second to cervical cancer in frequency. Endometrial carcinoma occurs most often in the sixth and seventh decades of life, with an average age at onset of 60 years. It is estimated that 75% to 85% of the cases occur in patients 50 years old and older, and 95% occur in patients over 40 years of age (2,3). The disease, although reported in patients as young as age 16 years, is rare in patients younger than 30 years of age.

Endometrial cancer is commonly confined to the uterus at diagnosis. Data from the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) program demonstrated that stage I disease was found in 73% of patients, and 10% had stage II disease (4). The 26th Annual Report of the International Federation of Gynecology and Obstetrics (FIGO) on 9,386 endometrial cancer patients demonstrated that 83% of patients were stage I-II (5). With the favorable disease distribution at presentation, it is not surprising that most patients have a favorable prognosis. Results from FIGO show that 85% to 91% of stage I patients are alive at 5 years, and patients in the SEER database with localized disease have 96% 5-year survival (4,5). As a result, endometrial cancer has been considered a "good cancer"; that is, most patients present with early-stage, highly curable disease. Despite the favorable characteristics for most patients, those with high-risk factors including increased age, higher tumor grade, aggressive histology, and advanced stage face real challenges.

The understanding and management of endometrial cancer has undergone continued evolution. In the past, most patients would receive some form of pre- or postoperative radiation in combination with a simple hysterectomy; postoperative treatment decisions were guided by pathologic factors identified following selective use of surgical staging. We are now in an era where, increasingly, surgical therapy has expanded to routine use of pelvic and para-aortic lymphadenectomy and acceptance of laparoscopic management. Understanding tumor biology as it relates to predicting recurrence and survival, and how molecular and genetic changes can be exploited to direct postoperative therapies, represent our next challenge. In 2001, the National Cancer Institute convened an expert panel to develop a national 5-year plan for research priorities in gynecologic cancers. The resulting report, Priorities of the Gynecologic Cancer Progress Review Group (PRG), specified

that understanding tumor biology was the central key toward controlling gynecologic cancers (6). For endometrial cancer, one of the top research priorities defined by the PRG was to identify prognostic and predictive markers for treatment efficacy and toxicity.

Current clinical controversies center on the extent of nodal surgery and the changing roles of radiation therapy and chemotherapy. Increased use of surgical staging has translated to less frequent use of radiation therapy and to changes away from pelvic radiation (7). There have been important developments in chemotherapy in endometrial cancer. Combination chemotherapy is increasingly used in the primary management of advanced and recurrent disease, and may hold promise in an adjuvant setting (8). Hormonal therapy remains an important option and our understanding of steroid receptors at a molecular level may help to determine which patients may benefit most (9). Enhanced understanding of biologically relevant targets has fostered the development of new classes of agents that attempt to exploit susceptible pathways in tumor cells (10,11).

ANATOMY

The uterus is a fibromuscular pelvic organ situated between the bladder and the rectum and enveloped by peritoneal reflections. It is divided into the fundus, isthmus, and cervix. The uterine wall is composed of the outer smooth muscle myometrium and inner cavity lined by glandular endometrial epithelium with supporting stroma (endometrium). Five paired ligaments cover or support the uterus: broad, round, utero sacral, cardinal, and vesico uterine. The utero-sacral and cardinal ligaments provide the greatest support within the pelvis and, contrary to cervical cancer, are infrequently involved with tumor spread. Blood is supplied to the uterus by the uterine artery, a branch of the hypogastric artery, which enters the wall of the uterus at the isthmus after it crosses over the ureter. It anastomoses with the ovarian artery in the ovarian ligament.

Malignant transformation of the endometrium is manifest in many fashions based on the anatomical relationships. Tumor growth may be confined to the endometrium, invade the underlying myometrium, penetrate to the uterine serosal surface or adjacent bladder or rectum, or extend into the cervical canal and invade cervical glands or stroma. Peritoneal disease spread may occur via transmigration from the fallopian tubes or through serosal penetration. Hematogenous spread is not uncommon in endometrial cancer.

The lymphatics of the myometrium drain into the subserosal network of lymphatics, which coalesce into larger channels before leaving the uterus. Lymph flows from the fundus toward the adnexa and infundibulopelvic ligaments. The

lymph flow from the lower and middle thirds of the uterus tends to spread in the base of the broad ligaments toward the lateral pelvic sidewall (12). There are four drainage channels from the uterus: from the fundus; in the folds of the broad ligament, along the mesosalpinx and fallopian tubes; and along the round ligaments. The drainage sites are principally reflected in metastatic potential to pelvic and para-aortic lymph nodes, and occasionally involve inguinal nodes.

EPIDEMIOLOGY AND RISK FACTORS

The most important risk factor for the development of endometrial cancer is age. Endometrial cancer is primarily a disease of postmenopausal woman, with median age at cancer diagnosis of 60 years (5). Approximately 85% of cases occur after the age of 50, the peak age-specific incidence is from 75 to 79 years (109 per 100,000), and only 5% of cases are from patients younger than 40 years of age (2,3,13). The ACS showed probability of developing a uterine cancer to be one in 142 from age 40 to 59, one in 124 from age 60 to 69, and one in 78 from age 70 and older (1). Not unexpectedly, with an aging U.S. population, the total number of cases of endometrial cancer has shown yearly increases, whereas the annual age-adjusted incidence rate peaked in the mid 1970s (33.8 per 100,000) and has remained stable at 23 to 25 cases per 100,000 women over the last 10 years (1).

Race also appears to play a role in the development of endometrial cancer. The rates of endometrial cancer are highest in North America and northern Europe, lower in eastern Europe and Latin America, and lowest in Asia and Africa (14). Factors accounting for these findings include differences in rates of obesity, use of hormone replacement therapy, and reproductive factors. In the United States, non-Hispanic white women have the highest age-adjusted incidence of endometrial cancer at 25.4 (per 100,000 women), compared to women of African American (19.5), Asian (15.8), or Hispanic (17) heritage (15). African American women, however, have a much higher mortality rate (7.1 vs. 3.9 per 100,000) and lower 5-year survival (61% vs. 84%) compared to non-Hispanic white women. Multiple explanations have been suggested to explain the differences in outcomes between racial groups including differences in frequency of high-risk tumor types, differences in access to care (reduced use of surgery and radiation), and differences in medical comorbidities among races. Data from SEER demonstrated that African American women were more frequently diagnosed with higher stage, grade, and high-risk histologies than non-Hispanic white women, but there was no difference in the frequency of recommended therapy types between races (4). In two analyses of nearly 1,200 patients with advanced or recurrent endometrial cancer participating in phase 3 chemotherapy trials conducted by the Gynecologic Oncology Group (GOG), African American race was independently associated with a lower likelihood of response to chemotherapy (relative odds of response 0.62) and decreased overall survival (hazard ratio, 1.26) compared to white women (16,17). These results suggest that racial disparity in outcomes exist even though patients were treated in similar fashion. Interestingly, one small study comparing microarray-based expression profiling between stage-, grade-, and histology-matched African American and Caucasian patients found no clear differences in global gene expression profiles, suggesting that environmental or social issues played a greater role in explaining disparity (18).

Most cases of endometrial carcinoma are thought to be sporadic; however, some cases clearly have a hereditary basis. The Lynch syndrome (hereditary nonpolyposis colorectal cancer

[HNPCC]) is an autosomal-dominant cancer susceptibility syndrome associated with early-onset colon, rectal, ovary, small bowel, ureter/renal pelvis cancers, and endometrial cancer. Lynch syndrome-related endometrial cancers account for 2% to 5% of all endometrial cancers, and occur in nearly 10% of women diagnosed with endometrial cancer less than 50 years of age (19). The lifetime risk of endometrial cancer in Lynch syndrome women is 40% to 60%, a risk similar to that of developing colon cancer. The risk of ovarian cancer is 10% to 12%. In about 50% of cases where patients have both colonic and gynecologic cancers (endometrial or ovarian), the gynecologic cancer precedes the diagnosis of colon cancer (20). The syndrome is most commonly due to germ-line mutations of one of the DNA mismatch repair genes *MSH2*, *MLH1*, or *MSH6*. In one study, 23% of endometrial cancer patients diagnosed at <50 years of age with one relative having a Lynch type cancer had a mismatch repair gene mutation (21). Prophylactic hysterectomy and bilateral salpingo-oophorectomy has been shown to be an effective strategy for preventing ovarian and endometrial cancers in these high-risk patients (22).

Controversy exists regarding the relationship between *BRCA1* and *BRCA2* mutations and the risk of endometrial cancer. Germ-line mutations of *BRCA1* and *BRCA2* account for a large proportion of hereditary breast and ovarian/primary peritoneal cancers. In 1999, Hornreich et al. presented a case report of sisters with the same *BRCA1* mutation who were diagnosed with serous carcinomas of the uterus and suggested a possible association (23). Several larger studies have attempted to address this hypothesis. In one study of 199 Ashkenazi Jewish patients with endometrial cancer from a single institution, Levine et al. genotyped all patients for founder *BRCA1* and *BRCA2* mutations that existed in that patient population. The frequency of germ-line mutations (3 per 199, 1.5%) in endometrial cancer patients was comparable to the baseline rate of 2% in the Ashkenazi population, suggesting no increased risk (24). In a large prospective study by Beiner et al., 857 known *BRCA1* and *BRCA2* carriers aged 45 to 70 were followed over time for the development of endometrial cancer (25). With an average length of follow-up of 3.3 years, six women developed endometrial cancer. Four of the six patients had used tamoxifen. Compared to the expected rate of endometrial cancer in a general population, *BRCA* carriers who did not receive tamoxifen did not have a significant increase in risk of developing endometrial cancer, whereas those patients who had received tamoxifen had a 11.6 incidence ratio ($p = 0.0004$).

The clinical picture in endometrial carcinoma is as varied as are the associated risk factors for its development. One of the paradigms for bridging the gaps between epidemiologic, clinical-pathologic, and molecular factors seen in endometrial cancer types is the relatively simple, yet attractive classification system of endometrial cancers suggested by Bokhman (26). Endometrial cancers are thought to broadly arise from one of two different pathways: estrogen dependent or estrogen independent (Table 23.1). Based on the clinical and histologic features, endometrial cancers have been divided into type I and type II tumors. Type I tumors are more common (85%), tend to be found in younger women, and develop via a precursor lesion of atypical hyperplasia. These tumors are associated with a predisposing history of hyperestrogenism. They tend to be well differentiated and have minimal myometrial invasion, and as a result typically have a favorable outcome. Type II tumors account for a small percentage of endometrial carcinomas, occur in an older population, and frequently develop in the face of an atrophic endometrium. About half of all relapses occur in this group. Serous, clear cell, and perhaps grade 3 tumors fit into the type II category. Despite the broad generalizations of the two categories, translational science data lends support for a separation into these groups at a molecular level.

TABLE 23.1

COMPARISON BETWEEN TYPE I AND TYPE II ENDOMETRIAL CANCERS

	Type I	Type II
CLINICAL FEATURES		
Risk factors	Unopposed estrogen	Age
Race	White > black	White = black
Differentiation	Well differentiated	Poorly differentiated
Histology	Endometrioid	Non-endometrioid
Stage	I/II	III/IV
Prognosis	Favorable	Not favorable
MOLECULAR FEATURES		
Ploidy	Diploid	Aneuploid
K-ras overexpression	Yes	Yes
HER2/neu overexpression	No	Yes
P53 overexpression	No	Yes
PTEN mutations	Yes	No
Microsatellite instability	Yes	No

For example, mutations of *TP53* are common in uterine papillary serous carcinoma (UPSC), and rare in type I tumors (27). In type I tumors, *PTEN* mutations are common, but are rare with UPSC tumors. Global gene expression profiles have also been shown to be different between type I and II tumors (28).

Endogenous or exogenous exposure to estrogen is believed to be an important risk factor for the development of endometrial hyperplasia and type I cancers (29). Estrogens not opposed by progestins lead to increased mitotic activity of endometrial cells, resulting in more frequent errors in DNA replication and somatic mutations (30,31). These genetic changes are manifest clinically in endometrial hyperplasia and cancer. Estrogen excess as an etiology for cancers is supported by epidemiologic features of the disease. Patients with chronic anovulation, nulliparity, early age of menarche, and late menopause have classically been identified with endometrial cancer. Occasionally, endometrial hyperplasia or cancer develops in the setting of an estrogen-producing ovarian tumor (granulosa cell tumor) (32). The use of unopposed estrogens as part of hormone replacement strategies was first defined as an important risk factor in 1975 when the age-adjusted rate for endometrial cancer peaked at nearly 33.8 per 100,000 (33,34). A meta-analysis of 30 studies showed that the relative risk of ever users of estrogen therapy was 2.3 compared to non-users, and it increased to 9.5 in users of 10 or more years (35).

Obesity is an increasingly common problem in the United States, and is estimated to account for 17% to 46% of endometrial cancer incidence in postmenopausal women (36). Studies have shown that plasma concentrations of androstenedione and estrogens are correlated with body weight in postmenopausal women (37,38). Aromatization of androstenedione to estrone in adipose cells is believed to be the principle mechanism of excess estrogen production (39). While much of the data suggests that the relationship is strongest between estrogen exposure and type I cancers, Weiss et al. demonstrated in a case-control study that the risk of more aggressive tumors (higher grade or higher stage) was also seen with unopposed estrogen therapy, obesity, low parity, and history of diabetes. The authors suggested that the risk of endometrial cancer was influenced by similar risk factors regardless of tumor aggressiveness (40). Diabetes has also been associated classically with type I endometrial cancers (41,42). Only non-insulin dependent diabetes (type 2 diabetes mellitus [DM]), characterized by insulin resistance and elevated insulin levels, appears to be

associated with endometrial cancer (43). Hyperinsulinemia and higher levels of insulin-like growth factor 1 are thought to have neoplastic potential and, coupled with increased estrogen, are responsible for cancer development (44–46).

Tamoxifen and Endometrial Cancer

Tamoxifen is a selective estrogen receptor modulator (SERM) with antiestrogenic properties in the breast and estrogenic effects in tissues such as bone, the cardiovascular system, and the uterus. It has been used in prevention and treatment for all stages of breast cancer. An association with tamoxifen and endometrial cancer was first reported by Killackey et al. in 1985 (47). The strongest data initially implicating tamoxifen use and the subsequent development of endometrial cancer were published in 1989 by Fornander et al. (48). The investigators reviewed the frequency of new primary cancers as recorded in the Swedish Cancer Registry for a group of 1,846 postmenopausal women with early breast cancer who were included in a randomized trial of adjuvant tamoxifen. They noted a 6.4-fold increase in the relative risk of endometrial cancer in 931 tamoxifen-treated patients compared to 915 patients in the control group. The dose of tamoxifen in this study was 40 mg/d, and the greatest cumulative risk of developing endometrial cancer was after 5 years of tamoxifen use.

Fisher et al. published data regarding the association between tamoxifen use and the development of endometrial cancer when they reported the findings of the National Surgical Adjuvant Breast and Bowel Project (NSABP) B-14 trial (49). Data regarding the rates of endometrial and other cancers were analyzed on 2,843 patients with node-negative, estrogen receptor (ER)-positive, invasive breast cancer randomly assigned to placebo or tamoxifen (20 mg/d) and on 1,220 tamoxifen-treated patients registered in NSABP B-14 subsequent to randomization. The average annual hazard rate for endometrial cancer in the placebo group was 0.2 out of 1,000 and 1.6 out of 1,000 for the randomized tamoxifen-treated group. The relative risk of an endometrial cancer occurring in the randomized, tamoxifen-treated group was 7.5. Similar results were seen in the 1,220 registered patients who received tamoxifen. The mean duration of tamoxifen therapy was 35 months, with 36% of the endometrial cancers developing within 2 years of therapy and six occurring less

than 9 months after treatment was initiated, suggesting that some of the cancers may have been present prior to starting tamoxifen therapy.

Any conclusions drawn regarding the risks of tamoxifen treatment in inducing endometrial cancer must weigh the benefits of tamoxifen in reducing breast cancer recurrence and new contralateral breast cancers. In the B-14 trial, the cumulative rate per 1,000 women with breast cancer relapse was reduced from 227.8 in the placebo group to 123.5 in the randomized tamoxifen-treated group. In addition, the cumulative rate of contralateral breast cancer was reduced from 40.5 to 23.5, respectively, in the two groups. Taking into account the increased cumulative rate of endometrial cancer, there was a 38% reduction in the 5-year cumulative hazard rate in the tamoxifen-treated group. Thus, the benefit of tamoxifen therapy for breast cancer outweighs the potential increase in endometrial cancer being reported.

The suspected mechanism for endometrial cancer development following tamoxifen exposure is thought to be related to its estrogenic effects on the endometrium. As such, type I, low-grade/early-stage cancers would be expected. A report from the Yale Tumor Registry by Magriples et al. suggested that uterine cancers occurring in breast cancer patients on tamoxifen may behave more aggressively and carry a worse prognosis (50). Other studies, however, have not been able to confirm these findings (Table 23.2) (49,51-53). It would appear from the available literature that there is no difference in the stage, grade, or prognosis of endometrial cancers associated with tamoxifen use.

More commonly, breast cancer patients are being managed with a different strategy compared to SERMs by preventing estrogen synthesis by inhibiting the conversion of androgens to estrogens. Third-generation aromatase inhibitors (anastrozole, letrozole, exemestane) are replacing tamoxifen for many breast cancer patients with ~50% of postmenopausal estrogen receptor-positive patients receiving aromatase inhibitors (54). In clinical trials, compared to tamoxifen, aromatase inhibitors have lower incidences of vaginal bleeding or endometrial cancer (55,56). In premenopausal patients, aromatase inhibitors have little activity, and tamoxifen will continue to have a role.

Protective Factors

Factors that reduce circulating estrogen levels (weight loss/exercise, cigarette smoking) appear to be protective against endometrial cancer. Similarly, progestins antagonize the effects of estrogen on the endometrium and prevent the development of hyperplasia and cancer when added to estrogens (endogenous or exogenous) (57). Combined estrogen-progestin hormone replacement therapy has been associated with reductions in the risk of endometrial cancer in most, but not all, studies. Prior use of oral contraceptives also appears to be protective against the development of endometrial cancer (58,59).

NATURAL HISTORY OF DISEASE

A better understanding of the natural history of endometrial cancer has developed through evaluation of the patterns of spread. In a landmark study, the GOG performed a surgical pathologic study (GOG 33) in 621 patients with clinical stage I-occult stage II endometrial cancer who underwent a standardized surgical procedure including exploration of the abdomen with biopsy of suspicious findings, collection of peritoneal fluid for cytologic evaluation, abdominal hysterectomy and bilateral salpingo-oophorectomy, and pelvic and para-aortic nodal dissection (60). The results of this study demonstrated important relationships regarding uterine tumor characteristics and spread of disease, and should be ingrained into the memory of those caring for patients with endometrial cancers.

Overall, 22% of patients with seemingly uterine confined disease were found to have extrauterine spread. Pelvic and/or para-aortic metastases were found in 11% of patients, 12% had positive peritoneal cytology, 5% had adnexal involvement, and 6% had gross intraperitoneal spread. Nodal metastases were related to tumor grade and depth of myometrial invasion, and patients with positive cytology, or adnexal or intraperitoneal spread also had increased frequency of nodal disease.

Patterns of failure in patients with recurrent endometrial cancer demonstrate, alone or in combination, hematogenous, lymphatic, intraperitoneal, or local/contiguous spread. As attention has increasingly focused on therapies (surgical, radiation, chemotherapy) to reduce particular sites of recurrences, several have argued for defining relationships between initial disease spread and subsequent risk of recurrence (61). In GOG 33, treatment was not specified by protocol, but results showed that outcomes could be predicted by extent of disease found at surgery, thus demonstrating the important relationship between what is learned at surgical staging and recurrence risk (62).

DIAGNOSTIC EVALUATION

Screening

Many endometrial cancers develop by way of a precursor lesion. Estrogen-related cancers frequently develop secondary to atypical endometrial hyperplasia (AEH) or demonstrate AEH in the uterus at the time of hysterectomy. Serous tumors also may develop through a precursor lesion, endometrial intraepithelial carcinoma (EIC) (63,64). Prompt recognition of precursor lesions with institution of proper treatment will prevent cancers and their sequelae. The relatively low prevalence of endometrial cancer in the population (5 per 1,000 women >45 years) makes standardized screening inefficient. There are a few uncontrolled studies lending some support to the efficacy of screening programs (65,66). No randomized trials have been published. No health economic data have been presented in relation to the published reports. The American College of Obstetrics and Gynecology (ACOG) and the Society of Gynecologic Oncology do not recommend routine screening of patients for uterine cancer (67,68). The American Cancer Society does recommend annual endometrial biopsies starting at age 35 for women known to have or be at risk for HNPCC.

In lieu of routine screening, prompt assessment of symptomatic patients and those at high risk should be considered. Because 95% of endometrial carcinomas occur in women 40 years old and older, and because endometrial hyperplasia tends to occur in premenopausal and perimenopausal women, it is appropriate to evaluate individuals past their fourth decade of life if there is abnormal bleeding. Similarly, a higher degree of suspicion should be held for younger patients with high-risk characteristics including significant obesity, polycystic ovarian syndrome/chronic anovulation, or tamoxifen exposure.

Prevention

Due to the increased risk of endometrial cancer associated with unopposed estrogens, women with an intact uterus should rarely, if ever, be prescribed estrogen-only replacement therapy. The addition of progestins to the regimens of patients treated with exogenous estrogen may prevent endometrial hyperplasia and protect against the development of carcinoma (57,58). Continuous or sequential progestin regimens may be used, but the most important factor is administration of a progestin for at least 10 to 14 days each month. In patients with chronic endogenous estrogen exposure such as obese women with polycystic ovarian syndrome or chronic anovulation, and perimenopausal women with menometrorrhagia, periodic treatment with a progestin to create scheduled withdrawal bleeding and prevent hyperplasia may be considered (69,70).

In most cases, patients with hyperplasia with atypia should be treated by vaginal or abdominal hysterectomy to prevent the development of endometrial cancer (71). Surgery is the definitive therapy as it stops bleeding, prevents cancer, and alleviates the potential of medical failure. Patients with AEH remain at high risk for recurrence of AEH or cancer during their lifetime, even after successful medical therapy (72). Most importantly, despite a preoperative diagnosis of AEH many patients will be found to have a cancer at the time of hysterectomy (72,73). Older data suggested that if the endometrial sample is obtained by a biopsy or curettage, 15% to 25% of patients with the diagnosis of atypical hyperplasia may have a uterine carcinoma (74,75). Prospective data from a large surgical-pathologic trial conducted by the GOG demonstrated that, of 289 patients with a community diagnosis of AEH, 40% had an endometrial cancer (73). Neither the type of preoperative endometrial biopsy (office endometrial biopsy [EMB] or dilatation and curettage [D&C]) nor the use of an expert pathology panel was associated with a better prediction of who had cancer or not. Patients with significant medical comorbidities, advanced age, or those desiring future fertility may be managed with progestational therapy (76). It has been suggested that a D&C should be performed in those patients who will be medically managed with progestins for therapeutic effect (surgical curettage of tissue) and to better define the risk of an unrecognized cancer, while the data to support these practices are limited. When progestins are used to manage AEH, the specific agents, doses, and schedules may mirror those used to manage dysfunctional uterine bleeding or advanced or recurrent cancer. To assess the success of medical therapy, endometrial biopsies should be performed at 3- to 4-month intervals provided cancer is not identified (77,78).

Screening and prevention strategies for women on tamoxifen are more challenging. Women with intact uteri who are taking tamoxifen for either treatment or prevention of breast cancer should be informed of the increased relative risk of developing endometrial cancer with the use of tamoxifen. This risk is balanced by the reductions in recurrence or development of a contralateral breast cancer. Women on tamoxifen should be encouraged to report abnormal bleeding or vaginal discharge. Screening of asymptomatic women on tamoxifen therapy with ultrasound or endometrial biopsies is not recommended (79,80).

CLINICAL PRESENTATION

The classic symptom of endometrial carcinoma is abnormal uterine bleeding. A variety of conditions give rise to abnormal bleeding, but particular suspicion should be held for postmenopausal women, and women age 40 and over with high-risk factors. Approximately 10% of symptomatic postmenopausal patients will be found to have a cancer on biopsy (81). In one series, using age >70 years, diabetes, or nulliparity as risk factors, patients with all three factors had an 87% chance of having an AEH/carcinoma diagnosis, whereas only 3% had significant pathology in the absence of all risk factors (82). Additionally, patients with endometrial cancer may present with vaginal discharge or have a thickened endometrium incidentally noted on ultrasound performed for another reason. Pap smear screening is not designed to identify endometrial cancer, but occasionally patients will have abnormal cervical cytology (atypical glandular cells of undetermined significance [AGUS], adenocarcinoma *in situ* [AIS]). Patients with intraperitoneal disease may present with similar complaints to patients with ovarian cancer such as abdominal distension, pelvic pressure, and pain.

Historically, when endometrial cancer was a clinically staged disease (FIGO 1971) fractional D&C was the procedure of choice to evaluate abnormal bleeding. Fractional D&C permitted assessment of the uterine size and allowed for endocervical curettage, important steps in the staging process. The standard procedure starts with curettage of the endocervix prior to cervical dilatation. Careful sounding of the uterus is performed followed by dilatation of the cervix, followed by systematic curetting of the entire endometrial cavity. Cervical and endometrial specimens should be kept separate and forwarded for pathologic interpretation.

Pathologic evaluation of the endometrium provides histologic diagnosis and can identify other etiologies of bleeding such as chronic endometritis, atrophy, polyps, cervical cancer, or unusual histologic variants (carcinosarcoma, serous carcinoma, placental nodule), which may alter management. Tissue evaluation by office EMB or D&C offer similar information when adequately performed. Today EMB has largely replaced D&C as the diagnostic procedure of choice. In the GOG hyperplasia study, 63% of the specimens were from EMB (Vabra, Novak, Pipelle) and 37% were from D&C (73). Results of endometrial biopsies correlate well with endometrial curettings, and the accuracy to detect cancer is 91% to 99% (83,84). The accuracy of identifying cancers with EMB is higher in postmenopausal patients than in premenopausal, and a positive study showing cancer is more accurate for identifying disease than it is in excluding it. Cases where office biopsy cannot be obtained (cervical stenosis, patient intolerance of procedure) or results are non-diagnostic should be followed by D&C. In cases of abnormal bleeding that persists despite negative biopsy, additional investigation is warranted.

Hysteroscopy has been advocated as an adjuvant to D&C to improve detection of pathology in the evaluation of postmenopausal bleeding. Whether it improves the sensitivity to detect hyperplasia and cancers is controversial (85–87). Hysteroscopy is more accurate in postmenopausal patients, and is more accurate in detecting cancer versus other pathology than it is in identifying cancer or hyperplasia versus other pathology. One concern is that hysteroscopy may promote transtubal migration of tumor cells, which can be detected as malignant pelvic washings on cytology. In one retrospective study, an odds ratio of 3.88 for positive cytology was seen in hysteroscopic D&Cs compared to D&C alone, and the authors cautioned against hysteroscopy to evaluate endometrial cancer (88). Similarly, a review of literature suggested that water-based hysteroscopy was associated with increased frequency of positive cytology at time of hysterectomy (89). Positive peritoneal cytology has the potential to upstage a patient (stage IIIA) resulting in additional/different adjuvant therapy being recommended. No prospective studies have been performed to date, and it remains uncertain what effect positive washing produced by hysteroscopy has, if any, on prognosis.

Ultrasound is commonly used as a less invasive tool to evaluate abnormal bleeding. The measurement of endometrial thickness (ET) has been shown to best predict the absence of carcinoma, with a false-negative rate of 4%, using a threshold value of <5 mm (90,91). The specific endometrial thickness used for a cutoff value depends on the menopausal status of the patient population evaluated and on the use of hormone replacement (HRT). For example, postmenopausal patients on HRT have a median ET 2 to 3 mm more than those not on HRT (92,93). In a meta-analysis of 85 studies, Smith-Bindman et al. reported that a cutoff level of >5 mm would detect 96% of cancers, and would have a 39% false-positive rate (91). Transvaginal ultrasound measuring the lining thickness of the endometrium has excellent negative predictive value for ruling out endometrial cancers or hyperplasia when the thickness is <5 mm, but provides less information when >5 mm.

Given a pretest probability of having endometrial cancer in a postmenopausal patient with vaginal bleeding of 10%, a normal endometrial stripe is associated with a 1% chance of a cancer. A consensus panel, composed of radiologists, pathologists, and gynecologic oncologists, suggested that when ET is <5 mm, the test can be considered negative for endometrial cancer (94). For patients with ET >5 mm, endometrial biopsy, D&C with hysteroscopy, or saline infusion sonohysteroscopy should be performed. Saline infusion sonohysteroscopy has been suggested to better define findings in the endometrial cavity noted on ultrasound and provide clearer distinction of polyps, fibroids, and cancers (95). It is more likely to be successful in pre- than postmenopausal patients. The role of vaginal ultrasound in the evaluation of bleeding remains somewhat controversial due to the belief of the importance of histology is defining treatment (for benign and malignant conditions) and of the concern for missed cancers. Good clinical judgment would suggest that patients with ET <5 mm who have persistent bleeding undergo tissue biopsy.

DIAGNOSTIC WORKUP

Preoperative Assessment

Following the diagnosis of endometrial cancer, the surgeon must assess the surgical risks of the patient, evaluate the patient for possible metastatic spread, and determine the most appropriate surgical procedure. Endometrial cancer patients are frequently elderly and suffer from obesity, hypertension, diabetes, or cardiac disease. In a series of 595 consecutive patients, Marziale et al. found an operability rate of 87% (96). Preoperative assessment must be performed, occasionally requiring consultation with additional specialists. At a minimum, patients require a thorough examination to evaluate for evidence of cardiac or pulmonary disease, and to determine the surgical approach. A chest x-ray and electrocardiogram (EKG), complete blood count, and assessment of electrolytes and renal function are standard in this population. Preoperative counseling includes obtaining permission to remove the uterus, tubes, and ovaries and permission for thorough intra-abdominal exploration with biopsy and tumor removal as necessary including removal of the pelvic and para-aortic lymph nodes.

Evaluation of Metastatic Spread

A thorough physical examination may discover suspicious supraclavicular, inguinal, and/or occasional pelvic lymph nodes as well as suggest the presence of pleural effusions, ascites, or omental caking. The pelvic examination can suggest cervical, vaginal, or adnexal spread. An assessment of uterine size and mobility is important, particularly in patients being considered for vaginal approaches (laparoscopic-assisted vaginal hysterectomy [LAVH], total vaginal hysterectomy [TVH]). A chest radiograph is done to search for metastatic tumor as well as to evaluate the cardiopulmonary status of the patient. For patients without obvious extrauterine disease, surgery is the next step. In cases where intra-abdominal, gross cervical, or distant disease spread is suspected, additional studies such as CT scans, magnetic resonance imaging (MRI), or cystoscopy and proctoscopy may be needed to assist with surgical planning.

In general there is very limited need for imaging studies prior to surgery since findings typically do not result in management changes as most patients present with stage I-II disease, and the

surgery is essentially the same for stage I-III patients. Imaging studies have significant limitations in detecting nodal disease, which tends to be microscopic in 90% of cases (97,98). Patient review of systems and clinical examination frequently lead to suspicion of gross extrauterine disease. Imaging studies may be of better use in certain situations. Serous and clear cell tumors have a greater frequency of extrauterine disease spread, and imaging studies may offer additional information in some cases. In some settings, imaging studies may help some to determine whether to refer to a gynecologic oncologist or perform surgical staging when it would not otherwise be considered. In addition, imaging studies may have their greatest utility in helping to counsel young patients who are considering fertility preservation options. Magnetic resonance imaging has been suggested to have more value than computed tomography (CT) scans in assessing myometrial invasion, cervical invasion, and nodal disease with several reports indicating a 75% to 90% accuracy rate for determining muscle involvement (99–102). However, limitations do exist, making routine use more difficult to recommend (103,104). At the present time, the only way to accurately diagnose the extent and depth of intrauterine invasion is by histologic examination of the hysterectomy specimen.

Attempts have been made to correlate the tumor marker CA-125 with extent of extrauterine disease as serum levels are frequently elevated in patients with advanced or metastatic endometrial cancer (105). This observation was first reported by Niloff et al. in 1984 (106). Values exceeding 35 U/mL were found in 14 (78%) of 18 patients with stage IV or recurrent disease, although none of 11 patients with stage I disease had elevations. Patsner et al., in 1988, reported 81 patients with endometrial cancer that appeared to be confined to the uterus (107). At laparotomy, 20 (87%) of 23 of their patients with elevated CA-125 were found to have occult extrauterine disease. Conversely, only 1 of 58 patients with a normal value had occult extrauterine disease. In a large study, Hsieh et al. (108) reviewed preoperative serum CA-125 levels, operative records, and pathologic reports in 141 patients diagnosed with endometrial carcinoma to find out if the preoperative level of CA-125 can provide additional information to determine the extent of lymphadenectomy required in the surgical staging and which cutoff is optimal in this respect. Of 141 patients, 124 were staged surgically and 24 (19%) were found to have lymph node metastasis. In the node-positive group, median preoperative serum levels were 94 U/mL (range 17 to 363 U/mL). Multivariate analysis showed lymph node metastasis had the most significant effect on the elevation of CA-125 levels (>40 U/mL). The sensitivity and specificity for screening lymph node metastasis were 78% and 84%, respectively. The data of Hsieh et al. give evidence that preoperative CA-125 levels greater than 40 U/mL can be considered an indication for full pelvic and para-aortic lymphadenectomy in the surgical staging of endometrial carcinoma. These results are in accordance with others (109–113). Rose et al. (114) found serial CA-125 measurements to be most useful in patients with high-risk disease whose initial stage was II, III, or IV, or whose tumor was grade 3 or of clear cell or serous histology. Fifteen (94%) of 16 patients with recurrent disease had an elevated CA-125 level. Serial measurements of CA-125 are also used to monitor for recurrence and to assess response to tumor therapy in patients whose levels were initially elevated at diagnosis.

Determining the Surgical Procedure

Of all the female pelvic malignancies, endometrial cancer seems to have more advocates for different treatment plans than any other. The standard treatment for this disease has been and remains a hysterectomy. However, through the

years, preoperative and postoperative irradiation has had an important role in the management of this disease. The first significant report of employing irradiation in the management of patients with endometrial cancer was the publication of the “Stockholm technique” by Heyman in 1935 (115). The use of intracavitary implants using Heyman’s method became increasingly popular in the ensuing years. Subsequently, reports comparing results in patients treated with a single intrauterine tandem with those treated with multiple intrauterine capsules revealed a lower incidence of residual disease and an improved 5-year survival rate, favoring the patients treated with capsules (116–118). Lewis et al. (119), in cooperative studies in the late 1960s, showed that 25% of patients had deep myometrial invasion if treated initially by surgery, and only 8% had deep invasion if treated by preoperative irradiation. Patients frequently were managed with preoperative radiation (whole pelvic radiation [WPR], low-dose-rate [LDR] implant with or without WPR) followed within 4 to 6 weeks by a complete hysterectomy. While surgical evaluation of lymph nodes in endometrial cancer was reported in the 1960s, it was not widely embraced (120–123). The GOG undertook the large surgical-pathologic study, GOG 33, of clinical stage I endometrial cancer to better define patterns of spread with the hope that defining pathologic relationships would lead to a tailored (rather than a universal) approach to radiation (60,122). The results of this study subsequently led to the incorporation of a surgical staging system (FIGO 1988).

Contemporary management for most patients with endometrial cancer remains surgical and includes, at the minimum, an initial surgical exploration with collection of peritoneal fluid for cytologic evaluation (intraperitoneal cell washings), through inspection of the abdominal and pelvic cavities with biopsy or excision of any extrauterine lesions suspicious for tumor, and total extrafascial hysterectomy with bilateral salpingo-oophorectomy. Where the tradition has been to perform this surgery abdominally (typically through a vertical midline incision), laparoscopic management has increasingly been integrated into the forefront. The uterus should be particularly observed for tumor breakthrough of the serosal surface. The distal ends of the fallopian tubes are clipped or ligated to prevent possible tumor spill during uterine manipulation. To complete the surgical staging of endometrial cancer, the removal of bilateral pelvic and para-aortic lymph nodes is also required.

When surgical staging is performed, a bilateral pelvic and para-aortic nodal lymphadenectomy is increasingly performed (9,123). The margins of the pelvic nodal dissection are comparable to what is used for a pelvic nodal dissection with cervical cancer and is outlined by the margins of the circumflex iliac vein distally, the bifurcation of the iliac vessels proximally, the lateral margin is the genitofemoral nerve, and the medial margin is the superior vesical artery. The floor of the dissection is the obturator nerve. Nodal/fatty tissue is skeletonized from these structures. In cases of bulky nodal disease, complete resection/debulking rather than biopsy to solely demonstrate metastatic disease is favored where possible. The common iliac nodes can be removed as a separate specimen, or divided at a midpoint along the vessels, submitting the inferior half with the pelvic nodes, and the superior half with the para-aortic nodes. Particularly on the left side, the common iliac nodes will be quite lateral in location and will require sufficient mobilization to visualize the nodes. Removal of para-aortic nodes can be performed through a midline peritoneal incision over the common iliac arteries and aorta or by mobilizing the right and left colon medially (124,125). In each case, lymph nodes are resected along the upper common iliac vessels on either side and from the lower portion of the aorta and vena cava.

At the present time, the inferior mesenteric artery is used to demark the superior extent of the para-aortic nodal dissection. Suspicious nodes extending to the renal vessels are removed.

In cases with gross omental or intraperitoneal disease spread, cytoreductive surgery with total omentectomy, radical peritoneal stripping, and occasionally bowel resection are required. The goal of reducing the residual disease to no or small volumes akin to what is performed for ovarian cancer is increasingly considered. In cases complicated by medical comorbidity, advanced age, or obesity, or when nodal dissection cannot or will not be performed, total vaginal hysterectomy with or without laparoscopic assistance may also be utilized. Following surgical assessment, patients may be classified based on pathologic features as to their risk of recurrence, and those deemed to be at sufficient risk may be offered adjuvant therapies.

Nonsurgical Management

The management of most patients with endometrial cancer is surgical. The decision to use surgery is a function of patient and disease status. Patients with significant medical comorbidities who are not acceptable candidates for surgery (markedly advanced age, diminished performance status, severe cardiac/pulmonary disease, massive obesity) may be managed by alternative means. Primary radiation therapy without surgery has been used, and is discussed later in this chapter. Progestational therapy may be used for those who are inoperable or in younger patients who elect for fertility preservation (76,126,127). If the pretreatment studies are complete, the patient may be clinically staged if she is not a surgical staging candidate. The clinical staging system proposed by the FIGO in 1971 (Table 23.3) is still applicable for cases that do not go to primary operative staging while those that do undergo initial hysterectomy are staged by the 1988 FIGO system (Table 23.4) (128). Patients who are obese, but otherwise surgical candidates may undergo an abdominal panniculectomy to enhance surgical expose to facilitate hysterectomy and nodal dissection (129,130). For patients presenting with disseminated or nonresectable disease, nonsurgical options including radiation, chemotherapy, or hormonal therapy have also been used. Surgery may be required to control vaginal bleeding in some of these cases.

Approximately 5% of women with endometrial cancer are diagnosed under the age of 40 (4). For some younger women, the standard treatment of hysterectomy is unacceptable due to

desires to maintain fertility. Endometrial cancer in younger women is usually associated with early-stage, low-grade disease and carries a favorable prognosis, making medical management an attractive option to some (77,78,127,131,132). Patients without myometrial invasion are thought to be the best candidates, and may undergo pelvic MRI to assess for myometrial involvement. Progestational therapy, most commonly with medroxyprogesterone acetate or megestrol acetate, has been successful in reversing malignant changes in up to 76% of cases (76,127,131). Because response may be temporary or incomplete, periodic sampling of the endometrium is advised.

Vaginal Hysterectomy

Vaginal hysterectomy with or without postoperative radiation may be another option for managing complicated patients. Vaginal hysterectomy has often been cited as the simplest and least morbid approach to hysterectomy, and has produced similar treatment outcomes in patients with clinical stage I endometrial cancer (133–135). It is often used as an alternative to an abdominal approach in obese and poor-surgical-risk patients (136,137). Limitations include the lack of exploration of the intraperitoneal cavity, inability to procure cytologic washings, greater difficulty in performing an oophorectomy, and inability to perform lymph node sampling. As lymph node metastasis is related to such high-risk features as poor differentiation, unfavorable histologic subtypes, and deep myometrial invasion, the risk of extrauterine disease following TVH must be estimated based on uterine pathology (60). Accurate assessment requires surgical staging, and understaging in clinical stage I disease has been reported to occur in 19% to 22% of cases (138).

Nodal Dissection

The value of staging any malignancy relates to the ability to describe the extent of disease at diagnosis, and to define comparable patient populations for whom prognosis and therapy are similar. Given the inability to accurately detect disease spread for many gynecologic malignancies, solely based on clinical examination and imaging studies, surgical staging systems that require pathologic evaluation of sampled sites have been largely incorporated into practice. The value of surgical staging as it relates to endometrial cancers has been the subject

TABLE 23.3

CORPUS CANCER CLINICAL STAGING, FIGO 1971

Stage	Characteristics
I	Carcinoma is confined to the corpus
IA	Length of the uterine cavity is 8 cm or less
IB	Length of the uterine cavity is more than 8 cm
Histologic subtypes of adenocarcinoma	
G1	Highly differentiated adenomatous carcinoma
G2	Differentiated adenomatous carcinoma with partly solid areas
G3	Predominantly solid or entirely undifferentiated carcinoma
II	Carcinoma involves the corpus and cervix
III	Carcinoma extends outside the uterus but not outside the true pelvis
IV	Carcinoma extends outside the true pelvis or involves the bladder or rectum

Note: FIGO, International Federation of Gynecology and Obstetrics.

TABLE 23.4**CORPUS CANCER SURGICAL STAGING, FIGO 1988**

Stages/grades	Characteristics
IA G123	Tumor limited to endometrium
IB G123	Invasion to less than half of the myometrium
IC G123	Invasion to less than half of the myometrium
IIA G123	Endocervical glandular involvement only
IIB G123	Cervical stromal invasion
IIIA G123	Tumor invades serosa or adnexae or positive peritoneal cytology
IIIB G123	Vaginal metastases
IIIC G123	Metastases to pelvic or para-aortic lymph nodes
IVA G123	Tumor invades bladder and/or bowel mucosa
IVB	Distant metastases including intra-abdominal and/or inguinal lymph node

HISTOPATHOLOGY, DEGREE OF DIFFERENTIATION
Cases should be grouped by the degree of differentiation of the adenocarcinoma:

G1	5% or less of a nonsquamous or nonmorular solid growth pattern
G2	6% to 50% of a nonsquamous or nonmorular solid growth pattern
G3	More than 50% of a nonsquamous or nonmorular solid growth pattern

NOTES ON PATHOLOGIC GRADING
Notable nuclear atypia, inappropriate for the architectural grade, raises the grade of a grade 1 or grade 2 tumor by 1. In serous adenocarcinomas, clear cell adenocarcinomas, and squamous cell carcinomas, nuclear grading takes precedence. Adenocarcinomas with squamous differentiation are graded according to the nuclear grade of the glandular component.

RULES RELATED TO STAGING
Because corpus cancer is now surgically staged, procedures previously used for determination of stages are no longer applicable, such as the finding of fractional D&C to differentiate between stages I and II. It is appreciated that there may be a small number of patients with corpus cancer who will be treated primarily with radiation therapy. If that is the case, the clinical staging adopted by FIGO in 1971 would still apply, but designation of that staging system would be noted. Ideally, width of the myometrium should be measured, along with the width of tumor invasion.

Note: D&C, dilatation and curettage; FIGO, International Federation of Gynecology and Obstetrics.

of increased scrutiny and debate over the last several years. For endometrial cancers, the ability of surgical staging to accurately identify spread to draining lymph node basins and how this information (or lack of it) changes prognosis and alters the use of postoperative therapies are a source of controversy. Proponents of routine surgical staging suggest that the ability to identify otherwise unrecognized disease spread to the nodes changes the postoperative therapies that are given, and is the most accurate way to assess risk. Most controversial is the assertion that surgical staging has a therapeutic benefit independent of the node status (positive or negative for metastatic disease).

Fundamentally, surgeons must determine for themselves whether or not they believe that surgical staging has sufficient value to offer it for all patients or only selectively based on risk factors identified pre- and intra-operatively. If a patient will not be offered surgical staging/nodal dissection, then minimizing surgical morbidity with a vaginal or laparoscopic-assisted approach seems warranted. In this case, lower risk/quicker recovery comes at the cost of less information. In cases where nodal dissection will or potentially will be performed, patients must be adequately counseled regarding the risks and benefits. The principle risks attributable to nodal dissections include increased operative time, potential for blood loss associated with vascular injury, genitofemoral nerve

injury with resulting numbness and paresthesias over medial thighs, lymphocyst formation, and lymphedema (Table 23.5) (62,139–141). In general, the risks associated with nodal dissections are low and acceptable. Patients who have nodal dissections and receive pelvic radiation therapy may be at a greater risk of bowel morbidity than those without dissections (142,143). Nodal dissections also require the involvement of someone trained and skilled to perform the procedure. The principle advantage of comprehensive staging is that the physician and patient are provided with the greatest amount of information. In the contemporary management of endometrial cancer, this information results in less use of radiation, and substitution of vaginal cuff brachytherapy for pelvic radiation (9,123,144).

The importance, extent, and technique of nodal dissection are hotly debated. Questions relate to which patients should be offered and could benefit from surgical staging (all, some, none), and what is the optimal surgical procedure to be performed (biopsy of enlarged/visible nodes, lymphadenectomy). Controversy also exists between those surgeons who perform only pelvic dissections and those who advocate pelvic and para-aortic nodal dissection. If para-aortic nodes are removed, are bilateral nodes required, and to what superior extent (inferior mesenteric artery, renal vessels) should the dissection proceed?

TABLE 23.5

RISKS ASSOCIATED WITH NODAL DISSECTION: SURGICAL COMPLICATION RATES ASSOCIATED WITH ABDOMINAL HYSTERECTOMY + PELVIC AND PARA-AORTIC LYMPH NODE DISSECTION

Nodal Dissection—None

In the United States, comprehensive surgical staging of endometrial cancer is infrequently performed. Only 30% to 40% of patients undergo nodal assessment, indicating that the majority of U.S. patients are not staged (6,145). Many gynecologists are neither trained in the techniques of lymphadenectomy nor familiar with the concept of full surgical staging. Full staging is more commonly performed by specialized surgeons, such as gynecologic oncologists (146,147). Philosophically, those opposed to nodal dissections suggest that most patients are at low risk for nodal disease, treatment decisions can be based on final pathologic information, and despite node dissection the majority of patients who are node negative do not get benefit (148). Most patients with endometrial cancer do present with low-risk features. In the entire GOG 33 study population of 621 patients, 75% had grade 1-2 tumors, 59% had inner one third or less myometrial invasion, and only 9% of patients had positive lymph nodes (60). The Post Operative Radiation Therapy in Endometrial Cancer (PORTEC) trial evaluated patients with stage IC, grade 1; stage IB-C, grade 2; or stage IB, grade 3 who underwent hysterectomy without lymph node dissection and compared observation to postoperative pelvic radiation (149). Of note, based on grade and depth of invasion, approximately 60% of patients enrolled in GOG 33 would have had disease characteristics required for eligibility in the PORTEC trial. This patient population managed without nodal dissection had favorable outcomes with or without radiation therapy (5-year survival rates of 85% observation, 81% with pelvic radiation) in the PORTEC study (149). Trimble et al. reported on data from stage I endometrial cancer patients collected by SEER from 1988 to 1993 and showed that 5-year relative survival for patients without nodal dissection was 98% compared to 96% in those undergoing nodal dissection and suggested that nodal dissection did not convey a benefit for the overall population (150). Unfortunately, data on adjuvant therapy use was not available. It is suspected that increased use of radiation in unstaged patients may produce similar outcomes to patients who are staged and who avoid radiation therapy.

In a nonrandomized trial comparing hysterectomy with or without pelvic lymphadenectomy, followed by radiation therapy, 14% of patients (N = 207) with negative nodes treated with vaginal cuff brachytherapy (VCB) recurred compared to 16% who did not have a lymphadenectomy (N = 660) (151). While the authors noted similar cancer-free survival between the groups, all patients who did not have nodal dissections received both pelvic radiation and VCB to attain these results. The only randomized trial comparing lymphadenectomy to no nodal assessment has recently concluded enrollment. A Study in

the Treatment of Endometrial Cancer (ASTEC) randomized patients with endometrial cancer treated with hysterectomy to pelvic lymphadenectomy or not. Following surgery, patients with stage I-IIA disease were then randomized again to observation or pelvic radiation therapy if they had grade 3, serous, or clear cell histology; >50% myometrial invasion; or endocervical glandular invasion (stage IIA). Treatment centers were also permitted to use VCB regardless of pelvic radiation assignment based on institutional preference. As a result, a patient with unknown nodal status and >50% invasion could receive VCB and not be considered to have received radiation therapy. This may produce a potential bias as groups treated with lymphadenectomy and no radiation may be compared to those which had no nodal dissection and received VCB. Preliminary results suggest that there was no advantage of routine lymphadenectomy (152). The final results of this study are eagerly awaited.

Without nodal information, physicians must rely on uterine factors to estimate the probability for nodal disease and pelvic failure to determine the need for postoperative radiation. Risk assessments may be based on nodal positivity estimates from GOG 33 or on patient risk groups treated with or without radiation therapy (PORTEC, for example). This estimation can result in a substantial increase in the use of radiation, particularly if the primary benefit of postoperative radiation is in node-positive patients. As a result, the lack of nodal information can lead to overtreatment of patients. The absence of nodal dissection may also lead to poorer outcomes. For example, a subset of 99 patients with stage IC, grade 3 endometrial cancer, who did not have lymph node dissection, were not eligible, but were treated with pelvic radiation and followed prospectively within the PORTEC trial (153). Five-year survival for this group of patients was 58%, and 12% had vaginal or pelvic failures despite whole pelvic radiation. It is interesting to note that the outcome of this group is poorer than what has been reported in patients with stage IIIC endometrial cancer managed by lymphadenectomy followed by radiation (154–156). If patients are not to have nodal dissection, then it would seem reasonable to consider vaginal approaches (TVH, LAVH) to reduce morbidity.

Nodal Dissection—Selective

Increasingly some form of nodal assessment has been integrated into the up-front management of endometrial cancer, and nodal assessment has been incorporated into the staging of endometrial cancer since 1988. Surgical staging is the most accurate way to determine the extent of disease spread. Palpation of pelvic lymph nodes is not sufficiently accurate, with a sensitivity of 72% in a recent prospective study (157,158).

TABLE 23.6**HISTOLOGIC GRADE AND DEPTH OF INVASION**

Depth	Grade, no. of patients			
	Grade 1 (%)	Grade 2 (%)	Grade 3 (%)	Total (% of total)

Many believe that nodal dissections should be reserved for those with sufficient risk of nodal disease (60,62,159,160). What risk of nodal disease (3%, 5%, 10%, etc.) warrants the procedure is debated. Data from GOG 33 demonstrated important relationships between tumor grade and depth of invasion and frequency of nodal disease that can be used to decide whether to perform nodal assessments (Tables 23.6 and 23.7) (60). For example, the risk of pelvic nodal disease was 3% for all patients with grade 1 tumors, but was 11% with deeply invasive (outer one-third myometrial invasion) tumors. Patients with grade 3 tumors had a risk of pelvic nodal metastases of 18%, and 34% with deep invasion. With cervical invasion, the rate of pelvic nodal disease was 16%. Patients

with serous or clear cell histology also warrant nodal dissection as ~30% to 50% will have nodal disease, and even in the absence of myometrial invasion, nodal metastases have been reported in up to 36% of patients (161). Some advocate that lymph nodes need not be sampled for tumor limited to the endometrium, regardless of grade, because less than 1% of these patients have disease spread to pelvic or para-aortic lymph nodes (60,162). A gray zone in deciding about lymph node sampling is represented by patients whose only risk factor is inner one-half myometrial invasion, particularly if the grade is 2 or 3. This group has 5% or less chance of node positivity (62). The overall surgical complication rate after this type of staging is approximately 20%. The serious complication rate

is $\leq 6\%$, and the rate of complications should be balanced by the probability of finding nodal disease (62,139–141).

An assessment of pelvic and para-aortic lymph nodes is required to assign stage according to FIGO 1988. Two principal nodal basins drain the uterus; the lower and middle portion of the uterus drains laterally to the pelvic lymph nodes, the upper corpus and fundus drain to the para-aortic nodes. In GOG 33, the rate of para-aortic nodal involvement was roughly 50% of the pelvic node rate. As an isolated finding, para-aortic nodes were involved in only 2% of cases. Para-aortic nodal dissection is more difficult to perform than pelvic dissection, by laparotomy or by laparoscopy, and is associated with greater risk. As such, some advocate for pelvic nodal dissections with only performing para-aortic nodal dissections selectively. In GOG 33, 46% of the positive para-aortic lymph nodes were enlarged, and 98% of the cases with aortic node metastases came from patients with positive pelvic nodes, adnexal or intra-abdominal metastases, or outer one-third myometrial invasion (62). These risk factors affected only 25% of the patients, yet they yielded most of the positive para-aortic node patients.

Intraoperative assessment of the uterus has been used to guide the surgeon as to when to perform a nodal dissection. Gross inspection of the uterus immediately following its removal can be used to estimate the degree of myometrial invasion. If the uterus is opened by the operating surgeon, care should be employed to avoid distortion of the anatomy. Optimally, the unfixed uterus should be opened by the surgical pathologist, who can grossly estimate the depth of invasion, assess involvement of the cervix, and later sample the tumor for histologic assessment. There is no typical gross appearance of an endometrial carcinoma. Most are polypoid or ulcerative. Carcinoma usually differs in texture and color from the surrounding normal endometrium. The normal endometrium is irregular and tan, but a carcinoma is usually shaggy, white to gray-white, and focally hemorrhagic. Areas of myometrial invasion may be visible as gray-white to white, with yellow areas disclosing necrosis (Figs. 23.1 and 23.2). The texture may be soft, friable, or firm depending on the degree of necrosis.

Doering et al. reported a 91% accuracy rate for 148 patients for determining the depth of myometrial invasion by gross visual examination of the cut uterine surface (163). A prospective study indicated that visual inspection of $<$ or $> 50\%$ correlated with microscopic assessment in 85% cases (158). However, the sensitivity of determining $> 50\%$ was lower at 72%. Invasion of the myometrium may be more

FIGURE 23.1. An ulcerating and deeply invasive adenocarcinoma that extends into the uterine cervix.

FIGURE 23.2. A polypoid adenocarcinoma of the endometrium that fills much of the lumen and superficially invades the myometrium.

extensive microscopically than is evident visibly because of the characteristic infiltrative growth pattern of the tumor. In a retrospective study by Goff and Riche, the gross estimation by pathologists of myometrial invasion in grades 2 and 3 tumors was poor (164). With invasion, the uterine cavity usually enlarges and the myometrium thickens, but a small uterus may have myometrial penetration to the serosa.

Nodal Dissection—Routine

Many gynecologic oncologists have moved toward performing uniform comprehensive surgical staging for nearly all patients with endometrial cancer (9). The rationale for uniform staging includes the lack of a patient population for whom nodal disease is so low that nodes should be omitted, the inaccuracy of preoperative or intraoperative assessments predicting the risk for nodal disease, the potential for therapeutic benefit in node-positive and -negative patients, and the lack of significant morbidity associated with the procedure. Postoperative adjuvant decisions are best made with the most complete information. If nodal assessment is the predominant factor by which to categorize patients into risk groups, routine nodal dissection is the best method by which to determine which few patients will require adjuvant therapy.

What constitutes an acceptable rate of nodal disease in endometrial cancer to warrant the procedure is surgeon dependent. In cervical cancer, routine pelvic lymphadenectomy is advocated for all stage IA2 tumors where nodal positivity rates are 3% to 5% (165). For clinical stage I ovarian cancer, para-aortic dissection is recommended for all given the 6% risk of para-aortic disease (166). In endometrial cancer, major complication rates associated with nodal dissection are 2% to 6%, suggesting that this might be an appropriate level of risk to balance against the risk of nodal metastases. Data from GOG 33 show that only patients with tumor limited to the endometrium had a risk of pelvic nodal disease $\leq 3\%$, and this group accounted for only 14% of the entire study population.

Frozen section assessment has been the traditional tool to facilitate decisions on selective nodal dissections. Several studies have demonstrated inaccuracies with frozen sections in the interpretation of grade and depth of myometrial invasion compared to final pathology (167–169). In one prospective evaluation, frozen section determination of depth of invasion correlated with final pathology in 67% of cases but resulted in up-staging in 28% of cases (167). Patients with grade 1 endometrial cancer or AEH were up-staged in 61% of cases.

The clinical significance of these errors has been debated (148), but many believe that such unexpected up-staging justifies routine staging even in seemingly low-risk patients (167,168). Data also suggests that the strategy of routine nodal dissection is more cost effective than either no staging or selective staging based on frozen section results (170,171).

The technique of nodal dissection has undergone evolution. In an era where everyone was to receive radiation therapy, there was little value for a complete evaluation of lymph nodes. Removal of palpably enlarged nodes, “plucking” of visibly noted nodes, and “sampling” have given way to a more thorough assessment. Only 10% of patients with metastases to lymph nodes will have grossly enlarged nodes and frequently, even in these cases, direct palpation through the overlying peritoneum will fail to identify them (60). Today, adjuvant therapies are based on the extent of disease, and often only reserved for node-positive patients. Nodal assessments should sufficiently examine sites at risk including external iliac, hypogastric, and obturator nodes in the pelvis, common iliac nodes, and para-aortic nodes. Moving from a sampling technique to a more thorough lymphadenectomy is not associated with increased complication rates (172). Nodal dissection should be bilateral given the frequency of both left and right para-aortic involvement (173,174). It is interesting to note that GOG 33 only specified right-sided para-aortic removal in the surgical protocol. Likewise, the nodal dissection is more apt to be representative when a larger number of nodes are removed.

The importance of para-aortic nodal spread in node-positive endometrial cancer cannot be ignored (Table 23.8). Data from GOG 33 showing that of all patients, isolated para-aortic nodal metastases occurred in 2% is often taken out of context (60). If the goal of nodal dissection is to identify the node-positive patient population, para-aortic disease is seen in 40% to 66% of patients with node-positive/stage IIIc endometrial cancer, including isolated positive para-aortic nodes in 7% to 21% of cases. If only pelvic nodes are removed, when they are positive, para-aortic nodes will be positive in addition in nearly 30% to 40% of cases. It makes little sense to remove only pelvic or only para-aortic nodes given this data. Data would also suggest that when positive, outcomes are improved in patients who have complete surgical resection of para-aortic nodes. Chuang et al. reported on their experience with selective pelvic

and or para-aortic dissections and found that failure to systematically remove pelvic and para-aortic nodes resulted in an increased frequency of recurrence in undissected retroperitoneal sites (175). Similarly, Mariani et al. showed that patients at high risk for para-aortic nodal disease (based on invasion >50%, palpable positive pelvic nodes, positive adnexa) who did not have para-aortic dissection or who had biopsy only and who were managed as though para-aortic nodes were positive had 5-year survival of 71% compared to 85% for those patients with positive para-aortic nodes who did undergo complete resection (172). Lymph node recurrences were detected in 37% of those not having para-aortic dissection compared to none in patients with positive but resected para-aortic nodes, suggesting a possible therapeutic effect of removing involved para-aortic nodes.

At the present time, the superior extent of para-aortic dissection should be at least to the level of the inferior mesenteric artery. Some suggest that dissections should proceed to the level of the renal vessels given the venous and lymphatic drainage following the infundibulopelvic ligament. In one series, 7 out of 11 patients had positive para-aortic nodes identified above the inferior mesenteric artery (176). This extended para-aortic dissection is feasible laparoscopically as well (177). Prospective data describing the frequency of high para-aortic/para-renal nodes are awaited.

No prospective data exist to adequately evaluate the claim that lymphadenectomy in endometrial cancer is therapeutic. The only prospective trial evaluating the role of lymphadenectomy (ASTEC trial) required only a pelvic lymphadenectomy and utilized a second randomization for pelvic radiation (152). Unfortunately, the study specified pelvic radiation for disease characteristics, which, following a negative nodal dissection, is typically avoided. Likewise, vaginal cuff radiation was permitted as per institutional practice irrespective of the assignment to pelvic radiation or not, making interpretations of any results likely difficult.

The retrospective data suggesting a therapeutic benefit supports but does not prove the hypothesis that lymphadenectomy is therapeutic. These studies are largely from single institutions, have short follow-up, suffer from selection biases, and do not clearly account for stage migration. Despite these limitations, the therapeutic value of lymphadenectomy is supported by several

TABLE 23.8

RELATIONSHIP BETWEEN PELVIC AND PARA-AORTIC NODAL INVOLVEMENT IN PATIENTS WITH NODE-POSITIVE ENDOMETRIAL CANCER

Study	N	Surgical technique	Pelvic (+) only (%)	Pelvic and para-aortic (+) (%)	Para-aortic only (%)	Any involvement of para-aortic nodes (%)

reports. Kilgore et al. were among the first to report a therapeutic effect of nodal dissections in a series of 649 clinical stage I-occult II patients who were classified based on the extent of nodal dissection (178). Patients who underwent multiple site pelvic nodal dissection (defined by nodal dissection of at least four pelvic nodal sites) and had a mean of 11 nodes removed had improved survival over those patients who did not have nodes sampled. The survival advantage for multiple site dissection persisted even when patients were stratified into low-risk (uterine-confined disease) and high-risk (extrauterine disease) groups who received radiation. An explanation for this may be the removal of unrecognized micrometastasis, which goes undetected by standard pathologic processing techniques. Girardi et al. performed complete pelvic lymphadenectomies in 76 patients with endometrial cancer (mean 37 nodes removed) and reported a 36% nodal positivity rate (179). Nodal tissue was processed as step serial sections and 37% of positive nodes were <2 mm in diameter, suggesting that nodal metastases may be missed in a proportion of node-positive patients processed in a less extensive manner. Others have shown improvement in outcomes following a more complete nodal dissection in node-negative populations. Cragan et al. evaluated 509 stage I-IIA patients who underwent selective pelvic +/- para-aortic lymphadenectomy and found a survival advantage for patients with grade 3 tumors who had >11 pelvic nodes removed, compared to those with ≤ 11 nodes removed (hazard ratio 0.25) (180). For patients with high-risk features (grade 3, >50% myometrial invasion, serous/clear cell tumors) 5-year survival was 82% when >11 nodes were removed versus 64% when ≤ 11 nodes were removed. Chan et al. reported on the effect of a more complete nodal dissection in over 12,000 women with endometrial cancer tracked in the SEER data system. In patients with high-risk disease (IB/grade 3, IC, II-IV), 5-year survival was proportional to the number of nodes removed, increasing from 75% to 87% when 1 versus >20 nodes were removed (181). In a multivariate analysis, a more extensive nodal assessment was an independent predictor of survival.

In patients with positive pelvic and/or para-aortic nodes, complete resection followed by adjuvant therapy results in superior outcomes. Mariani et al. showed that pelvic sidewall failure at 5 years was 57% for patients who had inadequate nodal dissection and/or no adjuvant radiation compared to 10% when patients had adequate (removal >10 nodes) lymphadenectomy and received radiation (182). Patients with bulky residual nodes have poorer survival compared to those who have the nodes successfully resected (183). The best outcomes reported for node-positive patients follow complete nodal dissection. For example, in one series, of 30 stage IIIC patients managed with systematic pelvic and para-aortic lymphadenectomy (average number nodes removed, 66) followed by radiation therapy and chemotherapy, 5-year survival was 100% for patients with positive pelvic nodes and 75% for positive para-aortic nodes (154).

The most cogent argument for routine staging is that following thorough nodal assessment, most patients with node-negative disease can accurately be classified as low risk, and may avoid pelvic radiation or receive vaginal cuff brachytherapy in lieu of pelvic radiation therapy. Three randomized trials comparing radiation to observation have failed to demonstrate a survival advantage for adjuvant pelvic radiation therapy in patients with stage I-II disease, suggesting that in the absence of nodal disease no therapy is a reasonable option (143,149,184). Retrospective studies have shown how the incorporation of a strategy using lymphadenectomy changes the use of postoperative radiation (9,123,139,144,185,186). In the absence of nodal disease, recurrence risk is low and overall survival is high, with no radiation or with the substitution of vaginal cuff brachytherapy.

Laparoscopic Management

Laparoscopic management of endometrial cancer has increasingly been integrated into standard practice. Laparoscopic techniques are utilized in the initial treatment of endometrial cancer (LAVH, total laparoscopic hysterectomy [TLH]) to stage patients with laparoscopic pelvic and para-aortic nodal dissection, and to re-stage patients following incomplete surgical staging. The decade of the 1990s advanced the use of minimally invasive surgery and introduced the laparoscopic techniques and tools required for comprehensive surgical staging of endometrial cancer. As the initial debate on laparoscopic vaginal hysterectomy focused on whether laparoscopic techniques could be substituted for abdominal ones, in endometrial cancer, debate has focused on whether laparoscopic surgical staging could be substituted for open procedures. Initial case reports and small single institutional series describing technique and demonstrating feasibility were replaced by large series, small randomized trials, and subsequently a multi-institutional randomized controlled trial (187-197).

Improvements in laparoscopic equipment facilitated the development of LAVH. Building on that experience, and coupled with the introduction of better optics for visualization, laparoscopic resection of lymph nodes became possible. Querleu et al. were the first to report pelvic lymphadenectomy for cervical cancer in 1991 (198), followed by Nezhat et al. who reported in 1992 on the use of laparoscopic pelvic and para-aortic lymphadenectomy with radical hysterectomy in cervical cancer (199). When first utilized in endometrial cancer, laparoscopic para-aortic node dissection only evaluated right-sided nodes (187). Techniques have subsequently been developed allowing for dissection to include the left para-aortic nodes (177,200-202).

Arguments have been advanced for and against each of the surgical approaches to endometrial cancer. Vaginal hysterectomy was once a favored operation, but it did not allow for routine removal of the ovaries in some patients, permit inspection of the peritoneal cavity or the retroperitoneum for metastatic disease, or allow collection of peritoneal fluid for cytology (203). Laparoscopic-assisted or total laparoscopic approaches overcome these limitations, however. Compared to open procedures, LAVH/TLH are thought to lead to reduced incisional complications, wound infections, ileus, hospital stay, cost, and improved rate of recovery and quality of life (194,195). In patients requiring postoperative radiation, laparoscopic surgical staging followed by radiation therapy is suggested to result in fewer bowel adhesions and radiation-induced bowel injuries (204). Criticisms of LAVH/TLH with laparoscopic nodal dissection relate to the learning curve required to learn new or unfamiliar procedures, the increased length of operative times, and concerns about the adequacy of the nodal dissection. Studies do suggest that with increased experience, operative times decrease and nodal counts increase (200,205). Laparoscopy also introduced different procedural-related complications (206-208). For example, the technique has the potential to produce port-site recurrences (209) or intraperitoneal dissemination (210) of disease by laparoscopic gas and/or uterine manipulation, although the frequency of these events is low. Results of long-term survival in laparoscopically treated endometrial cancer patients are still limited (190,193).

Childers et al. (187,188) described the initial experience of LAVH in 59 patients with clinical stage I endometrial carcinoma. Laparoscopic pelvic and right-sided aortic lymph node samplings were performed in patients with grade 2 or 3 lesions, or with grade 1 lesions and greater than 50% myometrial invasion on

frozen section. For the group, the mean weight was 153 pounds, and in two patients, laparoscopic lymphadenectomy was precluded by obesity. Six patients had the procedure converted to open due to intraperitoneal disease, and two patients required laparotomy to manage complications, including a transected ureter and a cystotomy. The mean hospital stay was 2.9 days. Since that time many retrospective series have appeared in the literature (242,303–307). Gemignani et al. compared the clinical outcomes and hospital charges for 69 women with early-stage endometrial cancer who underwent laparoscopically assisted vaginal hysterectomy compared to 251 who underwent an abdominal approach (194). Although the mean operating time was longer for the laparoscopic group, the overall complication rates, length of stay, and hospital charges were lower. With short follow-up, there was no significant difference in disease recurrence between the two groups.

A small prospective, randomized trial comparing laparoscopic-assisted vaginal versus abdominal surgery in patients with endometrial cancer was reported by Malur et al. (192). They randomized 70 patients with endometrial cancer FIGO stage I-III to laparoscopy-assisted simple or radical vaginal hysterectomy or simple or radical abdominal hysterectomy with or without lymph node resection. Thirty-seven patients were treated in the laparoscopic versus 33 patients in the laparotomy group. Lymph node resection was performed in 25 patients by laparoscopy and in 24 patients by laparotomy. Blood loss and transfusion rates were significantly lower in the laparoscopic group. The number of pelvic and para-aortic lymph nodes, duration of surgery, and incidence of postoperative complications were similar for both groups. No significant differences in disease recurrence rate and long-term survival were found between the laparoscopic and laparotomy groups (97.3% vs. 93.3% and 83.9% vs. 90.9%, respectively). There was no difference in duration of surgery between the two groups. Malur et al. explain this by an extensive exposure by laparoscopic surgery and laparoscopic lymphadenectomy in their team over the past 5 years, which helped to save time (192). They also found a significantly shorter duration of hospital stay in the laparoscopic group, which also has been reported by others (189,190,211). The conclusion of Malur et al. was that laparoscopic staging combined with laparoscopically assisted vaginal hysterectomy can be recommended for the treatment of women with endometrial cancer, offering a less invasive approach that is associated with less intraoperative and postoperative morbidity (192).

The largest and most comprehensive data set to date comes from the large prospective, randomized trial conducted by the GOG (Lap II trial) (196,197). The study was designed to compare laparoscopic hysterectomy with comprehensive surgical staging to the traditional laparotomy technique (using a 2:1 randomization favoring the laparoscopic arm) to determine the complete staging rates, safety, short-term surgical outcomes, and long-term cancer recurrence and survival. The study enrolled 920 patients to the open arm, and 1,696 to laparoscopy. The rate of conversion from laparoscopy to open procedure was 26%, and was most frequently related to poor visibility (15%), extrauterine cancer spread (4%), and bleeding (3%). The conversion rate increased with increasing patient obesity, with the laparoscopic success rate being 90% with a body mass index (BMI) <20, 65% with BMI = 35, and 34% with BMI = 50. Median number of removed nodes was similar between each technique as were the frequencies of patients found to have positive lymph nodes. Complication rates (combined rates of vascular, urinary, bowel, nerve, or other complications) for those who had an open procedure were 7.6%, compared to 9.5% of patients randomized to laparoscopy. Of the 1,242 patients randomized to laparoscopy who had the procedure successfully completed laparoscopically,

the complication rate was 4.9%. Comparing patients who underwent open surgery versus successful completion of laparoscopy, operative time was longer (median 70 minutes), but hospital time was shorter (2 vs. 4 days) with laparoscopy. Postoperative arrhythmia, pneumonia, ileus, antibiotic use, and any complication > grade 2 were lower in the laparoscopic group. Long-term recurrence and survival data are maturing. The authors concluded that laparoscopic surgical staging is an acceptable and possibly a better option, particularly when the surgery can be successfully completed laparoscopically.

Age and obesity have been suggested as relative contraindications to laparoscopic surgery. In the GOG Lap II trial, the median age was 63 years. Scribner et al. evaluated the surgical experience of uterine cancer patients age ≥ 65 years who underwent LAVH with pelvic and para-aortic lymphadenectomy (N = 67) or abdominal hysterectomy with pelvic and para-aortic lymphadenectomy (N = 45) (212). Laparoscopic staging could be completed in 78% of patients. In the laparoscopic group, the BMI was 29.5 kg/m² (range 15.9 to 54.7), and 33% had a history of prior laparotomy. For the 22% of patients who required a conversion to laparotomy, obesity (10%), bleeding (6%), and intraperitoneal disease (5%) were the most frequent reasons. Similar nodal counts (29 laparoscopy, 29 open) were noted, the operative time was longer (236 minutes vs. 148 minutes), and hospital stay was shorter (median 3 vs. 5.6 days) with laparoscopy. The authors concluded that with the anticipated growth of an aging patient population, laparoscopic management is a viable option.

Obese patients have also been suggested to be poor laparoscopic candidates due to difficulties in establishing pneumoperitoneum, poorer visualization, inability to tolerate steep Trendelenburg positioning needed to facilitate the surgery, and difficulties with ventilation. In the report by Childers et al. mean patient weight was only 153 pounds (187,188). It is important to recognize that regardless of surgical approach, complete surgical staging is more difficult in an obese patient. Scriber et al. compared 55 obese patients (median weight 96.6 kg, median BMI 40) who underwent LAVH with pelvic and para-aortic lymphadenectomy to 45 patients (median weight 101 kg, median BMI 39) who had abdominal hysterectomy with pelvic and para-aortic lymphadenectomy (213). Successful completion of laparoscopy was possible in 64%, with patients with a BMI <35 kg/m² having an 82% success rate compared to 44% when the BMI was >35 kg/m². Eltabbakh et al. evaluated 40 women with BMI between 28 and 60 who were treated with LAVH and compared them to 40 similar women treated by abdominal approach (214). Laparoscopic conversion was only required in 8% of patients. Laparoscopic surgery was associated with a longer operative time (195 minutes vs. 138 minutes), but more pelvic nodes (mean 11 vs. 5), less pain medicine requirement, and shorter hospital stay (2.5 vs. 5.6 days) were recorded. Total laparoscopic hysterectomy has also been shown to be feasible in heavier patients (215). In the prospective GOG series, there was $\geq 80\%$ success rate with patients with a BMI of 27 or less, but even at a BMI of 35, 65% could have successful laparoscopic surgery (196).

Whether an LAVH/TLH procedure is comparable to an open approach must be judged by the ability to accurately dissect appropriate nodal basins, to remove an adequate/representative number of lymph nodes, to identify metastatic disease, and by the rates of recurrence. The technique used to remove the uterus/ovaries is not the source of controversy. Comprehensive surgical staging allows for appropriate risk stratification to make appropriate treatment recommendations. Multiple reports demonstrated similar node counts for open and laparoscopic

technique in the surgical staging of endometrial cancer (189,194). Possover et al., reporting on 150 patients undergoing pelvic and para-aortic lymphadenectomy, demonstrated the adequacy of lymph node counts utilizing the laparoscopic procedure (216). The average pelvic lymph node count was 26 per patient and ranged between 10 and 56. Spirtos et al. documented 40 women who his group attempted to stage surgically, limiting the size to a BMI of 30 (200). Thirty-five completed the procedure and two of those failed to have left para-aortic nodes sampled, resulting in an 82.5% success rate. The node count was 12 to 42 with 27.7 being the average nodes per patient, and 20.8 pelvic nodes (11 right, 9.8 left). There was an average of 7.9 aortic nodes (3.8 right, and 4.1 left). In the GOG Lap II trial, median numbers of nodes from pelvic and para-aortic basins, and frequencies of positive nodes were comparable in the surgical arms (196,197). Despite the potential benefits of laparoscopic surgery, if laparoscopic nodal dissection cannot be performed, conversion to laparotomy is advised when incomplete staging results would yield inadequate information for treatment planning.

The laparoscopic surgery must be performed with an acceptable complication rate to be considered a viable option. In one series reporting on complication rates with an institution's first 100 pelvic and para-aortic nodal dissections, conversion to manage complications was required in five to control bleeding, and one to repair a ureteral injury (217). In another group's experience with 150 patients, seven major vascular injuries were reported, but only four patients required laparotomy (216). Querleu et al. reported on intraoperative and postoperative complications of laparoscopic node dissection from 1,192 pelvic and para-aortic nodal dissections (218). Only 13 open procedures were required to complete the nodal dissections, and a laparotomy was required in seven cases to manage complications. Eleven intraoperative vascular injuries were noted, but none required laparotomy to manage. In the GOG Lap II study, intraoperative complications were comparable (7.6% open, 9.5% randomized to laparoscopy, 4.9% successful completion of laparoscopy). Postoperative complications and short-term quality of life improvements favored laparoscopy.

Restaging

One of the more useful roles of laparoscopic surgery is in restaging patients who underwent hysterectomy only. Patients who undergo hysterectomy without nodal dissection and who have pathologic risk factors for potential nodal spread face a difficult dilemma. Patients may elect to receive radiation or chemotherapy (presume nodes are positive), elect observation (presume nodes are negative), or undergo a second operation. A second laparotomy can be difficult to accept. Laparoscopic staging offers the patient a less invasive option to collect information. Childers et al. reported the initial experience with restaging in 13 patients, finding disease in 3 patients (219).

Laparoscopic Recommendations

Laparoscopic surgery has demonstrated an important role in the management of endometrial cancer. Just as with an abdominal procedure, hysterectomy with pelvic and para-aortic nodal assessment is standard. Additional training and experience are required for successful completion of the procedure, just as they are with open procedures. The demonstration of comparable surgical endpoints (similar numbers of nodes removed, similar frequency of positive nodes) along with shortened hospital stay and quicker recovery compared to open procedures

suggest that appropriate patients should be counseled regarding this option. Challenges remain on how to increase the laparoscopic training of gynecologic oncologists in practice and fellows in training programs. Long-term follow-up demonstrating recurrence rates and survival are also required.

Surgical Management of Intraoperative Disease

The management of patients with stage IV disease depends on the ability to resect disease. In patients with distant metastasis, there may be a limited role for surgery such as to provide control of vaginal bleeding. In patients with intraoperative disease, options include resecting easily removable disease (uterus, adnexa, omentum) versus a more extensive cytoreductive effort. The value of extensive cytoreductive surgery in endometrial cancer has not been as well studied as it has in ovarian cancer. Historically, limitations in postoperative therapies (lack of enthusiasm for whole abdominal radiation, marginally effective chemotherapy regimens, reliance on hormonal therapy) perhaps reduced interest. Several retrospective reports suggest that survival correlates with volume of residual disease (220–222). Chi et al. showed that median survival was 31 months following cytoreduction to ≤ 2 cm residual disease compared to 12 months when debulked, but residuals were > 2 cm. Bristow et al. demonstrated that optimal cytoreduction (< 1 cm) could be obtained in 55% of stage IV patients, and required omentectomy (93%), peritoneal stripping (65%), and bowel resection (29%) to do it (221,222). In patients with serous histology, similar survival improvements were seen with optimal debulking of intraoperative disease (223).

Surgical Recommendations

The contemporary management of endometrial cancer has significantly changed. We believe the benefits of routine nodal dissections should be extended to all patients who are appropriate candidates for surgery. Patients who *a priori* are deemed not to be candidates for staging should be considered for vaginal or laparoscopic-assisted vaginal hysterectomies. We seldom perform simple abdominal hysterectomy without nodal dissection for this disease. Surgical therapy for endometrial cancer removes the disease and defines populations at risk for recurrence and death. Surgical staging, or the lack of it, defines patient groups into surgically staged node positive or negative, or unstaged. Comprehensive staging most accurately assigns stage and associated prognosis. Staging also allows for a more tailored approach to the use of adjuvant therapies. Laparoscopic techniques have been shown to result in comparable surgery to open procedures. Whether nodal dissections are therapeutic remains controversial, but retrospective data suggest that this potential may exist and should be explored in well-designed studies. For patients with resectable intraoperative disease, cytoreductive surgery can result in optimal volumes of residual disease, and perhaps improved outcomes.

PATHOLOGY

Hyperplasia

The current classification of endometrial hyperplasia accepted by both the International Society of Gynecologic Pathologists (ISGP) and the World Health Organization (WHO) is based on the schema of Kurman and Norris (224), which divides

TABLE 23.9

CLASSIFICATION OF ENDOMETRIAL HYPERPLASIA

Types of hyperplasia	Progressing to cancer (%)
Simple (cystic without atypia)	1
Complex (adenomatous without atypia)	3
Atypical	
Simple (cystic with atypia)	8
Complex (adenomatous with atypia)	29

hyperplasia on the basis of architectural features into simple or complex and on the basis of cytologic features into typical or atypical (Table 23.9). The resulting classification has four categories as follows: *simple hyperplasia* (SH), *complex hyperplasia* (CH), *simple atypical hyperplasia* (SAH), and *complex atypical hyperplasia* (CAH). Simple hyperplasia is defined as an increase in the number of endometrial glands, which may be dilated with little crowding or have an irregular outline and exhibit crowding. Complex hyperplasia is characterized by glands with irregular outlines, marked structural complexity, and back-to-back crowding. The designation atypical hyperplasia is used to denote a proliferation of glands exhibiting cytologic atypia, recognized as nuclear enlargement, the presence of nucleoli, or a change from an elongated to a more ovoid or round nucleus. The chromatin may be either evenly or irregularly dispersed. The justification for this classification system rests on three retrospective studies that demonstrate a higher rate of progression of CAH to adenocarcinoma (224–226). It is sometimes difficult to apply this system, which requires one to make a distinction between cytologically atypical nuclei and those without atypical nuclei since a spectrum of nuclear variability actually exists. As noted by Kendall et al. (227), the definitions of architectural complexity and nuclear atypia potentially rest on a multitude of criteria, and some but not all criteria may be fully developed in any given case.

Several reports have addressed the reproducibility of diagnoses of hyperplasia (227–229). Intraobserver reproducibility was generally found to be moderate to good, whereas interobserver reproducibility was poor to moderate for various diagnostic categories. These studies probably overestimate the interobserver reproducibility since they used expert gynecologic pathologists and specified the classification to be used. In a prospective study by the GOG, neither community-based nor expert panel diagnosis of atypical hyperplasia was highly accurate (73). The current classification of hyperplasia relies on a combination of multiple architectural and cytologic criteria. It is hardly surprising that interobserver reproducibility is relatively low when multiple criteria are used to classify a lesion since each pathologist must assign a relative value or weight to each potentially conflicting criterion. Other factors contributing to low reproducibility include (a) the fragmentary nature of curetings, (b) the presence of borderline lesions, (c) uncertainty about the significance of focal hyperplasia, (d) the inadequacy of published descriptions and understanding of terms used to define architectural or cytologic atypia, and (e) the difficulty associated with the translation of verbal descriptions into light microscopic interobserver reproducibility for images.

The gross manifestations of endometrial hyperplasia are highly varied. The endometrium is often of diffusely increased thickness (5 to 10 mm or greater), vaguely nodular, tan, and soft without hemorrhage or necrosis. However, hyperplasia may be focal or multifocal in a background of polyps or cycling endometrium, or even occasionally may be

associated with a diffusely thin endometrial lining. Part of the variability may reflect a reduction in the endometrial thickness due to prior endometrial sampling. Coexistent adenocarcinoma is present in 1% to 40% of hysterectomies performed to treat hyperplasia, with the latter number reflecting the frequent co-occurrence of carcinoma with atypical complex hyperplasia.

Endometrial Intraepithelial Neoplasia

Based on a combination of morphologic, molecular, and morphometric information, Mutter et al. have proposed an alternative classification scheme to replace the current WHO hyperplasia terminology (230–233). They have presented data that endometrial intraepithelial neoplasia (EIN) is the histopathologic presentation of a monoclonal endometrial preinvasive glandular proliferation that is the immediate pathologic precursor of endometrioid endometrial adenocarcinoma. Monoclonality and forward carryover of EIN mutations into subsequent carcinoma were the original molecular standards used for EIN diagnosis. Computer-assisted morphometric analysis of more than 20 features was carried out initially and the three features seen in molecularly defined precancers enabled an objective delineation of histologic diagnostic criteria (the D-score). The principal components assessed included a reduction in the volume of stroma, an increased variability in nuclear shape gland contour. Several of these features have been translated to characteristics that can be assessed subjectively by the surgical pathologist (Fig. 23.3). These features include the following: (a) the area of the glands

FIGURE 23.3. A lesion that could be classified in two different systems as either endometrial intraepithelial carcinoma (EIN) or complex atypical hyperplasia based on gland crowding and cytologic atypia. Note the presence of a residual inactive endometrial gland that may be used as a reference for estimating cytologic atypia.

exceeds that of stroma; (b) nuclear and cytoplasmic features of the affected glandular cells differ from those of the background glands, and may include loss of nuclear polarity or increased nuclear pleomorphism; in the absence of any background glands, a highly abnormal cytology is sufficient; (c) the maximum diameter exceeds 1 mm; (d) benign conditions including disordered proliferation, polyps, and repair are excluded; and (e) the cribriform or maze-like pattern of carcinoma is excluded. There is a high degree of concordance between EIN diagnoses rendered by computer and those made subjectively by pathologists, and either has superior cancer predictive value when compared to the 14-fold increased cancer risk conferred by the presence of atypia compared to lack thereof in the WHO hyperplasia schema. Clinical outcome studies have shown that almost 40% of women with an EIN diagnosis will be diagnosed with endometrial carcinoma within 1 year and, and for those who do not develop cancer within 12 months, a 45-fold increased risk of future endometrial cancer exists. Correspondingly, absence of an EIN lesion in an initial representative biopsy, including those with only benign hyperplasia, confers very high (99%) negative predictive value for concomitant or future adenocarcinoma.

While EIN shares many features with atypical complex hyperplasia, the two entities are not entirely overlapping. The concept of EIN is appealing since there appears to be a strong biologic basis, with EIN representing a clonal process, while disordered proliferation and hyperplasia remain as diffuse endometrial physiologic responses to an abnormal stimulus (unopposed estrogen stimulation).

Simple Hyperplasia

In simple hyperplasia, the endometrium is thicker than usual, with dilated glands that have outpouchings and invaginations, producing an irregular outline to the enlarged glands. The glands are crowded, the stroma is more densely cellular than usual, and some foam cells may exist within the stroma. Follow-up of patients with this condition reveals little or no progression to carcinoma.

Complex Hyperplasia

The endometrium is increased in thickness by back-to-back glands in cases of complex hyperplasia. Most glands have irregular outlines. There are papillary processes and intraluminal bridges. The two main features differentiating this from simple hyperplasia are the back-to-back glands and the intraluminal papillae. Epithelial pseudostratification is a frequent finding, producing an appearance of two to four cell layers. Mitotic activity is highly variable, but may range to up to ten mitotic figures per ten high-power fields.

Atypical Hyperplasia

Atypical hyperplasia is characterized by cytologic atypia of the glands. The gland outlines may reflect simple or complex hyperplasia, although it is usually complex. The cells lining the glands are enlarged, show nuclear hyperchromatism and nuclear enlargement, and have an increased nucleus-cytoplasm ratio. Nuclei are irregular in size and shape and have a thickened nuclear membrane, prominent nucleoli, and a coarse chromatin texture. The nuclei may appear clear with scattered, coarse chromatin clumps.

Progression From Hyperplasia to Cancer

The natural history of endometrial hyperplasia is difficult to define for a variety of reasons, four of which follow: (a) pathologic criteria—criteria and terminology for the various forms of hyperplasia have changed repeatedly; (b) initial sampling—the method of initial diagnosis is often curettage, which removes part or all of the lesion to be studied; (c) coexisting lesions—other lesions such as adenocarcinoma may coexist at the time of diagnosis without our knowledge, since the curettage or biopsy samples only a minority of the endometrium; and (d) subsequent intervention—hormonal or surgical intervention usually interrupts observations of the natural history of the hyperplasia. Nevertheless, there are reasonably good data to support the following assertions: (a) endometrial hyperplasia is commonly a consequence of unopposed prolonged estrogen stimulation; (b) some hyperplasias may regress if the estrogenic stimulus is removed or in response to progestational or antiestrogenic treatment; (c) some hyperplasias coexist with, or progress to, invasive adenocarcinoma; and (d) the probability of progression to adenocarcinoma is related to the degree of architectural or cytologic atypia. Progression from hyperplasia to carcinoma occurs in only 1% of patients with simple hyperplasia and in 3% of patients with complex hyperplasia (72). Progression from atypical hyperplasia is much higher; 8% of patients with simple atypical hyperplasia and 29% of those with complex atypical hyperplasia develop carcinoma (Table 23.9) (72,224). Glandular complexity superimposed on atypia probably places the patient at greater risk than does cytologic atypia alone, but the point is unsettled.

Pathologic Diagnosis

The ISGP and the WHO last revised the classification of uterine tumors in 1992 (234), and the portion pertaining to carcinomas of the endometrium is presented in Table 23.10. This relatively simple classification scheme accommodates the vast majority of endometrial carcinomas and distinguishes among neoplasms of significantly different prognosis. Mixed carcinomas with two distinctive cell types are relatively common, and are defined as those carcinomas in which the secondary component constitutes at least 10% of the neoplasm.

In most endometrial samples, the distinction of adenocarcinoma from hyperplasia is straightforward. However, a small fraction of problematic cases with complex proliferations

TABLE 23.10

CLASSIFICATION OF ENDOMETRIAL CARCINOMA

Metastatic carcinoma

truly tax the abilities of experts as well as novices to classify them correctly. The diagnosis of a well-differentiated adenocarcinoma is made in the presence of any of the following criteria: (a) irregular infiltration of glands in an altered fibroblastic stroma, (b) a confluent glandular pattern that results in either a cribriform arrangement or confluent interconnected glands, or (c) extensive papillary growth of epithelium and stroma into glandular lumina (224).

Histologic Grade

The differentiation of a carcinoma is expressed as its grade. Grade 1 lesions are well differentiated and are generally associated with a good prognosis. Grade 2 tumors (Fig. 23.4) are moderately well differentiated and have an intermediate prognosis, and grade 3 reflects poorly differentiated lesions, which frequently have a poor prognosis. Both architectural criteria and nuclear grade are used in the FIGO and ISGP-WHO committee (235) classification of tumors and are easily applied to most cell types (Table 23.10). The architectural grade is determined as follows: grade 1—an adenocarcinoma in which less than 5% of the tumor growth is in solid sheets; grade 2—an adenocarcinoma in which 6% to 50% of the neoplasm is arranged in solid sheets of neoplastic cells; grade 3—an adenocarcinoma in which greater than 50% of the neoplastic cells are in solid masses. Regions of squamous differentiation are excluded from this assessment. The FIGO rules for grading state that notable nuclear atypia, inappropriate for architectural grade, raises the grade of a grade 1 or grade 2 tumor by one. However, FIGO did not define notable nuclear atypia. Justification and clarification for this modification based on extreme nuclear pleomorphism were provided in a recent GOG study. For 715 women with nonserous endometrial carcinomas, three nuclear grades were defined as follows: grade 1—round to oval nuclei with even distribution of chromatin and inconspicuous nucleoli; grade 2—irregular, oval nuclei with chromatin clumping and moderate-size nucleoli; and grade 3—large, pleomorphic nuclei with coarse chromatin and large, irregular nucleoli. Patients with tumors of architectural grade 1 or 2, but with a majority of cells having nuclei of grade 3, had a significantly worse behavior, justifying an up-grading by one grade (236).

FIGURE 23.4. Endometrioid adenocarcinoma, grade 2. The glandular component is a caricature of proliferative phase glands, with stratification and a shared luminal border to the neoplastic cells. In grade 2 carcinomas, regions of solid neoplastic growth occupy between 5% and 50% of the surface area of the carcinoma.

Taylor et al. (237) proposed a two-tiered system for grading endometrial carcinoma based on a study of 85 patients with stage I and II endometrial cancer. They divided tumors at 10% intervals based on the percentage of solid tumor growth, and found that tumor recurrences were confined to the subset with greater than 20% solid tumor. They also found that this binary division yielded a higher degree of interobserver agreement than three architectural grades. Lax et al. (238) have presented preliminary data on a binary architectural grading system based on the presence of greater than 50% solid growth, a diffusely infiltrative growth pattern, and tumor cell necrosis. These methods will need to be replicated in a larger patient population before an assessment of their prognostic utility can be made. Some cell types (i.e., serous, clear cell, ciliated, and undifferentiated) are not easily architecturally graded because their growth patterns are architecturally limited. In these, the nuclear grading is more universally applicable (239).

Cell Types

Endometrioid Adenocarcinoma. Endometrioid adenocarcinoma is the most common form of carcinoma of the endometrium, comprising 75% to 80% of the cases (60,240). It varies from well differentiated to undifferentiated. Characteristically, the glands of endometrioid adenocarcinoma are formed of tall columnar cells that share a common apical border, resulting in a smoothly delineated, round or oval luminal contour. With decreasing differentiation, there is a preponderance of solid growth rather than gland formation, and the cells lining glandular lumina become more numerous but not necessarily clearly stratified. Stromal invasion manifested by a desmoplastic host response or vascular invasion is often not evident in the biopsy or curettage specimen.

Villoglandular Carcinoma. There has been considerable confusion about the definition and significance of papillary carcinoma of the endometrium. A variety of cell types of endometrial adenocarcinoma with differing biologic behavior, including serous, clear cell, mucinous, and villoglandular carcinoma, may grow in a papillary fashion. Thus, the adjective *papillary* does not represent a cell type but rather an architectural pattern (240,241).

Villoglandular carcinoma is a relatively common subtype of endometrioid adenocarcinoma characterized by neoplastic columnar cells covering delicate fibrovascular cores. The apical cytoplasmic borders are straight, the nuclei are usually low grade, and the tumor cells architecturally resemble those of other endometrioid adenocarcinomas, with which they are often admixed. In the largest study to date, villoglandular carcinomas were better differentiated than endometrioid carcinomas, but the age at diagnosis, depth of myometrial invasion, nodal spread, and survival were similar to those of endometrioid carcinomas, justifying their classification as a subtype of endometrioid adenocarcinoma (242).

Secretory Carcinoma. Secretory carcinoma is a variant of endometrial carcinoma, but it is unusual and represents no more than 2% of the cases (243,244). It is identified by its well-differentiated glandular pattern, consisting of columnar epithelial cells containing intracytoplasmic vacuoles similar to secretory endometrium. It is usually grade 1 architecturally and by nuclear features. There is minimal cellular atypia, stratification, and pleomorphism. The intracellular secretions are not mucin but glycogen. The cellular features of secretory carcinoma differentiate it from clear cell carcinoma, which is more papillary with more pleomorphic nuclei. By its lack of mucin, secretory carcinoma may be differentiated from mucinous carcinoma. Recognition of secretory carcinoma is important because it has a less virulent clinical course (244,245), although the clinical profile of patients is similar to that of

patients with adenocarcinoma. Confused identification may occur in patients who have been given progestogens before tissue sampling in what would have otherwise been an atypical hyperplasia or a well-differentiated endometrioid carcinoma. Atypical hyperplasia and endometrioid carcinoma may retain responsiveness to progestins and develop a secretory appearance. A good clinical history should be provided for the pathologist to avoid this confusion.

Ciliated Carcinoma. Ciliated carcinoma is rare. Grossly, it does not differ from ordinary endometrial carcinoma. Ciliated cells are more commonly identified in endometrial hyperplasia and in benign metaplasia (tubal metaplasia), but they may occur in endometrial carcinomas. Associated with prior exogenous estrogen use, this cell type is reported to have a good prognosis (246).

Adenocarcinoma With Squamous Differentiation. Foci of squamous differentiation are found in about 25% of endometrial adenocarcinomas (Fig. 23.5). Historically, the tumors were sometimes separated into adenoacanthoma or adenosquamous carcinoma based on whether the squamous component appeared histologically benign or malignant (247–251). However, in about 30% of cases, the squamous component is not clearly benign or malignant. In a GOG study of early-stage disease, it was noted that these tumors with squamous regions behave in a fashion similar to endometrioid carcinomas without squamous differentiation (252). The squamous areas usually mirror the degree of differentiation, which, coupled with assessment of histologic grade and other conventional prognostic factors, is thus more useful for prognostication and determination of adjuvant therapy than the historic terms *adenoacanthoma* and *adenosquamous carcinoma*, which are confusing and should be abandoned.

Mucinous Carcinoma. Mucinous adenocarcinoma is rare in the endometrium in contrast to its high frequency in the endocervix. It has been reported to represent between 1% and 9% of endometrial adenocarcinomas (253–255), but the former figure is probably more accurate. If present as the major cellular component of an endometrial carcinoma, this tumor resembles mucinous carcinoma seen in the ovary and endocervix. Two patterns occur: In one, the cells are columnar with basally oriented nuclei; in the other, the cells are more pseudostratified, as in an adenocarcinoma of the colon or mucinous

FIGURE 23.5. Endometrioid adenocarcinoma with squamous differentiation. The squamous component may form keratin pearls, but more often simply is characterized by acquisition of more abundant, deeply eosinophilic cytoplasm and distinct cell borders. The squamous component may appear histologically benign or malignant.

FIGURE 23.6. Mucinous adenocarcinoma. The apical cytoplasm cells as well as the lumens of glands are filled with a pale basophilic mucoid product.

carcinoma of the ovary (Fig. 23.6). The characteristic cellular pattern should represent over 50% of the entire tumor. Typically, there are papillary processes and cystically dilated glands lined by columnar or pseudostratified columnar epithelium. The cytoplasm is positive for carcinoembryonic antigen (CEA), mucicarmine, and periodic acid-Schiff stain (PAS), but it is diastase resistant (255). This tumor differs from clear cell carcinoma and secretory endometrium by having more mucin and less glycogen. Ordinarily, atypia and mitotic figures are not prominent features. The glandular architecture is usually well maintained, and most are well differentiated (253). To establish the origin in the endometrium, exclusion of a primary endocervical tumor is required. If the endocervical sample demonstrates the same neoplasm, the site of origin must be carefully established because this cell type is common in the endocervix (256). Neither the pattern nor the type of mucin staining nor the presence of CEA can reliably distinguish mucinous adenocarcinoma of the endometrium from its more common counterpart in the endocervix (257,258). Mucinous carcinoma of the endometrium has the same prognosis as common endometrial carcinoma (254).

Serous Carcinoma. Serous carcinoma of the endometrium closely resembles serous carcinoma of the ovary and fallopian tube because its papillary growth and cellular features are similar (Figs. 23.7 and 23.8). It is usually found in an advanced stage in older women (259). Fibrous papillary fronds are lined by epithelial cells, which are almost devoid of cytoplasm, but which manifest stratification, atypism, pleomorphism, mitotic figures, and bizarre forms. These fronds often detach or demonstrate a terminal growth of tiny papillary excrescences and individual cells, which detach easily. A second pattern of irregular gaping glands lined by cuboidal cells with scalloped, apical borders may be present, particularly in the deeper aspect of the tumor. Lymphatic invasion is commonplace in the myometrium. Distinction from clear cell carcinoma may be difficult but can usually be accomplished on the basis of a greater degree of papillary processes, greater nuclear atypia, and less cytoplasm in papillary serous carcinoma. Psammoma bodies are frequently observed in serous carcinoma, but solid growth is more common in clear cell carcinoma.

Serous carcinoma represents approximately 10% of endometrial carcinomas, which is fortunate because it is an aggressive tumor. The tumors often deeply invade the myometrium, and unlike typical endometrioid adenocarcinoma, there is a propensity

FIGURE 23.7. Serous carcinoma often arises in an otherwise atrophic polyp of older women.

for peritoneal spread. Unfortunately, advanced-stage disease or recurrence is common even when serous carcinomas are apparently only minimally invasive or even confined to the endometrium in polyps (161,260,261). Since the metastatic disease is often identified only microscopically, about 60% of patients are up-staged following complete surgical staging (161,259,262). A report by Wheeler et al. (263) stressed the prognostic importance of meticulous surgicopathologic staging. They and others found that serous carcinoma truly confined to the uterus had an overall excellent prognosis, whereas patients with extrauterine disease, even if only microscopic in size, almost always suffered recurrence and death from tumor (264,265).

Endometrial intraepithelial carcinoma (EIC) has recently been recognized as a histologically distinctive lesion that is specifically associated with serous carcinoma of the endometrium (Fig. 23.9) (266–270). Serous carcinomas most often arise from a background of atrophy or polyps rather than hyperplasia (266,267,269), and they are not epidemiologically related to unopposed estrogen stimulation. EIC has been proposed to represent a form of intraepithelial tumor characteristic of serous carcinoma, and it is the likely precursor to invasive serous carcinoma. EIC is usually found in the

FIGURE 23.8. Serous carcinoma is characterized by high-grade cytologic atypia in cells that do not share a common apical border. A papillary architecture is common, but sometimes relatively subtle.

FIGURE 23.9. Endometrial intraepithelial carcinoma (EIC) is considered the precursor of serous carcinoma. Highly atypical cells resembling those of serous carcinoma are present in glands immediately adjacent to atrophic endometrium.

endometrium harboring a serous carcinoma (267), but occasionally occurs in the absence of any invasive carcinoma. In such cases, it may be associated with synchronous serous carcinoma in the peritoneum (268).

Clear Cell Carcinoma. Clear cell adenocarcinoma of the endometrium is generally recognized and defined on the basis of the distinctive clearing of the cytoplasm of neoplastic cells growing in any combination of solid, glandular, tubulocystic, or papillary configurations. About 4% of endometrial adenocarcinomas are of clear cell type (271–278). In contrast with the diethylstilbestrol (DES)-related clear cell carcinomas of the vagina and cervix, clear cell carcinoma of the endometrium is almost exclusively a disease of menopausal women. The mean age at diagnosis is about 68 years, which is similar to that of serous adenocarcinoma and about 6 years older than that of typical endometrial adenocarcinoma (271,274,278). It is a biologically aggressive neoplasm, with a 5-year survival rate varying from only about 20% to 65% (5,271,274,276,278).

The hallmark of clear cell carcinoma is the presence of neoplastic cells with optically clear cytoplasm, reflecting an abundance of glycogen. Four basic architectural patterns of clear cell adenocarcinoma exist, including solid, glandular, tubulocystic, and papillary, but most cases display an admixture of patterns. The solid pattern consists of masses of large neoplastic cells of polygonal shape with clear to faintly eosinophilic cytoplasm and distinct cell membranes. The glandular pattern is reminiscent of the tubular glands of endometrioid adenocarcinoma, whereas the tubulocystic pattern is formed of dilated spherical-appearing glands. The papillary pattern is architecturally identical to that of serous carcinoma, with generally short, branching fibrovascular cores, often hyalinized, covered by neoplastic cells. The latter three patterns often have lining cells with a hobnail appearance, resulting from the scalloped apex of individual neoplastic cells that project along the surface (Fig. 23.10).

Squamous Carcinoma. Although focal squamous differentiation is common in endometrial adenocarcinoma, pure squamous carcinoma of the endometrium is extremely rare, representing less than 1% of endometrial carcinoma, and with only about 60 reported cases (279–283). Most patients are postmenopausal, and the average age at diagnosis is about 65 years (279,281). Squamous carcinoma of the endometrium is established as primary in the endometrium after a cervical origin is ruled out. There must be no connection with or spread from benign or malignant cervical squamous epithelium. It is

FIGURE 23.10. Clear cell carcinoma. A tubulocystic pattern with a lining of hobnail cells is present in this case, but other tumors may be solid or papillary, lined by clear or hobnail cells.

often associated with cervical stenosis, pyometra, and chronic inflammation. About 60% of the cases have been confined to the uterus, and the prognosis for these patients has been relatively good (279). In contrast, less than 15% of women with advanced-stage disease have survived 2 years after diagnosis. Histologic grade does not appear to correlate with the probability of survival.

Undifferentiated Carcinoma. Undifferentiated carcinoma of the endometrium has no glandular, squamous, or sarcomatous differentiation in routinely stained sections. Most contain epithelial antigens detected by immunologic stains. Selected cases may contain argyrophilic cells or neurosecretory granules demonstrated by immunohistochemical stains or electron microscopy. Neurosecretory products are apparently not released into the patient's circulation or are not in an active form because no affected women have manifested symptoms. Neuroendocrine granules, therefore, have no clinical or prognostic significance (284,285).

A *glassy cell carcinoma* has also been described, which comprises less than 1% of endometrial carcinomas. It is characterized by cytoplasm that has a ground-glass appearance, as in the cervix. Although few cases have been reported, like serous and clear cell carcinomas, glassy cell carcinoma appears to be aggressive (286,287).

Mixed Cell Type. If an endometrial carcinoma manifests two or more different cell types, each representing at least 10% or more of the tumor, the term *mixed cell type* is appropriate.

Metastatic Carcinoma to the Endometrium. Malignancies in other organs may metastasize to the endometrium. The most common extragenital sites are breast, stomach, colon, pancreas, and kidney, although any disseminated tumor could involve the endometrium. The ovaries are the most likely genital sources of metastasis. Metastatic carcinoma presents as abnormal vaginal bleeding, and the initial specimen for evaluation is usually a biopsy or curetting. Although the metastatic disease may appear as a large focus, individual and small groups of malignant cells may subtly intermingle with normal endometrium or myometrium. Lymphatics are usually involved. Special stains for mucin, CEA, or melanin may suggest that the cells are not of endometrial origin. In some instances, unusual cell types, such as signet-ring cells, may be present, suggesting a metastasis from the gastrointestinal (GI) tract. It is uncommon but not exceptional for the endometrial sample to be the first indication of an occult primary lesion (288,289).

Simultaneous Tumors. Cancers of an identical cell type may be discovered in the ovary and endometrium simultaneously (290). Usually, the primary site is assigned to the area having the largest tumor mass and most advanced stage. In certain situations, primary malignancies in the endometrium and ovary may coexist. This "field effect" of the "extended müllerian system" may occur in 15% to 20% of endometrioid carcinomas of the ovary (291,292). In a review of a GOG study of 74 patients with simultaneously detected endometrial and ovarian carcinoma with disease grossly limited to the pelvis, only 16% of women suffered a recurrence of disease, with a median follow-up of 80 months. This group of patients was atypical, with 86% having endometrioid histology in both sites. Recurrence was statistically related to the presence of microscopic metastases or high histologic grade (293).

Carcinomas of more advanced histologic grade and cell type are more difficult to assign to the field effect because of a higher probability of invasion and metastasis at the time of surgery (245). If the endometrial tumor is less than 5 cm in diameter, the ovarian lesion is unilateral, invasion is less than the middle third, vessels are not involved, and the endometrial carcinoma is well differentiated, metastasis to the ovary is unlikely (294).

MOLECULAR ALTERATIONS IN THE PATHOGENESIS AND PROGRESSION OF ENDOMETRIAL ADENOCARCINOMA

Deletions or mutations of the *PTEN* gene, and microsatellite instability (MSI) due to hypermethylation of the promoter for the mismatch repair gene, *bMLH1*, are both relatively common and early events in the development of a significant proportion of endometrioid adenocarcinomas. In contrast, these molecular alterations do not appear to be critical in the pathogenesis of serous or clear cell carcinoma. However, mutations in the p53 gene are found with high frequency not only in invasive serous carcinoma but also in endometrial intraepithelial carcinoma (270,295), the noninvasive precursor of serous carcinoma, suggesting that a different pathway is followed in the development of the second type of endometrial adenocarcinoma.

The function of the tumor-suppressor gene *PTEN* (MMAC1) includes inhibition of cell migration, spreading, and adhesion (296–300). The *PTEN* gene is located on chromosome 10q23 and about 40% of endometrial carcinomas display loss of heterozygosity of chromosome 10q23, which suggests the involvement of *PTEN* in this disease (296,301). *PTEN* mutations in 30% to 50% of endometrial carcinoma tumors make this the most frequent genetic alteration known in this disease (302–304). Risinger et al. (305) have in one study shown that inactivation of *PTEN* by mutation is associated with early disease in contrast to the study of Steck et al. (306) where *PTEN* gene alteration was linked to an advanced disease group.

MSI caused by shifts in allelic electrophoretic mobility results from replication error of repeated sequences (307). It was first described in HNPCC. One of the most common extracolonic tumors associated with this disease is endometrial cancer, and MSI has been demonstrated in both hereditary and sporadic tumors (308). MSI in endometrial cancer has been reported to be between 9% and 43% (309–313). In 71% to 92% of sporadic endometrial carcinoma, MSI has been found to be associated with hypermethylation of the *bMLH1* promoter region, whereas it seems to be less common in the promoter region of *bMSH2* (314,315). It is likely that methylation of the promoter region is an important mechanism of *bMLH1* gene inactivation in endometrial carcinoma

(316–320) and a precursor to MSI. Too few studies have been done to reach any conclusion regarding the importance of MSI as a prognostic factor in endometrial cancer.

TP53 is a tumor-suppressor gene, the product of which is a protein involved in the regulation of the cell cycle at the G₁ checkpoint, permitting replication of cells that have acquired various mutations (321). Mutations of the p53 gene often result in a protein with a longer half-life, which accumulates in the cell. Up-regulation of wild-type (i.e., nonmutated) p53 may occur after DNA damage and also results in overexpression that is detectable by immunohistochemistry. This appears to be an early event in the development of serous carcinoma, but it is a late event in endometrioid carcinomas for which it serves as an indicator of poor prognosis. In addition to the very frequent overexpression of p53 protein in serous carcinoma (322), it has also been related to a higher FIGO stage, clear cell histology, higher histologic grade, and increased depth of myometrial invasion (276,323–335). Lundgren et al. (336) studied p53 in relation to clinicopathologic variables in 376 consecutive patients with endometrial cancer stages I-IV. p53 overexpression was found to be a strong significant factor with regard to relapse-free survival in univariate analysis, but it failed to retain its significance when submitted to multivariate analysis.

In contrast, p53 mutations are not often found in low-grade endometrioid tumors (337). This suggests that different subgroups of endometrial cancers have different genetic pathways. Much more work is needed to understand the genetic mechanics at play and to translate this into use within the clinical and therapeutic field (338).

HER2/neu is a proto-oncogene, the product of which is a transmembrane growth factor receptor, p185erb-2, which shares some homology with the epidermal growth factor receptor. It is normally expressed at low levels in the cycling endometrium. Gene amplification and/or overexpression occurs in about 20% to 40% of endometrial carcinomas, and has been associated with advanced stage (339), decreased differentiation, aggressive cell types particularly including the clear cell type (340–343), and deep myometrial invasion (327). The significance of HER2/neu amplification or overexpression as a predictor of survival is somewhat unclear, with no apparent association of overexpression to outcome being identified in several studies (322,330,340,344,345), but a statistically significant relationship in most others (326,330,341,346–349) even after adjusting for other known risk factors (326,341,347). In addition to its potential utility as an indicator of poor prognosis, systemic therapy using antibodies directed against the HER2/neu protein is currently being investigated for patients with tumors that express the protein at high levels.

Abnormal expression of the oncogenes *beta-* and *gamma-catenin* and *E-* and *P-cadherin* may play a critical role in the initiation and progression of endometrioid neoplasia (350,351). Moreno-Bueno et al. (351) have evaluated the immunoreactivity of *beta-* and *gamma-catenin* and *E-* and *P-cadherin* in 149 patients with premalignant and malignant endometrioid lesions to correlate their membranous expression with clinical pathologic data. Their data indicate that abnormal expression of catenin and cadherin was common in premalignant and malignant endometrial lesions. Nonendometrioid endometrial cancer showed a greater reduction in *E-cadherin* expression, up-regulation of *P-cadherin*, and loss of heterozygosity at 16q21 than endometrial cancers. In contrast, nuclear accumulation of *beta-catenin* was frequently associated with a gene mutation characteristic of endometrioid lesions and may be an early event that is present in atypical endometrial hyperplasia. Reduced *E-cadherin* expression in endometrioid carcinomas is related to advanced stages, indicating a role for this molecule in tumor progression. Nuclear *beta-catenin* expression was found in

31.2% of endometrioid cancers and 3% of nonendometrioid cancers ($p = 0.002$) and was significantly associated with *beta-catenin* gene exon 3 mutations. *Beta-catenin* gene exon 3 mutations were associated with the endometrioid phenotype and were detected in 14 (15%) endometrioid cancers, but none of the nonendometrioid cancers ($p = 0.02$). *Gamma-catenin* nuclear expression was found in ten endometrial cancers. It was not associated with the histologic type but was associated with more advanced stages ($p = 0.04$) (350).

The activation of *RAS* proto-oncogenes through either point mutations or gene amplification has been identified in various malignant tumors. Mutations in the *K-ras* oncogene have been reported in endometrioid cancer and also in endometrial hyperplasia, suggesting that *K-ras* activation may be an early event in the development of endometrioid malignancy. Mutations in codon 12 of *K-ras* occur in only about 10% to 15% of endometrial carcinomas, and their significance is unknown. In most studies, the presence of *K-ras* mutations has not been related to stage, grade, depth of invasion, or survival (352–355).

Further studies have identified mutations in several tumor-related genes such as p16, *bMLH1*, *bMSH2*, and *bMSH6* in endometrial cancer (356–358). Salvesen et al. (359) have shown that loss of nuclear p16 protein expression is not associated with promoter methylation but defines a subgroup of aggressive endometrial carcinoma with a poor prognosis and found to be a strong independent prognostic factor.

PATHOLOGIC FACTORS OF PROGNOSTIC SIGNIFICANCE

Pathologic information has been used to estimate risk of nodal metastasis and to define prognosis (recurrence, survival) in endometrial cancer. Prognostic factors have been identified within each stage of endometrial cancer, and the discussion of prognostic factors is probably best served by discussing factors within comparably staged groups, more so than as isolated factors. For example, in GOG 99, which compared observation to pelvic radiation therapy in patients with stage I-II endometrial cancer and pathologically negative lymph nodes, a model based on combinations of patient age and tumor grade, depth of invasion, and lymphovascular space invasion (LVSI) could predict patients at highest risk for recurrence (143).

Predicting Nodal Disease

Based on pathologic information available at the time of surgery, the risk for nodal metastasis may be estimated. Physicians who selectively perform nodal dissections frequently do so based on the presence of uterine risk factors that suggest the potential for nodal disease. In patients who did not undergo a nodal dissection at the time of hysterectomy, decisions to offer radiation therapy are commonly based on the estimation of risk for nodal disease based on uterine risk factors. In the surgical pathologic study GOG 33, pelvic and para-aortic nodal disease was more frequent with increasing grade (percentage of pelvic nodal metastases: 3% grade I, 9% grade II, 18% grade 3), depth of invasion (1% endometrium only, 5% inner one third, 6% middle one third, 25% outer one third myometrial invasion), and LVSI (27% with LVSI, 7% without LVSI) (60). Pelvic and para-aortic nodal metastases were also more common with cervical involvement, when peritoneal cytology was positive, and when extranodal (adnexal, intraperitoneal sites) disease was found. In a multivariate model, grade, depth of invasion, and intraperitoneal

disease were independent predictors of pelvic nodal disease. In a further analysis of patients participating in GOG 33, 47 of 48 patients with para-aortic nodal disease had one or more factors of palpably enlarged para-aortic nodes, grossly positive pelvic nodes, gross adnexal disease, or outer one-third invasion (62). Despite the use of pathology to help predict nodal disease, many believe that routine lymph node assessment is superior as it provides actual information on nodal status, as opposed to an estimate, which can then be used to tailor therapy.

Prognostic Factors

FIGO Stage

Prognostic factors may be used to categorize patients into high- and low-risk groups and to guide the use of adjuvant therapies. Understanding these factors also allows for the development of novel strategies to reduce risk of recurrence or alter patterns of disease failure. Overall, the patients at highest risk for recurrence and death have spread of disease outside of the uterus, which is reflected by FIGO stage (62). The prognostic utility of surgicopathologic stage has been confirmed in multiple studies of large numbers of patients, using both univariate and multivariate analysis (60,232,271,360–365). FIGO surgical stage is often the single strongest predictor of outcome for women with endometrial adenocarcinoma in studies using multivariate analyses (271). Although the FIGO clinical staging system of 1971 was generally useful, retrospective comparison of the two methods demonstrated the clear superiority of surgicopathologic staging over clinical staging in predicting outcome.

Patients with intraperitoneal or distant metastases (stage IV) have the poorest prognosis with 5-year survival ranging from 20% to 25% (5). In GOG 122 comparing whole abdominal radiation therapy to doxorubicin/cisplatin chemotherapy as primary therapy for endometrial cancer patients with <2 cm residual disease stage III-IV, stage IV (compared to stage III) disease was an independent predictor of shorter progression-free survival (PFS) (hazard ratio [HR] 2.2.9) and survival (HR 1.9) (8). Gross intraperitoneal spread frequently indicates the presence of larger tumor burden as many patients with intraperitoneal disease also have adnexal and nodal disease. In GOG 33, 51% of patients with gross intraperitoneal spread had positive pelvic nodes, whereas only 7% without spread had positive pelvic nodes (60). Prognosis may be modified by the volume of residual disease after cytoreductive surgery (220–222).

Patients with nodal metastases (stage IIIC disease) also have poorer prognosis compared to node-negative populations. FIGO data shows 5-year survival to be 57% in stage IIIC patients compared to 74% to 91% when nodes are negative (stage I-II) (5). Patients with positive pelvic but negative para-aortic nodes have a better prognosis compared to those with para-aortic disease (62,366). Two retrospective series have also suggested that patients with nodal disease in addition to positive cytology, adnexa, or serosa have poorer PFS or survival compared to those patients with positive nodes alone (155,366). Lymphadenectomy (154,175,182), complete surgical resection of bulky nodes (367), and use of chemotherapy (8,152,368) have been suggested to improve outcomes in patients and modify the prognostic effect of nodal disease.

Patients with stage IIIA disease represent a heterogeneous population having adnexal, peritoneal cytology, and/or serosal involvement, but with negative lymph nodes. Positive peritoneal cytology or adnexal involvement may be prognostic factors, but must be interpreted in the setting of whether a patient was completely staged or not. In the GOG 33 study,

12% of all patients had positive cytology, and of these, 25% had positive pelvic nodes and 19% had metastases to para-aortic lymph nodes (60). Six percent of clinical stage I-II patients have spread of tumor to the adnexa, and of these, 32% have pelvic node metastases compared with 8% pelvic node positivity if adnexal involvement is not present (60). Twenty percent have positive para-aortic node metastases, which is four times greater than if adnexal metastases were not present.

For patients who are completely staged and found to have no extrauterine disease, 4% to 6% of patients have positive cytology as an isolated finding (60,191,369). Published opinions are mixed about the significance of this finding (370–378). Kadar et al. (379) found that positive peritoneal cytology had an adverse outcome on survival only if the endometrial cancer had spread to the adnexa, peritoneum, or lymph nodes, but not if disease was confined to the uterus, suggesting that not all cells that are found in the peritoneal cavity are capable of independent growth. Positive peritoneal cytology associated with extrauterine disease is a marker for aggressive disease and carries a worse prognosis. Cytology appears to carry the same significance as adnexal involvement (380).

Histologic Cell Types

The histologic classification of endometrial adenocarcinoma is important not only because it facilitates the recognition of lesions as carcinoma, but also because the cell type has consistently been recognized as being important in predicting the biologic behavior and probability of survival. Endometrioid adenocarcinoma accounts for the majority of tumors in the uterine corpus and carries a relatively favorable prognosis. Consequently, the virulence of other cell types is usually related to endometrioid adenocarcinoma.

Adenocarcinoma with squamous differentiation is similar to typical endometrioid adenocarcinoma with respect to the distribution by age and frequency of nodal metastasis, and is associated with a slightly increased probability of survival. *Villoglandular carcinoma* has a biologic behavior similar to that of endometrioid adenocarcinoma (242,381). *Serous carcinoma* has been considered an aggressive histologic type, with overall survival rates varying from 40% to 60% at 5 years (5,260,262,274,382–385). *Clear cell carcinoma* also has a highly aggressive behavior, with 5-year survival rates of 30% to 75% (272,273,278,386–389). One of the problems with using histology as a marker for prognosis is that serous cancers are more likely to have spread at presentation than endometrioid tumors. Patients with serous or clear cell tumors present with stage III-IV disease in 41% and 33%, respectively, compared to 14% with endometrioid type (5). Studies suggest that 40% to 70% of serous tumors will have extrauterine spread at presentation; therefore, complete surgical staging is warranted in this tumor type (161). Given this level of disease spread, it is not surprising that unstaged/clinical stage I serous patients appear to have similar prognosis to stage III-IV endometrioid types. Once patients with serous or clear cell tumors are appropriately allocated into the correct stage, the importance of histology appears to be less (390–393). For example, Creasman et al. evaluated FIGO data and showed that patients with stage I serous tumors had comparable outcomes to those with stage I, grade 3 endometrioid tumors. Five-year survival for stage IB and IC serous tumors was 81% and 55% compared to 84% and 66% for grade 3 tumors (393). In advanced and recurrent endometrial cancer patients participating in phase 3 GOG chemotherapy trials, response rate to chemotherapy was not associated with histologic type, and serous tumor type was not independently associated with PFS (17).

Grade

The degree of histologic differentiation has been considered to be an indicator of tumor spread. The GOG and other studies have confirmed that as grade becomes less differentiated, there is a greater tendency for deep myometrial invasion and, subsequently, higher rates of pelvic and para-aortic lymph node involvement (60,394–396). Survival has also been consistently related to histologic grade, and in a GOG study of more than 600 women with clinical stage I or occult stage II endometrioid adenocarcinoma, the 5-year relative survival was as follows: grade 1% to 94%; grade 2% to 84%; grade 3% to 72% (62). In patients with early-stage endometrial cancer participating in the Post Operative Radiation Therapy in Endometrial Carcinoma (PORTEC) trial, the risk of cancer-related death for patients with grade 3 tumors was 4.9 compared to grade 1–2 tumors (149).

Myometrial Invasion

Deep myometrial invasion is one of the more important factors correlated with a higher probability of extraperitoneal tumor spread, treatment failure, and recurrence, and with diminished probability of survival (Fig. 23.11) (143,360,397,398). In a GOG study of over 400 women with clinical stage I and occult stage II endometrioid adenocarcinoma, the 5-year relative survival was 94% when tumor was confined to the endometrium, 91% when tumor involved the inner third of the myometrium, 84% when the tumor extended into the middle third, and 59% when the tumor invaded into the outer third of the myometrium (62). Even in node-negative patients, deep myometrial invasion retains prognostic information. For example, Mariani et al. reported that for stage I (node-negative) patients, deep invasion (>66% myometrial invasion) was an independent predictor for recurrence and distant site of failure (399).

Lymphovascular Space Invasion

Several studies have suggested that lymphatic space invasion (LVSI) is a strong predictor of recurrence and death, and is independent of depth of myometrial invasion or histologic differentiation (Fig. 23.12) (271,400–403). In one investigation of FIGO stage I endometrial adenocarcinoma, 9 of 15 patients with LVSI died of tumor, whereas none of the 78 without identified vascular invasion died of cancer (400). Zaino et al. (365) found that LVSI was a statistically significant indicator of death from tumor in early clinical stage but not early surgical

FIGURE 23.11. Myometrial invasion by endometrial adenocarcinoma may be accompanied by a desmoplastic reaction, but often no such reaction is present, as in this case.

FIGURE 23.12. Lymphatic or capillary invasion by endometrial adenocarcinoma. Nests of neoplastic cells occupy the lumen of an endothelial-lined space.

stage endometrial adenocarcinoma. This suggests that lymphatic invasion helps to identify patients likely to have spread to lymph nodes or distant sites, but that its importance is diminished for those in whom thorough sampling of nodes has failed to identify metastasis. Vascular space invasion or capillary-like space (CLS) involvement with tumor exists in approximately 15% of uteri containing adenocarcinoma (60,401,403). Pelvic lymph nodes are positive in 27% of cases, which is four times more often if malignant cells are found in the CLS than if absent. The risk of para-aortic node metastases when LVSI was present was 19%, which is a sixfold increase over negative CLS involvement (60). Lymphovascular invasion is identified in 35% to 95% of serous carcinomas of the endometrium, where it has generally been associated with an elevated risk of tumor recurrence or death from disease (262,382,384).

Patterns of Failure

Another way to approach pathologic information is to understand the pathologic relationships that predict particular patterns of failure. For example, in patients with pathologic negative-node, stage I endometrial cancer, pelvic sidewall recurrences are rare, and failures occur most frequently at the vaginal cuff or at distant sites (143,404,405). High-risk stage I patients who do not undergo nodal dissections have both pelvic sidewall and distant sites of failure, even with routine use of radiation therapy (153). Patients with node-positive disease frequently have recurrences at distant sites, with rare intra-abdominal failures (155,156). Patients with stage IV/intraperitoneal disease most commonly fail in the peritoneal cavity. The implications of patterns of failure data are that we may choose our postoperative therapies better by defining patterns of failure for a particular stage distribution or based on the presence of risk factors. The Mayo Clinic group has advocated this approach following a review of patterns of failure data from their group (399,406–409). For example, these investigators suggested that hematogenous, lymphatic, and peritoneal failures could be predicted based on pathologic factors, and that therapy should be directed to reduce failures at these sites depending on pathologic information (61). Whether their finding can be validated in a prospective manner, or if existing therapies effectively control disease at particular sites needs to be evaluated.

GENERAL MANAGEMENT

Results of Standard Therapy and Their Sequelae

Early uncontrolled trials suggested that progestin therapy after surgery or irradiation was associated with a decreased risk of recurrence in patients with disease confined to the uterus (410). However, large prospective, randomized trials failed to show a survival advantage (411–413). Radiation therapy has been and remains the standard adjuvant treatment modality for most patients at risk for recurrence. This standard continues to evolve, however. An older, poorly designed adjuvant cytotoxic chemotherapy showed no benefit for patients treated with single-agent doxorubicin and arrested interest in adjuvant chemotherapy for many years (414). Recently, two prospective trials comparing radiation therapy to chemotherapy have since shown similar outcomes for patients treated with chemotherapy or radiation therapy (415,416). Adjuvant chemotherapy improved PFS and survival in patients with advanced-stage disease compared to whole abdominal radiotherapy, suggesting an important role for first-line therapy that includes chemotherapy (7). Current research focuses on whether outcomes may be improved by adding chemotherapy either sequentially or concomitantly with radiation.

ADJUVANT RADIATION THERAPY

Radiation therapy plays a significant role in the management of endometrial cancer. It is often used as an adjuvant treatment after surgery or as definitive treatment for patients who are medically inoperable or with local recurrence. In the past, most patients were treated with preoperative intracavitary brachytherapy with or without external beam radiotherapy followed by hysterectomy. This approach is not without its merit, especially in patients with gross cervical involvement. However, most patients nowadays undergo surgery first; then, depending on the prognostic features obtained from the pathology review, the need for radiotherapy is determined.

Early-Stage Disease

Most of the data on adjuvant radiation in endometrial cancer pertain to patients with early-stage (I-II) disease. The role of radiation in this group of patients, however, has been undergoing significant scrutiny in the last 10 years. Most of the debate focuses on the benefit of adjuvant radiation and to a lesser extent on the type of radiation that needs to be used.

Benefit of Adjuvant Radiation

Two prospective, randomized trials compared surgery alone to surgery and postoperative external beam radiation. The first trial was conducted by the GOG (study 99) where 392 patients with stage IB-IIB endometrial cancer who underwent total abdominal hysterectomy/bilateral salpingo-oophorectomy (TAH/BSO) and pelvic/para-aortic lymph node sampling were randomized to observation ($n = 202$) or postoperative pelvic radiation ($n = 190$) to a total dose of 50.4 Gy in 28 fractions (143). With a median follow-up of 69 months, the 4-year survival rate was 92% in the radiation arm compared with 86% in the observation arm (Relative hazard: 0.86; $p = 0.557$). The

estimated 2-year cumulative incidence of recurrence was 3% versus 12% in favor of the irradiation arm (RH: 0.42; $p = 0.007$). Specifically, the rate of vaginal recurrence was 6.4% (13 out of 202) in the surgery alone arm compared to 1.05% (2 out of 190) in the radiation arm. Of interest, these two patients were randomized to radiation but refused it. The second trial was the PORTEC study where 714 patients with stage IB grade 2,3 and IC grade 1,2 were randomized after TAH/BSO and no lymph node sampling to observation ($n = 360$) or pelvic radiation ($n = 354$) to a total dose of 46 Gy in 23 fractions (149). With a median follow-up of 52 months, the 5-year vaginal/pelvic recurrence rate was 4% in the radiation arm compared to 14% in the observation arm ($p < 0.001$). The corresponding 5-year survival rates were 81% and 85%, respectively ($p = 0.37$).

Despite the fact that adjuvant radiation significantly improved locoregional control, most of the debate focuses on the lack of improvement in overall survival. Obviously, the endpoint of overall survival is the gold standard for any randomized trial in cancer, but when dealing with early-stage endometrial cancer, the data should be interpreted with caution. First, in GOG 99, the primary endpoint was not overall survival but rather progression-free survival, which was significantly better in the radiation arm. Second, because of the relatively high incidence of other comorbidities such as hypertension, diabetes mellitus, and obesity as well as other cancers, the chance of dying from an intercurrent illness is as high if not higher than dying from endometrial cancer. In the radiotherapy (RT) arm of the PORTEC trial (149), the 8-year mortality rate from endometrial cancer was 9.6% compared to 14.4% from other causes and 5.3% from other cancers. In the no-RT arm, the corresponding rates were 7.5%, 10.6%, and 5.3%. Similar data that emerged from GOG 99 were that approximately half of the deaths were due to causes other than endometrial cancer or treatment. This led the authors of GOG 99 to state the following: “With this number of intercurrent deaths in both arms, even if RT reduces the risk of endometrial cancer–related deaths, the size of this trial is not adequate to reliably detect an overall survival difference.” Thus, it is clear that the competing causes of death in this group of patients who have a low mortality rate to start with make overall survival a very elusive endpoint to attain. Third, even in patients who die from endometrial cancer, the most common cause is distant rather than local relapse. In the PORTEC trial, the 8-year mortality rate from local versus distant relapse was 1.1% and 7.9%, respectively, in the RT group and 2% and 5.2% in the surgery alone group (149). It is unrealistic to expect a local treatment modality such as radiation to alter this pattern of relapse. Fourth, in both GOG 99 and PORTEC trials most of the patients did not have poor prognostic features, thus making it difficult to demonstrate any survival advantage to adjuvant radiation. When the impact of adjuvant radiation in GOG 99 was assessed in the subset of patients with high-risk features (based on age, grade, depth of myometrial invasion, and presence of lymphovascular invasion) the death rate was somewhat lower in the radiation arm (RH: 0.73; 90% CI, 0.43 to 1.26). Lee et al. in their analysis of the SEER data also showed an overall survival advantage to pelvic radiation for patients with IC grade 1 and grade 3/4 ($p < 0.001$) endometrial cancer over those treated with surgery alone. This survival advantage of adjuvant pelvic radiation was significant even in patients who had surgical lymph node staging (417). All these issues need to be considered when assessing the benefit of adjuvant radiation. Such debate is not new in the field of oncology, but it is important to note that other oncologists treating cancers of the breast or rectum, to name a few, when faced with similar results from prospective, randomized trials, have recognized the importance of a multimodality approach.

Type of Radiation

There are two types of radiation (intravaginal brachytherapy or pelvic external beam radiation) that could be used either alone or in combination for early-stage endometrial cancer. Over the last three decades, the debate about the type of radiation to use has undergone a full circle. In the 1970s and mid-1980s, there was a shift from intravaginal brachytherapy alone to pelvic radiation plus intravaginal brachytherapy. Then, in the late 1980s and early 1990s, there was a shift toward pelvic radiation alone. More recently, and with the increase in surgical lymph node staging, there has been resurgence in the use of intravaginal brachytherapy alone.

Intravaginal Brachytherapy Alone or Combined With Pelvic Radiation. Aalders et al. (418) reported on 540 patients with stage IB-IC endometrial cancer who underwent TAH/BSO without lymph node sampling, and postoperative intravaginal brachytherapy to 60 Gy to the vaginal mucosa. The patients then were randomized to observation ($n = 277$) or to supplemental pelvic radiation to 40 Gy ($n = 263$). A significant reduction in local recurrence rates was seen with the addition of pelvic radiation (1.9% vs. 6.9%; $p < 0.01$). With regard to overall survival, there was no significant difference between the two arms of the study, but in the subset of patients with grade 3 disease and deep myometrial penetration, there was a survival advantage (cause-specific survival) of 18% versus 7% in favor of the pelvic radiation arm (418). The data from this trial somewhat contributed to the shift in treatment policies from intravaginal brachytherapy alone to external beam pelvic radiation.

Pelvic Radiation Alone or Combined With Intravaginal Brachytherapy. Greven et al. (419) reviewed the experience of two institutions in order to compare the outcome of the two approaches. In that study, there were 270 patients with stage I-II endometrial cancer: 173 were treated with postoperative pelvic radiation alone and 97 with a combination of intravaginal and pelvic radiation (419). The corresponding 5-year pelvic control and disease-free survival rates were 96% versus 93% ($p = 0.32$) and 88% versus 83% ($p = 0.41$). This study as well as others called into question whether the addition of vaginal radiation is needed (420,421). A number of other reports (422,423), however, suggest that vaginal vault radiation can be added to pelvic radiation with minimal morbidity and a very low rate of recurrences. Of interest, the two randomized trials (143,149) comparing surgery to adjuvant radiation both employed pelvic radiation alone with a local recurrence of only 2% to 4%. At Memorial Sloan-Kettering Cancer Center (MSKCC), when postoperative pelvic radiation is indicated it is often used alone to a dose of 50.4 Gy.

Intravaginal Brachytherapy Alone. With the increase in surgical lymph node staging, the use of postoperative intravaginal brachytherapy alone regained its appeal, the rationale being that full surgical lymph node staging could potentially eliminate the need for pelvic radiation, whereas vaginal brachytherapy could still address the risk of vaginal cuff recurrence. Several reports in the past 10 years indeed showed a very low rate of recurrence either in the vagina or in the pelvis with such an approach (139,186,424–427).

From the above discussion, it is clear that the options available for patients with early-stage endometrioid endometrial cancer are numerous. Perhaps it is better to consider different options based on the following factors: first, according to stage and grade; second, whether surgical lymph node staging was done; and third, based on the risk of nodal versus vaginal recurrence.

Stage IA Grade 1,2. The risk of pelvic lymph node positivity (60) is $\leq 3\%$ and the 5-year progression-free survival rate in this group is of the order of 95% to 98%. It is unlikely that postoperative pelvic external beam radiation would add anything to the final outcome (422,428). The role of intravaginal radiation in these patients is also of questionable benefit because of an almost negligible risk of vaginal recurrence with surgery alone. Straughn et al. reported no vaginal recurrence in 103 patients with stage IA grade 1,2 treated with surgery alone (404).

Stage IA Grade 3. In GOG 33, there were only eight patients with stage IA grade 3 disease, making it difficult to draw any meaningful conclusion (60). There were no relapses in the three patients receiving postoperative radiation as compared with one failure in the five patients who received no postoperative therapy. The risk of lymph node metastasis in this group of patients is negligible. Straughn et al. reported on eight patients with stage IA grade 3 disease treated with surgery alone, with two of the patients developing isolated vaginal recurrence (404). At MSKCC, these patients are offered either intravaginal brachytherapy alone or observation (Table 23.11).

Stage IB Grade 1,2. This group of patients constitutes the most common stage subgroup of all endometrial cancers. The outcome of patients who have lymph node dissection and no adjuvant radiation seems to be very good. Straughn et al. reported on 296 patients with IB grade 1,2 and found only nine (3%) vaginal recurrences and one (0.3%) pelvic recurrence (404). Horowitz et al. reported on 62 patients who had surgical lymph node staging and received adjuvant intravaginal brachytherapy. There was one (1.6%) vaginal recurrence and no pelvic recurrence (424). In comparison, data from the MSKCC on 233 patients with IB grade 1,2 showed a vaginal recurrence rate of only 1% and pelvic recurrence of 2% using

TABLE 23.11

TREATMENT RECOMMENDATIONS AT MSKCC FOR SURGICALLY STAGED I-II PATIENTS

Stage/grade	1	2	3
IA	Observation	Observation	IVRT or observation ^a
IB	IVRT or observation ^a	IVRT or observation ^a	IVRT
IC	IVRT	IVRT	IVRT or IMRT ^b
IIA	IVRT	IVRT	IVRT
IIB < 50% CSI	IVRT	IVRT	IVRT
IIB > 50% CSI	IMRT	IMRT	IMRT

Note: CSI, cervical stromal invasion; IMRT, intensity-modulated radiation therapy; IVRT, intravaginal radiotherapy.

^aObservation is offered to patients <60 years old and without LVI (lymphovascular invasion).

^bIMRT if outer third invasion and/or positive LVI.

TABLE 23.12

OUTCOME FOR IB GRADE 3 ENDOMETRIAL CANCER AFTER SURGICAL LYMPH NODE STAGING AND INTRAVAGINAL RADIATION THERAPY (IVRT) ALONE

Author	Year	No. of patients	Median F/U	Vaginal rec	Pelvic rec
Fanning (185)	2001	21	52 mo	0%	0%
Horowitz (424)	2002	31	65 mo	0%	0%
Alektiar (429)	2007	21	46 mo	4.8% (1/21)	4.8% (1/21)
Total	—	73	—	1.3% (1/73)	1.3% (1/73)

Note: F/U, follow-up.

postoperative intravaginal brachytherapy alone without routine surgical lymph node staging (429). In addition, Sorbe et al. reported on 110 patients with IB grade 1,2 who were part of a prospective, randomized trial evaluating two different intravaginal brachytherapy doses; the rate of vaginal recurrence was 0.9% and pelvic recurrence 1.8% where pelvic lymph node sampling was not routinely done either (430). Thus, it seems reasonable to suggest that either observation or intravaginal brachytherapy (irrespective of surgical staging) is a reasonable option. But when deciding on whether adjuvant radiation is needed, it is important to address three issues. First, older patients tend to have higher rates of relapse. In the study by Straughn et al., eight of the ten vaginal/pelvic recurrences were in patients ≥ 60 years old (404). Second, patients with lymphovascular invasion (LVI) have a higher chance of vaginal recurrence as demonstrated by Mariani et al. (406) who reported on 508 patients with stage I endometrial cancer treated with surgery alone (152 out of 508 were stage IA). The presence of LVI increased the vaginal relapse rate from 3% to 7% ($p = 0.02$). Third, often the indications for adjuvant radiation are rather arbitrarily based on the amount of myometrial invasion defined in thirds and on whether the tumor is grade 1 versus 2. Yet the amount of myometrial invasion in this group of patients and whether an endometrial cancer is assigned as grade 1 as opposed to 2 in general do not appear to be significant predictors of outcome (431,432). At MSKCC, patients with IB grade 1,2 without LVI and < 60 years old are offered observation or intravaginal radiation while those with LVI or ≥ 60 years old are offered intravaginal radiation.

Stage IB Grade 3 to IC Grades 1,2,3. Up until the last 10 years, most data in the literature on this group of patients were based on pelvic radiation either alone or in combination with intravaginal brachytherapy (421,422,433,434). But with the increase in surgical lymph node staging, a shift has occurred with regard to the role of radiation for stage IB grade 3 and even in stage IC disease. Therefore, the treatment decision is primarily based on whether the patient had surgical lymph node staging. The adequacy of the lymph node sampling/dissection should, at a minimum, meet the GOG guidelines of sampling the obturator, external iliacs, internal iliacs, common iliacs, and para-aortic lymph node stations and the minimum number of nodes sampled should be ≥ 10 .

Surgically Staged Patients. For patients with IB grade 3 disease the data on intravaginal brachytherapy alone after surgical staging is encouraging (Table 23.12). The average rate of vaginal recurrence and pelvic recurrence is 1.3% for both. This compares favorably with the data from the PORTEC trial where the 5-year rates for vaginal and pelvic recurrence, in the subset of patients with IB grade 3 disease treated with pelvic radiation ($n = 35$), were 0% and 3%, respectively. A

multi-institutional review of 220 patients with stage IC endometrial cancer by Straughn et al. compared adjuvant radiation to no radiation in patients with negative nodes on surgical staging (405). The investigators concluded that adjuvant radiation is not needed even though the 5-year disease-free survival was 74.5% for those treated with surgery alone compared to 92.5% for those treated with adjuvant radiation ($p = 0.0134$). It is unlikely that observation alone, even in those patients with full surgical staging, will be accepted by the radiation oncology community or even the patients when they see an 18% statistically significant difference in disease-free survival from a retrospective study in which most likely those patients with the worst prognostic features were the ones who received radiation.

A better alternative to observation in those patients who had surgical lymph node staging is intravaginal brachytherapy alone (Table 23.13). Several investigators have shown the feasibility of such an approach with an average vaginal recurrence rate of 1.6% and pelvic control rate of 2.1%. Thus, intravaginal brachytherapy alone after surgical staging in patients with IB grade 3 and IC endometrial cancer, the preferred approach at MSKCC, seems to provide better local/regional control than surgery alone and an equivalent control to adjuvant pelvic radiation (424,435–438). The exception to this would be patients with stage IC with a combination of other poor prognostic factors such as age ≥ 60 years, grade 3, outer third myometrial invasion, and LVI where pelvic radiation ought to be considered. In the study from MSKCC of 40 patients with surgical stage IC treated with intravaginal brachytherapy alone, the 2 patients with vaginal/pelvic relapse both had the above-mentioned poor risk factors (436).

No Surgical Lymph Node Staging. In those patients with stage IB grade 3 IC and any grade without surgical lymph node staging, intravaginal brachytherapy alone does not seem to be adequate. In the Aalders et al. randomized trial, the rate of local recurrence in the subset of patients with IB grade 3 to IC was 9.3% (13 of 137) for those treated with brachytherapy alone compared to 1.3% (2 of 146) for those treated with brachytherapy and external radiation (418). This is not surprising since no lymph node sampling was done in that trial. Whether intravaginal brachytherapy needs to be added to external beam therapy in this group of patients is debatable. Weiss et al. reported on 61 patients with stage IC endometrial cancer who were treated with postoperative pelvic radiation alone. With a median follow-up of 69.5 months, there was only one recurrence in the pelvis (1.6%). Their review of the published data from the literature on patients with stage IC showed a pelvic recurrence of 1.04% in 240 patients treated with pelvic radiation alone compared to 0.97% in 301 patients treated with pelvic and intravaginal radiation. Their conclusion was that

TABLE 23.13**OUTCOME FOR IC ENDOMETRIAL CANCER GRADE 1-3 AFTER SURGICAL LYMPH NODE STAGING AND INTRAVAGINAL RADIATION THERAPY (IVRT) ALONE**

Author	Year	No. of patients	Median F/U	Vaginal rec	Pelvic rec

Note: F/U, follow-up; rec=recurrence.

pelvic radiation alone is sufficient, and efforts should focus instead on trying to reduce the risk of distant relapse in this group of patients (439).

Stage II. It is important to recognize the distinction between gross and occult cervical involvement in endometrial cancer. Gross cervical involvement increases the risk of parametrial extension as well as spread to pelvic lymph nodes in a fashion similar to primary cervical cancer. Patients with gross cervical involvement from endometrial cancer could undergo radical hysterectomy and pelvic lymph node dissection or preoperative radiation including pelvic radiation and intracavitary brachytherapy followed by simple hysterectomy. For occult cervical involvement, the treatment often consists of simple hysterectomy with or without lymph node surgical staging and adjuvant radiation. The type of radiation most often utilized is pelvic radiation and intravaginal brachytherapy. Pitson et al. reported on 120 patients treated with such a combination (440). The 5-year disease-free survival rate was 68% and the rate of pelvic relapse was 5.8% (7 of 120).

There are also emerging data on the role of intravaginal brachytherapy alone in patients with occult cervical involvement who also had surgical lymph node staging. The rate of pelvic recurrence in four such series ranged from 0% to 6%, but the data need confirmation on a larger number of patients and longer follow-up (424,426,441,442). Another important distinction to make in stage II endometrial cancer is the difference between glandular versus stromal invasion. Intravaginal brachytherapy alone could be used for surgically staged IIA patients (424,443), whereas those with IIB disease should be treated with pelvic radiation with or without intravaginal brachytherapy boost, especially if there is more than half cervical stromal invasion.

Advanced-Stage Disease

Radiation

The outcome of patients with isolated adnexal involvement (stage IIIA) treated with pelvic radiation is reasonably good. Connell et al. reported on 12 patients treated with postoperative pelvic radiation with a 5-year disease-free survival of 70.9%. The weighted average of 5-year disease-free and overall survival rates from literature review in that study were 78.6% and 67.1%, respectively (444). Patients with isolated serosal involvement (stage IIIA) do worse than those with isolated adnexal involvement. Ashman et al. reported on 15 patients with isolated serosal involvement who were treated with pelvic radiation (445). The 5-year disease-free survival

was only 41.5%. If pelvic node involvement (IIIC) is the only major risk factor, treatment with postoperative pelvic radiotherapy can yield a 60% to 72% long-term survival rate in these patients (156,446,447). Patients with stage IIIC disease, by virtue of para-aortic node involvement, represent a particularly high-risk group. Following surgery, these patients are generally treated with extended field radiation to encompass the pelvis and the para-aortic regions. With this aggressive approach, several investigators have reported 30% to 40% survival rates in small patient populations (448–450). The question of whether it is safe to omit radiation even after adequate surgical lymph node staging in patients with IIIC endometrial cancer was addressed in a study from the Mayo Clinic. Mariani et al. reported on 122 patients with node-positive disease; at 5 years the risk of pelvic recurrence was 57% after inadequate lymph node dissection and/or no RT compared to 10% with adequate lymph node dissection (>10 pelvic nodes and ≥ 5 para-aortic nodes) and radiation. This difference was statistically significant on univariate ($p < 0.001$) and multivariate analysis ($p = 0.03$), indicating the need for postoperative radiation even after adequate surgical staging (182).

The recognition that a significant number of patients with stage III disease fail in the abdomen (407,446) has prompted a number of investigators to evaluate whole abdominal radiotherapy in these patients (451,452). The GOG also did a pilot study (GOG study 94) on patients with maximally debulked stage III and IV disease using whole abdominal radiotherapy to a total dose of 30 Gy at 1.5 Gy per fraction followed by a pelvic boost for an additional 19.8 Gy at 1.8 Gy per fraction. The 3-year disease-free and overall survival rates for the 58 patients with stage III typical adenocarcinoma were 34.5% for both, and for stage IV the corresponding rates were 10.4% and 21.1%, respectively (453). Using a different technique capable of delivering higher doses of radiation to the areas at risk for relapse in the abdomen, Stewart et al. reported 5-year disease-free and overall survival rates of 62% and 67%, respectively, in 62 patients with stage III endometrioid adenocarcinoma (454).

Chemoradiation

In the GOG 122 trial, there were 396 patients with stage III and optimally debulked stage IV disease who were randomized to whole abdomen radiation ($n = 202$) or to doxorubicin-cisplatin chemotherapy ($n = 194$). With a median follow-up of 74 months, there was significant improvement in both progression-free (50% vs. 38%; $p = 0.007$) as well as overall survival (55% vs. 42%; $p = 0.004$), respectively, in favor of chemotherapy (8).

At first glance the results of this trial seem to seal the fate of adjuvant radiation in advanced endometrial cancer; however, before concluding that chemotherapy alone is the answer a closer examination of the data is warranted. First, the overall absolute rate of relapse was 54% in the radiation arm compared to 50% in the chemotherapy arm, a small difference if any, yet the corresponding 5-year progression-free survival rates were 38% and 50% ($p = 0.007$), respectively. Why the discrepancy? The answer is that the 5-year progression-free survival rate for the radiation arm was 38% while the chemotherapy arm has two separate 5-year rates. The first one, called unadjusted, was 42%, which is not that significantly different from the 38% rate with radiation, and the second, called "adjusted for stage," was 50%, which was significantly different from the radiation arm. This led us to the second issue: Was the adjustment for stage warranted? The answer is no. Numerically, there were more patients with lymph node involvement in the chemotherapy than the radiation arm, but having positive lymph nodes was not an independent predictor of poor outcome in this study. Therefore, the adjustment was not warranted, and if any adjustment was needed it should have gone to the radiation arm since there were more patients with positive cytology in this arm, a factor with a hazard ratio of 1.8 (95% CI, 0.89 to 1.55) in predicting poor outcome. Third, what should be made of the significant difference in overall survival? There were 15 deaths unrelated to endometrial cancer or protocol treatment in the radiation arm compared to only 6 in the chemotherapy arm, raising a question about whether the two arms of the study were truly balanced. Another randomized trial comparing adjuvant radiation to chemotherapy (doxorubicin-cisplatin-cyclophosphamide) in patients with stage I-III was recently reported and showed no difference in outcome between the two arms (415). With a median follow-up of 95.5 months, the 5-year disease-free survival was 63% in both arms ($p = 0.44$) and the 5-year overall survival rates were 69% in the radiation arm compared to 66% in the chemotherapy arm ($p = 0.77$). What those two trials show is that chemotherapy at a minimum is equivalent to radiation in this group of patients and ought to be used, not alone, but rather in combination with radiation. Greven et al. reported the results of Radiation Therapy Oncology Group (RTOG) 9708 on 44 patients with stage I-III endometrial cancer who were treated with pelvic radiation and intravaginal brachytherapy given concurrently with cisplatin 50 mg/m² on days 1 and 28 of radiation followed by four cycles of cisplatin (50 mg/m²) and paclitaxel (Taxol) (175 mg/m²). The 4-year disease-free and overall survival for those with stage III disease (66% of patients) were 72% and 77% respectively (455).

SPECIAL SITUATIONS

Stage IIIA Disease (Positive Cytology Without Adnexal or Serosal Involvement)

In this subset of patients, the presence of other adverse features such as aggressive histologies or deep myometrial invasion should be determined first. If they are present, then the patients should be considered to be in a true advanced stage and be treated as such. On the other hand, if they are absent, then the true prognostic value of positive peritoneal cytology is still unclear (456). The literature regarding the benefits of treatment in this setting is mixed; even if treatment is beneficial, the appropriate modality still has to be defined. Based on the concept that the entire peritoneal cavity is at risk, intraperitoneal radioactive colloidal ³²P has been used by some with results that were better than in historic controls (457).

Eltabbakh et al. reported on 27 patients with FIGO grade 1,2 and <50% myometrial invasion who were treated with intravaginal brachytherapy and megestrol acetate (Megace). None of the patients relapsed or died from their disease. Megace was given for 1 year, and at the end of therapy, 24 patients underwent second-look laparoscopy and peritoneal cytology. In 23 patients, the cytology was negative and the remaining patient with persistent positive cytology received an additional year of Megace after which cytology was confirmed to be negative (458).

Definitive Radiation for Inoperable Disease

Patients with medically inoperable stage I-II uterine cancer are usually treated in a fashion similar to those with cervical cancer by using intracavitary applicators with or without pelvic radiation. For patients with clinical stage I grade 1 or 2 and no evidence of myometrial invasion or lymph node metastasis on MRI, intracavitary brachytherapy alone is sufficient. Usually a Fletcher-Suit or Henschke applicator with one or two tandems (depending on uterus size) and ovoids is used to deliver 70 to 75 Gy to point A. The loading of the tandems is usually different than that in cervical cancer. This is done in order to provide wider coverage of the uterus laterally and superiorly. When pelvic radiation is added, the dose is usually 45 to 50 Gy supplemented with 30 to 35 Gy from intracavitary brachytherapy to bring the total dose to point A to 80 to 85 Gy. Rouanet et al. (462) treated 250 patients with endometrial cancer according to this approach, which yielded a 5-year disease-specific survival of 76.5%. An alternative brachytherapy approach would be to use the Hymen or Simon afterloading system, which consists of multiple Teflon tubes that are inserted into the uterine cavity. With such a treatment approach, Grigsby et al. (463) reported that the 5-year progression-free survival rate of patients with clinical stage I disease treated with a combination of external and intracavitary radiotherapy was 94% for grade 1 disease, 92% for grade 2 disease, and 78% for grade 3 disease. More recently, high-dose-rate brachytherapy is also being employed (464,465). For patients with stage IIIB disease (vaginal involvement), an uncommon presentation, these patients are usually not surgical candidates and are also treated with definitive radiation including a combination of external beam and intracavitary/interstitial radiotherapy tailored to the extent of their disease (466).

RADIATION THERAPY TECHNIQUES

Intravaginal Brachytherapy

The purpose of this treatment modality is to deliver the highest dose of radiation to the vaginal mucosa while limiting the dose to the surrounding normal structures such as the bladder, rectum, and small intestines. Intravaginal brachytherapy could be delivered with low-dose-rate ¹³⁷Cs sources, which requires admission to the hospital for a few days. The dose is usually 60 Gy prescribed to the vaginal mucosa or 30 to 35 Gy prescribed to 0.5 cm depth from the vaginal mucosa. The type of applicator used is generally the two ovoids from a Fletcher-Suit applicator, where only the vaginal cuff is irradiated. Alternatively, a cylinder could be used to treat one half to two thirds of the length of the vagina. Occasionally, the whole length of the vagina needs to be treated, especially in patients with grade 3 tumors, which have the tendency for relapse in the distal periurethral region. High-dose-rate brachytherapy using ¹⁹²Ir sources has been shown to be an

attractive alternative to low-dose-rate brachytherapy. The treatment is given on an outpatient basis without the need for anesthesia and without the radiation exposure to medical personnel. At MSKCC, patients start their treatment 4 to 6 weeks postoperatively depending on the vaginal cuff healing. The treatment is given in three fractions of 7 Gy to a total dose of 21 Gy. The interval between each fraction is 1 to 2 weeks. The dose is prescribed to 0.5 cm depth from the mucosal surface. The treatment is usually delivered using a 3-cm diameter cylinder to treat one half to two thirds of the length of the vagina, or the whole vagina in grade 3 tumors. Occasionally, the dose per fraction is lowered to 6 Gy instead of 7 Gy if the diameter of the cylinder is less than 3 cm. This is usually done to avoid a very high dose of radiation to the vaginal mucosa. The dose per fraction is also lowered to 4 to 5 Gy when pelvic radiation is added.

External Beam Radiation

Pelvic Radiation

Most patients are treated in the postoperative setting. At the time of simulation, the small bowel is opacified using oral contrast, a vaginal marker is used to define the vaginal cuff, and the rectum is opacified with barium or CT-compatible contrasts. Patients are usually placed in the prone position to displace the small intestines from the radiation field. The target volume consists of the pelvic lymph nodes, including obturator, external, internal, and lower common iliac groups, and the proximal two thirds of the vagina. High-energy linear accelerators (15 MV) are preferred because of their sparing of the skin and subcutaneous tissue. The ideal beam arrangement with conventional radiation is the four-field pelvic-box technique to reduce the dose to the small intestines and to some extent the bladder and rectum. For the anteroposterior/posteroanterior (AP/PA) fields, the superior border is L5-S1, the inferior border is the bottom of the obturator foramina, and the lateral border is 2 cm beyond the widest point of the inlet of the true bony pelvis. For the lateral fields, the anterior border is in front of the pubis symphysis and the posterior border at least at S2-3. The superior and inferior borders are the same for the AP/PA fields. All fields are treated daily to a dose of 1.8 Gy. A total dose of 50.4 Gy is generally used when pelvic radiation is used alone or 45 Gy when combined with intravaginal brachytherapy.

Extended Field

This technique is mainly used for patients with documented positive para-aortic nodes. The preferred approach is the four-field box technique in order to lower the dose to the small intestines. However, attention should be paid to the dose that the kidneys might receive with the four-field arrangement. The lower border is the same as in pelvic radiation but the upper border is extended usually to the T12-L1 interspace. The typical dose is 45.0 Gy at 1.8 Gy per fraction or 1.5 Gy per fraction if patients develop acute gastrointestinal toxicity.

Whole Abdomen Radiation

The standard approach is AP/PA open fields with five half-value layer (HVL) kidney blocks placed over the PA field only (if patient is lying supine) from the start of the treatment. The dose is usually 30.0 Gy at 1.5 Gy per fraction followed by a 19.8 Gy boost to the pelvis at 1.8 Gy per fraction. The upper border is usually placed 1 cm above the diaphragm, and the lateral borders should extend beyond the peritoneal reflections. The lower border is usually at the bottom of the obturator foramen.

Complications of Radiation

Pelvic Radiation

In the PORTEC randomized trial (149), the overall (grades 1 to 4) rate of late complications was 26% in the RT group compared to 4% in the observation group ($p < 0.0001$). Most of the late complications in the RT group, however, were grades 1,2 (22%) and only 3% were grades 3,4. It is also important to note that many patients in this trial were treated with AP/PA fields in which the overall rate of complications was 30% compared to 21% for those treated with the four-field box ($p = 0.06$). The morbidity rate of pelvic radiation could be reduced even further by using intensity-modulated radiation therapy (IMRT). Mundt et al. demonstrated a significant reduction in acute and chronic gastrointestinal toxicity when IMRT was compared to conventional radiation (467,468). At MSKCC, postoperative IMRT is used for most patients with endometrial cancer who need pelvic radiation (Fig. 23.13).

Whole Abdomen Radiation

The toxicity of whole abdomen radiation is more pronounced than that of pelvic radiation but not as high as expected. In the radiation arm of GOG study 122, the GI toxicity did not exceed 2% for grade 4 and 11% for grade 3, whereas in the chemotherapy arm the corresponding figures were 7% and 13%. Grade 4 liver toxicity was seen in 1% of patients in the radiation arm while the grade 4 cardiac grade toxicity was 4% in the chemotherapy arm (8).

Intravaginal Brachytherapy

The main advantage of intravaginal brachytherapy is its ability to deliver a relatively high dose of radiation to the vagina while limiting the dose to the surrounding normal structures such as the bowels and bladder. This advantage is manifested with the low rate of severe late toxicity seen with this treatment technique, ranging from 0% to 1% (469–471). But such a very low rate of severe complications cannot be taken for granted because special attention needs to be paid to the depth of prescription, the dose per fraction, the length of vagina treated, and the diameter of the cylinder used (472).

FIGURE 23.13. (See color plate section.) Pelvic IMRT demonstrating the sparing of bladder and bowel.

Radiation Therapy for Local Recurrence

Radiation therapy can be curative in a select group of patients with small vaginal recurrences who have not received prior radiation. The 5-year local control rate ranges from 42% to 65% and the 5-year overall survival rate from 31% to 53% (473–475). Creutzberg et al. reported on survival after relapse from the PORTEC randomized trial (476). In patients who were initially randomized to surgery alone ($n = 46$ out of 360), the 5-year survival after vaginal relapse was 65%. But before adopting salvage radiation as a treatment policy for all early-stage endometrial cancer, a few aspects of this trial need to be addressed. First, the 5-year survival rate from the PORTEC trial is much higher than what is reported in the literature. Most likely, the vaginal recurrences in this trial were detected very early, unlike patients in the community. The extent and size of local recurrence in endometrial cancer are very significant predictors of outcome (473). Second, this high rate of salvage pertains only to isolated vaginal recurrence. The rate of survival at 3 years for pelvic recurrence in the PORTEC trial was 0%. Third, although the trial does not mention any data on complications, it is not unrealistic to expect a higher complication rate than what is normally seen with adjuvant radiation. With salvage radiation, external beam RT and brachytherapy are often combined and the doses of radiation required are much higher than those used with adjuvant radiation. A recent study from the M. D. Anderson Cancer Center by Jhingran et al. clearly highlights these issues (477). They reported on 91 patients who were treated with definitive radiation for isolated vaginal recurrence. The 5-year local control and overall survival rates were 75% and 43%, respectively. The median dose of radiation was 75 Gy, which often included external radiation and brachytherapy. The rate of grade 4 complications (requiring surgery) was 9%. Thus, when talking with a patient about adjuvant radiation versus radiation reserved for salvage, these issues need to be addressed and compared to the excellent local control and low morbidity obtained with adjuvant intravaginal brachytherapy.

SYSTEMIC THERAPIES

Endocrine Therapy

Hormonal agents have been found to be valuable, particularly in the patient with recurrent disease, and reviews of their use have been extensively published. Response rates to a variety of

endocrine agents including progestins, antiestrogens, and aromatase inhibitors are presented in Table 23.14 (478–485).

The overall response to progestins is approximately 25%. However, some trials demonstrate lower response rates, usually in the range of 15% to 20%. These studies generally used more rigorous response criteria and had multi-institutional participation. A higher dose of progestin does not appear to increase the response rate. In one randomized trial of 200 mg/d versus 1,000 mg/d of medroxyprogesterone acetate (MPA), the overall response rate was actually 25% versus 15% favoring the low-dose arm (486). The time to treatment failure and median overall survival of the low- versus high-dose regimen, respectively, were 3.2 versus 2.5 months and 11.1 versus 7.0 months, all showing no advantage for an increased dose. Prognostic factors related to response were performance status, grade, and progesterone receptor level. The response rate was only 8% in poorly differentiated tumors. A phase 2 trial of high-dose megestrol (800 mg orally daily) in 63 patients was associated with a response rate of 24% overall, which is similar to lower-dose regimens with doses of 40 mg po qid (487). As in the majority of studies with hormonal agents, response rates were statistically higher in patients with grade 1 or 2 lesions (37%) versus grade 3 lesions (8%); $p = 0.02$ (400). In addition to grade, a long disease-free interval (exceeding 2 or 3 years) and positive estrogen or progesterone receptor status have all been associated with an increased frequency of response (Table 23.15) (478,481,486,487). Age, location of metastatic disease, number of metastatic sites, prior therapy, and weight have also been analyzed by several investigators, but they have not been convincingly linked with response.

Tamoxifen has been investigated in patients with recurrent disease in several studies (484,488). Results have varied, but in general, response rates have been modest in untreated patients. A GOG study evaluated 68 patients with advanced or recurrent disease receiving tamoxifen at 20 mg po bid and showed an overall response rate of 10% (90% CI, 5.7 to 17.9) (484). The median progression-free interval was short at 1.9 months (90% CI, 1.7 to 3.2 months) and the overall survival was 8.8 months (90% CI, 7.0 to 10.1 months). One small randomized phase 2 study comparing megestrol acetate to megestrol acetate with tamoxifen showed no advantage in response rate for the combination, with response rates of 20% versus 19%, respectively (489). The lack of synergistic response is supported by observations of endometrial carcinoma treated in a nude mouse model. Tumors treated with medroxyprogesterone or tamoxifen plus medroxyprogesterone were devoid of progesterone receptor during the growth inhibitory and regrowth phase of the tumor resulting from receptor down-regulation (490). The possibility

TABLE 23.14

RESPONSE TO ENDOCRINE THERAPY

Hormonal agent	References	Average dose	Response rate (%)	Range (%)
Hydroxyprogesterone caproate (Delalutin)	478,479	1–3 g IM q wk	29	9–34
Medroxyprogesterone acetate (Provera)	476	200–1,000 mg IM q wk or po qd	22	14–53
Megestrol acetate (Megace)	479	40–800 mg po qd	20	11–56

TABLE 23.15

RESPONSE TO PROGESTATIONAL THERAPY AS A FUNCTION OF TUMOR GRADE

Study	Treatment	Grade	N	RR
Podratz 1985	Various progestins	1	10	40%
		2	71	15%
		3	73	2%
Lentz 1996	MA 800 mg/d	1	14	37% (grade 1-2)
		2	17	
		3	27	8%
Thigpen 1999	MPA 200 mg/d vs. 1,000 mg/d	1	59	37%
		2	113	23%
		3	127	9%
Whitney 2003	Tam 40 mg/d + alternating weekly MPA 200 mg/d	1	15	Overall RR 33%
		2	17	
		3	27	
Fiorica 2003	MA 160 mg/d × 3 wk, alternating with Tam 40 mg/d × 3 wk	1	16	38%
		2	17	24%
		3	22	22%

Note: MA, megestrol acetate; MPA, medroxyprogesterone acetate; RR, response rate; Tam, tamoxifen.

of alternating tamoxifen with megestrol acetate in order to exploit the recruitment of progesterone receptors by tamoxifen is an interesting strategy. The GOG performed a phase 2 study with 56 patients with advanced or recurrent endometrial cancer who had not previously received chemotherapy or hormonal manipulation (491). Patients were treated with megestrol acetate at 160 mg/d for 3 weeks alternating with tamoxifen 40 mg po qd for 3 weeks. An overall response rate of 27% (90% CI, 17.3 to 38.4) with a 21.4% complete response rate was seen, with the duration of response exceeding 20 months in 8 of 15 responders. The response rate was 38% for patients with grade 1 disease and 22% for those with grade 3 disease. In another phase 2 GOG study, a similar patient population was treated with tamoxifen 40 mg po daily plus alternating weekly cycles of medroxyprogesterone acetate 200 mg po daily (492). Of the 58 evaluable patients, the response rate was 33% (6 complete, 13 partial). Although these phase 2 results are intriguing, a randomized study would be required to determine if alternating hormones is superior to single-hormone approaches. Positive receptor status has been associated with improved disease-free and overall survival rates (126,493,494). These data indicate that the receptor status provides important biologic information and that receptor-positive tumors tend to be better differentiated and slower growing than are their receptor-negative counterparts. Chemotherapy had no effect on hormone receptor capacity in a nude mouse model of xenografted endometrial cancer (495). Other factors, such as changes in vaginal cytology during treatment (496), and results in the subrenal capsule chemosensitivity assay (497) and in the nude mouse model (498) may help predict response to progestins.

Several studies have evaluated gonadotropin-releasing hormone analogs in patients with metastatic endometrial cancer. Gallagher et al. (499) noted one complete and five partial responses to leuprolide or goserelin in 17 patients (35% response; 95% CI, 13% to 58%) with metastatic disease. Of note, the duration of remission ranged from 7 to 30 months, and 14 of the 17 patients had been previously treated with progestins. Another report described four responses in seven postmenopausal patients with endometrial cancer treated with goserelin (500). *In vitro* studies in human endometrial cancer cell lines have suggested that such growth inhibition may have been due to apoptosis (501). The GOG recently studied goserelin at 3.6 mg subcutaneously

monthly in 40 patients with advanced or recurrent disease. Seventy-one percent of patients had received prior radiotherapy. There were two complete (5%) and three partial (7%) responses with an overall response rate of 11% (95% CI, 4% to 27%). Goserelin is felt to have limited activity in this patient population, and no additional single-agent studies are planned (479).

Investigation is under way in patients with uterine cancer to evaluate the activity of selective estrogen receptor modulators (SERMs). These agents have estrogen receptor (ER)-antagonist activity in breast and uterine tissues and ER-agonist activity in bone. The first reported study to date is from the GOG and evaluated anastrozole at 1 mg po daily orally in 23 unselected patients (i.e., 9 patients had grade 2 tumors and 14 patients had grade 3 tumors). A partial response rate of 9% was seen (90% CI, 3% to 23%). It is noted that the partial response rate of 9% in this study is similar to the 8% reported in grade 3 patients treated with standard progestins (487,493). A more recent study evaluated the investigational SERM arzoxifene in 37 patients. Twenty-six patients were ER positive and 22 were progesterone receptor (PR) positive. A response rate of 31% (95% CI, 25% to 51%) was seen in this selected patient population with a median duration of response of 13.9 months (480). Additional study of these agents in patients with well-differentiated tumors is warranted (502).

Cytotoxic Chemotherapy

Both single-agent and combination regimens are capable of inducing objective responses, yet the median time to treatment failure is on average 3 to 6 months and the overall survival of patients with metastatic endometrial cancer is generally less than 12 months. The role of chemotherapy in the recurrent disease setting remains palliative, and minimizing side effects is of equal importance when selecting a regimen. Responses to treatment are usually partial and have lasted an average of only 3 to 6 months. Also, the time to progression in most trials tends to be short, ranging from 4 to 6 months, with median survival averaging 7 to 10 months. Patients with complete response may have long progression-free intervals lasting 1 to 2 years, but such patients comprise only a minority of those treated. Particularly for patients with grade 1 histology, or small-volume asymptomatic metastatic disease, hormonal

therapy may provide better initial palliation, reserving chemotherapy for rapidly progressive or symptomatic disease (503,504).

Single-Agent Trials

The wide variety of single agents that have been tested are presented in Table 23.16 (505–508). Despite the number of drugs evaluated, the most commonly used single agents today based on response rates of at least 20% include cisplatin, carboplatin, doxorubicin, epirubicin, ifosfamide, docetaxel, and paclitaxel, and more recently topotecan has been added to this list.

The response rate to cisplatin dosages of 50 to 60 mg/m² given every 3 weeks was similar in patients with prior (25%) (509,510) and no prior chemotherapy (21%) (511–513). Carboplatin given in dosages of 300 to 400 mg/m² every 4 weeks has been associated with response rates of 29% (514–516), which is similar to cisplatin. Doxorubicin in dosages of 55 to 60 mg/m² has been associated with an overall response rate of 26% (517–519) and epirubicin with a response rate of 26% (520). Liposomal doxorubicin was recently reported in a GOG study of 46 patients receiving 50 mg/m² every 4 weeks with an overall response rate of 9.5%

(95% CI, 2.7% to 26%) (521). It is important to note that 32 patients had received prior doxorubicin therapy. A second study evaluated its efficacy in 19 patients without prior chemotherapy treatment and resulted in a 21% response rate (522). Of the antimetabolites, 5-fluorouracil given in dosages of 15 mg/kg for 5 consecutive days and then every other day until dose-limiting toxicity occurred. It has displayed a 21% response rate in 34 patients, whereas methotrexate (523) and mercaptopurine (524) have been inactive. Vincristine given on a weekly schedule was associated with a response rate of 18% in 33 untreated patients (525), but dose-limiting neurotoxicity was substantial. In a phase 2 trial of paclitaxel conducted by the GOG (506), 28 patients with recurrent or advanced endometrial cancer received a dose of 250 mg/m² every 21 days. Patients who had received prior pelvic irradiation were treated at an initial dose of 200 mg/m². Complete responses were noted in four patients (14%) and partial responses in six (21%) for an overall response rate of 36%. A more contemporary GOG study evaluated paclitaxel at 200 mg/m² (175 mg/m² with prior radiotherapy) every 3 weeks in pretreated patients showing an overall response rate of 27.3% (95% CI, 15% to 42.8%). The median duration of response was 4.2 months with an overall survival of 10.3 months (526). A similar study showed a response rate of 43% (95% CI, 6% to 80%) in patients who had all previously been treated with platinum-based therapy (527). A multicenter trial recently reported showed a response rate of 21% with PFS of 12 weeks and overall survival (OS) of 43 weeks in 35 patients receiving weekly docetaxel at 35 mg/m² (508).

Topotecan was evaluated in a phase 2 trial of untreated advanced or recurrent endometrial cancer administered initially at 1.5 mg/m² every day for 5 days every 3 weeks. The trial was suspended for toxicity, but reopened and completed at 1 mg/m² q day for 5 days (or 0.8 mg/m²/d for patients with prior radiotherapy). An overall response rate of 20% was seen with median duration of response of 8.0 months and overall survival of 6.5 months (528). A subsequent smaller study by Traina et al. using weekly topotecan dosing of 2.5 to 4.0 mg/m² on a 2 of 3 weeks schedule followed by 1 week off showed one partial response for 54 weeks with two patients having stable disease for 15 weeks each. Only two patients required dose reduction for toxicity using the weekly schedule (552).

The frequent variability in response rate noted for the same agent is probably related to several factors, including prior treatment, performance status, extent of disease, and the response criteria used for evaluation. No current data suggest that dose-response relationships exist for single-agent therapy, and doses and schedules are generally adjusted to minimize toxicity for an individual patient.

Combination Therapy

The results of treatment with combination regimens are presented in Table 23.17 (509,518,529–544). The first combination to be explored was cyclophosphamide with doxorubicin in four trials in chemotherapy-naïve patients (518,533, 538,542) using doxorubicin dosages of 40 to 50 mg/m² repeated every 3 to 4 weeks. The objective response rates for these trials were similar to single-agent doxorubicin and showed no advantage for the addition of cyclophosphamide. The GOG also compared doxorubicin alone with the same dose and schedule of doxorubicin plus cyclophosphamide (518). All patients had failed progestin therapy, had measurable lesions, and had no prior chemotherapy. The complete and partial response rates for patients receiving the doxorubicin (132 patients) and combination regimens (144 patients) were 22% and 30%, with a median progression-free interval of 3.2 and 3.9 months and a median survival of 6.9 and 7.3 months, respectively.

The addition of cyclophosphamide and doxorubicin to cisplatin (CAP) (509,532,535,536) and doxorubicin to cisplatin (AP) (530,539,541,543,544) has been associated with response rates ranging from 38% to 76%. The overlap of the 95% confidence intervals for CAP and AP regimens suggests no significant difference in response rates, thus allowing the AP regimen to become the “standard” to which more contemporary approaches are compared. Barrett et al. (530) studied a chronobiologically defined schedule of doxorubicin (60 mg/m² at 6:00 AM) and cisplatin (60 mg/m² at 6:00 PM) in an attempt to maximize the therapeutic index of the combination. The regimen in a phase 2 trial produced a 60% response rate, similar to other AP trials (539,541,544), but the median survival of 14 months was somewhat longer than in other AP trials. Toxicity was substantial, with 43% of patients developing white blood cell (WBC) counts of >1,000/mm³. GOG 139 represented a randomized trial of standard versus circadian-timed cisplatin and doxorubicin, and found no difference in response rate (46% vs. 49%) or progression-free (6.5 vs. 5.9 months) or overall survival (11.2 vs. 13.2 months) (545). The results of GOG 107 comparing doxorubicin (60 mg/m² every 3 weeks) with the same doxorubicin dose and cisplatin (50 mg/m² every 3 weeks) in 223 patients with advanced or recurrent endometrial cancer have shown a significantly higher response rate for the combination (42% vs. 25%; *p* = 0.004), but a progression-free and overall survival of 5.7 versus 3.8 months and 9.2 versus 9.0 months, respectively (543). Moderate to severe nausea and vomiting (16% vs. 2%), platelet counts of 50,000 mm³ (14% vs. 2%), and WBCs of 2,000 mm³ (61% vs. 39%) were more common for the combination regimen. This study confirms a higher response rate with combination therapy, but the difference in progression-free survival is modest and likely not clinically meaningful; the overall survival is identical in the two groups.

Given the increased response rate of the doxorubicin combination, and the phase 2 activity of single-agent paclitaxel, the GOG conducted a randomized trial (GOG 163) for patients with primary stage III and IV or recurrent endometrial cancer comparing doxorubicin and cisplatin to doxorubicin with 24-hour paclitaxel and granulocyte colony-stimulating factor (G-CSF). There were no significant differences in response rate (40% vs. 43%), PFS (median 7.2 vs. 6 months), or OS (median 12.6 vs. 13.6 months) for arm 1 and 2, respectively (546).

The disadvantage of GOG 163 was the lack of platinum in the taxane-containing arm, however. The addition of a taxane was subsequently studied in GOG 177. Doxorubicin (60 mg/m² or 45 mg/m² in patients with prior radiotherapy) with cisplatin (50 mg/m²) as the standard arm versus paclitaxel (160 mg/m²) with doxorubicin (45 mg/m²) and cisplatin (50 mg/m²) and G-CSF as the investigational regimen (547). The primary objective was to determine if the addition of paclitaxel improved response rate and progression-free and overall survival, and a secondary objective explored the relationship between HER2/*neu* overexpression and outcome with doxorubicin-based therapy. Two hundred and seventy-three patients were enrolled, and the study was balanced for history of prior RT (50% vs. 46%), serous carcinoma (15% vs. 19%), stage, grade, and body surface area (BSA). Grade 3 and 4 platelet toxicity was higher in the three-drug arm (21% vs. 2%), but other hematologic toxicity was ameliorated with G-CSF: absolute neutrophil count (ANC) 36% versus 50% and neutropenic fever 3% versus 2%. Nonhematologic grade 3,4 toxicity was higher in the three-drug arm: gastrointestinal 59% versus 39% and metabolic 25% versus 13%. Response rates were better with the triplet: complete response 22% versus 7%, partial response 36% versus 27%, and overall response rate (RR) 57% versus 34%. Median PFS was 8.3 months versus 5.3 months (*p* < 0.0005) and median overall survival was 15.3 months versus 12.1 months (*p* = 0.024).

^aCircadian timed regimen doxorubicin at 0600 (6 AM) and cisplatin at 1800 (6 PM) hours.

Responses were similar in serous (48%) versus nonserous histology (45%). Overall, paclitaxel doxorubicin cisplatin (TAP) chemotherapy increased 12-month survival to 59% compared to 50% with AP with an HR of 0.75 (0.56 to 0.998). As the secondary objective using available specimens (HER2/neu testing was not done in approximately 12% of patients) approximately 20% stained 3+, which was neither prognostic nor predictive of outcome in this patient population (547).

Although the TAP regimen produced an improvement in response rate and PFS, survival was minimally increased, and it is associated with greater toxicity. The combination of paclitaxel and carboplatin as a doublet has also been evaluated in a variety of phase 2 trials and retrospective studies with response rates in the 43% to 80% range (548,549). No direct phase 3 comparisons between doxorubicin and platinum versus paclitaxel with platinum are currently available. A randomized phase 2 study was presented in abstract form evaluating doxorubicin with cisplatin versus paclitaxel with carboplatin in 70 patients with advanced or recurrent endometrial cancer showing a response rate of 27.9% versus 35.3%, respectively, but a phase 3 study would be required to comment on a progression-free or overall survival advantage (550). GOG 209 is currently accruing patients and comparing doxorubicin, cisplatin, and paclitaxel with cisplatin and paclitaxel and will provide an important comparison of efficacy and toxicity between these two regimens.

The results of combining chemotherapy with progestin therapy are presented in Table 23.18 (551–557). Complete and partial remission rates have ranged from 17% to 86%, although none is convincingly different than for chemotherapy alone. There are no data to suggest that endocrine therapy in conjunction with chemotherapy is superior to chemotherapy or endocrine therapy alone. Many of these trials have included small numbers of patients, and median survival rates have generally been less than 1 year. In most combined progestin-chemotherapy regimens, most patients had no prior progestin treatment, although in almost all of the chemotherapy trials most patients had prior progestins before entry.

Two other randomized trials compared different chemotherapy regimens with all patients receiving megestrol acetate (Megace) (534,555). Response rates for both these regimens were similar, with median survival times of approximately 7 and 10 months, respectively. In the trial of Horton et al. (555),

many patients had prior progestins, but this did not appear to affect the response to chemotherapy, and the response to prior progestin therapy was not related to treatment results. In the study by Cohen et al. (534), response rate was also not related to prior progestin therapy, age, disease-free interval, metastatic site, or tumor grade.

Investigational Agents

A variety of investigational agents have been proposed as appropriate for evaluation in patients with endometrial cancer. These agents have generally failed to demonstrate sufficient activity for further development. More recently, as in other tumor types, agents targeting specific molecular pathways are in various early stages of evaluation.

mTOR Inhibitors. The *PTEN* tumor suppressor gene has been shown to be inactivated in a variety of tumors including 36% to 83% of endometrial carcinomas (558,559). Loss of *PTEN* leads to constitutive activation of AKT, which in turn leads to up-regulation of the mammalian target of rapamycin (mTOR) (296,560). Preclinical data has shown the activity of rapamycin in various cell endometrial cancer cell lines by inhibiting cell proliferation (561). Proposed mechanisms of mTOR blockade include inhibition of S6K1 and 4E-BP1 phosphorylation and the prevention of cyclin-dependent kinase activation, which leads to an arrest of the cell cycle in the G₁ to S transition. Preclinical studies have suggested that the degree of S6K1 inhibition in peripheral blood mononuclear cells (PBMCs) is identical to sampled tissue levels in mice, and PBMC levels may be able to be used as a surrogate for tissue levels in humans as phase 1 trials are performed (552). Rapamycin as a parent compound has poor solubility and stability in solution and several analogues (CCI-799 or temsirolimus, RAD-001 or everolimus, and AP-23573 or ARIAD) have been produced and are being evaluated in a variety of tumor types including endometrial carcinoma (562).

c-Kit, Abl, and Platelet-Derived Growth Factor Inhibitors. An immunohistochemical study of 63 patients showed positive staining for Abl, c-Kit, and platelet-derived growth factor receptor (PDGFR) in 85%, 0%, and 91% of the 33 primary endometrioid cancers; 92%, 25%, and 100% of the recurrent endometrioid cancers; and 73%, 0%, and 73% of the primary uterine papillary serous carcinomas (563). As data

^bTotal dose.

regarding imatinib has emerged, it is clear that the presence of targets as demonstrated by immunohistochemistry is not a surrogate for activity. Trials with uterine papillary serous carcinoma have been proposed, but enthusiasm has diminished for this agent given the negative data in serous ovarian carcinoma (564).

Epidermal Growth Factor–Targeted Agents. Epidermal growth factor (EGF) is expressed in normal epithelium and is overexpressed in 60% to 80% of endometrial carcinomas. It has been associated with advanced stage and poor outcome (565). Multiple downstream targets of the EGF pathway have been identified. Furthermore, the relationship between loss of function mutations for key tumor suppressors and resistance to EGF inhibitors is being explored (566). Preclinical models have shown differences in responses to EGF inhibitors between type I (Ishiwaka H) and II (Hec50co) endometrial cancer models.

While gefitinib blocked the autophosphorylation of epidermal growth factor receptor (EGFR) in both models with demonstrable downstream effector consequences, continued growth of type II tumors suggested constitutive activation of other signaling pathways. This supports the hypothesis that for optimal clinical effectiveness, multiple pathway interruptions may be required (565,566). Single-agent studies have shown limited clinical activity, and trials evaluating combination treatment with EGF inhibitors and chemotherapy are ongoing.

HER2/neu-Targeted Agents. HER2/neu gene overexpression and amplification have been shown in the subset of uterine cancers with serous histology (342,567,568). An oligonucleotide microarray study with the objective of detecting differences in genes between uterine papillary serous carcinomas and ovarian serous carcinomas showed that HER2/neu is the most strikingly overexpressed gene in

tumors of uterine origin when the two are compared (569). *In vitro* uterine papillary serous carcinoma cell lines resistant to natural killer cells were found to be sensitive to trastuzumab-mediated antibody-dependent cytotoxicity (570). Clinical trials evaluating trastuzumab in uterine papillary serous cancers are ongoing. It is noted that in the GOG study of trastuzumab in ovarian serous cancers, the frequency of HER2/neu overexpression was low, and the objective response rate was only 7.3% with a median PFS of 2 months, showing limited clinical value in serous tumors of ovarian origin (571).

Vascular Endothelial Growth Factor–Targeted Agents. The importance of vascular endothelial growth factor (VEGF) and angiogenesis in tumorigenesis is underscored by its overexpression in the majority of solid tumors as well as in lymphomas and hematologic malignancies (572). The prognostic and therapeutic implications of VEGF expression have been clearly shown in patients with ovarian cancer and particularly in those with malignant ascites, but the data in endometrial cancer have been less straightforward (573–575). Increased tumor VEGF levels in patients with endometrial cancer have been associated with higher-grade tumors, deep myometrial invasion, nodal metastasis, and more advanced-stage disease in some series (576,577). However, another study reported a lack of association between VEGF and its receptor expression and overall survival in 115 patients with endometrioid histology (578). A recent phase 2 trial of thalidomide in 27 patients with chemotherapy refractory endometrial cancer showed partial and stable disease responses of 12.5% and 8.3%, respectively, with a progression-free and overall survival of 1.7 months and 6.3 months (579). Thalidomide did not decrease VEGF or basic fibroblast growth factor (bFGF) levels in these patients, and elevated levels were associated with increased risk of progression or death in this study. Clinical trials with more potent inhibitors of angiogenesis such as bevacizumab are currently ongoing.

MANAGEMENT OF PATIENTS WITH SEROUS AND CLEAR CELL HISTOLOGIES

Serous cancer and, to a lesser extent, clear cell cancer tend to spread in a fashion similar to ovarian cancer with a high propensity for upper abdominal relapse. Therefore, whole abdomen radiation has been extensively studied in this group of patients (459). Lim et al. (460) reported on 78 patients with stage I–IIIA papillary serous carcinoma: 58 were treated with whole abdomen radiation and 20 were not. The corresponding 5-year disease-specific survival rates were 74.9% and 41.3%, respectively ($p = 0.04$). In GOG study 94, the 3-year disease-free and overall survival for the 60 patients with stage III papillary serous or clear cell carcinomas were 40.9% and 45.0%, respectively (453). The data on whole abdomen are somewhat encouraging, but the rate of relapse is still substantial, indicating the need for effective systemic therapy.

Based on the response rates of paclitaxel and carboplatin in other tumors of serous histology, trials investigating paclitaxel and carboplatin in uterine papillary serous carcinomas have reported response rates of 60% to 70% (580,581). No randomized, prospective trials evaluating multi-modality therapy for either early- or late-stage uterine papillary serous carcinomas have been reported. The GOG protocol 184 closed in 2004. This study randomized women with optimally stage III or IV endometrial carcinoma (including uterine papillary serous carcinoma [UPSC]) to doxorubicin and cisplatin chemotherapy versus doxorubicin, cisplatin, and paclitaxel chemotherapy following volume-directed radiation therapy.

The data is not yet mature, and at recent follow-up only approximately 13% of patients in either arm had serous histology, so definitive conclusions regarding the best treatment for UPSC will not likely be possible from this study. A single-institution phase 2 trial for advanced-stage uterine papillary serous histology administered paclitaxel and platinum-based chemotherapy for three cycles followed by volume-directed radiation therapy. Patients then received an additional three cycles of chemotherapy. The most common toxicity was hematologic and occurred during chemotherapy following radiation therapy. The PFS for the nine women treated is 46.4 months (582). A similar study administered four cycles of platinum with paclitaxel or epirubicin followed by whole pelvic and vaginal brachytherapy. The 5-year overall survival for this group was 58.9% (583).

With regard to stage I disease, the available data for designing a treatment plan is retrospective. A study of 74 stage I patients with UPSC between 1987 and 2004 who underwent complete staging at Yale University was reported (461). Patients were divided into those who had no residual cancer in the hysterectomy specimen versus those who did. Stage IA patients who had residual in the hysterectomy specimen and who were treated with platinum-based chemotherapy had no recurrences ($n = 7$) versus 6 of 14 (43%) who did not receive treatment. Of 15 patients with stage IB disease, there were no recurrences in the treated group but 10 of 13 nontreated patients (77%) recurred. Platinum-based chemotherapy was associated with improved progression-free ($p < 0.01$) and overall survival ($p < 0.05$). Furthermore, no patient who received radiation to the vaginal cuff recurred at the cuff versus 6 of 31 (19%) of those who did not receive vaginal cuff irradiation (461). Recognizing the limits of retrospective studies, these data support the potential benefit of a regimen of platinum-based chemotherapy with cuff irradiation in patients with UPSC. Randomized, prospective data is needed to accurately define the best approach in these patients.

FUTURE DIRECTIONS

In 2001, the National Cancer Institute convened an expert panel to develop a national 5-year plan for research priorities in gynecologic cancers. The resulting report, Priorities of the Gynecologic Cancer Progress Review Group (PRG), specified that understanding tumor biology was the central key toward controlling gynecologic cancers (6). For endometrial cancer, one of the top research priorities defined by the PRG was to identify prognostic and predictive markers for treatment efficacy and toxicity. One of the key research issues in endometrial cancer relates to developing a more comprehensive and detailed understanding of cancers at a genetic and molecular level. By understanding these factors, a more rational development of targeted agents is hoped. One such large research effort involves a 3,500 patient trial conducted by the GOG, including patients with endometrial cancer who are to undergo hysterectomy with pelvic and para-aortic lymphadenectomy. Blood, urine, and cancer tissue at the time of initial surgery and at the time of recurrence are being collected to create a large tumor bank for translational research. The primary goals are to determine what biologic, molecular, and genetic changes are responsible for metastasis, and to develop biomarkers that predict response and prognosis. Epidemiologic information is also being collected and will be linked to molecular/genetic information and clinical outcome. Through this unprecedented study, researchers hope to foster new understanding of this cancer that will lead to promising avenues for treatment and prevention.

SUMMARY

Endometrial cancer is the most common gynecologic malignancy, and an understanding of presentation, surgical management, and treatment options is required for gynecologic oncologists. Surgical therapy is a mainstay of endometrial cancer with lymphadenectomy and laparoscopy increasingly integrated. A thorough knowledge of the relationships between uterine factors and extrauterine disease spread is essential (60). Surgical staging defines extent of disease and largely defines risk of recurrence. Pelvic radiation is associated with better local control, but no improvement in survival for patients with stage I-II endometrial cancer in randomized trials (143,149,184).

Chemotherapy is increasingly integrated into up-front management of advanced-stage endometrial cancer, and may have a role in early-stage disease (8,416). Combination therapy with radiation and chemotherapy is under evaluation. Targeted agents hold promise; however, a better understanding of molecular and genetic changes is required to improve efficacy.

CHAPTER 24 ■ CORPUS: MESENCHYMAL TUMORS

GREGORY SUTTON, JOHN KAVANAGH, AARON WOLFSON,
AND CARMEN TORNOS

Uterine sarcomas are rare malignancies accounting for as few as 6% of the estimated over 40,000 cases of cancer of the uterine corpus in the United States in 2009 (1). In contrast to the generally favorable prognosis in endometrial adenocarcinomas, uterine sarcomas are generally aggressive; overall mortality rates approached 90% in early reports (2). In a 1997 Norwegian survey, uterine sarcomas accounted for 26% of all deaths from uterine malignancies (3). Uterine sarcomas encompass a broad spectrum of neoplasms from pure mesenchymal tumors and endometrial stromal tumors (leiomyosarcomas and endometrial stromal sarcomas) to mixed epithelial/stromal tumors such as adenosarcoma and carcinosarcoma. Several classification systems exist (4), most of which are based upon the original work of Ober (5); the World Health Organization histologic classification system of uterine sarcomas is summarized in Table 24.1.

EPIDEMIOLOGY AND RISK FACTORS

Leiomyosarcoma and Carcinosarcoma

The two major sarcomas, leiomyosarcoma and carcinosarcoma, are distinguishable in several ways including clinical presentation, spread patterns, mean age at diagnosis, racial distribution, apparent relative incidence, method of diagnosis, and history of prior radiotherapy.

Median Age at Diagnosis

Figure 24.1 demonstrates mean ages at diagnosis for common uterine sarcomas and endometrial adenocarcinomas. Patients with carcinosarcomas are on the average older (mean 65 [2], 67 [6] years) than those with endometrial adenocarcinomas (mean 59.1 years [7]), müllerian adenosarcomas (mean 57.4 [8], 58 [9] years), leiomyosarcomas (mean 53.5 [1], 55 [10], 11, 56.2 [12] years), and endometrial stromal tumors (mean 41 [13], 46 [14], 48 [15] years). Olah et al. (6) observed a bimodal age distribution among 423 cases of uterine sarcoma; they attributed this to a premenopausal peak for patients with leiomyosarcomas and a postmenopausal maximum for those with carcinosarcomas. Thus, many patients with carcinosarcomas are postmenopausal, whereas those with leiomyosarcomas may be premenopausal or perimenopausal at the time of diagnosis. In a review of 208 patients with leiomyosarcomas from the Mayo Clinic (11), only 41% were postmenopausal.

Racial Distribution

Zelmanowicz et al. (16) are the most recent investigators to note that women with carcinosarcomas are more likely to be of African American descent (among 453 patients and controls, 28% versus 4%, $p = 0.001$) than those with endometrial adenocarcinomas. In the reviews of Mortel et al. and Norris et al. (17,18), 33% and 24% of patients with carcinosarcomas were nonwhite, respectively. Brooks et al. (12) reported that the age-adjusted incidence of uterine sarcomas in African American women was twice that of controls. The age-adjusted incidences of leiomyosarcomas for black and white women, respectively, were 1.5 and 0.9 per 100,000. Those for carcinosarcomas in black and white women, respectively, were 4.3 and 1.7 per 100,000.

Relative Incidence

Carcinosarcomas and leiomyosarcomas constitute about 4% and 1.5% of all uterine malignancies in clinical series, respectively (6). Echt et al. (19) reported on 66 patients diagnosed with uterine sarcomas over a 21-year period at the University of Southern California and found carcinosarcomas in 48%, leiomyosarcomas in 36%, and endometrial stromal sarcomas in 15%. Because the risk profile of carcinosarcomas so closely parallels that of endometrial adenocarcinomas with regard to obesity, diabetes, anovulation, and low parity, Silverberg et al. (20) have suggested that they be regarded as “metaplastic” endometrial carcinomas instead of true sarcomas. Many other pathologists agree with this notion (21).

In series of uterine sarcomas referred for histopathologic diagnosis, leiomyosarcomas are seen more commonly than carcinosarcomas. The differentiation between benign, malignant, and “of uncertain malignant potential” smooth muscle tumors is more subtle than the diagnosis of carcinosarcoma.

Prior Radiotherapy

Although as many as a third of patients with carcinosarcomas in some series have a history of antecedent pelvic radiotherapy, this is rarely, if ever, an etiologic factor in patients with leiomyosarcoma of the uterus. Christopherson et al. (22) described two cases among 33 patients with uterine leiomyosarcoma who had a history of radiotherapy. In the series of carcinosarcomas reported by Norris et al. (18), 9 of 31 patients (29%) had received pelvic radiotherapy from 7 to 26 years prior to diagnosis. Among 1,208 uterine malignancies in the report by Meredith et al. (23), 30, or 2.4%, occurred in patients exposed to pelvic radiotherapy. Only 8 of these 30 patients had been irradiated for a gynecologic malignancy, with the others

being treated for uterine bleeding, polyps, or fibroids. Of irradiated patients, five (17%) developed carcinosarcomas, for a crude association of 11%. The risk of endometrial adenocarcinoma arising after radiation was 2%. It has been suggested that postirradiation carcinosarcomas occur at a younger average

age than those arising *de novo* (24). Latency to diagnosis of malignancy is generally shorter in older patients, however (23). Carcinosarcomas in previously irradiated patients also tend to present in advanced stage, perhaps because radiotherapy is often associated with cervical stenosis and, thus, no telltale uterine bleeding.

Müllerian Adenosarcoma

Clinically, these neoplasms occur in women aged 14 to 89 years (median 58 years) (25), with no racial predilection or noteworthy reproductive characteristics. The most common symptoms were bleeding, pelvic pain, prolapse, and vaginal discharge. On clinical examination, about 40% of patients had tissue protruding from the cervical os (25). In the series of Clement and Scully, five patients had a history of radiation therapy 8 to 30 years before diagnosis. In 1996 Clement et al. (9) reported six patients who developed müllerian adenosarcomas of the uterine corpus after taking tamoxifen for periods of 6 months to 4 years. An additional such case was reported by Bocklage et al (26).

CLINICAL PRESENTATION

Vaginal bleeding is the most common presenting symptom in women with uterine sarcomas in general (27,28) and is nearly universal in those with carcinosarcomas (29). Vaginal bleeding occurs in as few as 40% of women with leiomyosarcomas, however. A typical presentation of carcinosarcoma is vaginal bleeding associated with a protuberant, fleshy mass from the cervix. Uterine enlargement is common with carcinosarcomas. These neoplasms arise in the endometrial lining but often grow in an exophytic pattern within the endometrial cavity (Fig. 24.2). Bleeding and uterine cramping are common.

Uterine enlargement and a presumptive diagnosis of uterine *leiomyomata* are nearly universal findings in patients with leiomyosarcoma (Figs. 24.3 and 24.4). The incidence of leiomyosarcoma in all patients with a clinical picture of myomas is less than 1% but increases with age to slightly over 1% in the sixth decade of life (30).

DIAGNOSIS AND EVALUATION

Whereas the diagnosis of carcinosarcoma is confirmed, or at least suggested, at the time of endometrial biopsy or curettage, leiomyosarcomas are rarely diagnosed before hysterectomy (11). Although positron emission tomography and magnetic resonance imaging offer the potential of differentiating between benign and malignant smooth muscle tumors of the uterus, these techniques are not sufficiently sensitive and specific at the present time.

FIGURE 24.1. Mean age at diagnosis of common uterine sarcomas and endometrial adenocarcinomas.

FIGURE 24.2. Exophytic pattern of growth in carcinosarcoma.

Berchuck et al. reported that in 14 patients with leiomyosarcomas undergoing dilatation and curettage, a pre-hysterectomy diagnosis was made in only 8 (31). Although the diagnosis of carcinosarcoma may be missed because endometrial biopsy or curettage does not adequately sample both the epithelial and stromal components of the tumor, appropriate preoperative referral is made because of the presence of a malignancy, and staging is accomplished at the time of hysterectomy. Conversely, most leiomyosarcomas are diagnosed after hysterectomy at the time of histologic review of the surgical specimen. Referral and disposition decisions are therefore made *a posteriori*. More often than not, staging is omitted from the initial procedure. This dichotomy in the presentation of the two main uterine sarcomas was highlighted in a staging study published by the Gynecologic Oncology Group (GOG) (32). Far fewer patients with leiomyosarcomas were referred for enrollment in the study than those with the diagnosis of carcinosarcoma (301 carcinosarcomas, 59 leiomyosarcomas, and 93 endometrial stromal tumors and adenosarcomas). Restaging after primary surgery may have been an obstacle to entry of patients with leiomyosarcoma. In fact, the investigators who performed this study, Major et al. (32), deigned that “[i]n light of the small number of leiomyosarcoma cases with positive lymph nodes, re-exploration [*solely for staging*] is not recommended in patients with leiomyosarcomas.”

Patients with uterine carcinosarcomas, much like high-grade endometrial lesions, unless presenting with clinical metastases, should be managed in referral centers where

FIGURE 24.3. Leiomyosarcoma, gross.

FIGURE 24.4. Leiomyosarcoma, gross, showing heterogenous appearance.

appropriate surgical staging can be performed. Although vaginal sonography and magnetic resonance imaging may reveal myometrial involvement, the frequency of occult nodal, omental, and peritoneal metastases makes appropriate surgical evaluation paramount. Yamada et al. (33) underscored this fact in their staging study of 62 patients, 38 (61%) of whom had surgically detected extrauterine metastases.

Since the most common sites of metastases for uterine sarcomas other than leiomyosarcoma are pelvic and para-aortic lymph nodes, studies such as computed tomography (CT) of the abdomen and pelvis are probably not justified in patients with clinical stages I and II disease; on the other hand, if an extensive uterine mass is present, these evaluations may identify findings that suggest a palliative rather than curative approach to the patient. Radionuclide bone scans and imaging of the brain are of little value in the absence of pulmonary metastases. Preoperative radiographs are helpful in excluding pulmonary metastases and are often medically indicated in patients of advanced age or with compromised health. The utility of chest tomography in uterine sarcomas has not been formally addressed but should be considered in patients with high-grade lesions, especially if there is evidence that palliation rather than curative therapy would be appropriate.

Porter et al. (34) reviewed 600 patients with nonthoracic T2 soft-tissue sarcomas and concluded that routine chest CT identified metastases in 19.2% of patients but at a cost of \$27,594 per patient with metastases. If scanning were limited to patients with high-grade histologies only, the cost per patient with metastases was reduced to \$418 per patient with metastases. Since no specific data are in place for uterine sarcomas, CT scanning may be indicated in patients with high-grade sarcomas to determine extent of surgery.

STAGING AND NODAL INVOLVEMENT

By convention, the 1988 International Federation of Obstetrics and Gynecology (FIGO) staging criteria for endometrial cancer (see Table 23.4) are used to assign stages in uterine sarcomas.

Whereas carcinosarcomas, like endometrial adenocarcinomas, commonly metastasize to pelvic or para-aortic lymph nodes, leiomyosarcomas rarely spread to nodal sites. In the review of 203 stage I and II carcinosarcomas surgically staged as part of a GOG study reported by Silverberg et al. (20), nodal metastases were detected in 34 cases (16.7%). Nearly all subjects had lymphatic or vascular involvement in the myometrium; lymphatic channel involvement was a much

better predictor of nodal metastases than tumor grade or mitotic index. Doss et al. (2) confirmed that pelvic lymph nodes were the most common site of metastasis in carcinosarcomas, and others have confirmed a rate of nodal spread in clinically localized disease between 13.2% and 31.0% (33,35).

Multiple nodal metastases were noted in 66% of patients with any nodal spread in Chen's report (36), and Norris et al. (18) described lymph node disease in 90% of fatal cases.

Lymph node metastases were identified in only 3.5% of patients with clinically localized leiomyosarcomas at the time of surgical staging in the GOG study reported by Major et al. (32). In the recent Mayo Clinic series (11), 4 of 36 (11%) patients had nodal spread, but only 1 of these (2.6%) had isolated nodal metastases. Data from three series (28,30,37) indicate that lymph nodes were histologically positive only if clinically enlarged or associated with obvious intra-abdominal spread. Thus, the need for lymph node dissection in patients with leiomyosarcomas remains unsubstantiated.

Among patients with müllerian adenosarcomas who underwent surgical staging including lymph node sampling (38), 20% were found to have spread outside the uterus to involve lymph nodes, vagina, parametrium, ovary, and malignant peritoneal washings. Similar yields are reported for endometrial stromal sarcomas.

PATHOLOGY

Malignant mesenchymal tumors can be classified into pure mesenchymal tumors and tumors with a mixed epithelial and mesenchymal components. In the first group the most common is leiomyosarcoma, followed by endometrial stromal sarcoma, and rarely others including rhabdomyosarcoma, liposarcoma, angiosarcoma, chondrosarcoma, osteosarcoma, and alveolar soft part sarcoma. Mixed epithelial and mesenchymal tumors include carcinosarcoma and adenosarcoma. In addition, there are two rare mesenchymal tumors occurring in the uterus: uterine tumors resembling ovarian sex-cord tumors (UTROSCTs) and perivascular epithelioid cell tumors (PEComas).

Leiomyosarcoma and Other Smooth Muscle Tumors

Leiomyosarcomas are malignant smooth muscle tumors that usually arise *de novo*. Recent studies have shown that some tumors show areas with benign morphology, suggesting some progression from leiomyoma to leiomyosarcoma (39) but clonality studies only support this progression in a small percentage of cases (40). Unlike leiomyoma, leiomyosarcoma is rarely a solitary poorly circumscribed mass with a soft and fleshy consistency. The cut surface is variegated with gray areas intermixed with yellow areas of necrosis and sometimes hemorrhagic areas. The epicenter of the tumor is the myometrium and most leiomyosarcomas are intramural. Occasionally, they can extend into the cervix or beyond the uterus (Fig. 24.5).

Microscopically, most leiomyosarcomas are overtly malignant and have hypercellularity, coagulative tumor cell necrosis, abundant mitoses (more than 10/10 high power fields [hpf]), atypical mitoses, marked cytologic atypia, and infiltrative borders (Fig 24.6). Some cases lack some of these features, and occasionally the differential diagnosis between a benign and a malignant lesion can be controversial. The three most important criteria are coagulative tumor cell necrosis, high mitotic rate, and significant cytologic atypia (41). Coagulative tumor cell necrosis (FCN) has an abrupt transition from viable to necrotic tissue (Fig. 24.7). In contrast, the hyaline necrosis seen in some leiomyomas has an area of hyalinized

FIGURE 24.5. Leiomyosarcoma, gross, with extension beyond uterus.

tissue between the necrotic and viable tumor. Some smooth muscle tumors have histologic features that are not worrisome enough to render an unequivocal diagnosis of sarcoma. These tumors can be classified as atypical leiomyomas, smooth muscle tumors with low malignant potential (low probability of an unfavorable outcome), or smooth muscle tumors of uncertain malignant potential (STUMP) (insufficient numbers have been studied to predict their behavior). Figure 24.8 summarizes the classification of uterine smooth muscle tumors based on their histologic characteristics. This classification is based in large part upon a large retrospective study from Stanford

FIGURE 24.6. Leiomyosarcoma, microscopic.

FIGURE 24.7. Leiomyosarcoma, microscopic, with abrupt transition from viable to necrotic tissue.

University published in 1994 (39), the largest to date. A multi-institutional study of 77 leiomyosarcomas presented at the United States Clinical and Anatomic Pathology meeting in 2006 (42) reported three leiomyosarcomas with minimal atypia and no tumor cell necrosis. This same study found the presence of tumor cell necrosis coexisting with areas of hyaline necrosis typical of leiomyosarcomas. Tumors that clinically and pathologically appear to be leiomyomas but have up to 15 mitoses per 10 hpf behave in a benign fashion and are classified as mitotically active leiomyomas (43,44). Leiomyomas are more likely to have a high mitotic count if they are excised during the secretory phase of the menstrual cycle, during pregnancy, or while patients are receiving exogenous progesterone therapy.

There are some tumors that are not represented in Figure 24.8, for example, tumors without tumor necrosis, with focal or multifocal atypia, and with more than 20 mitoses per 10 hpf.

These tumors are rare but some behave as sarcomas (42). Since there are few of these cases reported they should be considered at least STUMPs. There are tumors that lack one of the three major diagnostic criteria (mitoses, atypia, necrosis) but have other worrisome features such as infiltrative borders, lymphovascular invasion, or atypical mitoses. Classification of such cases is always problematic. It is recommended that these unusual cases be reviewed by a gynecologic pathologist.

Infarcted necrosis of benign leiomyomas can be seen sometimes during pregnancy, after uterine artery embolization, thermal balloon endometrial ablation, therapy with tranexamic acid, or therapy with high-dose progestins. In addition, pedunculated submucosal leiomyomas can undergo spontaneous torsion, and infarction, even with protrusion through the cervix. Infarcted leiomyomas should not be confused with leiomyosarcoma. The infarcted necrosis is not tumor cell necrosis, as mentioned before. In addition, infarcted leiomyomas are not associated with significant cytologic atypia, high mitotic rate, atypical mitoses, or invasive borders. An accurate clinical history can be very useful in many of these cases.

Classification criteria of smooth muscle tumors with either myxoid or epithelioid features differ from those used for spindle cell tumors. Epithelioid tumors have cells that are round rather than spindle shaped and have round nuclei mimicking epithelial cells (hence the term “epithelioid”) (Fig. 24.9). Epithelioid leiomyosarcomas have significant cytologic atypia, at least three mitoses per 10 hpf and tumor cell necrosis in 50% of cases (45). At least one previous study suggests that epithelioid tumors may behave more aggressively than spindle cell tumors and have a higher tendency to metastasize (46).

Myxoid leiomyosarcomas are rare and may be deceiving because of minimal atypia and a low mitotic rate. However, they are always infiltrative and this feature can be used to render the diagnosis of sarcoma (Fig. 24.10). Lymphovascular invasion is also indicative of malignancy. Myxoid leiomyosarcoma has a clinical behavior similar to other leiomyosarcomas (47,48).

Histologic parameters of leiomyosarcomas that have been shown to be prognostic indicators include grade, mitotic rate, extensive tumor cell necrosis, and lymphovascular invasion. However, multivariate analyses from large studies vary in their

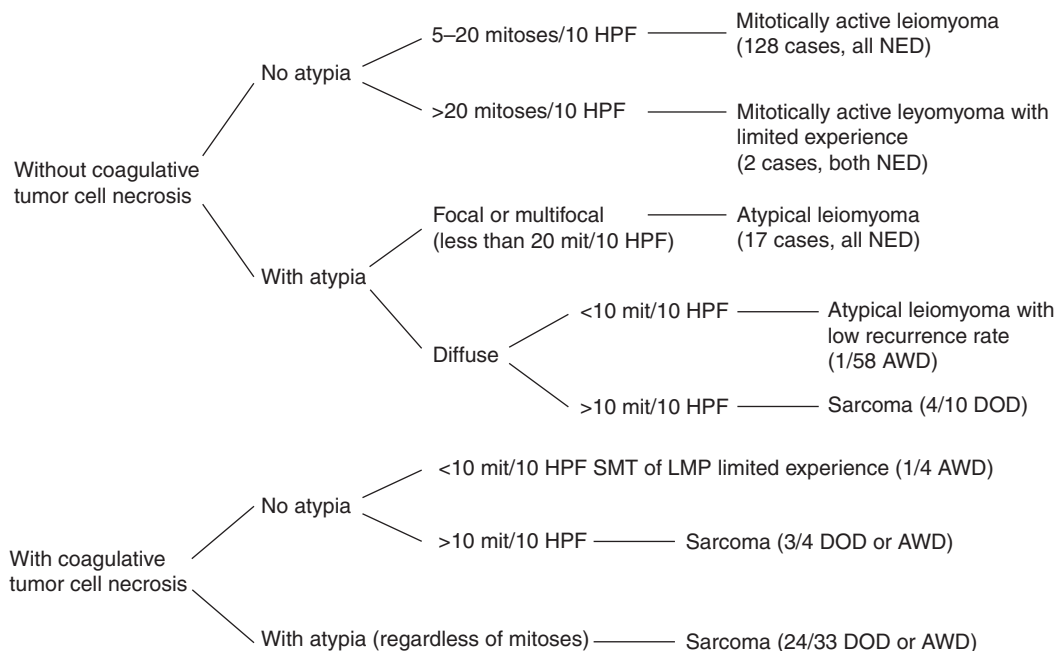

FIGURE 24.8. Uterine smooth muscle tumors (excluding epithelioid and myxoid types and cervical tumors). *Note:* AWD, alive with disease; DOD, dead of disease; HPF, high power fields; LMP, low malignant potential; NED, no evidence of disease; SMT, smooth muscle tumor.

FIGURE 24.9. Epithelioid leiomyosarcoma, microscopic appearance.

results (11,49). Estrogen and progesterone receptors are expressed in a large percentage of leiomyosarcomas (38% to 60%), but this does not seem to correlate with overall survival (50,51), nor does it suggest that hormonal therapy is beneficial.

Carcinosarcoma

Uterine carcinosarcomas, also called malignant mixed müllerian tumors, are lesions containing carcinomatous and sarcomatous elements (Fig. 24.11). Numerous studies have shown that these tumors are clonal malignancies derived from a single stem cell (52–54) and should be considered “metaplastic carcinomas.”

Most carcinosarcomas are polypoid tumors that fill the endometrial cavity and may protrude through the cervical os (Fig. 24.12). The tumors are soft and fleshy with areas of necrosis and hemorrhage. Occasionally, they show gross myometrial invasion, and may extend into or through the cervix. The size of the tumor is quite variable and may range from less than 2 cm to over 20 cm in diameter.

Microscopically, the tumors have a typical biphasic pattern with carcinomatous and sarcomatous elements. The carcinoma is usually high grade and reminiscent of serous carcinoma, although some cases have undifferentiated, endometrioid, clear cell, or even squamous carcinoma. The sarcomatous

FIGURE 24.10. Myxoid leiomyosarcoma, microscopic appearance.

FIGURE 24.11. Carcinosarcoma, microscopic appearance.

component is always high grade and may be homologous or heterologous. In homologous tumors, the sarcomatous component is usually high-grade fibrosarcoma, although varieties such as leiomyosarcoma, malignant fibrous histiocytoma, or undifferentiated sarcoma may be found as well. Heterologous elements are seen in half of the cases. The most common heterologous sarcoma is rhabdomyosarcoma, followed by chondrosarcoma, and less often osteosarcoma and liposarcoma (55). Most carcinosarcomas have myometrial invasion (85% in a recent study), most commonly into less than half of the wall (55). Lymphovascular invasion is present in 60% (55) and the carcinomatous element is usually the component invading myometrium and lymphovascular spaces.

Most studies suggest that the behavior of carcinosarcomas is predicted by the carcinomatous component. Tumors typically metastasize through lymphatic channels similar to endometrial carcinomas. Most metastases and recurrences are composed of pure carcinoma (20,56,57). In two recent studies, adverse prognostic factors included heterologous elements (in stage I tumors) and a high percentage of sarcomatous components in the main tumor and in the recurrences (55,58); these factors did not affect prognosis according to other studies (20,59–61).

Müllerian carcinosarcomas may arise in extrauterine sites. Most cases have been reported in the peritoneum (62–65) or retroperitoneum (66,67). Some cases occur at the site of previous radiotherapy, and some cases arise in areas of endometriosis (67).

Endometrial Stromal Neoplasms

In the current World Health Organization classification, endometrial stromal tumors are classified into endometrial stromal nodules, endometrial stromal sarcomas (by definition low grade), and undifferentiated endometrial sarcoma. Both endometrial stromal nodules and endometrial stromal sarcomas are composed of cells identical to those found in the stroma of proliferative endometrium. Undifferentiated endometrial sarcomas, on the other hand, are high-grade sarcomas that do not resemble endometrial stroma and diagnosis is by excluding other uterine sarcomas.

The differential diagnosis between an endometrial stromal nodule and an endometrial stromal sarcoma is important since the nodules are always benign lesions. Differential diagnosis is based upon the presence of infiltrating margins with or without angioinvasion in endometrial stromal sarcoma. These two features are not seen in stromal nodules, which are always well circumscribed and have pushing margins (68). It is impossible

FIGURE 24.12. Carcinosarcomas, gross photographs of four cases demonstrating polypoid nature of lesions.

to render a definitive diagnosis based upon curettage material alone; final diagnosis requires a hysterectomy specimen. If the patient is young and wants to preserve fertility, a combination of diagnostic imaging and hysteroscopy must be used to monitor tumor growth and direct excision (69).

Stromal Nodule

Stromal nodules are by far the least common of the pure endometrial stromal neoplasms. They are usually solitary masses with diameter varying from 1.2 to 22 cm with an average of 7.1 cm (70).

On cut section, endometrial stromal nodules are fleshy and often tan-yellow. Microscopically, they are composed of uniform bland, small cells resembling normal endometrial stromal cells with fusiform nuclei and scant cytoplasm. Abundant arterioles reminiscent of the spiral arterioles of the normal endometrium are also present. The mitotic rate is low, with most tumors having fewer than five mitoses per 10 hpf. Most endometrial stromal nodules are cellular, and some have variable amounts of intercellular collagen, which occasionally forms dense collagen bands or nodules (Fig. 24.13). Another common finding is the presence of clusters of foamy histiocytes within the tumor. The borders between the tumor and the adjacent myometrium are microscopically well defined (pushing). Occasionally, they may have more irregular borders with minimal areas of tumor extending into adjacent myometrium, usually within 3 mm of the main tumor mass (70,71). Endometrial stromal nodules lack associated lymphovascular invasion. Other changes that can be seen in endometrial stromal nodules include smooth muscle metaplasia, cystic degeneration, sex-cord-like areas, and necrosis.

Endometrial stromal nodules may be confused with cellular leiomyomas. Since both tumors are benign, the misdiagnosis of one for the other is probably of no clinical consequence as long as the tumor is found in a hysterectomy specimen. If the tumor is found in a curettage specimen, it is impossible for

the pathologist to distinguish a stromal nodule from a stromal sarcoma. If the tumor is misdiagnosed as a cellular leiomyoma in a curettage, the consequences may be dramatic. There are some histologic features that favor a leiomyoma: blood vessels with thick muscular walls, cleft-like spaces, and merging with the adjacent myometrium. In addition, a battery of immunohistochemical stains may be of use. CD10 is usually present in endometrial stromal cells, and smooth muscle tumors stain positively for desmin and h-caldesmon (72,73).

Endometrial Stromal Sarcoma

Endometrial stromal sarcomas (ESSs) are, by definition, always of low grade and have uniformly bland cells reminiscent of endometrial stromal cells. On gross examination, some are comprised of a single visible mass, and others have multiple

FIGURE 24.13. Endometrial stromal nodule, microscopic appearance.

FIGURE 24.14. Endometrial stromal sarcoma, low grade, microscopic appearance.

masses or diffuse myometrial infiltration by worm-like masses (Fig. 24.14). Typically, these tumors show permeation of the myometrial wall, in some cases up to the serosa (Fig. 24.15). Most tumors have fewer than ten mitoses per 10 hpf, but even mitotically active variants behave in a similar indolent manner. Some ESSs have unusual histologic features that may confound the diagnosis. These features include myxoid changes, fibroblastic and/or smooth muscle differentiation, epithelioid changes,

FIGURE 24.15. Endometrial stromal sarcoma, low grade, gross appearance.

and extensive endometrioid glandular differentiation (73–75). No single histologic parameter can be used to predict behavior of low-grade ESSs, including mitotic rate and lymphovascular invasion. However, in a recent study, all low-grade ESSs with high androgen or low estrogen receptor expression behaved aggressively (76).

Low-grade ESSs may occur in extrauterine sites including ovary, fallopian tube, cervix, vagina, vulva, pelvis, abdomen, retroperitoneum, placenta, sciatic nerve, or round ligament (77–84). Some of these cases have been associated with endometriosis. Histologically, they are similar to uterine ESSs, and a uterine tumor needs to be excluded before accepting the lesion as a primary extrauterine ESS. The relapse rate for extrauterine ESS is 62%, which is similar to advanced low-grade uterine ESS. Mitosis and atypia do not correlate with prognosis.

Sixty percent of low-grade endometrial stromal tumors (including ESS and stromal nodule) have cytogenetic abnormalities involving rearrangements of chromosomes 6, 7, and 17. The most characteristic translocation of these tumors, t(T7;17) (Tp15;q21), generates a fusion of the *JAZF1* and *JJAZ1* genes. The presence of this chromosomal abnormality may be of use in the diagnosis of difficult cases or recurrent tumors (85).

Undifferentiated endometrial sarcomas have cytologic atypia to the extent that they cannot be recognized as arising from endometrial stroma. Morphologically, these high-grade lesions resemble undifferentiated mesenchymal tumors and behave as high-grade sarcomas (86). It is advisable to use a term such as “high-grade sarcoma,” “undifferentiated sarcoma,” or “poorly differentiated uterine sarcoma” (86) rather than “endometrial stromal sarcoma.” This last term may inaccurately suggest an indolent tumor. Undifferentiated uterine sarcomas are usually seen in patients older than 50 years, have a recurrence rate of over 85%, and are usually fatal. There have been reports of synchronous or metachronous low-grade ESS with undifferentiated endometrial sarcoma. These cases behave like high-grade tumors and should be diagnosed as such (87).

Müllerian Adenosarcoma

Clement and Scully (8) described müllerian adenosarcomas in 1974 and updated their experience with 100 cases in 1990 (25). These are mixed müllerian tumors composed of malignant stromal and benign epithelial components.

Most adenosarcomas arise in the endometrium and rarely in the endocervix, lower uterine segment, and myometrium (88). Grossly, the majority are solitary polypoid masses with a spongy appearance secondary to the presence of small cysts. Occasional cases appear as multiple polyps or masses and can be multicentric. Their size is variable, being from 1 to 17 cm (mean 5 cm).

Microscopically, the tumors have a benign epithelial component usually covering the surface of the polyps and in the form of benign glands uniformly distributed throughout the tumor. The mesenchymal component is usually a low-grade sarcoma that resembles endometrial stroma. The presence of hypercellular stroma around the glands is common, and some tumors have a leaf-like papillary growth pattern (Fig. 24.16). Sometimes the diagnosis of adenosarcoma may be difficult because of the very low-grade nature of the sarcoma. Minimal criteria were described by Clement and Scully in a review of 100 cases of adenosarcoma published in 1990 (25). They include at least one of the following: two or more stromal mitoses per 10 hpf, marked stromal hypercellularity, and significant stromal cell atypia. Even with these criteria, some cases are deceptively bland, and several cases have been seen

FIGURE 24.16. Müllerian adenosarcoma, microscopic appearance.

in which the diagnosis was only possible after multiple “recurrences” of uterine polyps were reviewed. A minority of cases have “sarcomatous overgrowth,” when more than 25% of the tumor is composed of pure sarcoma. In these cases, the sarcoma is typically high grade and the lesions are aggressive (Fig. 24.17) (88).

Most adenosarcomas without stromal overgrowth express estrogen receptors in the sarcomatous component and this may be used for therapeutic purposes (89,90).

Müllerian adenosarcomas have been described in extrauterine sites including the ovary and areas of endometriosis in the vagina, rectovaginal-septum, gastrointestinal tract, urinary bladder, pouch of Douglas, peritoneum, and liver (91–98).

Uterine Tumor Resembling Ovarian Sex-Cord Tumor

In 1976, Clement and Scully (99) coined the term uterine tumors resembling ovarian sex-cord tumors (UTROSCTs) to describe a series of uterine neoplasms with sex-cord-like patterns. Since then, sex-cord-like patterns have been demonstrated in endometrial stromal neoplasms, smooth muscle

FIGURE 24.17. Müllerian adenosarcoma with sarcomatous overgrowth, microscopic appearance.

FIGURE 24.18. Uterine tumor resembling ovarian sex-cord tumor (UTROSCT), microscopic appearance.

neoplasms, and in cases lacking clear endometrial stroma and smooth muscle differentiation. The term UTROSCT should be reserved for this last category (100). True UTROSCTs are rare tumors, usually submucosal and well circumscribed, with a yellow cut surface. Histologically, they are composed of sertoliform tubules with low mitotic activity and little nuclear atypia (Fig. 24.18) (100). These tumors behave in a benign fashion.

Perivascular Epithelioid Cell Tumors

Perivascular epithelioid cell tumors (PEComas) are rare neoplasms presumably derived from perivascular epithelioid cells that co-express melanocytic and smooth muscle markers. Other tumors that belong to the same family include angiomyolipoma (AML), clear cell/sugar tumor of the lung, lymphangioliomyomatosis (LLM), and myelomelanocytic tumor of ligamentum teres/falciform ligament. PEComas have been described in a variety of locations including visceral organs, soft tissues, skin, oral mucosa, orbit, and base of skull (101). Uterus and gastrointestinal tract are the most common locations for visceral PEComas. About 8% of PEComas occur in patients with the tuberous sclerosis complex. Most uterine PEComas are histologically and clinically benign. They can be either grossly well-circumscribed or focally infiltrative masses. Histologically, they are composed of epithelioid cells with clear or eosinophilic cytoplasm, sometimes associated with spindle cells, and a prominent vasculature (102,103).

Approximately 25% of reported cases developed metastases and/or recurrences. Most malignant tumors have more than one of these three histologic features: necrosis, mitoses >2 per 50 hpf, and lymphovascular invasion, but there is not a single reliable prognostic indicator other than the presence of lymphovascular invasion.

The concept of PEComa as a true entity is debatable and some authors believe that the tumor represents a variant of smooth muscle neoplasm (104–106).

RADIATION THERAPY

Since the utilization of radiation therapy for patients with uterine sarcomas has been almost exclusively in the postoperative setting (107), the role of primary or palliative radiotherapy

will not be presented. As they are more fully explored in the chapter on epithelial tumors of the corpus, a detailed discussion of the techniques and complications of adjuvant radiation therapy will not be presented in this section.

Uterine Sarcomas

Most of the published papers on sarcomas of the uterus have been retrospective in nature, often requiring many years, if not decades, to accumulate enough patients to perform meaningful statistical analyses. Furthermore, these studies have often had to combine many types of sarcomas to attain numbers sufficient for evaluation (12,108–118). Thus, most of these retrospective studies have not achieved statistical power to reach definite conclusions. However, the data from the non-randomized review of the Surveillance, Epidemiology, and End Results (SEER) analyses of 2,677 cases of uterine sarcoma did demonstrate a statistically significant improvement in survival favoring adjuvant radiotherapy for stage II, III, and IV (but not stage I) uterine sarcomas (12).

The GOG previously conducted two prospective clinical trials involving selected patients with uterine sarcomas. The earliest study reported on 156 evaluable patients with surgically staged I or II sarcomas of the uterus (119). Patients were enrolled from 1973 to 1982 and randomized (GOG protocol 20) to receive either at least one cycle of adjuvant doxorubicin or no adjuvant chemotherapy. Prior to study randomization, patients could receive optional adjuvant radiotherapy either preoperatively (external pelvic treatment of 40 Gy in 4 to 5 weeks with intracavitary vaginal brachytherapy of 20 Gy to point A) or postoperative pelvic external beam irradiation alone to 50 Gy in 5 to 6 weeks (120).

It should be noted that 11 of 48 (23%) patients with leiomyosarcomas in GOG 20 underwent adjunctive radiotherapy. Furthermore, 49 of 109 patients (45%) with “non-leiomyosarcomas” (85.3% were carcinosarcomas) had adjuvant external beam therapy of the pelvis. Radiotherapy did not seem to affect recurrence in general. However, Table 24.2 shows that there was a notable decrease (119) in vaginal recurrences in patients with carcinosarcomas. Moreover, Table 24.2 also demonstrates an increase in extravaginal failures in the group receiving radiotherapy. Furthermore, Table 24.3 demonstrates a significant reduction in pelvic relapses (10%) in treated patients compared with those untreated (23%) (120).

The second main GOG trial for patients with uterine sarcomas involved a clinicopathologic evaluation of patients with clinical stage I and II disease (GOG protocol 40). This study opened in February 1979 and subsequently closed in October 1988 (32).

Source: Modified from Hornback NB, Omura G, Major FJ. Observations on the uterine sarcomas of adjuvant radiation therapy in patients with stage I and II uterine sarcoma. *Int J Radiat Oncol Biol Phys* 1986;12:2127–2130.

Of the 453 eligible patients, 430 (95%) had the mandated extrafascial hysterectomy, bilateral salpingo-oophorectomy, and selective retroperitoneal lymphadenectomy. Of this latter group, there were 301 (70%) patients with carcinosarcomas, of which 240 (80%) had surgical stage I/II disease. From this subset, Table 24.4 depicts the locations of first relapse(s). Although adjuvant pelvic external beam therapy was not mandated in this surgical trial, there appeared to be a possibility that adjuvant radiation plays a role in reducing pelvic relapses.

Currently, there is one completed prospective phase III clinical trial that focused on the role of adjuvant radiation therapy for patients with all three main cell types of uterine sarcomas (protocol 55874 of the European Organization for Research and Treatment of Cancer [EORTC]). When initially published in abstract form (121), this trial reported on 224 patients, of which 91 had carcinosarcomas, 103 leiomyosarcomas, and 28 endometrial stromal sarcomas. This study opened in July 1987 and closed to patient accrual in July 2001. Eligible patients underwent an initial surgical resection that involved mandatory total abdominal hysterectomy and bilateral salpingo-oophorectomy. Retroperitoneal lymph node dissection was optional. Due to the time period of the inception of this trial, there were no recommendations regarding either collection of peritoneal washings or omentectomy.

Those subjects in EORTC 55874 with surgical stage I or II disease were then randomized to either no further treatment or external beam irradiation of the whole pelvis. At the time of the abstract, there was a significant reduction in local recurrences (14 of 112 or 12.5%) in the adjuvantly treated arm versus 21.4% (24 out of 112) local relapses in the observation group ($p = 0.004$). Despite the significant improvement in local control, there was no survival benefit afforded the irradiated

cohort. Of further note was the fact that this impact on pelvic control was only present in patients with carcinosarcomas. Moreover, due to the lack of rigorous sarcomas surgical staging, it is impossible to know the proportion of patients with occult higher-stage disease in each study arm, which may have affected the results.

EORTC 55874 has been recently updated (122). Compared to the initial report, there are now 221 evaluable patients—92 with carcinosarcomas, 99 with leiomyosarcomas, and 30 with endometrial stromal sarcomas. The dose fractionation for EORTC 55874 centered upon delivering approximately 50.4 Gy in 28 fractions for 5 to 6 weeks to the whole pelvis with all fields being treated daily. The number of “any local recurrence” for carcinosarcomas was 11 out of 46 (23.9%) and 21 out of 45 (46.7%) for irradiated and nonirradiated patients, respectively. In addition, for leiomyosarcomas there were 10 of 50 (20%) and 12 of 49 (24.5%) with “some aspect” of local failure for the corresponding adjuvant and nonadjuvant arms. For carcinosarcomas, there were 2 of 46 (4.4%) in the adjuvantly irradiated arm and 11 of 45 (24.4%) in the observation subset with isolated local relapses. For leiomyosarcomas, 1 of 50 (2%) in the radiotherapy group and 7 of 49 (14.3%) in the untreated cohort developed isolated local failures.

Thus, it is apparent that patients with isolated local failures evaluated in EORTC 55874 are in the minority for both carcinosarcomas (13 out of 32 [40.6%]) and leiomyosarcomas (8 out of 22 [36.4%]), respectively. In fact, distant metastases as any component of relapse occurred in 29 out of 91 (31.9%) and in 45 out of 99 (45.5%) for carcinosarcomas and leiomyosarcomas, respectively. Finally, the 3-year progression-free survival was not statistically significant between the two study arms (57.7% and 51.9% for the irradiated and nonirradiated subsets, respectively). By the same token, the patients treated postoperatively had a nonsignificant median survival advantage of 8.5 years versus 6.7 years for the observational cohort with a hazard ratio of 1.02 (95% confidence interval [CI], 0.68 to 1.53; $p = 0.92$).

However, in a novel pilot study from France (123), 18 patients (13 of 18 with leiomyosarcomas) with optimally debulked surgical stage I, II, and III sarcomas received adjuvant doxorubicin, cisplatin, and ifosfamide (three cycles) followed by sequential external beam radiotherapy to a total dose of approximately 45 Gy in 5 weeks with or without vaginal brachytherapy. These investigators then performed a matched case-control study utilizing 18 patients of whom 16 underwent pelvic radiotherapy alone and 2 received no adjuvant treatment. With a median follow-up of 43 months (range, 23 to 56 months), this study found that only five patients (27.8%) had suffered recurrences. All failed solely in extrapelvic sites. Moreover, neither median survival nor disease-free survival had been reached for study patients at last follow-up.

Uterine Carcinosarcomas

Other reports have been limited to one histologic type of sarcoma. The most common of these pertained to what is currently being termed as “mixed epithelial and stromal tumors of the uterus” (124) or historically known as uterine carcinosarcomas (110,125–134). Results are inconsistent with some studies demonstrating no benefit for radiotherapy (110,128,130,131,133), while others have shown a significant impact of adjuvant pelvic radiotherapy on survival for patients with carcinosarcomas (125,127,132,134). One of these studies (134) involved a review of the nonrandomized SEER database of 2,461 women with carcinosarcomas from 1973 to 2003. In this data set, 890 patients received adjuvant radiotherapy. The overall 5-year survivals of those

receiving radiotherapy versus no irradiation were 41.5% and 33.2%, respectively ($p < 0.001$). Furthermore, a significant improvement in survival in this study was observed for all stages of disease, including stage IV. Finally, there have been several published retrospective reports suggesting that combined adjuvant radiotherapy and chemotherapy may impart even longer survival, especially in stage I and II disease (35,129,135).

There has been one randomized phase III prospective trial of adjuvant radiotherapy in carcinosarcomas, (GOG 150). This study compared whole abdominal irradiation to three cycles of cisplatin-ifosfamide chemotherapy with respect to recurrence rates, and disease-free and overall survival. Also evaluated were therapeutic toxicities. Eligible were patients with carcinosarcomas confined to the abdomen who underwent optimal surgical debulking with no postsurgical residual disease greater than 1 cm. Patients randomized to receive radiotherapy were prescribed a total dose of 30 Gy to the whole abdomen using external beam therapy followed by a pelvic boost to an approximate cumulative pelvic dose of 50 Gy. The first published report (136) of the two treatment cohorts was based upon an analysis done in December 2005. There were 224 patients enrolled, of whom 206 were evaluable. In this latter group, 105 patients underwent adjuvant radiotherapy, while 101 were given chemotherapy. The estimated death rate for patients receiving chemotherapy was 32.8% lower than for those receiving radiotherapy ($p = 0.042$). A subsequently published update (137) of this study based upon a May 2006 analysis demonstrated that this reduction in estimated death rate by chemotherapy had dropped to 31% relative to radiotherapy ($p = 0.046$).

The most recent evaluation of the data of patients on GOG 150 occurred in November 2006 (138). At the time of this analysis, the median duration of follow-up for patients alive at last contact was 63 months. The breakdown of surgical stages for patients in the radiotherapy versus chemotherapy arms is as follows: stage I—35 out of 105 (33.3%) versus 29 out of 101 (28.7%); stage II—11 out of 105 (10.5%) versus 15 out of 101 (14.9%); stage III—45 out of 105 (42.9%) versus 47 out of 101 (46.5%); and stage IV—14 out of 105 (13.3%) versus 10 out of 101 (9.9%). The estimated crude probability of relapse within 5 years was a nonsignificant 58% versus 52% for the radio- and chemotherapy groups, respectively. The sites of first failure are presented in Table 24.5. Although not statistically significant, there were fewer vaginal but more abdominal relapses in the adjuvant radiotherapy group as

TABLE 24.5

PATTERNS OF FAILURE

Sites of recurrence ^a	WAI (n = 105), number of cases	Chemotherapy (n = 101), number of cases
Vagina	4	10
Pelvis	14	14
Abdomen	29	19
Distant	27	24

Note: n, total number of cases in each arm; WAI, whole abdominal irradiation.

Source: Modified from Wolfson AH, Brady MF, Rocereto T, et al. A Gynecologic Oncology Group randomized phase III trial of whole abdominal irradiation (WAI) vs. cisplatin-ifosfamide and mesna (CIM) as postsurgical therapy in stage I-IV carcinosarcoma (CS) of the uterus. *Gynecol Oncol* 2007;107:177–185.

FIGURE 24.19. Overall survival in Gynecologic Oncology Group protocol 150, whole abdomen radiotherapy versus cisplatin plus ifosfamide chemotherapy.

compared to the chemotherapy arm. Figure 24.19 demonstrates that the estimated 5-year survival was approximately 35% for those randomized to adjuvant radiotherapy versus 45% for those receiving chemotherapy. After adjusting for stage and age at diagnosis, there was a further death rate reduction to 23% for those receiving chemotherapy compared with radiotherapy (HR = 0.712; 95% CI, 0.484 to 1.048; $p = 0.085$; two-tail test). Of interest is the fact that those patients who received adjuvant radiotherapy had more late complications, mainly gastrointestinal, than those having cytotoxic therapy ($p < 0.001$). In addition, two patients undergoing radiotherapy died as a direct result of radiation-induced hepatitis.

Based upon the results of GOG protocol 150, the role of adjuvant radiotherapy for the management of patients with carcinosarcomas continues to remain uncertain. Since there were more vaginal failures in the chemotherapy arm of GOG protocol 150 and other sites of relapse were similar or less common in frequency (abdominal recurrences) than those in the radiotherapy arm, then perhaps postoperative vaginal brachytherapy (either high or low dose rate) with chemotherapy should be considered for any patient having optimally debulked carcinosarcomas in future trials. It is anticipated that the next GOG-led adjuvant trial will compare two chemotherapy regimens, with radiation chosen by the treating physician.

Uterine Leiomyosarcomas

The second most frequent type of uterine sarcomas is leiomyosarcomas. Table 24.6 presents the overall pelvic/extrapelvic relapse rates of 16.6% and 42.0% for patients with uterine leiomyosarcoma. There still remains a paucity of information that specifies between upper abdominal and extra-abdominal distant sites of tumor involvement. The respective pelvic/extrapelvic percentages were 18.5% (22 out of 119)/41.2% (49 out of 119) for nonirradiated and 12.9% (8 out of 62)/43.5% (27 out of 62) for patients treated with postoperative radiotherapy (32,139,140). From this overview, it does not appear that postoperative radiotherapy has any real effect on reducing recurrences for patients with uterine leiomyosarcoma. However, two of the listed series (32,139) combined to yield an 11.1% (4 out of 36) pelvic relapse rate with radiation versus 61.1% (22 out of 36) without the implementation of adjuvant radiation therapy. Yet the major problem is that the majority of these patients have distant extra-abdominal metastases, such as the lung, despite having local control (32,139). In addition, a more recent retrospective study from a single institution (11) performed a case-control study of patients with uterine leiomyosarcomas that “showed a trend toward improved survival in the 31 cases with adjuvant pelvic irradiation compared with the controls who did not receive adjuvant radiation therapy.” This would suggest that adjuvant systemic therapy must be added in order to have an impact on the outcome of these patients.

Endometrial Stromal Sarcomas

Table 24.7 focuses on patients with endometrial stromal sarcomas (ESSs), the third most common type of uterine sarcomas. This class of endometrial sarcoma can be subdivided (141) by mitotic index into either a low-grade category (endometrial stromal sarcoma) or a high-grade sarcoma now termed undifferentiated uterine sarcoma. The total pelvic and extrapelvic rates of relapse depicted in Table 24.7 are 42.2% and 33.3%, respectively. Only one (142) of the listed studies clearly attempts to subdivide the sites of disease relapse by sarcoma type.

It can be ascertained from this latter report (142) that there were no reported abdominal or distant recurrences independent of the administration of adjuvant irradiation for all stages of

^cNo RT for one patient.

low-grade ESS. Yet, there was a 33.3% (6 out of 18) pelvic recurrence rate, of which the majority did not undergo any radiation therapy. This latter finding suggests that postoperative external pelvis radiotherapy should at least be considered for the subset of patients with low-grade ESS.

A more recent report (143) retrospectively reviewed 28 patients with endometrial stromal sarcomas of which 19 were low grade and 9 were high grade. Fifty percent of the patients in this series underwent adjuvant pelvic radiotherapy with no difference in the survival of the patients. In addition, almost 30% of those receiving adjuvant radiotherapy relapsed within the treatment field. Regarding undifferentiated endometrial sarcomas, one study documented multiple sites of recurrence, including abdominal (34.8% [11 out of 32]), distant (34.8% [11 out of 32]), and pelvic (40.6% [13 out of 32]) sites of relapse (144). Thus, unless vaginal brachytherapy finds a niche, there appears to be no definite indication for postoperative radiotherapy for patients with these high-grade lesions.

CHEMOTHERAPY

Uterine sarcomas, although far less common than endometrial carcinomas, exhibit two features that increase the need for systemic therapy: a recurrence rate of at least 50%, even in early-stage disease, and a high propensity for distant failure. The comparatively low incidence of uterine sarcomas has made randomized, controlled trials difficult. Despite this, cooperative group studies have provided data from phase II and III trials for the rational selection of systemic chemotherapy.

Crucial to the understanding of the use of chemotherapy in uterine sarcomas is the observation that these neoplasms are heterogeneous. The first two subtypes, malignant mixed müllerian tumors (carcinosarcomas) and leiomyosarcomas, constitute 90% of cases entered into clinical trials. These two histologic subtypes are usually the only uterine sarcomas with sufficient numbers to permit meaningful phase III studies; however, as these two histologic subtypes appear to respond differently to chemotherapy, they should be studied separately.

Limited Disease

Uterine sarcoma has a high rate of distant metastases even in the absence of intraperitoneal or lymph node metastases. It has been concluded that this is due to the high rate of hematogenous and lymphatic dissemination (145). Even for surgical stage I disease, the recurrence is as high as 53% (32). To date, the largest randomized trial of adjuvant chemotherapy in patients with uterine sarcoma did not segregate different histologic subtypes. Although the recurrence rate and median survival of patients treated with doxorubicin compared to no therapy were 39% versus 51% and 73 months versus 55 months, respectively, this GOG trial concluded that there was no significant difference (119). As with advanced disease, more recent trials began to segregate the histologic subtypes. A nonrandomized study using adjuvant combination chemotherapy of etoposide, cisplatin, and doxorubicin demonstrated a 2-year survival of 92% of 23 patients with surgical stage I and stage II uterine malignant mixed müllerian tumors. The fact that seven patients also received radiation therapy makes the result controversial (146). A pilot study concluded that multimodality treatment consisting of chemotherapy with epirubicin and cisplatin as well as radiation resulted in a 74% overall survival at a median follow-up of 55 months in 38 patients with surgical stages I and II malignant mixed müllerian tumors (35). However, the high dropout made the conclusion of multimodality treatment controversial. A more recent GOG study by Sutton et al. reported that 65 patients with completely resected stage I and II malignant mixed müllerian tumors of the uterus were treated with adjuvant ifosfamide and cisplatin (Fig. 24.20) (147). The 2- and 5-year survivals were 82% and 62%, respectively. Since more than half of the recurrences involved the pelvis, the study suggested that a combined sequential approach with chemotherapy and radiotherapy might be beneficial for this group of patients, which should be verified in a randomized phase III study.

Previous studies reported that an effective adjuvant chemotherapy regimen was a combination of cyclophosphamide, vincristine, doxorubicin, and dacarbazine (DTIC) with 68% to 89% 5-year survival in stage I uterine sarcomas (148–151).

FIGURE 24.20. Survival in patients with stage I and II carcinosarcomas treated with adjuvant cisplatin and ifosfamide.

To date, there have been no separate prospective studies on patients with uterine leiomyosarcomas. Two factors continue to limit the study of adjuvant therapy in patients with uterine leiomyosarcomas: the relatively low frequency of the disease, which makes it difficult to complete randomized trials in a reasonable period of time, and the lack of highly active agents.

Advanced and Recurrent Disease

Leiomyosarcomas

Numerous single agents have been and continue to be tested in patients with leiomyosarcomas (Table 24.8) (152–174). Doxorubicin and ifosfamide are the most active agents investigated as primary single-agent chemotherapy in recurrent and advanced uterine leiomyosarcomas. As shown in other types of soft-tissue sarcoma, gemcitabine has demonstrated its activity in one (2.3%) complete response and eight (18.2%) partial responses in persistent or recurrent uterine leiomyosarcomas (162). Unfortunately, the results have been unimpressive. In 1983, the GOG demonstrated seven responses among 28 patients (25%) treated with doxorubicin every 3 weeks as a single agent (158). To date, this has been considered to be the most active single agent. Later the GOG reported that treatment with liposomal doxorubicin yielded one complete (3.2%) and four partial (12.9%) responses and no advantage over historical results with doxorubicin (152). The GOG demonstrated that ifosfamide had moderate activity, with six partial responses among 35 patients (17%) (155), whereas limited activity was seen with single-agent paclitaxel, which was associated with a 9% overall response in 33 patients (154). Intravenous single-agent etoposide was shown to have an overall response of 10.7% in 28 patients (171), whereas prolonged oral etoposide had an overall response of 6.9% among 29 patients (170). However, no complete or partial responses were observed in another GOG phase II study with single-agent intravenous etoposide 100 mg/m² daily for 3 days every 3 weeks (156). Topotecan was tested in 36 patients with complete response in 1 (3%), partial response in 3 (8%), stable disease in 12 (33%), and increasing tumor in 20 (56%) (153). Single-agent cisplatin also had a poor overall response of 3% to 5% in phase II trials (157,174). The antifolate compound trimetrexate was used in a small study reported in 2002, which was associated with an overall response of 4.3% in 28 patients who had received prior

treatment (169). Mitoxantrone (173), diaziquone (161), amonafide (172), aminothiadiazone (160), and piperazinedione (159) were inactive as single agents.

Combination chemotherapy yields greater response rates (Table 24.8) (158,175–181). In 1983, the GOG demonstrated that the combination of doxorubicin and dacarbazine resulted in an overall response rate of 30%. Two years later, the same group demonstrated a 19% response rate using the combination of doxorubicin and cyclophosphamide (181). Both of the phase III trials were too small to make any definite conclusions. However, as mentioned, the trials did serve the purpose of allowing researchers to observe that leiomyosarcomas had a different chemotherapeutic response profile compared to malignant mixed müllerian tumors, resulting in the separation of the two different histologic entities in subsequent trials.

In 1996, the same group demonstrated an 18% overall response with a combination of dacarbazine, etoposide, and hydroxyurea (178). In the same year, using a combination of ifosfamide and doxorubicin, the GOG demonstrated an overall response of 30.3% in patients with advanced leiomyosarcoma with no history of prior treatment (179). The most recent study from the GOG showed that the use of mitomycin, doxorubicin, and cisplatin produced an overall response rate of 23% in 35 patients. Pulmonary toxicity was appreciable, however (177). Based on this study, the GOG conducted a phase II study with dacarbazine, doxorubicin, mitomycin, and cisplatin (DAMP), which produced a 27.8% response rate, but the complexity and toxicity of the regimen precluded further investigation, and the study was closed after the first stage of accrual (175). Gemcitabine plus docetaxel was proven highly active and tolerable (53% overall response rate) in treated and untreated patients with leiomyosarcomas (180). The effort in leiomyosarcomas continues to focus on the identification of active drugs and combinations in phase II trials. Given the paucity of survival data available from the randomized trials to compare various chemotherapy regimens, a pooled analysis of phase II studies was undertaken to compare the difference of response rate between single-agent and combination therapy. It showed that patients who received first- or second-line chemotherapy for the treatment of metastatic leiomyosarcoma had a higher response rate with combination chemotherapy than with single-agent chemotherapy (182). However, current phase III randomized clinical trials are only suggestive of the role of combination chemotherapy in advanced or recurrent uterine leiomyosarcomas.

Uterine Carcinosarcomas

Several drugs have been studied in this group of tumors as single agents (Table 24.9) (158,173,175,183–196). However, only three drugs have demonstrated clear-cut activity: ifosfamide, cisplatin, and paclitaxel (183–186,190,195,196). Of the three drugs ifosfamide is the most active single agent studied to date.

In a 5-day schedule, ifosfamide produced 25 complete and 12 partial responses (overall response of 36%) among 102 patients with no prior chemotherapy (185).

In patients with prior chemotherapy, cisplatin produced an 18% response in 28 patients (195). A repeat trial in patients with no prior chemotherapy documented essentially the same response rate of 19% among a larger group of patients (183).

Both trials used cisplatin at 50 mg/m² every 3 weeks. Investigators at the M. D. Anderson Cancer Center employed a higher dose ranging from 75 mg/m² to 100 mg/m² every 3 weeks. Only 12 patients with measurable disease were entered into the trial, but one complete and four partial responses were observed (overall responses 42%) (196). The lack of randomization and the small number of cases in this trial preclude conclusions about the merits of the higher dose. Paclitaxel as a single agent was associated with a response rate of 21.2% in a group of 33 patients with uterine sarcoma who had prior chemotherapy, with an 8.2% response rate in patients who failed appropriate local therapy (190).

Doxorubicin, generally regarded as the most active agent in soft-tissue sarcomas, unfortunately demonstrated inconsistent activity in three trials of patients with malignant mixed müllerian tumors. The first two studies constituted one arm of each of two randomized trials. In the first, four responses among 41 patients (10%) with mixed mesodermal tumors (158) were observed. The other demonstrated a 19% response rate utilizing a dose of 60 mg/m² every 3 weeks in recurrent or advanced uterine sarcomas (181). The third, which employed a range of doses from 50 mg/m² to 90 mg/m² every 3 weeks, resulted in no response among the nine patients with measurable disease (187). Topotecan 1.5 mg/m² daily for 5 days had unimpressive activity (10% response rate) in patients with advanced or recurrent uterine malignant mixed müllerian tumors previously treated with chemotherapy (188). Demonstrating negligible activity in phase II studies were etoposide (200), mitoxantrone (173), piperazinedione (164), diaziquone (193), amonafide (191), trimetrexate (93), and aminothiadiazole (192).

In the history of chemotherapy development, combination therapy usually results in a higher response rate than single-agent treatment. However, not all combination regimens have had an impact upon survival. This is clearly seen in the treatment of uterine carcinosarcomas.

There have been numerous reports of combination chemotherapy for uterine carcinosarcomas (Table 24.9) (158, 181, 185, 189, 197–201). A combination of cyclophosphamide, vincristine, doxorubicin, and DTIC had a reported 23% (61) overall response rate. A combination of etoposide, hydroxyurea, and DTIC resulted in a response of 15% in 32 patients (198). Later EORTC reported a trial based upon 48 patients with unresectable or recurrent malignant mixed müllerian tumor who were treated with a combination of cisplatin, doxorubicin, and ifosfamide. The overall response rate was an impressive 56%. Unfortunately, this regimen was also associated with a high incidence of nephrologic and hematologic toxicities. The group concluded that alternative platinum-based regimens with more favorable toxicity profiles should be explored (201). Indeed, evaluation of the true value of combination chemotherapy requires randomized phase III trials.

The first randomized study in 1983 by the GOG, which combined malignant mixed müllerian tumors with other sarcomas, resulted in patient numbers being too small for subset analysis (158). Nonetheless, combining doxorubicin and DTIC resulted in an overall response of 23% and a trend toward greater response as compared to single-agent doxorubicin (10%). A significant improvement in progression-free and overall survival could not be demonstrated, but two conclusions could be drawn from this trial. The first was the fact that a greater response to chemotherapy was significantly associated with an increase in overall survival and the disease-free survival. The second observation was that malignant mixed müllerian tumors had a different response profile compared to leiomyosarcomas. Two years later, the GOG compared cyclophosphamide plus doxorubicin to single-agent doxorubicin. A response of 25% was observed in malignant mixed müllerian tumors; again, however, numbers were inadequate to show any significant benefit compared with

single-agent doxorubicin. The trial was also closed early because of failure to reach statistical significance (181).

With the recognition of the difference in response to therapy between malignant mixed müllerian tumors and leiomyosarcomas, randomized trials began to regard each of the two major histologic subtypes as separate patient populations. Unfortunately, this increased the time necessary to complete clinical trials. Nonetheless, a large randomized trial was performed and reported in 2000. The GOG evaluated the addition of cisplatin to ifosfamide in 194 eligible patients and found that this improved the overall response rate from 36% to 54% and prolonged the median progression-free interval by an absolute 2 months. However, this advantage was not associated with a significant overall survival gain (185).

More recently and based upon the finding of moderate activity (18% response rate) of paclitaxel for this disease, the GOG carried out a phase III trial of ifosfamide with or without paclitaxel in advanced uterine malignant mixed müllerian tumors. The group found that the addition of paclitaxel produced a 45% response rate compared with 29% in the ifosfamide single-agent arm with overall survival significantly improved. There was a significant decrease in the hazard of death and progression but more sensory neuropathy, as expected (189).

In conclusion, there is moderate evidence to support the use of combination chemotherapy in advanced or recurrent uterine carcinosarcomas (Table 24.10). Combination regimens that result in significant improvements in survival are needed.

Endometrial Stromal Sarcoma

Randomized phase III trials with stromal sarcomas are limited due to the rarity of this disease. Only two randomized trials compared single-agent and combination chemotherapy in advanced uterine sarcoma, without response rate of stromal sarcomas reported separately. The GOG reported a phase II study of ifosfamide treatment in 21 cases with recurrent or metastatic endometrial stromal sarcomas. Three patients experienced complete response and four had partial responses, for an overall response of 33.3% (202). Another noncontrolled study observed a 50% response rate to doxorubicin therapy in ten patients with recurrent endometrial stromal sarcomas (203). Many other literatures are case reports and retrospective studies with a small number of cases. Published chemotherapy regimens include carboplatin and paclitaxel (204); doxorubicin, cisplatin, and ifosfamide (205); doxorubicin and ifosfamide (206); doxorubicin, vincristine, and cyclophosphamide (207); and prolonged oral etoposide (208).

Interest in endometrial stromal sarcomas continues owing to the difference in the prognosis of patients with low-grade disease versus those with high-grade disease. In recurrent stromal sarcoma, reports support hormone therapy for patients with low-grade subgroup and chemotherapy for high-grade tumors (209). Current definitions do not include high-grade lesions as a component of endometrial stromal sarcoma.

Toxicity

The most common toxicities of chemotherapy are hematologic and gastrointestinal toxicity. The grade 3-4 adverse effects of chemotherapy with overall response rate higher than 5% in leiomyosarcomas and mixed mesodermal tumors are listed in Tables 24.11 and 24.12. Combination chemotherapy has a much higher incidence of grade 3-4 side effects compared with the single-agent regimen. The overall response rate of combination with ifosfamide plus cisplatin is 54%; however, the grade 3-4 of leukopenia is 97%, and six deaths occurred before the first dose reduction of ifosfamide (185). The current phase III trial with ifosfamide plus paclitaxel reported a 45%

overall response rate with tolerable toxicities (189), which seems a relatively effective and safe regimen. Among other phase II trials of different chemotherapeutic regimens, liposomal doxorubin, paclitaxel, doxorubicin, cisplatin, and etoposide plus cisplatin plus doxorubicin were reported to have less toxicity with moderate effect.

Hormonal Therapy

Although the role of hormonal therapy is clear in breast and endometrial cancers, few uterine sarcomas contain sufficient estrogen- or progesterone-receptor protein to influence therapy, the only exception being low-grade endometrial stromal sarcomas or stromal nodules. It has been found that estrogen and progesterone receptors were found in 55.5% and 55.8%, respectively, of samples from patients with various types of uterine sarcomas, but the median concentrations were substantially lower than those observed in breast or endometrial cancers. Endometrial stromal sarcomas had higher receptor levels (210). Uniquely, low-grade endometrial stromal sarcomas are hormonally responsive in roughly two thirds of cases and long-term maintenance therapy should be beneficial.

Progestins, gonadotropin-releasing hormone (GnRH) analogues (211), or aromatase inhibitors (209,212) have been used in the treatment of patients with advanced or recurrent stromal sarcomas and successfully gain long-term stability in case reports. Several papers reported that long-term use of tamoxifen for the treatment of breast cancer was related to the development of uterine sarcoma (213,214).

Lantta et al. (215) published two cases of extensive intraperitoneal low-grade endometrial stromal sarcoma associated with high levels of progesterone receptors in complete remission with hormonal therapy. Three patients reported by Baker et al. (216) had partial responses or stabilization of disease on oral megestrol acetate; all had concentrations of progesterone receptors exceeding 674 fmol/mg. Piver et al. (217), in a collaborative survey of endolymphatic stromal myosis, recorded complete or partial responses to hormonal therapy in 6 of 13 patients (46%) treated with progestational agents. Scribner and Walker (218) reported a patient with an extensive endometrial stromal sarcoma of the uterus whose tumor was reduced to resectable size by the administration of leuprolide acetate and megestrol acetate. Endometrial stromal sarcomas of a lower grade have also been reported to express *srp27*, an estrogen-induced 24-DK protein suggesting hormone responsiveness (219). Medroxyprogesterone acetate has induced major responses in pulmonary metastatic lesions from endometrial stromal sarcoma (130,220,221). GnRH analogues were reported to control the progression of a recurrent low-grade endometrial stromal sarcoma with moderate estrogen and progesterone receptor positivity (211). Medroxyprogesterone acetate and aromatase inhibitors, such as letrozole, were observed to be highly effective and have sustained progression control in six of ten cases with low-grade stromal sarcoma (222). Spano et al. presented two cases of endometrial stromal sarcoma with lung metastases treated with aminoglutethimide who achieved complete response and remained disease-free for 14 and 7 years, respectively (209). However, there presently is no prospective study on hormonal treatment for stromal sarcoma published.

Hormonal therapy has not been extensively evaluated in mesenchymal uterine tumors. There are anecdotal reports of responses to hormonal therapy in adenomas and low-grade leiomyosarcomas (223). One case of letrozole therapy in high-grade malignant mixed müllerian tumor with marked tumor control was reported, but the area has not been well studied (224).

Biologic Therapy

Since the high recurrence and poor response to radiotherapy and chemotherapy, biologic therapy may have more promise in the area of uterine sarcoma, as well as other types of soft-tissue sarcoma. The recent advances in the biology of uterine sarcoma related to probable treatment target have concentrated on tyrosine kinase receptors and vascular endothelial growth factor (VEGF).

Since the discovery that high proto-oncogene *c-kit* expression in gastrointestinal stromal tumors (GISTs) may be amenable to control with tyrosine kinase inhibitors, such as imatinib mesylate and sunitinib, some interest has been focused upon uterine sarcomas (225). However, the expression of *c-kit* in the uterine sarcoma varies greatly in different studies. Some studies demonstrated the presence of *c-kit* in 41.3% to 83% of uterine leiomyosarcoma (226–228), but other studies documented little presence (229–232). Given the great progress made in the GISTs with imatinib mesylate, a GOG phase II evaluation of sunitinib maleate in the treatment of recurrent or persistent leiomyosarcoma of the uterus was completed with negative results.

Emoto et al. demonstrated inhibition of a VEGF-expressing malignant mixed tumor cell line by TNP-470, an angiogenesis inhibitor (232). Another angiogenesis inhibitor, thalidomide, was studied in recurrent or persistent malignant mixed müllerian tumor of the uterus by the GOG. No activity was seen.

Advances in the understanding of the biology of uterine sarcomas may provide more treatment targets and make long-term control of the disease possible.

Systemic Therapy Summary

The current role of chemotherapy in the management of uterine sarcomas involves the treatment of patients with advanced or recurrent disease, and an emphasis on palliative intent. In leiomyosarcomas, the active drugs are doxorubicin, ifosfamide, gemcitabine, and docetaxel. For malignant mixed müllerian tumors, the drugs of choice are ifosfamide, cisplatin, and paclitaxel. Hormonal therapy, including progestational agents, GnRH analogues, and aromatase inhibitors, may have a role in the treatment of advanced or recurrent endometrial stromal sarcomas. The use of hormonal agents in the treatment of other histologic subtypes has not been well studied. Efforts to identify additional active agents continue.

LONG-TERM RESULTS OF THERAPY

Leiomyosarcoma

The prognosis of patients with uterine leiomyosarcoma is uniformly poor. The reported 5-year survival of uterine leiomyosarcoma varies between 30% and 48% (6, 233–236). However, leiomyosarcoma may tender a worse prognosis than malignant mixed müllerian tumor when adjusting for stage and mitotic count (6,233).

Major et al. reported a progression-free survival at 3 years of 31% and the recurrence rate was 71% in 59 patients with leiomyosarcomas. The mitotic index was the only factor significantly related to progression-free interval (32). In the study of 423 uterine sarcomas of Olah et al. (6), overall 5-year survival was 31%; 42% of patients with endometrial stromal sarcomas, 34% of those with leiomyosarcomas, and 33% with malignant mixed müllerian tumors were alive at the end of the study period with median survival times of 30, 17, and 13 months,

respectively. These researchers also found that stage, degree of differentiation, age, and histologic type were the four common factors influencing survival in a multiple regression analysis (6,11).

Carcinosarcomas and Müllerian Adenosarcomas

Major et al. (32) reported a recurrence rate of 53% for 301 patients with clinical stage I and II malignant mixed müllerian tumors. This included 61 patients (20%) who were “up-staged” based upon surgical findings. The prognostic factors based on multivariate analysis were adnexal spread, lymph node metastases, histologic cell type, and grade of sarcoma. Median survival in patients with clinically recurrent or advanced-stage malignant mixed müllerian tumors ranged from 4 to 13 months (2,8,237,238) despite therapy.

Kaku et al. (239), in a review of GOG materials, indicated that müllerian adenosarcomas were usually locally invasive; 30% of the 31 cases in their review suffered recurrences. Among the 100 patients reported by Clement and Scully (25), 26.1% developed recurrent disease. Generally, müllerian adenosarcomas are regarded as locally invasive and are managed in some cases with local excision. However, sarcomatous overgrowth has been described in as many as 57% of cases (90,239) and is associated with a fulminant clinical course and death.

Endometrial Stromal Sarcoma

Virtually no endometrial stromal nodule will recur after hysterectomy. In the series of Dionigi et al. (240), there were no reported relapses in patients followed for a median of 43.5 months and a maximum of 214 months.

In comparison with leiomyosarcoma and malignant mixed müllerian tumor, patients with endometrial stromal sarcoma tend to present with low-grade and early-stage disease with favorable prognosis (236,241). Denschlag et al. (236) reported a 5-year survival of 82% among women with endometrial stromal sarcoma, which was significantly better than other subgroups. It may be difficult to determine the prognosis of endometrial stromal sarcoma in a given patient, however. Although mitotic count may be important, Chang et al. (242) suggested that stage (stage I versus stages II-IV) was more important in determining survival. Their series was largely referral material, and few patients had undergone complete surgical staging. Perhaps as a result, 36% of patients with stage I in their paper experienced relapse and 23% of these died of the disease. Remarkably, median time to relapse in patients with stage I tumors was 69 months. Patients with stage I endometrial stromal sarcomas most commonly experienced recurrences in the pelvis or abdomen, strongly suggesting a role for complete surgical staging and, perhaps, adjuvant radiotherapy. Eight of 73 patients (11%) with stage I disease either presented with or developed pulmonary metastases. However, the median time to pulmonary relapse was 116 months.

In the large series of Chang et al. (242), mitotic count successfully predicted outcome in patients with stage II-IV endometrial stromal sarcomas. Utilizing the ten mitoses per 10 hpf criteria, 8 of 13 (62%) patients with undifferentiated endometrial sarcomas experienced disease recurrence compared with 35 of 77 (45%) of those with low-grade tumors.

Young et al. (243) and Berchuck et al. (203) have suggested that patients with ovarian preservation at the time of hysterectomy for endometrial stromal sarcoma were more likely to develop recurrences. Although this was not the case in the report of Chang et al. (242) (seven cases with no recurrences

after hysterectomy), bilateral salpingo-oophorectomy would seem to be prudent given the potential for low-grade endometrial stromal sarcomas to express estrogen receptors and respond to hormonal therapy.

Patterns of Failure

Although Echt et al. (19) reported no difference in recurrent patterns between patients with malignant mixed müllerian tumors and leiomyosarcomas, others have reported a propensity for malignant mixed müllerian tumor to relapse in the abdomen or pelvis and leiomyosarcomas to metastasize to the lung (120). In the follow-up of the GOG staging study reported by Major et al. (32), 28 of 301 patients with malignant mixed müllerian tumors developed lung metastases (9.3%) versus 24 of 59 (40.7%) of those with leiomyosarcomas. Recurrences with a pelvic component were 63 (20.9%) and 8 (13.6%), respectively, for the two tumor types. The decision to use postoperative irradiation in this study was made by treating physicians.

In patients whose tumors were initially confined to the uterus, there were purely distant recurrences in only 4 of 51 (7.8%) patients with malignant mixed müllerian tumors reported by Nielsen et al. (244) and Shaw et al. (245), but 22 of 35 (62.9%) in the patients with leiomyosarcoma reported by Punnonen et al. (246) and Yu et al. (247). In a 10-year review of uterine leiomyosarcomas at Massachusetts General Hospital, Dinh et al. (248) reported that 20 of 27 patients either presented with or developed pulmonary metastases.

CLINICAL TRIALS

The GOG has played a leading role in developing new drugs for advanced and metastatic leiomyosarcomas and uterine malignant mixed müllerian tumors through a series of phase II studies in both previously treated and chemotherapy-naïve patients. It will be important to include available biologic and immunologic agents in this series of studies. The GOG has also completed one phase III study of ifosfamide with or without paclitaxel in patients with persistent or recurrent mixed müllerian tumors (185). Several existing GOG phase II studies are ongoing, such as trabectedin in advanced, persistent, or recurrent leiomyosarcoma of the uterus.

MOLECULAR BIOLOGY, GENETICS, FUTURE DIRECTIONS, AND CONCLUSIONS

There has been a slow evolution in the understanding of the basic science of uterine sarcomas. The majority are felt to be sporadic with no specific etiology and most have complex karyotypes (249). However, in an increasing number of non-uterine sarcomas, specific chromosomal translocations resulting in fusion genes that are constitutive and involve activation of transcription factors have been identified. Clear cell sarcomas, myxoid liposarcomas, alveolar rhabdomyosarcomas, and alveolar soft-part sarcomas all have been associated with translocation-induced fusion genes that result in activated transcription factors and uncontrolled growth (249). Perhaps the most striking advance was the identification of *c-kit* tyrosine kinase activation in GISTs, which are histologically indistinguishable from leiomyosarcomas of the small bowel. The specific inhibitor of *c-kit*, imatinib mesylate (KSTI-571), may produce long-term responses in patients with metastatic GISTs.

The reported *c-kit* immunoreactivity was present in 0% to 83% of uterine leiomyosarcomas (226–231). Whether this finding will translate into a role for sunitinib maleate in these malignancies remains to be seen in future clinical trials.

In leiomyosarcomas, other avenues may be explored. Human immunodeficiency virus–immunocompromised pediatric patients are unusually susceptible to leiomyosarcomas. The causative agent in these tumors appears to be the Epstein-Barr virus (250). Similar smooth muscle tumors associated with the Epstein-Barr virus have been described in a few adult organ transplant recipients (251). Only one report about this virus is expressed in an immunocompetent adult with leiomyosarcomas (252). A common intermediary factor may exist, which is as yet unrecognized.

Trials of adjuvant chemotherapy are appropriate in early-stage, resected leiomyosarcomas. Recurrence rates after surgery alone are unacceptably high; the risk of mortality associated with recurrent leiomyosarcoma easily offsets any morbidity derived from adjuvant chemotherapy in this population of relatively young patients. One ongoing study utilizes sequential docetaxel plus gemcitabine followed by doxorubicin in women with high-grade, stage I and II leiomyosarcomas.

A variety of potential markers are overexpressed in uterine malignant mixed müllerian tumors and include p53, *mdm-2* (253), platelet-derived growth factor receptor- β , *c-abl* (254), *HER2/neu* (255,256), vascular endothelial growth factor (257), and insulin-like growth factor (IGF)-II (258). None is associated with prognostic implications (259,260); the evolving concept of malignant mixed müllerian tumors as metaplastic endometrial carcinomas may result in elucidation of new means of prevention and therapy. Combination or sequential radiation and chemotherapy have a great deal of appeal (31).

Endometrial stromal sarcomas have been associated with the translocation t(7;17) (p15–21;q12–21) in over a third of cases (261); this information, in addition to the established hormone responsiveness of low-grade stromal sarcomas, may provide a basis for therapeutic strategies in the future.

A basic understanding of uterine sarcomas and their differences is paramount to the understanding of surgical and adjuvant therapy as well as palliative treatment in patients with these rare neoplasms; this knowledge is essential to the practice of gynecologic oncology.

CHAPTER 25 ■ EPITHELIAL OVARIAN CANCER

GINI F. FLEMING, BRIGITTE M. RONNETT, JEFFREY SEIDMAN, RICHARD J. ZAINO, AND STEPHEN C. RUBIN

Epithelial ovarian cancer is the leading cause of death from gynecologic cancer in the United States. Data from the Surveillance, Epidemiology, and End Results (SEER) program of the U.S. National Cancer Institute (NCI) suggest that 21,650 new cases of ovarian cancer and 15,520 deaths from ovarian cancer are expected in the United States for 2008 (1). This makes ovarian cancer the eighth most common major cancer and the fifth most common cause of cancer death in U.S. women. It has been estimated that, in the United States, one woman in 70 will develop ovarian cancer, and one woman in 100 will die of the disease.

Worldwide, ovarian cancer is the sixth most common form of cancer in women. In general, the highest incidence rates are found in European and North American population groups with the lowest rates in Asian population groups (Fig. 25.1). In Japan, the incidence has increased since the 1970s, although it remains lower than in many Western countries (2). In the United States, rates for black American women are about two thirds of those for white women, and rates for women of Asian/Pacific Islander descent are similar to those of black women (3). Rates of hysterectomy and oophorectomy in a population will affect the rate of ovarian cancer; 40% to 50% of women in the United States have a hysterectomy by age 60 to 70, and about half of them have their ovaries removed at the same time (4).

Despite some apparent advances in therapy, survival in the United States from ovarian cancer has increased only slightly over the past decades. Small but significant improvements in survival have been noted for white women but not for black women. Overall 5-year relative survival rates increased from 37% during 1975 to 1977 (36% for whites and 43% for blacks) to 45% during 1996 to 2002 (45% for whites and 39% for blacks). These numbers are affected by the exclusion of borderline tumors from the 1996 to 2002 survival rates (1). Outcomes in black women are worse even when controlling for age, stage, and histology. The reasons for this are not clear. However, in a retrospective analysis of six Gynecologic Oncology Group (GOG) studies for women with advanced-stage disease, race was not associated with progression-free survival or overall survival in the clinical trial setting after controlling for other prognostic factors (5).

RISK FACTORS AND PATHOGENESIS

Established risk factors (reviewed in more detail in Chapter 1) for ovarian cancer include increasing age, family history, nulliparity, early menarche, and late menopause. Breast-feeding is protective. Aside from having a first-degree relative with the

disease, age is the most important risk factor for ovarian cancer (Fig. 25.2). Fifty percent of all U.S. cases occur in women over the age of 65 (6). Older women have a much worse prognosis overall (Fig. 25.3), which is in part because they have an increased incidence of high-stage and high-grade disease at the time of diagnosis (Table 25.1) (7). However, in an analysis of the SEER database, age remained a poor prognostic factor even when results were adjusted for stage, grade, histologic cell type, race, and surgical treatment. The relative risks (RR) associated with endocrinologic factors are much smaller, though important, because they are potentially subject to modulation.

Risk Factors for Mucinous Tumors

The epidemiologic risks associated with mucinous tumors may be different from those associated with serous or other histologic subtypes (8), although the infrequency of this histologic subtype and the potential for contamination of the sample with metastatic tumors from other organ sites make it difficult to draw firm conclusions. The Danish MALOVA case-control study reported that the overall risk (OR) of ovarian cancer decreased with ever being pregnant (OR 0.40), with increasing number of pregnancies, and with use of oral contraceptives (OR 0.67) and risk increased with ever use of hormone replacement therapy (HRT) (OR 1.3). These effects were all present for serous tumors, endometrioid tumors, and tumors of other histologies, but not for mucinous tumors. In contrast, current smoking was an increased risk factor only for mucinous tumors (OR 1.78) (9). Smoking has also been associated with a three-fold increased risk of benign mucinous ovarian tumors (10). Both invasive mucinous tumors and borderline mucinous tumors are more common in women of Asian descent.

Dietary and Environmental Factors

There have been no consistent relationships reported of specific dietary components to ovarian cancer risk. Although some studies have associated a diet high in meat and animal fat or a diet high in lactose with development of ovarian cancer (8,10), most large recent studies, including the European prospective investigation into cancer and nutrition (EPIC) study, which recruited 366,521 European women (11), and the California Teachers Study, which included 97,275 women with 280 ovarian cancer cases (12), failed to demonstrate any relationship between consumption of animal foods and the development of ovarian cancer. The investigators for the California Teachers Study concluded that while dietary consumption of isoflavones may be marginally associated with decreased

Ovary etc., Incidence: ASR (World) (per 100,000) (all ages)

ovarian cancer risk, most dietary factors are unlikely to play a major role in ovarian cancer development. Coffee has not been consistently associated with ovarian cancer. A few studies have suggested a relationship between alcohol intake and ovarian cancer (13), but this has not been consistent (12). Smoking is a risk factor for mucinous tumors (14). There does appear to be a modest inverse correlation between moderate physical activity and ovarian cancer risk (15,16,17), and obesity has shown a positive association with ovarian cancer risk in 24 of 28 studies reviewed in a recent meta-analysis (15). One interesting cohort control study showed that both recent obesity (OR 1.93; 95% CI, 1.3 to 2.88) and obesity at age 20 (OR 4.38; 95% CI, 1.88 to 10.2) were associated with an increased risk of benign serous tumors (16).

Reproductive and Hormonal Factors

The protective effects of parity and oral contraceptive use support both the “incessant ovulation” hypothesis and the “gonadotropin” hypothesis of ovarian cancer etiology. According to the “incessant ovulation” hypothesis, ovarian cancer develops from an aberrant repair process of the surface epithelium, which is ruptured and repaired during each ovulatory cycle (17). The probability that ovarian cancer will develop is therefore a function of the total number of ovulatory cycles together with a genetic predisposition and undefined environmental factors. In support of this theory, it is well known that domestic egg-laying hens, which are forced to ovulate incessantly, have a high incidence of what are believed to be ovarian-derived tumors with peritoneal carcinomatosis (18). However, it fails to account for the increased risk of ovarian cancer with obesity and polycystic ovary syndrome (19). Alternatively, excessive gonadotropin secretion has been theorized to play a role in ovarian oncogenesis (20). Under excessive gonadotropin stimulation and resulting estrogenic stimulation, the surface epithelium is entrapped in inclusion cysts where it proliferates and undergoes malignant transformation. However, not all epidemiologic evidence supports this hypothesis. In particular, HRT, which suppresses postmenopausal gonadotropin levels, has been shown to increase, not decrease, the risk of ovarian cancer.

Another hypothesis has suggested a role for androgens and progestins in ovarian cancer development (21). Ovaries contain androgen receptors, and elevated androgen levels have been associated with an increased risk of ovarian cancer. Cottreau et al. reported that women who took danazol (a synthetic androgen) for endometriosis had a 3.2-fold higher risk of developing ovarian cancer than those who took a gonadotropin-releasing hormone (GnRH) agonist (22). Progestins, on the other hand, may be protective. Ovaries also contain progesterone receptors. Progestin levels are increased during pregnancy, and progestin-only oral contraceptives that do not suppress ovulation have a protective effect similar to that observed with contraceptive preparations with a greater suppressive effect on ovulation (23). These effects, however, are not simple; another case-control study suggested that users of the progestin norethindrone at low doses (0.5 mg or less) had a significantly reduced risk of ovarian cancer compared to women using 10 mg norethindrone (24). Cramer et al. have hypothesized that ovarian cancer risk is associated with “stromal hyperactivity” (25). He theorizes that granulosa and theca cells remain in the ovarian stroma after ovulation and control steroid production. By reducing ovulatory cycles, the number of residual follicles in the stroma with functioning granulosa-theca cells would also be decreased.

Another hypothesis for ovarian cancer development is based on the association of endometriosis and pelvic inflammatory disease with increased risk of ovarian cancer. Endometriosis is particularly associated with clear cell and endometrioid histotypes (26). The “inflammation” hypothesis states that any inflammatory agent or condition increases the risk of ovarian cancer. Some (27,28), but not all (29), epidemiologic data suggest that the use of anti-inflammatory agents, including aspirin and nonsteroidal anti-inflammatory drugs, protects against ovarian cancer development. Smith and Xu have provided an alternative hypothesis based on their observation that loss of basement membrane is an early event leading to morphologic transformation of ovarian surface epithelium (30,31). In preovulatory stimulation of the ovarian surface epithelium by gonadotropins, the basement membrane of the ovarian surface is similarly degraded. As loss of basement membrane is mediated through prostaglandins produced by gonadotropin-induced cyclo-oxygenase-2 (COX-2), this observation provides another mechanism for the possible preventive effect of nonsteroidal anti-inflammatory agents against ovarian cancer.

Oral Contraceptive Use

Case-control studies have consistently documented that users of oral contraceptives have a 30% to 60% smaller chance of

developing ovarian cancer than do women who have never used oral contraceptives (OCPs) (31). The largest study reported, the Cancer and Steroid Hormone study (CASH) reported that OCP use for even a few months reduced the risk by 40% for women between the ages of 20 and 54 years (32). The World Health Organization (WHO) reported on 368 women with ovarian cancer and 2,397 matched controls (33). The relative risk for women who had ever used OCP was 0.75. The risk further decreased with increasing time since cessation of use and, in contrast to some other studies (34), the risk decreased with longer duration of use. In addition, the decreased risk was substantially greater in nulliparous compared to parous women (0.16 vs. 0.85, respectively).

Ovulation-Inducing Drugs

Some, but not all, studies have shown a link between fertility-inducing drugs such as clomiphene, and an increased risk of ovarian cancer. An older pooled analysis of 12 case-control studies found an odds ratio of 2.8 (95% CI, 1.3 to 6.1) for women who had ever used fertility drugs compared to those who had no history of infertility (35). The odds ratio for low malignant potential (LMP, borderline) tumors was 4.0. The risk was highest among nulliparous women, with an odds ratio of 27 (95% CI, 2.3 to 315.6). More recent studies have found either a weak association or no association between infertility treatment and ovarian cancer risk; the literature is well summarized in some comprehensive reviews (36,37).

Tubal Ligation

The Nurses' Health Study of 121,700 nurses was used to determine the effect of tubal ligation and hysterectomy on the subsequent risk of ovarian cancer (38). There was a strong inverse association between tubal ligation and ovarian cancer (RR 0.33). There was a weaker protective effect of hysterectomy (RR 0.67). The mechanism for the protective effects is unclear. Tubal ligation may affect circulating hormone levels by interfering with ovarian circulation. Statistically significant reductions in the risk of ovarian cancer after tubal ligation were also observed in a collaborative analysis of 12 U.S. case-control studies (OR 0.59; 95% CI, 0.38 to 0.53) (39). There was no association between age at surgery or time since surgery.

Hormone Replacement Therapy

Numerous studies have reported a modest association between HRT and risk of ovarian cancer, and a meta-analysis of nine published studies (only one of which did not show a relationship

between HRT and ovarian cancer) confirms this (40). Included among these is a prospective, randomized study, the Women's Health Initiative (WHI) (41). Almost 17,000 postmenopausal women who had not had a hysterectomy were randomized to placebo or one tablet per day of 0.625 mg unconjugated estrogen plus 2.5 mg of medroxyprogesterone acetate. The hazard ratio for invasive ovarian cancer in the women receiving HRT was 1.58, but the overall number of ovarian cancer cases was small ($n = 32$), and the confidence interval was wide (95% CI, 0.77 to 3.24). In the largest analysis, a publication from the Million Women Study, 1.3 million women who had been invited for screening for breast cancer completed questionnaires that included information about HRT (40). Current users of HRT were significantly more likely to develop and die from ovarian cancer than never users (relative risk 1.2 for incident disease and 1.23 for death). The risk appeared to be primarily for serous tumors. Past users were not at increased risk, and there did not appear to be any significant risk with less than 5 years of use. Because of the lack of association with past risk, it has been suggested that HRT stimulates the growth of pre-existing, undiagnosed cancers, rather than increasing the risk of malignant transformation.

Progestins, as noted above, have been proposed to be protective against ovarian cancer, and the risk of ovarian cancer may be greater for estrogen-only HRT than for estrogen-progestin combinations. A Swedish case-control study reported an increased risk associated with the use of unopposed estrogens and sequential estrogen-progestin preparations, but not with the use of continuous progestin regimens (42). The risk of ovarian cancer in the Million Women Study did not differ significantly between those using estrogen-only and those using estrogen-progestin combinations, but the trend was for lower risk with the estrogen-progestin combination (RR 1.53 for more than 5 years of use for estrogen-only preparations versus RR 1.17 for more than 5 years of use of estrogen-progestin combinations).

Hereditary Ovarian Cancer

The clinical genetics of ovarian cancer are reviewed in more detail in Chapter 2. Approximately 10% of cases of invasive epithelial ovarian cancer are estimated to be the result of autosomal dominant high-penetrant genetic factors, predominantly germ-line mutations in the *BRCA1* or *BRCA2* genes. The *BRCA* genes function as classic tumor suppressors, with loss of function of both alleles required for cancer formation. The gene products appear to function in the cellular response to certain types of DNA damage. The lifetime risk of ovarian cancer for women with *BRCA1* mutations and *BRCA2* mutations has been estimated to be 40% and 20%, respectively (43,44).

Hereditary Nonpolyposis Colorectal Cancer Syndrome

Epithelial ovarian cancer is also a component of the hereditary nonpolyposis colorectal cancer syndrome (HNPCC; Lynch syndrome II). This syndrome is a result of germ-line mutations in genes involved in the DNA mismatch repair pathway, and mutation carriers have a predisposition not only to colorectal cancer, but to endometrial and ovarian carcinoma as well as other cancers, including those of the small bowel and biliary tract. HNPCC-related tumors frequently exhibit microsatellite instability (MSI). Not all tumors exhibiting MSI, however, are associated with hereditary syndromes; hypermethylation of the *MLH1* promoter region has been found in MSI-positive cancers of the ovary that do not contain germ-line *MLH1* mutations (45). Five genes are known to be involved in HNPCC: *MLH1*, *MSH2*, *MSH6*, *PMS1*, and *PMS2*. Mutations in *MLH1* and *MSH2* account for about 90% of the mutations detected in families with HNPCC, with *MSH2* being particularly associated with an excess of endometrial and ovarian carcinomas. Ovarian cancer occurs in approximately 10% of women with HNPCC

(46), and tends to occur at an earlier age than sporadic ovarian cancer. Domanska et al. reviewed the Swedish Cancer Registry for epithelial ovarian cancer developing in women under the age of 40 years, and evaluated mismatch-repair status using immunohistochemical evaluation for *MLH1*, *PMS2*, *MSH2*, and *MSH6*. Among 98 cases there was loss of expression of *MLH1/PMS2* in 2, loss of *MSH2/MSH6* in 1, and loss of *MSH6* in 3 tumors. Five of the six demonstrated a microsatellite instability-high phenotype (47).

Clinical Features of *BRCA*-Associated Ovarian Cancer

In 1996 Rubin et al. reported results of a retrospective analysis suggesting that there are distinct clinical and pathologic features of *BRCA1*-associated ovarian cancer (48). Among 53 patients with germ-line *BRCA1* mutations, the average age at diagnosis was only 48 years, and the vast majority of cancers were serous adenocarcinomas. Cancers associated with *BRCA1* mutations had a relatively favorable prognosis, with an actuarial median survival of 77 months compared to 29 months for matched controls (Fig. 25.4).

Most subsequent reports have confirmed that *BRCA1* carriers with ovarian cancer have a younger age at diagnosis, are more likely to have cancers of serous histology and less likely to have borderline or mucinous tumors, and have a somewhat better prognosis than matched controls (49). The number of *BRCA2*-associated ovarian cancers is smaller, and it is not clear if there are differences in the clinical features of *BRCA2*- versus *BRCA1*-associated ovarian cancers. Boyd et al. performed a retrospective cohort study of invasive ovarian cancers in patients of Jewish origin (67 *BRCA1* and 21 *BRCA2*) (50). The average age at diagnosis was 54 years for *BRCA1* mutation carriers, 62 years for *BRCA2* mutation carriers, and 63 years for Jewish women with sporadic ovarian cancers. The histology, grade, stage, and success of cytoreductive surgery were similar for hereditary and sporadic cases, although there were no mucinous tumors and only two clear cell tumors observed among 88 *BRCA*-associated cases, versus five mucinous and seven clear cell tumors among 101 sporadic cases. The median disease-free interval after initial chemotherapy was 14 months for the *BRCA*-associated group and 7 months for the sporadic group ($p < 0.001$). Advanced-stage (III and IV) *BRCA*-linked cases also survived significantly longer than sporadic cases. These observations do not hold only for Ashkenazi-related mutations. A recent report notes that odds of a complete response to initial chemotherapy were 3.2-fold greater in non-Ashkenazi mutation

FIGURE 25.4. Actuarial survival among 43 patients with advanced ovarian cancer and *BRCA1* mutations compared to matched controls without known mutations. Source: Rubin SC, Benjamin I, Behbakht K, Takahashi H, et al. Clinical and pathological features of ovarian cancer in women with germ-line mutations of *BRCA1*. *N Engl J Med* 1996;335:1413-1416.

carriers compared to women with sporadic tumors, with a median overall survival of 101 months versus 51 months (51).

It has been hypothesized that the longer survival of women with *BRCA*-associated ovarian cancers is related to the fact that loss of function of *BRCA* proteins, which are believed to participate in DNA damage recognition and repair, results in a more favorable response to DNA-damaging chemotherapy. Decrease in *BRCA1* mRNA levels (PCR-based measurement) was associated with a significantly longer survival in 57 unselected ovarian cancers (52). Decrease in *BRCA1* protein expression, as measured by immunohistochemistry, was also associated with prolonged survival in a separate series of 230 sporadic ovarian cancers (53). On the other hand, women with ovarian cancers exhibiting methylation of the *BRCA1* gene promoter region, which might be expected to have decreased *BRCA1* gene expression, have been reported to have a worse survival than women with sporadic ovarian cancers (54). Further exploration of these observations will be important as specific targeted agents are developed that may be more active in subsets of cancers. For example, reports of preclinical studies suggest that deficiency in either *BRCA1* or *BRCA2* induces profound cellular sensitivity to the inhibition of poly(ADP-ribose) polymerase (PARP) activity (55). An early report of a phase 1 trial using the PARP inhibitor KU-0059436 suggested preferential single-agent activity in ovarian cancer patients who are known carriers of a *BRCA* mutation (56).

Effect of Reproductive Risk Factors on *BRCA* Mutation Carriers

In general, most studies have shown that the reproductive and hormonal factors that affect ovarian cancer risk in the general population also affect the ovarian cancer risk for women who carry *BRCA1* and *BRCA2* mutations. Narod et al. from Toronto initially reported a 60% reduction in risk of ovarian cancer for carriers of the *BRCA1* or *BRCA2* mutation with use of OCPs for 6 or more years (57). Three smaller studies confirmed this observation (58–60), but in a large population-based study from Israel no protective effect was seen (61), and the use of OCPs as a means to prevent ovarian cancer in *BRCA* mutation carriers prior to oophorectomy has therefore remained controversial. More recently, the Toronto group has reported their results from a greatly expanded database including 670 women with a history of *BRCA1*-associated ovarian cancer, 124 with a history of *BRCA2*-associated ovarian cancer, and 2,424 mutation carriers with no history of ovarian cancer (43). Use of OCPs reduced the risk of ovarian cancer both in women with *BRCA1* mutations (OR 0.56) and in those with *BRCA2* mutations (OR 0.39). Breast-feeding was protective for carriers of a *BRCA1* mutation (OR 0.74). An effect of similar magnitude was seen for breast-feeding in *BRCA2* mutation carriers, although it was not statistically significant (OR 0.72). Although the Toronto group had previously reported that tubal ligation was protective against ovarian cancer in mutation carriers as well as noncarriers, the association in this expanded cohort was not significant for carriers of either a *BRCA1* mutation (OR 0.8) or a *BRCA2* mutation (OR 0.63). Pregnancy, which had previously been reported to be protective for women carrying a *BRCA* mutation (61), was found to be protective for carriers of *BRCA1* mutations (OR 0.67), but was associated with increased risk for carriers of *BRCA2* mutations (OR 2.74). The reasons for this are not clear.

Prophylactic Oophorectomy for Prevention of Hereditary Ovarian Cancer

No current screening techniques, including serum CA-125 levels, pelvic ultrasound, and frequent pelvic examinations, have been shown to decrease the risk of death from ovarian cancer in women who carry *BRCA1* or *BRCA2* mutations. The U.S. National Institutes of Health (NIH) Consensus Development

Panel recommended that prophylactic oophorectomy be considered in women with ovarian cancer syndromes at age 35 years or after childbearing is completed (62). This appears to substantially decrease ovarian cancer risk, although some risk of primary peritoneal cancer remains. In one large study 1,828 known carriers of a *BRCA1* or *BRCA2* mutation were identified from an international registry and asked to complete questionnaires at baseline and follow-up. The overall reduction in risk of cancer of ovaries, fallopian tubes, or peritoneum as a result of oophorectomy was 80%; the estimated cumulative incidence of peritoneal cancer was 4.3% at 20 years after oophorectomy (63). It is important to remove (and completely pathologically examine) the fallopian tubes at the time of oophorectomy, as an excess of invasive and noninvasive fallopian tube carcinomas, particularly involving the tubal fimbria, has been reported in prophylactic adnexectomy specimens from women with *BRCA* mutations undergoing prophylactic surgery (64). Removal of the ovaries may also reduce the risk of breast cancer in *BRCA* mutation carriers (65).

The Pathologic Examination of Risk-Reducing Salpingo-oophorectomy Specimens

In the largest series of *BRCA*-associated ovarian cancers with centralized pathology review (66), cancers in *BRCA* carriers were compared to those in noncarriers. Among 220 women, mutation-associated tumors were of significantly higher grade and stage and less often mucinous as compared to non-mutation-associated tumors. No mucinous and no borderline tumors were found in the mutation-associated group. Primary peritoneal carcinoma occurred rarely in both groups. Nonserous histology also appears to be less common in mutation carriers.

Microscopic occult carcinomas have been identified in risk-reducing salpingo-oophorectomy (RRSO) specimens in about 2% of *BRCA* mutation carriers. In one prospective series, seven ovarian and three tubal carcinomas (and one case in which washings showed malignant cells but no primary cancer was identified) were found among 490 women who underwent RRSO (63). The appropriate examination of RRSO specimens begins with efforts by the surgeon to avoid contact with the surface of the ovary intraoperatively, in order that the delicate surface epithelium not be abraded. The pathologist should submit for microscopic examination the entirety of the fallopian tubes and ovaries. This is best accomplished by serial cross sections across the short diameter of the ovaries and fallopian tubes. Levels of some sections should be obtained if foci of atypia are identified histologically, since foci of *in situ* or invasive occult carcinoma may be very subtle and less than 1 mm in maximum diameter.

Peritoneal lavage is becoming a standard portion of the procedure with RRSO. Occult carcinoma is occasionally identified in these cytology specimens. Colgan et al. found malignant cells in 3 of 35 specimens. One microscopic ovarian surface carcinoma and one *in situ* tubal carcinoma were found; no carcinoma could be identified in the third patient. Twenty-two percent of specimens showed endosalpingiosis (67). In rare cases, others have also reported malignant cells in washings at RRSO without an identifiable carcinoma by histology (63), and in two studies, positive cytology specimens led to the discovery of early-stage tubal carcinomas (64,68).

Ovaries derived from RRSO have been examined by several groups for potential precursor lesions of high-grade serous carcinoma. Surface epithelial inclusions, invaginations (clefts), papillomatosis, calcifications, and other features have been studied. The inclusion epithelium has been examined for atypia, and the inclusions and clefts have been counted and measured. Published studies of these high-risk ovaries have generated conflicting results. Some studies suggest that these ovaries have more cortical inclusions, surface epithelial invaginations, surface papillomatosis and/or deeper cortical invaginations than control ovaries (69–72), but these findings have

not been confirmed by others (70,73–75). Some investigators have found a higher degree of cytologic atypia in the epithelium lining these inclusions (74,76) or the surface epithelium (70), but again these findings have not been confirmed (73). Some studies have significant methodologic limitations involving the methods of counting and measuring inclusions, control group issues, and in many studies it is not clear whether the data were collected by an experienced pathologist who can reliably separate inclusions and clefts from their mimics, which include rete ovarii, peritoneal folds, and adherent tubal plicae (77). At present, none of these features are conclusively identified as features predictive of significant risk of cancer development.

Genetic Counseling

The level of potential risk reduction with salpingo-oophorectomy makes awareness of the potential that a patient carries a *BRCA1* or *BRCA2* mutation very important. While treatment for *BRCA* mutation-associated ovarian cancers is not currently different from treatment of sporadic ovarian cancers, genetic counseling for relatives of index patients may save lives. Factors that should trigger consideration of genetic counseling/testing in women with invasive ovarian cancer include Ashkenazi Jewish ancestry, very young age, personal history of breast cancer, or a family history of ovarian cancer or breast cancer (particularly multiple first-degree relatives, or relatives with breast cancer at a young age, including paternal relatives). In Ontario, Canada, 20% of women diagnosed with ovarian cancer between the ages of 30 and 40 years were

found to carry a mutation in the *BRCA1* or *BRCA2* genes (78). Among Ashkenazi Jewish women with ovarian cancer there is about a 40% to 50% chance that the disease is related to a *BRCA1* or *BRCA2* mutation (79). Even in Ashkenazi Jewish ovarian cancer patients with no family history of breast or ovarian cancer, the risk of a mutation is 13% to 23% and warrants genetic counseling (80).

PATHOLOGY

This section addresses the general pathologic classification and features of ovarian borderline tumors and carcinomas, but it also specifically emphasizes several areas of high clinical impact in which our understanding of ovarian cancer has recently advanced, as follows: the pathogenesis of ovarian carcinoma, the distinction between low-grade and high-grade serous carcinoma; the definition and significance of types of implants and micropapillary architecture in serous borderline tumors; the significance of stromal microinvasion; primary peritoneal carcinoma; and the criteria and the distinction of primary from metastatic mucinous carcinoma involving the ovary.

Pathologic Classification

Ovarian cancer, although inappropriately often considered as a single entity, consists of many types, each with subtypes. The classification in Table 25.2, presented in detail for the common

TABLE 25.2

HISTOLOGIC CLASSIFICATION OF COMMON EPITHELIAL TUMORS OF THE OVARY

SEROUS TUMORS

Benign

- Cystadenoma and papillary cystadenoma
- Surface papilloma
- Adenofibroma and cystadenofibroma
- Borderline tumor (atypical proliferative tumor)
- Cystadenoma and papillary cystadenoma
- Surface papilloma

Malignant

- Adenocarcinoma
- Surface papillary adenocarcinoma

MUCINOUS TUMORS

Benign

- Cystadenoma
- Adenofibroma and cystadenofibroma
- Borderline tumor (atypical proliferative tumor)
- Intestinal type
- Endocervical-like

Malignant

- Adenocarcinoma
- Malignant adenofibroma
- Mural nodule arising in mucinous cystic tumor

ENDOMETRIOID TUMORS

Benign

- Adenoma and cystadenoma
- Adenofibroma and cystadenofibroma
- Borderline tumor (atypical proliferative tumor)

Malignant

- Adenocarcinoma
- Adenoacanthoma
- Adenosquamous carcinoma
- Malignant adenofibroma with a malignant stromal component
- Adenosarcoma
- Endometrial stromal sarcoma
- Carcinosarcoma, homologous and heterologous
- Undifferentiated sarcoma

CLEAR CELL TUMORS

Benign

- Borderline tumor (atypical proliferative tumor)

Malignant

- Adenocarcinoma

TRANSITIONAL CELL TUMORS

Brenner's tumor

- Proliferating Brenner's tumor
- Malignant Brenner's tumor
- Transitional cell carcinoma (non-Brenner type)

SQUAMOUS CELL CARCINOMA

MIXED EPITHELIAL TUMORS (SPECIFY TYPES)

Benign

- Borderline tumor (atypical proliferative tumor)

Malignant

- Undifferentiated carcinoma

Notes: WHC, Washington Hospital Center, Washington, D.C. Atypical proliferative includes those with microinvasion and/or intraepithelial carcinoma. Epidermoid cysts (nonteratomatous) are classified as benign squamous tumors. Seromucinous are included in mucinous.

^aTwo “serous peritoneal” tumors were carcinosarcomas. The total number of cases differs from that in the text due to slightly differing time periods.

epithelial tumors, has been developed and updated under the auspices of WHO, the International Federation of Gynecology and Obstetrics (FIGO), the International Society of Gynecologic Pathologists, and the Society of Gynecologic Oncologists (SGO) (81).

The surface epithelial tumors are the most frequently encountered form of ovarian tumors, and they account for more than 90% of all ovarian cancer in adults (Tables 25.3 and 25.4). However, accurate determination of the relative frequencies of ovarian epithelial neoplasms is relatively limited, with very few published series of ovarian tumors that are population based and include all cell types that have been reviewed in a uniform manner according to standardized criteria (82). A recent review of unselected cases seen at a large community hospital included 1,287 consecutive ovarian tumors from 2000 through 2007, of which 802 were surface epithelial tumors (Table 25.3) and 485 were nonepithelial tumors (237 germ

cell, 85 stromal, 163 metastatic). Notable differences from historical reports include the low frequency of primary ovarian mucinous carcinoma (<1% of primary epithelial tumors), the high frequency of ovarian carcinosarcoma, and the high proportion of primary peritoneal serous carcinoma (83). Serous carcinoma represented 52% of the total, and this is significant since it appears that both the pathogenesis and response to therapy differ according to the cell type.

Pathogenesis of Ovarian Carcinoma

During embryonic life, the coelomic cavity forms and is lined by a mesothelial lining of mesodermal origin, part of which becomes specialized to form the serosal epithelium covering the gonadal ridge. By a process of invagination, this same mesothelial lining gives rise to the müllerian ducts, from which

Notes: FIGO, International Federation of Gynecology and Obstetrics. Excludes microinvasive tumors, noninvasive micropapillary serous carcinoma, and carcinomas arising in nonsurface epithelial tumors (i.e., squamous cell carcinoma in teratoma).

Three serous tumors and one endometrioid were of unknown stage.

^aTwo were carcinosarcoma, one was transitional cell carcinoma.

arise the fallopian tubes, uterus, and wall of the vagina. As repair follows multiple ovulations, the surface epithelium of the ovary often extends into the ovarian stroma to form inclusion glands and cysts. Other mechanisms may also contribute to the formation of intraparenchymal epithelial inclusions. The epithelium, in the process of neoplastic transformation, may exhibit differentiation toward a variety of müllerian-type cells, which are, in order of decreasing frequency, (a) serous (resembling the fallopian tube); (b) mucinous (resembling the endocervix); (c) endometrioid (resembling endometrium); (d) clear cell (glycogen-rich cells sometimes resembling either embryonic müllerian epithelium and at other times secretory phase endometrial glands); and (e) urothelial or transitional (resembling Walthard's rests and bladder).

For the purpose of understanding pathogenesis, it is important to recognize that ovarian carcinoma may be separated into two broad divisions: those that arise *de novo*, i.e., without an identifiable precursor lesion, and those that arise via a stepwise progression in an adenoma-carcinoma sequence as occurs in the colon.

The vast majority of fatal ovarian cancers are high-grade serous carcinomas. These tumors are believed to arise *de novo* from the surface epithelium of the ovary, or perhaps sometimes from the mucosa of the fallopian tube, and progress rapidly. Accordingly, diagnosis of high-grade serous carcinoma in stage I is a rare and fortuitous event. Regrettably, this hinders our understanding of the early phase of this process and also makes screening and early detection difficult.

Most of the remaining cell types of ovarian carcinomas appear to follow an adenoma-carcinoma sequence. Nearly all clear cell carcinomas and a large proportion of endometrioid carcinomas arise in endometriosis, and appear to progress through an adenoma (or hyperplasia)-borderline tumor-carcinoma sequence. Similarly, mucinous carcinomas most probably transit through a mucinous cystadenoma-borderline tumor-intraepithelial carcinoma sequence before invasion occurs. Since a mass is often detected while still in the early phases of the sequence, such tumors are much more likely to be diagnosed while still confined to the ovary, and they therefore comprise most curable ovarian carcinomas. Low-grade serous carcinoma is a recently described and relatively small subset of ovarian serous carcinoma that also often appears to follow a stepwise progression from borderline tumor to invasive carcinoma. Its morphology and behavior are described later in this chapter.

Molecular biologic evidence (84) provides support for this dualistic model of ovarian carcinogenesis. High-grade serous carcinomas typically have p53 mutations in contrast to low-grade serous carcinomas, which usually have mutations in K-ras and *BRAF* genes. The identification of Pten mutations in endometrioid tumors and K-ras in mucinous tumors also supports the stepwise progression model.

Very recently, Lee et al. have proposed that many high-grade serous carcinomas thought to be of ovarian or peritoneal origin actually arise in the mucosa of the fimbriated end of the fallopian tube (85). This concept results from a convergence of data obtained from meticulous studies in which the fallopian tubes were sequentially sectioned and blocked for microscopic and molecular analysis. Much of the work has only been presented in abstract form, and it has not been corroborated by other investigators to date, but it is highly provocative and reasonably compelling. In brief, they found that in eight cases of ovarian carcinoma with coexisting *in situ* carcinoma of the fallopian tube mucosa, the same p53 mutations were identified in both sites (86). In cases diagnosed according to WHO criteria for primary peritoneal carcinoma, more than half of the fallopian tubes displayed tubal mucosal involvement, often with *in situ* carcinoma (87). In a series of RRSO specimens from women with *BRCA* mutations, clusters of p53-positive cells and intraepithelial carcinomas were identified in the mucosa of the

fallopian tubes of about 30% of the women, while they were not present on the ovarian surface (64). Although all of these data are open to other interpretation, it is likely that the mucosa of the fimbriated end of the fallopian tube serves as the source of some of the carcinomas that previously have been considered to be of ovarian or primary peritoneal origin.

Specimen Examination

Although thorough sampling of an ovarian tumor for microscopic analysis is an often-stated requirement for optimal pathologic examination, thoroughness cannot be equated with a formula for a specified number of slides taken randomly, which often provides little additional information (88). Instead, careful gross examination and directed sampling of any unusual-appearing areas in addition to representative areas are essential (89). For example, adhesions on the surface of an ovary, although usually inflammatory in origin, are sometimes an indication that a tumor has penetrated the capsule. While four or five sections may be sufficient to provide the grade and histologic type of a grossly obvious malignant ovarian neoplasm, it is recommended that at least one section of neoplasm be taken for each centimeter of the maximum diameter (for tumors up to 10 cm in diameter and two per centimeter for those greater than 10 cm in diameter) of the lesion for suspected borderline tumors in order to establish the diagnosis and reduce the possibility of occult invasion. At the NCI-sponsored consensus conference on borderline tumors in 2003, it was suggested that grossly normal omentum removed from women with borderline tumors be submitted for histologic examination at a proportion of one block per 2 cm maximum diameter of omentum (89a).

The ovarian tumor specimen should be serially sectioned at close intervals and each piece carefully examined for differences in texture. Serous tumors tend to show greater uniformity than mucinous tumors, which are notorious for great variation, with only a small percentage of slides disclosing features diagnostic of cancer. Mucinous adenocarcinomas are commonly composed almost exclusively of cysts typical of adenoma or borderline tumors, whereas only a few areas are solid and show the diagnostic features of carcinoma. Solid areas preferentially should be submitted for microscopic examination. Benign serous tumors tend to be unilocular. Serous borderline tumors tend to have clusters of numerous papillae that are larger and more edematous than those of adenocarcinomas, which are solid or relatively fine. Blocks taken from the base of papillary processes are particularly helpful to avoid overlooking occult areas of poorly differentiated carcinoma. As transition forms between benign and malignant epithelia are well documented (90), careful gross examination of the specimen is mandatory to help identify both the regions of borderline tumor and the invasive carcinoma.

Borderline Tumors

Despite disagreement about the optimal terminology for borderline tumors (which are also known as atypical proliferative tumors or tumors of low malignant potential), there is widespread agreement on the histologic appearances and behavior of these tumors. Their reproducible identification among pathologists is not considered a major problem, but it must be recognized that extensive sampling (one or two sections of tissue per maximum diameter in centimeters of the neoplasm) is required to firmly establish the diagnosis. Consequently, underestimation in the severity of the process is frequent at the time of intraoperative diagnosis, and this needs to be recognized by both the pathologist and the operating surgeon. Effective communication of pathologists with gynecologic oncologists is essential to minimize inappropriate initial surgical therapy.

An appreciation of heterogeneity is critical to understanding the biologic behavior of borderline tumors. Accordingly, the natural history, recurrence and survival rates, and treatment of patients with borderline tumors should be considered according to five features, as follows: (a) cell type, (b) stage, (c) implant type (for serous borderline tumors), (d) the presence of a micropapillary architecture (for serous borderline tumors), and (e) microinvasion. Three decades ago, serous and mucinous borderline tumors were described, with 5-year survival rates of about 75% to 90%. More subtypes and special features have been recognized in the past 10 years, and the borderline category is now much better understood. No tumor deaths from the three rare subtypes of endometrioid, clear cell, and transitional borderline tumors have been well documented, and they are very uncommon (representing from less than 1% to 10% of borderline tumors). Consequently, no definitive conclusions can be drawn regarding their natural history, but no cancer deaths have been reported for women with borderline tumors of these three cell types.

Serous Tumors

About 20% of serous tumors are malignant, 2% are borderline tumors, and about 78% are benign. The mean age for patients with cancer is 56 years. Patients with benign and borderline tumors are generally younger, with mean ages at diagnosis of 45 and 48 years, respectively. Approximately one of six serous adenomas is bilateral. Serous borderline tumors are bilateral in one third of cases. Serous adenocarcinomas that are stage I are bilateral in one third of cases. Those of higher stage are bilateral in two thirds of cases.

Serous Borderline Tumors

Well-staged borderline tumors that are confined to the ovary are associated with a survival that approaches 100% at

10 years. However, the prognosis for women with tumors that have associated peritoneal lesions is diminished, and it varies according to the type of implant that is identified histologically. A fundamental source of potential confusion results from the presence of peritoneal lesions associated with a primary ovarian tumor in which invasion cannot be demonstrated. The designation of these lesions as “implants” is entrenched and implies the unproved assumption that the peritoneal lesions are derived from the ovarian neoplasm. (In fact, limited molecular biologic evidence suggests that in some cases, the peritoneal lesions arise independently.) The division of implants into invasive and noninvasive (epithelial and desmoplastic) types represented a tremendous advance in providing prognostic information.

Gross Appearance. Serous borderline tumors are similar in most respects to their benign counterparts, usually formed of a unilocular or paucilocular cyst with clear fluid and lining that varies from smooth to papillary. The papillations are usually more numerous, larger, and softer in texture in borderline tumors. Polypoid structures, 1 to 10 mm in greatest dimension, are frequently seen (Fig. 25.5). Their surfaces frequently are covered by relatively fine papillae. Necrosis is absent. Serous borderline tumors may secrete a fluid that has a higher mucin content than serous cystadenomas, and this can cause confusion with a mucinous neoplasm at the time of gross examination.

Microscopic Appearance. Serous borderline tumors are characterized microscopically by dichotomously branching, fine to coarse papillary fronds in which atypical, stratified neoplastic cells cover a thick core of fibrovascular stroma (Fig. 25.6). The general histologic features used to diagnose borderline tumors include (a) architectural complexity of glandular structures; (b) epithelial papillae (especially in serous tumors), with detached atypical cell clusters as single or small groups of cells; (c) cellular stratification (especially in mucinous tumors); (d) increased mitotic activity; and (e) nuclear atypia (increased nuclear:cytoplasmic ratios, hyperchromatism, and prominent

FIGURE 25.5. Serous borderline tumor. This 10-cm-diameter unilocular cystic neoplasm has a lining that varies from finely granular to rough and polypoid. In contrast, most serous cystadenomas have a smooth lining and most serous carcinomas have solid areas with foci of necrosis.

FIGURE 25.6. Serous borderline tumor. The fibrovascular papillae correspond to the rough or granular lining that is visible grossly. The papillae branch dichotomously into progressively smaller fibrovascular cores that are covered by a multilayered atypical epithelium.

FIGURE 25.7. Micropapillary serous tumor. In contrast to the dichotomously branching fibrovascular cores of the usual serous borderline tumor, micropapillary tumors have relatively large papillae of fibrous tissue from which long, thin columns of atypical epithelium emanate directly.

FIGURE 25.8. Micropapillary serous tumor. At higher magnification, it is evident that the height:width ratio of the atypical epithelium exceeds 5:1. In this case, bridging of atypical epithelium results in a cribriform or sieve-like pattern.

nucleoli). The epithelium that characterizes serous tumors resembles the lining of the normal fallopian tube. If well differentiated, the cells may display cilia as is seen in the normal tubal epithelium. If less well differentiated, they have only eosinophilic cytoplasm. Laminated, calcific concretions, known as psammoma bodies, are often numerous. Mucin, if demonstrable, is confined to the apical border of the cell. The diagnosis of a borderline tumor requires that no area contain stromal invasion that exceeds 5 mm in diameter. The presence of smaller foci of microinvasive tumor does not alter the patient's otherwise excellent prognosis (91).

Micropapillary Serous Tumors. The fibrovascular fronds of the typical borderline serous tumors display a mantle of epithelial cells on the surface of dichotomously branching, progressively smaller fibrovascular cores. In contrast, micropapillary serous tumors have relatively large papillae of fibrous tissue from which emanate long, thin columns of atypical epithelial cells, with a height:width ratio that exceeds 5:1 (Figs. 25.7 and 25.8). This architectural pattern must occupy at least a 5-mm-diameter focus in order to be considered a micropapillary serous tumor.

Micropapillary architecture was first recognized in the late 1970s (92,93), but data suggesting its adverse prognostic significance were not reported until 1996 (94,103). Unfortunately, the term micropapillary serous carcinoma (MPSC) has been used for two morphologically distinct entities and this has caused some confusion among clinicians. The noninvasive form of MPSC is a variant of serous borderline tumor. The invasive form of MPSC has always been classified as carcinoma and is the typical form of invasive well-differentiated serous carcinoma (see above). Thus, invasive MPSC is essentially synonymous with low-grade serous carcinoma (95).

Ten percent to 15% of serous borderline tumors display the micropapillary pattern (defined as a 5 mm area uninterrupted

by typical serous borderline tumor [SBT]). The behavior of serous borderline tumors with a micropapillary pattern is clear. Stage I patients have 100% survival, based on over 2,000 reported SBTs among which 10% to 15% can be assumed to be micropapillary tumors (97). For advanced-stage patients, the survival depends upon the type of implants present and is similar to that of typical SBT with similar types of implants. More importantly, the micropapillary architecture is strongly associated with invasive implants. In eight studies of advanced-stage tumors with a total of over 300 patients, 49% of micropapillary tumors were associated with invasive peritoneal implants as compared to 6% of typical SBTs (98–105).

Advanced-stage patients with MPSC have a 10-year survival of 50% to 60%. These data have been confirmed by multiple investigators. Proponents of continuing to classify MPSC as borderline tumors contend that noninvasive MPSC has the same behavior as all other serous borderline tumors with similar implants. This is correct; the survival rates are virtually identical. The weakness of this argument becomes apparent as follows. It is now agreed that invasive implants are invasive carcinomas. So the argument is essentially this: MPSC has the same behavior as usual borderline serous tumor once the presence or absence of carcinoma is accounted for. That is like saying that the behavior of benign and malignant tumors is basically the same once the presence or absence of metastases (including occult micrometastases) is accounted for. The critical point is that MPSC is strongly associated with invasive implants, i.e., invasive carcinoma, in contrast to usual borderline serous tumors, which only rarely are associated with invasive carcinoma, just as malignant tumors are strongly associated with metastases in contrast to benign tumors, which very rarely produce metastases.

Microinvasion. Microinvasion (defined variously as a maximal invasive focus size of 2, 3 or 5 mm, or an area of 10 square mm) can be found in up to 10% of borderline

FIGURE 25.9. Microinvasion—microinvasion in a serous borderline tumor. A small focus of destructive stromal invasion is present in an otherwise typical serous borderline tumor. The stromal margins appear retracted around the purely epithelial papillae. This focus is less than 3 mm in maximum diameter. Its presence is not associated with any significant decrease in the survival rate.

FIGURE 25.10. Noninvasive epithelial implant. This form of implant is characterized by a well-circumscribed proliferation of atypical epithelium on the surface of the peritoneum or between fat lobules of the omentum.

tumors (Fig. 25.9). Review of 94 reported cases as of 2000 showed a survival of 100% (97). More recently, a few tumors with microinvasion have been reported to have demonstrated malignant behavior. In that report, however, most of the patients had either invasive or indeterminate implants, and therefore the independent prognostic significance of microinvasion in these cases is not clear (101). The overall prognosis for the patient with microinvasion in a borderline tumor is currently considered to be no different from that of a borderline tumor without microinvasion. Larger foci of destructive invasion in a borderline tumor are considered to represent the presence of a serous carcinoma. When papillae invade into the stroma, the stromal margins may appear to be retracted and display relatively pointed contours in relief. Solid clusters of cells may exhibit a cribriform pattern (intraglandular bridging) indicative of autonomous growth and, hence, adenocarcinoma. Usually, invasion is accompanied by a fibrous stromal reaction.

Implants. *Noninvasive epithelial implants* are characterized by papillary proliferation of epithelium present on the surface of the peritoneum or in smoothly contoured submesothelial invaginations or between fat lobules, in the absence of a significant stromal response (Fig. 25.10). The papillae are composed of stratified cuboidal or columnar cells with varying degrees of cytologic atypia. *Noninvasive desmoplastic implants* are characterized by a marked stromal reaction to tumor cells in a similar distribution (Fig. 25.11). *Invasive implants* are recognized by an irregular, aggressive-appearing infiltration into the underlying submesothelial tissue or within lobules of fat from the omentum by small glands or solid nests of cells or papillae (Fig. 25.12) (106). There is now a consensus that invasive implants are associated with a poor outcome and behave as low-grade carcinoma. According to the NCI-sponsored Borderline Tumor Conference (89a), the terms “invasive serous carcinoma” and “invasive

FIGURE 25.11. Noninvasive desmoplastic implant. These implants are characterized by a marked stromal granulation tissue-like reaction to tumor cells, in the absence of any irregular infiltration of underlying tissue.

FIGURE 25.12. Invasive implants. This type of implant can be recognized by an irregular, aggressive-appearing infiltration of the omental fat or underlying submesothelial tissues by small glands or solid nests of atypical epithelial cells or papillae.

implant” can be used synonymously. The survival at 5 years for women with noninvasive implants exceeds 95%, while for those with invasive implants it is 67% (97). The clear separation of these groups might not have been possible without the recognition of the desmoplastic noninvasive implant, which is histologically pseudoinvasive and highly deceptive to pathologists unfamiliar with it.

The accuracy of implant subclassification has been a frequently raised issue. The highly significant difference in survival rates ($p < 0.001$) in published reports of about 500 women with invasive versus noninvasive implants suggests that they are being separated reliably (97). In some cases, a small biopsy of an implant makes it difficult to assess for invasion, and it has been suggested that one can classify a small implant without underlying tissue as noninvasive based on the assumption that it had been easily removed (107,108). However, surgeons with sharp knives tend to disagree with this statement. At the 2006 annual meeting of the U.S. and Canadian Academy of Pathology, five experts independently classified implants from photomicrographs. Despite concerns about reproducibility, the results were extremely encouraging and indicated very good reproducibility among experts.

In evaluating peritoneal biopsies, implants of borderline tumors must be distinguished from reactive peritoneal hyperplasia and benign epithelial inclusions, and endosalpingiosis. Müllerian inclusion cysts are another finding to be considered when dealing with serous borderline tumors. These occur in the form of individual round to oval glands with an obvious lumen and are found in both the omentum and lymph nodes. A peripheral basement membrane is present and cilia may be prominent. The epithelium is usually only one cell layer thick, and stratification, if present, is minimal. The nuclei are basally situated, mitotic activity is absent, and there is no nuclear atypia.

Lymph Node Involvement in Serous Borderline Tumors.

Lymph node “involvement” has been reported in over 100 cases of serous borderline tumors (97,98,109). Some evidence suggests an independent origin of some of these lesions from nodal endosalpingiosis. A 2000 review showed that the survival of 43 reported patients with lymph node involvement was 98% after a mean follow-up of 6.5 years (97). In the 2006 Stanford series, 8 of 31 patients (26%) with lymph node involvement had invasive peritoneal implants. Among 22 patients with follow-up, 4 were alive with disease and there were two deaths, one in a patient with “indeterminate” peritoneal implants. The presence of nodular aggregates of cells in the nodes was found to be an adverse prognostic factor (109a). If patients with invasive implants in other sites or indeterminate implants (histologically indeterminate or slides unavailable) are excluded, then the overall survival for patients with lymph node involvement is 97%.

Serous Carcinoma

Histologically malignant epithelial tumors are uncommon in women under the age of 35 years. By the time a carcinoma reaches clinical detection, it has often already spread beyond the ovary and seeded the peritoneum.

Destructive growth, an important feature of malignancy, helps to distinguish frank malignancies from borderline tumors. Infiltrative destructive growth is best demonstrated by individual or small clusters of cells growing in a disorganized pattern with angulated, sharp borders that dissect into stromal planes and are usually associated with desmoplasia.

Gross Appearance. Serous adenocarcinomas have the most variegated appearance. They range in size from small (2 to 3 cm) to quite large. Serous carcinomas often present as solid masses bounded by a capsule, often containing areas of necrosis and hemorrhage. The ovary from which the neoplasm has arisen is frequently not apparent grossly or microscopically. Cysts and foci of papillarity are commonly present. If one postulates an origin from the surface epithelium that covers the ovary, it is surprising that so few serous carcinomas display substantial surface papillary growth covering an otherwise normal ovary. It is hypothesized that the neoplastic transformation actually occurs either in inclusion cysts or the tubal mucosa. The gross appearance of a typical high-grade serous carcinoma is not distinctive, and it may be mimicked by other high-grade epithelial ovarian neoplasms, granulosa cell tumors, and carcinomas metastatic to the ovary.

Microscopic Appearance. Serous adenocarcinomas are distinguished from borderline serous tumors by the presence of stromal invasion. The tumor may appear as large sheets of polygonal cells growing autonomously without stromal support or as broad to fine clusters of cells related to papillae that irregularly dissect through the stroma, accompanied by a host desmoplastic response. The nuclei are typically large and pleomorphic, with variably sized nucleoli, and numerous mitotic figures.

Two grading systems for serous carcinomas have been proposed and tested in the past decade: a three-grade system by Shimizu et al. (110), and more recently, a binary system of high-grade and low-grade serous carcinoma by Malpica et al. from the M. D. Anderson Cancer Center (MDACC) (111). The MDACC system appears to be both easy for the pathologist to use in routine practice and corresponds more closely to the dichotomous morphologic appearance, molecular features, and clinical behavior of serous carcinoma (Figs. 25.13 and 25.14) (96). In contrast to high-grade serous carcinoma, low-grade neoplasms are characterized by cells with only mild to moderate nuclear atypia, evenly distributed chromatin, variable nucleoli, and fewer than ten mitoses per ten high-power fields (HPF). A micropapillary architecture is very frequently

FIGURE 25.13. Serous carcinoma. The vast majority of serous carcinomas are of high grade, with marked cytologic atypia, large nucleoli, and more than ten mitoses per ten high power fields.

FIGURE 25.14. Serous carcinoma. Less than 10% of serous carcinomas of the ovary are of low grade, and many of them are of micropapillary type. They are characterized by mild to moderate cytologic atypia, variable nucleoli, and fewer than ten mitoses per ten high power fields.

observed (see above). The binary system separates over 90% of advanced-stage serous carcinomas into the high-grade group. This distribution is reflected in the overall behavior of advanced-stage serous carcinoma, which is associated with a 5-year survival of about 25%. In contrast, the 5- and 10-year survivals for women with advanced-stage low-grade serous carcinoma are about 85% and 50% to 60%, respectively.

Serous carcinomas nearly always stain positively with immunohistochemistry for WT1, cytokeratin (CK) 7, and negative or only focally positive for CK20 and calretinin. A panel that includes these antibodies is frequently employed to evaluate a carcinoma whose primary site is uncertain. Pancreatic and breast carcinomas have the same CK7/20 profile and thus other markers are needed for these sites. GCDFP-15 (gross cystic disease fluid protein) is often positive in breast carcinoma and only rarely positive in ovarian. Immunohistochemistry is rarely needed for serous carcinoma and is much more useful for the problematic mucinous tumors (see Mucinous Tumors).

Serous Psammocarcinoma. This is considered to be a rare variant of serous adenocarcinoma that is characterized by massive psammoma body formation. It is categorized as a carcinoma since it often displays destructive invasion or vascular invasion on microscopic examination; in half the cases, the extraovarian tumor also invades peritoneal sites. Despite these features, the cytologic attributes are more in keeping with a low-grade neoplasm, and the behavior is generally similar to that of serous borderline tumors.

Mucinous Tumors

Primary ovarian mucinous tumors represent about 10% of all common epithelial tumors and include three types: cystadenomas, borderline tumors, and carcinomas. The cystadenomas

(81%), followed by the borderline tumors (13%), are the most commonly encountered, whereas primary ovarian mucinous carcinomas are much less common (5%). The mean age for patients with mucinous adenocarcinoma is 52 years, which, as with serous adenocarcinoma, is greater than the mean age of patients with benign and borderline tumors (44 and 49 years, respectively).

The cystadenomas and borderline tumors are noninvasive and are distinguished from one another primarily by their degree of complexity and epithelial proliferation. The carcinomas are distinguished from these two types of tumors by the presence of stromal invasion, which is required for a diagnosis of carcinoma. Intermediate forms exist, such as cystadenomas with focal epithelial proliferation and borderline tumors with intraepithelial carcinoma and/or microinvasion, providing evidence that these tumors form a morphologic spectrum with individual types representing steps in the sequence of mucinous carcinogenesis in the ovary.

The other types of mucinous tumors encountered in the ovary include metastatic mucinous carcinomas derived from various sites, most commonly the gastrointestinal tract, and low-grade mucinous tumors of appendiceal origin secondarily involving the ovary in association with the clinical syndrome of pseudomyxoma peritonei. Both metastatic mucinous carcinomas and low-grade mucinous tumors of appendiceal origin in the ovary can simulate primary ovarian mucinous tumors, including both the borderline (atypical proliferative) mucinous tumors and the primary ovarian mucinous carcinomas. Refined diagnosis of ovarian mucinous tumors in recent years, with distinction of these nonovarian tumors from true primary ovarian mucinous tumors, has been instrumental in clarifying the behavior of ovarian mucinous tumors. Accurate diagnosis and understanding of tumor behavior are essential for determining proper therapy, including both surgical management and chemotherapeutic regimens.

Mucinous Borderline Tumors

Mucinous borderline tumors differ in some respects from serous borderline tumors. There are two types of borderline mucinous tumors: the gastrointestinal type and the endocervical type (also referred to as the müllerian or seromucinous type).

Review of the literature on tumors meeting the diagnostic criteria for borderline mucinous tumor, gastrointestinal type, reveals that these tumors have demonstrated an overwhelmingly benign behavior (93,112–130). Specific aspects of the behavior of these tumors can be summarized as follows: (a) The vast majority of borderline mucinous tumors of gastrointestinal type are stage I; (b) of over 600 stage I tumors reported, less than 1% of these patients have been reported to have died of disease (most of these fatal tumors had inadequate or an unknown degree of sampling and are reported in the older literature; most recent studies report 100% survival); (c) a smaller number (~100) of so-called “advanced-stage borderline mucinous tumors” have been reported, with nearly 50% mortality; more than 85% of these tumors have been associated with the clinical syndrome of pseudomyxoma peritonei. However, recent studies have established that virtually all cases of pseudomyxoma peritonei are of gastrointestinal (usually appendiceal), not ovarian, origin (see below) (128–136). Therefore, the existence of true primary ovarian borderline mucinous tumors of advanced stage is questionable. When these questionable advanced-stage tumors are removed from the primary ovarian borderline mucinous tumor category, the remainder consists overwhelmingly of stage I tumors with benign behavior.

The endocervical (or seromucinous) type mucinous borderline tumors are much less common than the gastrointestinal type of mucinous borderline tumors. Based on a small number of studies, these tumors, including those with implants and intraepithelial and microinvasive carcinomas, have also demonstrated a benign behavior (137–141).

Gross Appearance. Mucinous tumors can grow to extremely large sizes, being among the largest of any recorded tumor in the body. Sizes exceeding 40 kg and 30 cm in greatest diameter are not uncommon.

The *gastrointestinal type of mucinous borderline tumor* is typically a large, multicystic tumor with a smooth capsule. This type of mucinous tumor is unilateral in >95% of cases, with mean and median sizes of 20 to 22 cm (126,142). The locules of the tumor are usually filled with mucinous material and the lining appears smooth, without grossly evident papillations.

The *endocervical (or seromucinous) type of mucinous borderline tumors* are grossly, microscopically, and immunophenotypically distinct from the gastrointestinal type tumors (143). The former are more frequently bilateral, can be intracystic or exophytic, and architecturally are identical to serous borderline tumors.

Microscopic Appearance. Microscopically, the *gastrointestinal type of mucinous borderline tumor* is composed of cysts that are lined by stratified, proliferative, gastrointestinal type mucinous epithelium exhibiting tufted and villoglandular or papillary intraglandular growth and displaying variable (usually mild to moderate) nuclear atypia; by definition, these tumors lack stromal invasion (Figs. 25.15 and 25.16).

The *endocervical (seromucinous) type of mucinous borderline tumors* have hierarchical branching of papillae, similar to serous tumors, but are lined by endocervical type mucinous as well as serous (ciliated cell) type epithelium. The epithelium exhibits tufting and stratification, with generally mild nuclear atypia and low mitotic activity.

Tumors composed predominantly of cystadenoma with a minor component of borderline tumor (<10%) are probably best diagnosed as a mucinous cystadenoma. The presence of

FIGURE 25.15. Borderline (atypical proliferative) mucinous tumor, gastrointestinal type. The tumor is composed of cysts lined by stratified and tufted mucinous epithelium with gastrointestinal-type differentiation; the periphery of the cyst is composed of crypts, but stromal invasion is lacking.

focal borderline tumor should not generate overly aggressive treatment, given the literature indicating that *bona fide* mucinous borderline tumors are virtually always stage I, have an overwhelmingly benign behavior, and can be managed conservatively.

Mucinous Borderline Tumors With Intraepithelial Carcinoma. Based on the FIGO and WHO classification schemes of the early 1970s, the sole criterion for distinguishing a mucinous borderline tumor from mucinous carcinoma was the absence of stromal invasion. Shortly thereafter, the criteria for mucinous carcinoma were expanded to include tumors displaying marked overgrowth of atypical epithelial cells manifested as epithelial cell stratification in excess of three layers, cribriform intraglandular proliferations, or finger-like projections of solid cellular masses without connective tissue support; these patterns were often accompanied by marked nuclear atypia. In addition, the presence of marked nuclear atypia alone was added as a diagnostic feature of mucinous carcinoma (144,145). Since then, mucinous tumors lacking stromal invasion but displaying epithelial overgrowth and atypia have been referred to as intraglandular or intraepithelial carcinomas. Proposed diagnostic criteria for intraepithelial carcinoma vary slightly (Fig. 25.17) among different studies, but all studies (115,120,126,127,146) consider tumors with marked nuclear atypia as intraepithelial carcinomas. Stage I intraepithelial carcinomas have demonstrated an excellent prognosis (~95% survival overall in the literature, with most recent studies reporting 100% survival) (112–115,117,118,120,126,127,141,146,147).

Mucinous Borderline Tumors With Microinvasion. Microinvasion in borderline mucinous tumors has been defined as either small foci of stromal invasion characterized

FIGURE 25.16. Borderline (atypical proliferative) mucinous tumor, gastrointestinal type. Mucinous epithelium displays stratification and papillary tufts, with mild to moderate nuclear atypia, differentiation toward the papillary tips, and proliferative activity primarily confined to the crypts.

FIGURE 25.17. Borderline (atypical proliferative) mucinous tumor, gastrointestinal type, with intraepithelial carcinoma. The epithelium lining the cyst exhibits excessive stratification and marked nuclear atypia.

by single cells, glands, or small clusters/nests of mucinous epithelial cells within the stroma or as small foci of confluent glandular or cribriform growth within the stroma (Fig. 25.18). Some investigators have variably used 1, 2, 3, and 5 mm in greatest linear extent or 10 square mm as the size limit for each individual focus with no requirement regarding the number of such foci allowed (114,115,120,126,127,146,148,149). Irrespective of the size criterion chosen, based on the relatively small number of microinvasive tumors with follow-up that have been reported, no recurrences or deaths due to disease have been observed, with the exception of one inadequately sampled tumor (114,115,118,120,126,127,146,148,149).

Mucinous Adenocarcinoma

Studies focused on refined diagnosis of ovarian mucinous tumors have established that primary ovarian mucinous carcinomas are much less common than previously believed. It is important to recognize that when evaluating the literature on behavior and therapeutic responses of primary ovarian mucinous carcinomas, some reports likely include a subset of misclassified metastatic mucinous carcinomas from the gastrointestinal tract to the ovary (see below).

Gross Appearance. Primary ovarian mucinous carcinomas are often grossly similar to borderline mucinous tumors in that they are typically large, unilateral, multicystic mucinous tumors with smooth capsules and have mean and median sizes of 18 to 22 cm (126,142). They may contain solid areas, and regions of necrosis and rupture with surface involvement can occur. A thick, tenacious mucinous material may fill the cysts. Bilaterality is very uncommon, occurring in less than 5% of cases.

FIGURE 25.18. Borderline (atypical proliferative) mucinous tumor, gastrointestinal type, with microinvasion. A small area containing clusters of mucinous epithelial cells haphazardly arranged within edematous/reactive stroma is present adjacent to areas of typical borderline tumor.

FIGURE 25.19. Primary ovarian mucinous carcinoma. Mucinous tumor is characterized by a confluent glandular proliferation exhibiting a labyrinthine pattern that is sufficiently complex to indicate a form of invasive carcinoma.

Microscopic Appearance. Microscopically, mucinous carcinomas typically are well differentiated and form a variety of glandular patterns, with many tumors having areas of borderline tumor identified adjacent to areas of carcinoma. The traditional definition of mucinous carcinoma required the presence of destructive stromal infiltration by malignant mucinous epithelium as the primary microscopic feature to establish a diagnosis of invasive carcinoma. Other recent studies of ovarian mucinous tumors have further refined the definition of invasive mucinous carcinoma to include a second type of invasion, termed the “confluent glandular” or “expansile” pattern of invasion (120,126). In this pattern of invasion, the glandular epithelium is markedly crowded, with little intervening stroma, and interconnected in a confluent or labyrinthine pattern (Figs. 25.19 and 25.20).

Primary ovarian mucinous carcinomas commonly exhibit this pattern of invasion and the presence of an infiltrative pattern of stromal invasion should raise concern for metastatic mucinous carcinoma (see below). Based on recent studies recognizing this pattern of invasion, it appears that patients with stage I mucinous carcinomas of this type have a survival rate of ~90%; despite a few exceptions, adverse prognosis is much more commonly associated with the infiltrative rather than the confluent glandular pattern of invasion (120,126,127,150,151). Most pathologists agree that the confluent glandular pattern reflects a type of invasive well-differentiated mucinous carcinoma which should be diagnosed as such, although some pathologists might classify tumors with this pattern as borderline tumor with intraepithelial carcinoma rather than as invasive carcinoma. For tumors comprised predominantly of borderline tumor the focus of confluent growth should measure more than the upper size limit allowed for a diagnosis of microinvasion to qualify for the diagnosis of invasive carcinoma.

FIGURE 25.20. Primary ovarian mucinous carcinoma. Mucinous glands are well differentiated, moderately atypical, and sufficiently back to back to qualify as invasive mucinous carcinoma.

Ovarian Mucinous Tumors Associated With Pseudomyxoma Peritonei. Recent studies have redefined pseudomyxoma peritonei as a specific clinicopathologic syndrome in which mucinous ascites is accompanied by low-grade neoplastic mucinous epithelium (not carcinoma), intimately associated with pools of extracellular mucin and fibrosis (131,133,153). Morphologic, immunohistochemical, and molecular genetic studies have provided compelling evidence that virtually all cases of pseudomyxoma peritonei are derived from appendiceal low-grade (adenomatous) mucinous tumors and the ovarian involvement is secondary (128–136). This concept is further supported by other studies showing that ruptured primary ovarian mucinous tumors have not been associated with the subsequent development of pseudomyxoma peritonei. Because the ovarian mucinous tumors associated with pseudomyxoma peritonei are almost invariably derived from the gastrointestinal tract, usually the appendix, they are reported as secondary involvement of the ovary by low-grade (adenomatous) mucinous tumor; such tumors should not be labeled with the same diagnostic terms used for primary ovarian tumors (cystadenoma or borderline tumor) so that clinicians are not confused about the established or suspected primary site. When intraoperative consultation with frozen section leads to diagnosis of a mucinous ovarian tumor in the setting of pseudomyxoma peritonei, the need for appendectomy should be conveyed to the surgeon and the pathologist should examine the entire appendix microscopically. The rare exception to this theory of the appendiceal origin of pseudomyxoma peritonei is the occurrence of mucinous tumors arising in ovarian mature cystic teratomas associated with pseudomyxoma peritonei (152).

The terms “disseminated peritoneal adenomucinosis” (131,133) and “involvement by low-grade appendiceal mucinous neoplasm” (153) are recommended as specific pathologic

diagnostic terms for these low-grade peritoneal mucinous tumors. This recommendation is based on studies demonstrating that peritoneal mucinous tumors with the histologic features of the low-grade tumors are pathologically and prognostically distinct from mucinous carcinomas, with the latter having significantly worse survival (133,134,154).

Metastatic Mucinous Carcinomas

Despite improved recognition of metastases, the problem of distinguishing primary from metastatic mucinous carcinomas in the ovary persists. The difficulty in recognizing metastases that morphologically simulate primary ovarian mucinous tumors not only at the time of intraoperative frozen section analysis but also on permanent sections is compounded by the fact that some metastases present first in the ovary, without a clinically evident extraovarian primary mucinous tumor. In addition, ancillary techniques such as immunohistochemical analysis with currently available markers, while useful in certain situations (e.g., colorectal carcinomas vs. primary ovarian carcinomas), are limited in their ability to distinguish some metastases from primary ovarian mucinous tumors (e.g., pancreaticobiliary tract carcinoma vs. primary ovarian mucinous tumors). Metastatic mucinous carcinomas are usually readily recognized as such when the ovarian tumors exhibit any or all of the following features: bilaterality, smaller size (typically less than 10 cm), ovarian surface involvement, a nodular pattern of involvement, and an infiltrative pattern of stromal invasion (126,142,155,156). It is important to recognize that some metastatic mucinous carcinomas, especially those derived from the colorectum, pancreaticobiliary tract, appendix, and endocervix, can exhibit deceptive patterns of invasion simulating primary ovarian mucinous borderline tumors with intraepithelial carcinoma or well-differentiated mucinous carcinomas of confluent glandular type (Fig. 25.21) (157–160). Not infrequently, some of these metastases display highly differentiated areas adjacent to carcinoma, simulating benign and “borderline” precursor lesions and suggesting origin in the ovary. Recognizing such tumors as metastatic is especially problematic when the ovarian tumor represents the presenting finding of disease, is unilateral and large, and a primary mucinous carcinoma of another organ is not identified. Recent studies have found that when mucinous tumors in the ovary are rigorously classified based on refined criteria and awareness of the deceptive patterns mentioned above, metastatic mucinous carcinomas are much more commonly encountered than primary ovarian mucinous carcinomas (142,156). The presence of any of the above-mentioned features characteristic of metastatic mucinous carcinoma in the ovary, or the presence of extraovarian disease at the time of intraoperative evaluation of a mucinous tumor in the ovary, should prompt the pathologist to consider the possibility of metastatic mucinous carcinoma and suggest that the surgeon examine the gastrointestinal tract, including pancreaticobiliary tract and appendix, for a primary tumor. Immunohistochemical analysis with antibodies such as CK7, CK20, CDX-2, and p16 can be useful for identifying some metastatic mucinous carcinomas; however, the utility of currently available markers is limited due to overlapping immunoprofiles of primary ovarian mucinous tumors (particularly with those of upper gastrointestinal tract origin) (157,161–164). Thus, further clinical evaluation is often required to exclude metastatic mucinous carcinoma in the ovary derived from a clinically occult nonovarian source.

Endometrioid Tumors

Endometrioid tumors account for a relatively small proportion of the common epithelial tumors, but most endometrioid tumors are malignant. About 15% of the endometrioid tumors

FIGURE 25.21. Metastatic endocervical adenocarcinoma in the ovary. The tumor exhibits a growth pattern that appears noninvasive, simulating a primary ovarian borderline (atypical proliferative) tumor and making recognition as a metastasis exceedingly difficult.

are of borderline type. The mean age of patients with cancer is 57 years, which is substantially higher than that associated with benign and borderline tumors (40 and 48 years, respectively). Approximately 10% of cases, with reports of up to 40% (165), are associated with endometriosis, implying that, in at least some cases, this tumor arises as neoplastic transformation of the endometriosis (166). Over 10% of endometrioid tumors of the ovary are also associated with endometrial tumors of an identical histologic variant, each appearing as if it were primary in its respective organ (167). Features that favor metastasis to the ovary include bilateral involvement; small, solid, multinodular ovaries; surface and hilar spread of tumor; and high-grade or deeply invasive tumor in the endometrium associated with lymphatic invasion. A large, cystic, unilateral ovarian tumor of low histologic grade arising in a background of endometriosis of the ovary with a low-grade, superficially invasive carcinoma of the endometrium is likely to represent a separate primary tumor. However, no single feature can clearly distinguish a metastasis from a second primary tumor. The similar histology and subtype and high survival rate of these patients (80% at 10 years) suggest that the majority are synchronous primaries rather than metastases (168). Many of these patients also have coexisting endometriosis (168,169).

Gross Appearance

Borderline tumors range in size from small to large. They average 10 cm in diameter and are predominantly solid (170). Necrosis is rare. The cysts vary from small to about 9 cm in size and are filled with fluid that may be serous, mucinous, or hemorrhagic.

Endometrioid adenocarcinomas, like serous carcinomas, vary in size with an average of 10 cm. Wide zones of necrosis are common, especially if the tumor is large or poorly differentiated. Endometrioid tumors are more cystic than serous tumors and surface papillations are relatively infrequent.

Microscopic Appearance

Two variants of borderline tumors are recognized: the more common, which arises in adenofibromas, and the less common, which arises as a papilla. About 15% of the patients have associated endometriosis. An occasional borderline tumor may show only microscopic foci of invasion. The few recorded cases have behaved in a clinically benign fashion, suggesting that, as with serous tumors, tiny microscopic foci of invasive endometrioid tumor have little influence on later clinical behavior.

Endometrioid adenocarcinomas resemble adenocarcinomas of the endometrium. Like endometrial tumors, they can vary from well differentiated (grade 1) to poorly differentiated (grade 3) and may contain squamous cells of varying degrees of differentiation (endometrioid adenocarcinoma with squamous differentiation). Endometrioid carcinomas are more commonly well differentiated and of lower stage than serous carcinomas, which may also account for the overall better prognosis of endometrioid compared to serous tumors. When controlled for stage, the survival rate for endometrioid tumors is similar to that of serous adenocarcinoma in some studies (171) but better in others (172).

Endometrioid Neoplasms With Stromal Component

The classification of endometrioid neoplasms includes a subset of tumors that contain an endometrial-type stromal component. Endometrioid stromal sarcomas are tumors in which the neoplasm is composed exclusively of malignant endometrial-type stroma. The müllerian adenosarcoma displays a malignant stromal component and an epithelial component that appears proliferative or hyperplastic. As expected, spontaneous tumor rupture, high grade, or the presence of a high-grade sarcomatous component is associated with a poor prognosis (173). The ovarian carcinosarcoma is composed of malignant cells that display both mesenchymal and epithelial differentiation. The gross and microscopic features of these tumors are identical to carcinosarcomas arising in the endometrium (174). The clinical behavior also mirrors that of uterine carcinosarcoma, with a very poor prognosis when spread occurs beyond the ovary.

Clear Cell Tumors

Clear cell tumors are uncommon. The mean age for patients with clear cell adenocarcinoma is 53 years (175), which is similar to the other categories of cancers of common epithelial origin. About half of the cases are associated with endometriosis.

Gross Appearance

Clear cell tumors resemble endometrioid tumors on gross examination and cannot be distinguished with any reliability from serous tumors. Sometimes clear cell tumors, when arising within an endometriotic cyst, may appear as a pedunculated polyp. Clear cell adenocarcinoma is bilateral in under one sixth of cases (13%).

Microscopic Appearance

The ability to distinguish the rare clear cell borderline tumor from the frankly malignant tumor is difficult or impossible, since the latter, especially when small, may appear to be deceptively benign. A tumor is considered to be malignant when (a) the glands and islands of epithelial cells manifest

FIGURE 25.22. Clear cell adenocarcinoma. The sheets of tumor cells have clear cytoplasm.

high-grade cytologic characteristics of malignancy; and (b) invasion is present as evidenced by a desmoplastic or myxoid response of the stroma to the cells or a haphazard extension of cells into the stroma.

Clear cell adenocarcinoma of the ovary is morphologically similar to the clear cell adenocarcinoma that occurs sporadically in the endometrium of older women and in the vagina and cervix of young women who were exposed prenatally to diethylstilbestrol (DES) (Fig. 25.22). Clear and “hobnail” cells are its hallmark, but it is important to recognize that the diagnosis rests upon architecture as well as optically clear cytoplasm. When present, the clear appearance of the cytoplasm results from glycogen that has leached as the tissue specimen is prepared for microscopic examination. The hobnail cells contain bulbous nuclei that protrude into the lumen at the apparent cytoplasmic limits of the cell. The clear cells usually appear as sheets of cells that have the appearance of a solid growth, but may also line tubules. The hobnail cells, and sometimes flat cells, are encountered more commonly in the pattern of growth showing tubules and cysts.

The clear cell carcinoma may also resemble the endodermal sinus (yolk sac) tumor. Historically, the two tumors were considered as being the same until it was recognized that clear cell tumors are müllerian in origin and endodermal sinus tumors are of germ cell origin. Immunohistochemistry has been of limited value in this distinction, since some keratins and alpha-fetoprotein can be expressed in both neoplasms. Recently, the presence of staining for the onco-fetal protein glycican-3 has been suggested as a means to distinguish yolk sac tumor from clear cell carcinoma (176).

Uncertainty exists whether ovarian clear cell adenocarcinoma is more aggressive than the other common epithelial malignancies. In some studies specifically addressing correlates of survival, advancing stage, and increased mitotic rate (>six mitoses per ten HPF or high MIB1 activity) were adverse prognostic indicators (177). Other investigators (178) emphasize young age, stage, or vascular invasion as being poor prognostic factors and the presence of a predominantly (>75%) papillary or tubulocystic morphology as a favorable prognostic factor. Many of the differences found in analyses appear to reflect the relative compositions of stage and grade

and whether the more poorly differentiated tumors are correctly categorized by their true cell type.

Transitional Cell Tumors

Brenner Tumor

Brenner tumor, a tumor of urothelial differentiation, is the rarest of the common epithelial tumors. It is believed to arise from the pelvic mesothelium through transitional cell metaplasia, much in the same manner as Walthard's rests arise. Most of these tumors are small, benign, and discovered incidentally. Rarely are these borderline tumors or frankly malignant. Malignant tumors are of two types. Malignant Brenner tumor, which is exceedingly rare, consists of a poorly differentiated transitional cell-type epithelium in which definitive foci of benign Brenner tumor are present. The transitional cell carcinoma, which in some cases may be a malignant Brenner tumor in which foci of benign Brenner tumor cannot be found, is an entity that has been separated from the categories of malignant Brenner tumor and undifferentiated carcinoma.

Gross Appearance. Borderline Brenner tumors usually occur as large cysts, with a coarse papillary lining. Malignant Brenner tumors tend to be substantially more solid, but sometimes contain cysts.

Microscopic Appearance. Brenner tumors, unlike other common epithelial tumors, have two components. One is epithelial cords, which are composed of ovoid to polyhedral cells with large, longitudinally grooved nuclei (coffee-bean shaped). The cellular arrangement often resembles urothelium (179), with the most superficial layer of cells often displaying copious, mucin-rich cytoplasm. The second component is a dense, fibrous stroma in which are found the nests of transitional cells. The stroma is typically prominent and at times so massive as to nearly obscure the epithelial component. Minute foci of stromal calcification are found in over half the tumors.

The distinction between borderline and malignant Brenner tumor may be difficult. Borderline Brenner tumors exhibit papillae lined by a proliferating transitional epithelium typical of that found in low-grade bladder tumors. Malignant Brenner tumors have transitional epithelium that may be high grade or focally resemble squamous cell carcinoma. By definition, both borderline and malignant Brenner tumors have foci of a clearly identifiable benign Brenner's component.

Transitional Cell Carcinoma

Transitional cell carcinoma is a second form of ovarian cancer with urothelial differentiation. Unlike malignant Brenner tumor, which by definition arises from demonstrable pre-existing benign or proliferative Brenner tumor, the transitional cell carcinoma lacks such a component.

The transitional cell carcinoma is considered to be a separate variant of ovarian cancer based on both clinical and histologic grounds, although some consider it a variant of serous carcinoma.

Transitional cell tumors of the ovary, although appearing as urothelial-like, show immunoreactivity differences from true urothelium. The tumor of ovarian origin is immunoreactive with cytokeratin 7, whereas the bladder tumors show no such reactivity (180).

Squamous Cell Carcinoma

Squamous cell carcinoma is the newest category of surface epithelial-stromal tumors recognized by the WHO classification scheme for ovarian tumors. As for most epithelial

tumors, the diagnosis is usually made in postmenopausal women, with an average age of about 56 years, and most of the tumors are stage II or III. The stage and grade of the tumor correlate best with overall survival (181). Pure squamous carcinomas are exceedingly rare, and some arise in endometriosis. Other squamous carcinomas reflect a teratomatous origin and arise consequent to malignant degeneration in a mature cystic teratoma.

Undifferentiated Carcinoma

Undifferentiated carcinoma refers to epithelial tumors that are so poorly differentiated based on examination of hematoxylin and eosin stained slides as to preclude further classification into any of the types described above. However, several subtypes of undifferentiated carcinoma display immunohistochemical and biochemical evidence of differentiation.

Small Cell Carcinoma

Small cell carcinoma is a subgroup of undifferentiated tumor. This tumor, which is of at least two types, the hypercalcemic and pulmonary types, is enigmatic in both its histogenesis and classification (182). The *hypercalcemic tumor* typically occurs in young women (mean age 24 years) (183). Two thirds have systemic hypercalcemia, which is commonly reversed after the tumor has been excised (184). This variety of small cell carcinoma is virtually always unilateral, but has spread beyond the ovary in half of patients by the time of diagnosis. Diffuse sheets of small, closely packed cells punctuated by variable numbers of follicle-like spaces characterize its histology. The individual cells have scant cytoplasm and a single nucleus. Mitotic activity is typically brisk. Although the DNA content is nearly always diploid, over 60% of patients with stage IA tumors die of the disease or have recurrences. Features in stage IA tumors associated with a more favorable outcome are age <30 years, normal preoperative serum calcium, and small tumor size. A large cell variant of the small cell type has also been described (185).

The second form of small cell carcinoma resembles small cell carcinoma of the lung (186). The tumor occurs in older women (mean, 59 years), and half of the tumors are bilateral. Neuron-specific enolase and reactivity are common, whereas chromogranin reactivity are only occasionally found. The majority of tumors are aneuploid. The mean survival is 8 months following diagnosis.

A third and rare form of undifferentiated carcinoma is the *neuroendocrine tumor of the non-small cell type* (187). Microscopically, the neuroendocrine component immunoreactive for chromogranin is in sheets, usually as closely packed islands, cords, or trabeculae of epithelial cells with little intervening stroma. The prognosis is poor (188). Metastasis from a respiratory origin must be excluded when the diagnosis of small cell or large cell undifferentiated carcinoma of the ovary is entertained.

Mixed Carcinoma

Perhaps as many as 10% of all ovarian tumors of common epithelial origin are mixed, when defined as a carcinoma in which more than 10% of the neoplasm exhibits a second histologic cell type. It has been commonly underreported since there is a tendency to place all high-grade carcinomas in the category of serous carcinoma. One common specific malignant combination is mixed clear cell and endometrioid carcinoma, both being related to endometriosis. Serous and endometrioid carcinomas are also commonly encountered. The behavior of mixed carcinomas of the ovary has not been elucidated.

Primary Peritoneal Serous Carcinomatosis

About 80% to 90% of women with peritoneal serous carcinomatosis (excluding advanced-stage endometrial serous carcinomas) have normal-sized ovaries with only surface implants of tumor. These are classified as primary peritoneal serous carcinomas, although a small proportion may represent primary tubal carcinomas (see below). Primary peritoneal carcinoma was defined by the GOG as follows: (a) ovaries are of normal size or enlarged by a benign process; (b) ovarian involvement is absent or limited to the surface and/or superficial cortex with no tumor nodule within the ovarian cortex exceeding 5×5 mm; (c) serous histology; and (d) volume of extraovarian disease significantly exceeds that of ovarian disease.

Primary peritoneal serous carcinomas may be more common than previously appreciated. A recent large series from a community hospital found that 22% of cases of peritoneal serous carcinomatosis were classified as peritoneal (83). In addition, there is reason to believe that the GOG criteria are too restrictive. A 5 or 6 mm nodule of serous carcinoma can be seen with tumors that fulfill all of the other criteria for peritoneal origin, and may even display the characteristic multi-nodular pattern of metastatic tumor to the ovary. The pathology and response to treatment of peritoneal serous carcinomas are essentially identical to that of ovarian serous carcinomas. However, the true relative incidence of ovarian versus peritoneal carcinoma is of pivotal importance because it directly impacts on the type of surgery recommended for prophylaxis in high-risk women as well as on the precise risk of developing serous carcinoma after prophylactic surgery.

The contribution of the fallopian tube to peritoneal serous carcinomatosis is unknown. It has recently become apparent that the tubal fimbriae may be an important source of carcinomatosis in the absence of the typical features of primary tubal carcinomas (i.e., a dilated fallopian tube with a large mucosal lesion). Furthermore, the intramural portion of the tube is not removed if there is no hysterectomy, and therefore this segment is theoretically a potential source of serous carcinoma even after prophylactic bilateral salpingo-oophorectomy.

In conclusion, lesions designated as primary peritoneal carcinoma are likely a heterogeneous collection of carcinomas that have arisen from the ovary, fimbria of the fallopian tube, or the pelvic peritoneum.

Fallopian Tube Carcinoma

Gross Appearance

The gross appearance of the fallopian tube affected by papillary carcinoma is typically described as enlarged, deformed, or fusiform, with agglutination of the fimbriae and, frequently, distal obstruction (Fig. 25.23) (188–191). When the tumor is confined to the mucosa, the tube is generally soft to palpation, and the initial impression of the surgeon is often hematosalpinx, pyosalpinx, or hydrosalpinxeale. Turbid fluid frequently fills the lumen, with a friable, exophytic, papillary, or nodular mass affixed to the mucosal surface. The most frequent site of origin is the ampulla, followed by the infundibulum (192,193). In about 10% of cases in a recent large study, the tumor arose in the fimbriated end of the fallopian tube. All of these tumors were less than 3 cm in diameter (194,195). Sometimes, multiple minute tumors stud the mucosal surface, or the entire lumen may be replaced by a necrotic mass. With more advanced disease, neoplastic cells penetrate the muscular wall and serosa of the tube, and extension to the ovary may result in a tubo-ovarian complex. In the latter situation, it is usually obvious that a malignant neoplasm has infiltrated the

FIGURE 25.23. Carcinoma of the fallopian tube.

organs, but the distinction of tubal carcinoma from that of the ovary may not be possible, and reliance on arbitrary criteria usually results in the classification of the tumor as being ovarian in origin (see below). The carcinoma affects the left and right tube with about equal frequency and displays bilateral involvement in about 5% to 30% of cases (196–201).

Recently, a radically different presentation of fallopian tube carcinoma has been reported. Occult invasive or *in situ* carcinoma has been found to involve the fallopian tube in risk-reducing salpingo-oophorectomy (RRSO) specimens obtained from women with a strong family history of ovarian cancer or known *BRCA1* or *BRCA2* germ-line mutations (67,202,203). Such tumors may not be visible macroscopically, and it is suggested that the entire fallopian tube as well as the ovary be serially sectioned and examined microscopically in this clinical setting.

Microscopic Appearance

The current WHO histologic classification of epithelial tumors of the fallopian tube is similar to that of other sites in the upper female genital tract and is divided into serous, mucinous, endometrioid, clear cell, transitional, squamous, glassy cell, and mixed carcinomas (195). This change in terminology reflects an increased recognition of both endometrioid and transitional cell differentiation in carcinomas of the fallopian tube during the past 10 years.

Papillary serous adenocarcinoma is the most frequent primary malignant neoplasm of the fallopian tube, and was previously reported to represent about 90% of the 300 new cases annually occurring in the United States (188). In more recent studies, its frequency has been lower, reflecting the increasing recognition by pathologists that tumors of other cell types may legitimately arise in the fallopian tube (189,190). In superficial lesions, the plicae, which are ordinarily covered by a simple columnar epithelium of ciliated and secretory cells, are replaced by multiple layers of columnar or cuboidal cells with pleomorphic and hyperchromatic nuclei (Figs. 25.24 and 25.25). The papillary configuration of the epithelium is usually preserved, but secretory activity and cilia are usually not preserved at the light microscopic level. Mitotic figures are frequent. Invasion of the muscular wall occurs early in the course of disease, and, as the tumor enlarges, necrosis becomes a common feature. It is critical for the pathologist to examine and liberally section the site of tumor carefully since the probability of survival is markedly different for women whose tumors are confined to the mucosa compared with those whose tumors either invade the muscular wall or extend to the serosa of the tube (201). Capillary or lymphatic vascular invasion is common even in

FIGURE 25.24. Hyperplasia of the fallopian tube. Pseudostratification of cells and crowding of nuclei discovered as an incidental finding in a fallopian tube removed from a 49-year-old female with stress incontinence.

early-stage disease, and has also been associated with a diminished probability of survival (200).

Endometrioid carcinomas involving the fallopian tube are more common than previously reported, and over 50 cases have been documented in the literature (204). They are formed of tubular glands, sometimes with foci of either benign or malignant-appearing squamous differentiation (189,191,205). In at least one case, the tumor arose in tubal endometriosis. The tumor usually resembles typical adenocarcinoma of the endometrium, but it may simulate female adnexal tumors of probable wolffian origin (195,206,207). It may be distinguished from the latter by the greater degree of cytologic atypia, mitotic activity, and at least focal endometrial-type gland formation (206,208). Many of the endometrioid carcinomas are either noninvasive or only superficially invasive, and appear to have a more favorable prognosis than serous carcinomas.

Transitional cell carcinomas resemble tumors of urothelial type, with papillae formed of broad masses of cells covering a fibrovascular core (189,204–210). These papillae are distinguished from those of serous carcinomas by having a smooth surface rather than the scalloped surface of serous carcinoma, and by the presence of longitudinal grooves in the nuclei of some cells. This was the predominant histologic pattern in 12 of 21 primary tubal carcinomas from Japan (210), but represented only about 10% of cases in a large series from the United

FIGURE 25.25. Multifocal neoplasia involving the fallopian tube. Papillary carcinoma of low malignant potential is depicted on the serosa of the fallopian tube, whereas psammoma bodies are noted in the lumen.

States (189). The survival has been reported to be either better than or similar to that of serous carcinoma (201,210).

Too few cases of clear cell, undifferentiated, or mixed types of carcinoma have been reported to characterize their behavior.

The histologic grade of fallopian tube carcinoma is usually simply designated as well, moderately, or poorly differentiated. In contrast to the depth of invasion, the degree of histologic differentiation has generally not been related to prognosis (192,193,196,198,200,211), although a few series have demonstrated a better probability of survival when the tumor was well differentiated (177). It is unclear whether this inability to prognosticate reflects the lack of biologic importance of histologic grade or simply the absence of reproducible criteria for grading.

No distinctive immunohistochemical markers of fallopian tube differentiation exist. Carcinoembryonic antigen is widely distributed in the lower intestinal tract during embryonic development and is present in mucinous neoplasms of the cervix and ovary, but it is absent from the postnatal normal or neoplastic fallopian tube. CA-125 can be detected immunohistochemically in both the benign and malignant fallopian tube (211,212); however, it is also found in endometrial and ovarian serous carcinomas, and thus cannot help the pathologist to discriminate whether a carcinoma has arisen in the fallopian tube or ovary.

The data are insufficient to offer conclusions about the frequency or significance of oncogene overexpression in fallopian tube carcinoma. In one study of HER2/neu using a quantitative polymerase chain reaction assay, no tumors displayed amplification of the oncogene (213). The frequency of HER2/neu overexpression has varied from 26% to 89%, whereas that of p53 has ranged from 60% to 83% (202,214). In contrast to ovarian carcinoma, their overexpression in fallopian tube carcinoma has not been associated with a worsened prognosis. Immunohistochemical overexpression of *c-myc* has also been reported in 61% of cases in one study (214). K-RAS point mutations in codon 12 have been reported to be present in seven of eight carcinomas of the fallopian tube (215).

Estrogen receptors have been identified in the nuclei of fallopian tube epithelium and in a minority of fallopian tube carcinomas (216,217); however, no data on the relationship between the presence of estrogen receptors and response to hormonal therapy for fallopian tube cancer exist.

Rare Malignant Neoplasms of the Fallopian Tube

Most types of tumors found in the uterine corpus have also been reported to occur in the fallopian tube. About 50 cases of malignant mixed mesodermal tumors have been described (215,218–221). The average age at diagnosis is 58 years. The lesions grossly resemble those of fallopian tube carcinoma, with a dilated tube that contains an intraluminal papillary mass. However, in addition to a carcinoma arranged as glands or papillae, there is also a malignant stromal component. The tumors are further divided into homologous or heterologous types according to the absence or presence of differentiation of the stromal elements into cell types not normally found within the müllerian duct system, such as skeletal muscle or cartilage. The overall 5-year survival is about 15%, with a mean survival of about 17 months. The presence or absence of heterologous elements has not been related to outcome. A single positive observation is the markedly better probability of survival for women with tumors confined to the muscularis (220).

Three examples of primary squamous cell carcinoma (222), immature teratoma (223), glassy cell carcinoma (224), Wilms' tumor, and rare pure sarcomas, including leiomyosarcoma, angiosarcoma, malignant fibrous histiocytoma, stromal sarcoma, and fibrosarcoma, have been reported to occur in the fallopian tube (225–229). Other pure squamous carcinomas in the fallopian tube have been generally described as part of an extended *in situ* transformation that involves uterine

cervix and corpus, frequently associated with cervical stenosis (see section Multifocal Carcinoma of the Müllerian System, Including the Fallopian Tubes below).

Serous, mucinous, and endometrioid tumors of low malignant potential occasionally occur in the fallopian tube (194,230–232). Their biologic behavior appears to mimic that of low malignant tumors of the ovary.

About 100 cases of gestational choriocarcinoma arising in an ectopic tubal pregnancy have been reported (233). It displays pathologic and biologic characteristics identical to those of uterine choriocarcinoma (233,234). Nongestational choriocarcinoma of the fallopian tube has been reported in a prepubertal girl.

Papillary carcinoma of the tube typically occurs in menopausal women; however, in a handful of cases, it occurred in adolescent females or was discovered during pregnancy or at postpartum tubal ligation (224,235–237).

The precise, but awkward, appellation “female adnexal tumors of probable wolffian origin” has been given by Young and Scully to a rare neoplasm identified along the serosal surface of the distal portion of the fallopian tube or within the broad ligament or ovary (238). About 20 such tumors have been reported in women between 28 and 79 years of age. These tumors are typically unilateral, lobulated, grossly encapsulated, solid, or partially cystic masses that measure from 1 to 20 cm in diameter. A variety of microscopic patterns have been described, including cystic, closely packed tubules, sieve-like spaces, or diffuse proliferation. Usually, the cells have bland, oval nuclei and little mitotic activity. It is these cytologic features that help distinguish them from mesotheliomas or common epithelial malignancies. Intracytoplasmic mucin is absent. Although the majority of the tumors behave in a benign fashion, the presence of nuclear pleomorphism and, especially, increased mitotic activity (>10 mitoses per ten HPF) has been associated with more aggressive behavior.

Distinction of Fallopian Tube Carcinoma From Ovarian Carcinoma

Because the gross and microscopic characteristics, as well as spread, of carcinoma of the fallopian tube is identical to those of the ovary, the determination of the site of origin of a tumor that forms a solid or cystic tubo-ovarian mass is arbitrary. In the past, some investigators have quite reasonably designated such tumors as tubo-ovarian carcinoma (205). Hu et al., in 1950, proposed criteria for differentiating primary from metastatic carcinoma that involves the fallopian tube. These criteria, slightly modified, are outlined in Table 25.5 (239). Many tumors of probable tubal origin fail to meet these stringent criteria, and the fault with this approach is the possibility that the incidence of fallopian tube carcinoma is greatly underestimated. This may simply reflect the rigidity of our definitions. Carcinomas that occur in a scarred tube or those that provoke

an inflammatory response with fibrosis are likely to form localized masses that we classify as primary to the fallopian tube. In contrast, early dissemination of cells from carcinomas arising in the mucosa of the fimbriated end of a fallopian tube that is not sealed may result in a mass that is larger in the ovary or the peritoneum than in the fallopian tube. By convention, these carcinomas would be classified as primary ovarian or primary peritoneal carcinomas, although the neoplasm may have had an origin in the tube. The recent studies of Crum et al. suggest that this may be a very frequent occurrence, and the fallopian tube may actually be the source of many high-grade serous carcinomas that are considered as primary to the ovary (239a).

Hyperplasia and Preinvasive Carcinoma of the Fallopian Tube

The sequence of histologic changes that precedes the development of invasive adenocarcinoma of the fallopian tube has not been well described. Proliferation of the pseudostratified columnar cells in the absence of marked cytologic atypia or mitotic activity is referred to as epithelial hyperplasia (Fig. 25.24). The degree of proliferation varies and may result in a multilayered epithelium with focal tufting and, rarely, a cribriform pattern of cells. Tubal hyperplasia is more commonly observed as an incidental finding in patients with salpingitis (particularly tuberculous salpingitis), endogenous or exogenous estrogen stimulation, or serous ovarian tumors of low malignant potential (239–240). Moore and Enterline (241) prospectively sectioned entire oviducts from 124 nonselected hysterectomies and found hyperplasia in 19% of women, frequently as a focal lesion. The significance of hyperplasia is thus unknown, but the pathologist should be cautious not to overinterpret proliferative lesions as intraepithelial carcinoma.

In a very recent series of studies using serial sectioning of fallopian tubes from a variety of conditions, Crum et al. have suggested that mutations in the p53 tumor suppressor gene, either as an isolated finding or in association with cytologic atypia and increased proliferation, may serve to identify a molecular signature of various precursors of tubal carcinoma.

Preinvasive carcinoma (dysplasia, carcinoma *in situ*) of the fallopian tube was rarely reported prior to the practice of RRSO for women with *BRCA* mutations (241,242). In contrast to hyperplasia, the diagnosis of carcinoma *in situ* requires the presence of marked cytologic atypia. The proliferation usually results in the formation of multilayered epithelium composed of cells with large, pleomorphic nuclei, often prominent nucleoli, and interspersed mitotic activity. The evidence that supports the designation of lesions as carcinoma *in situ* is their frequent occurrence in the transition between normal tubal epithelium and invasive carcinoma and their presence as part of multifocal *in situ* and early invasive neoplasia that involves the fallopian tube and ovary (242). *In situ* carcinoma of the fallopian tube is one of the most common findings in grossly normal ovaries and fallopian tubes removed for cancer risk reduction in women with *BRCA* mutations (67,203,243–245) (see The Pathologic Examination of Risk-Reducing Salpingo-oophorectomy Specimens).

Chronic inflammation commonly coexists in fallopian tubes that contain carcinoma (201,246); this fact has resulted in speculation that acute and chronic salpingitis is a cause of fallopian tube cancer. However, it is more likely that inflammation is a response to the presence of the neoplasm coupled with obstruction of the fallopian tube rather than a carcinogenic factor. First, although acute salpingitis is usually a bilateral disease, the tube contralateral to the one that contains the carcinoma is frequently free of salpingitis. Second, fallopian tube carcinoma is a disease of postmenopausal women, a group with a low incidence of tubal infection. Nevertheless, in a pathologically based case-control study of the nonneoplastic

TABLE 25.5

CRITERIA FOR PATHOLOGIC DIAGNOSIS OF PRIMARY FALLOPIAN TUBE CARCINOMA

1. The main tumor is in the tube and arises from the endosalpinx.
2. The pattern histologically reproduces the epithelium of the mucosa and usually shows a papillary pattern.
3. If the wall is involved, the transition between benign and malignant tubal epithelium should be demonstrable.
4. The ovaries and endometrium are either normal or contain less tumor than the tubes.

contralateral tube from 14 women with fallopian tube carcinoma, changes significantly more common included luminal dilatation, plical atrophy, and chronic inflammation, which are all changes consistent with chronic, healed salpingitis (247).

In contrast to chronic salpingitis, the relationship between tuberculous salpingitis and carcinoma is more complex. More than two dozen cases of carcinoma arising in the tube affected by tuberculosis have been reported (248). Although some of the examples are well documented, with evidence of metastatic spread occasionally, there is some concern that not all of the cases truly represent coexisting invasive neoplasia. The diagnosis of invasive carcinoma should be made cautiously in the fallopian tube afflicted with tuberculosis and should be reserved for cases in which infiltration of the muscularis with a desmoplastic host response is obvious.

Cytology in Diagnosis of Fallopian Tube Carcinoma

Although exfoliative cervicovaginal cytology has been reported to be positive in as many as 40% to 60% of women with tubal carcinoma (200,239,249), in most series, abnormal Papanicolaou (Pap) smears were distinctly uncommon (0% to 18%) (193,250,251). When present, the neoplastic cells are indistinguishable from those shed from endometrial adenocarcinoma, although several features may suggest that the tumor has arisen in the tube rather than the uterus. The malignant cells are scant in number and degenerate; malignant cells often present a spherical or papillary configuration; and the background is free of cellular debris (tumor diathesis) (252).

Because occult spread of tubal carcinoma outside the pelvis with serosal seeding occurs frequently, cytologic examination of peritoneal washings has been recommended (253). The presence of ascites or positive peritoneal cytology correlates well with an advanced stage of disease (252,254). A significantly worse prognosis has been reported for patients with exfoliated malignant cells in the peritoneum. In one study, the 5-year survival was 67% when the cytologic findings were negative but only 20% when malignant cells were present (241). Peritoneal fluid or washings should routinely be obtained at surgery for cytologic examination.

Multifocal Carcinoma of the Müllerian System, Including the Fallopian Tube

Multifocal carcinomas that involve the fallopian tube can be divided into three patterns: synchronously detected multifocal neoplasia within the fallopian tubes; multifocal neoplasia that involves various genital organs, including the fallopian tube; and direct spread of carcinoma (frequently intraepithelial) along the mucosa of the cervix and endometrium to involve the fallopian tube.

About 20% of patients with fallopian tube carcinoma have bilateral involvement. Although many specimens display a distinct site of mucosal tumor in each tube, it is unclear what percentage of patients reported to have bilateral disease actually have two, synchronously detected primary tubal neoplasms rather than metastasis from the contralateral tube (255). Unfortunately, most series do not include sufficient information to resolve this issue.

Multifocal carcinoma of the upper genital tract, including the fallopian tube, is relatively common (256,257). Sometimes, multiple papillary serous carcinomas are found in the ovary and on the serosa or in the lumen of the fallopian tube. These findings may reflect neoplastic transformation of the common embryologic field, which includes the coelomic epithelium that covers the ovary, fallopian tube, and other pelvic peritoneum (Fig. 25.25). At other times, endometrioid carcinomas are present in the endometrium, in the ovary, and in the mucosa of the tube. The frequent presence of endometriosis in these patients has led to the suggestion that it

is the site of multifocal neoplastic transformation (257). Multifocal neoplasia may be even more common than generally noted. In one series of 133 women with serous ovarian carcinoma, carcinoma *in situ* or early invasive carcinoma of the serially embedded fallopian tube was found in 4. The lesions were often focal, and none was grossly detected (155).

However, it is sometimes difficult to distinguish multiple primary neoplasms that arise in the fallopian tube and ovary or endometrium from endometrial or ovarian carcinoma metastatic to the tubal mucosa. For example, retrograde reflux of aggregates of neoplastic cells into the lumen of the fallopian tube may be observed in the hysterectomy specimen resected for endometrial adenocarcinoma (258). Occasionally, these refluxed tumor cells may implant and grow in the tubal mucosa since tumor types rarely observed primarily in the tube (such as clear cell carcinoma or endometrioid carcinoma) coexist with endometrial carcinomas of these types. Direct spread of carcinoma *in situ* or invasive squamous carcinoma of the cervix along the mucosa of the endometrium and into the fallopian tubes has been occasionally reported (221). This extensive surface growth of malignant cells may reflect either horizontal spread with displacement of glandular epithelium by neoplasm or concurrent squamous metaplasia and neoplastic transformation in the cervix, endometrium, and fallopian tube. In view of the rarity of primary squamous carcinoma of the fallopian tube, the first hypothesis seems much more plausible.

Carcinoma Metastatic to the Fallopian Tube

The most common carcinoma that involves the fallopian tube is metastatic, generally from another site in the female genital tract. Carcinoma of the ovary is particularly likely to spread to the fallopian tube and may be found in up to half of patients with ovarian cancer (199,259). Metastasis to the fallopian tube is reported to occur in 12% of patients with uterine corpus carcinoma and 4% of patients with cervical carcinomas (260). Although the tubal mucosa or muscular wall may be affected, primary involvement of the serosa is typical of ovarian carcinoma. Lymphatic or vascular space involvement is frequently identified in tumors metastatic from the uterus, and the entire wall of the fallopian tube may be permeated by tumor (260). Isolated examples of breast and bladder carcinoma metastatic to the fallopian tube have also been reported (261,262).

Endometrial stromal sarcomas, leiomyosarcomas, and malignant mixed mesodermal tumors that arise in the uterine corpus may invade directly into the adnexa and secondarily involve the fallopian tube. Lymphoma and leukemia also may spread to the fallopian tubes but usually do so as part of widespread organ involvement.

Lesions That Mimic Primary Carcinoma of the Fallopian Tube

The difficulty in distinguishing primary carcinoma of the fallopian tube from metastatic tumor has been addressed. In addition, several conditions, both neoplastic and nonneoplastic, may be confused with fallopian tube carcinoma (263–265).

Salpingitis isthmica nodosa is the term given to a localized diverticulosis of the isthmus portion of the fallopian tube. The gross appearance, when visible, is of a firm, nodular expansion of the isthmus, with a diameter of less than 2 cm. Microscopically, a complex proliferation of branching glandular arrays is seen extending from the lumen to deep within the muscular wall (Fig. 25.26), often associated with hypertrophy of the muscularis. In spite of this architectural abnormality with pseudoinvasion, no cytologic atypia occurs, and the normal epithelial cell types of the fallopian tube mucosa may be readily identified.

Adenomatoid tumors represent benign mesotheliomas, which may occur along the serosa or deep muscularis of the

FIGURE 25.26. Salpingitis isthmica nodosa. In this cross section of the fallopian tube, the luminal mucosa (L) appears unremarkable.

fallopian tube (Fig. 25.27). They are usually small (1 to 2 cm in diameter) nodular masses, formed of multiple, spherical, or slit-like channels lined by an attenuated layer of cells. The absence of cytologic atypia or significant mitotic activity permits the distinction from carcinoma. Immunohistochemical and ultrastructural studies provide convincing evidence of mesothelial cell differentiation for these lesions.

Metaplastic papillary tumor of the fallopian tube is a rare, incidental finding in pregnant or postpartum women. Focal, noncircumferential replacement of normal mucosa is accomplished by small papillae covered with large epithelial cells with abundant eosinophilic cytoplasm. Mitotic activity, severe cytologic atypia, and invasion are not seen. The behavior of these lesions is benign (266).

Natural History and Patterns of Spread

Ovarian carcinomas are distinctive by virtue of their propensity to exfoliate malignant cells into the peritoneal cavity. There the cells follow the normal circulation of peritoneal fluid up the right paracolic gutter and to the undersurface of the right hemidiaphragm, where they may implant and grow as surface nodules. The omentum is also a frequent site of involvement, and, indeed, all intraperitoneal surfaces are at risk. Such exfoliation and implantation are one of two primary modes of spread of ovarian cancer. The other is via the

FIGURE 25.27. Adenomatoid tumor. An eccentrically located subserosal mass is present in the fallopian tube.

TABLE 25.6

SUBCLINICAL METASTASES IN APPARENT EARLY OVARIAN CANCER

Site	No. of patients with involvement	Total patients	% involved
Diaphragm	17	223	7.6
Omentum	21	294	7.1
Cytology	13	69	18.8
Peritoneal	6	61	9.8
Pelvic nodes	18	202	8.9
Aortic nodes	35	285	12.3

Source: Modified with permission from Moore DH. Primary surgical management of early epithelial ovarian carcinoma. In: Rubin SC, Sutton GP, eds. *Ovarian Cancer*. New York: McGraw-Hill; 1993.

retroperitoneal lymphatics that drain the ovary. These follow the ovarian blood supply in the infundibulopelvic ligament to terminate in lymph nodes lying along the aorta and vena cava up to the level of the renal vessels. Lymph channels also pass laterally through the broad ligament and parametrial channels to terminate in the pelvic sidewall lymphatics, including the external iliac, obturator, and hypogastric chains (267). Spread may also occur along the course of the round ligament, resulting in involvement of the inguinal lymphatics. Lymph node metastases are correlated with the stage of disease, and retroperitoneal node involvement has been found in the majority of advanced ovarian cancer cases (268).

The initial spread of ovarian cancer, by both the intraperitoneal and lymphatic routes, is clinically occult. As many as 30% of women with ovarian cancer that grossly appears to be confined to one or both ovaries have widespread disease. The extent of their disease can be detected only by histologic examination of visually normal tissues sampled during careful surgical staging (269). It has been estimated that approximately 10% of patients with apparently localized ovarian cancer that appears to be confined to the ovaries will have metastases to the aortic nodes (269). Many patients with apparently localized disease will also have occult disease in peritoneal washings or in biopsies of the diaphragm and omentum (Table 25.6).

Fallopian Tube: Patterns of Spread and Prognostic Factors

The spread of fallopian tube carcinoma is identical to that of the ovary, with frequent involvement of the peritoneum, omentum, bowel, and ovaries (192,239,270–272). In some series, half or more of all recurrences presented outside the peritoneal cavity, most often in the liver, lungs, and pleura, as well as in the vagina, kidney, brain, cervix, and skin. Although some investigators have reported that lymphatic spread is uncommon, this finding in part may have reflected a tendency not to perform lymph node dissections (201,239). The principal lymphatic drainage of the fallopian tube appears to be via the para-aortic lymph nodes. Pelvic or para-aortic lymph node involvement has been identified in 10% to 30% of patients at initial operation (253), in about one third of women with recurrent disease (273), and in 75% (9 of 12) of patients at autopsy (253). As previously stated, the presence of capillary or lymphatic space involvement in early tubal carcinoma has been associated with diminished probability of survival at 5 years compared with patients in whom vascular invasion is not identified (29% vs. 83%) (241).

Transcoelomic spread of tumor is an important mode of spread of fallopian tube carcinoma (196). Initially, exfoliation of neoplastic cells from the distal fimbriated end of the tube has been suggested as the mechanism by which this occurred (239). It is difficult to reconcile this theory with the typical gross appearance of a dilated tube with a sealed distal tubal ostium (201). Schiller and Silverberg (201), in a retrospective review of 76 published cases of fallopian tube carcinoma, documented the important relationship between the depth of invasion by tumor and survival. A crude 5-year survival of 91% was found for intramucosal lesions, 53% for tumors with mucosal wall invasion, and 25% or less for cases in which the tumors penetrated the tubal serosa. Using these data, they proposed a staging system for fallopian tube carcinoma based in part on the depth of invasion. Very similar 5-year survival rates by stage were recently reported in a study of 151 patients treated at the Norwegian Radium Hospital (190). In a univariate analysis of survival, the stage, presence of residual disease, ascites, depth of tubal invasion, a hydrosalpinx-like appearance, age, and vascular invasion were all of statistical significance. However, several of these factors, such as depth of invasion and vascular space invasion, are interrelated. When subjected to a multivariate analysis, residual disease, stage, and a hydrosalpinx-like appearance retained strong statistical significance (190). In a subgroup analysis of 41 patients with stage I disease, depth of invasion and intraoperative tumor rupture were independent prognosticators. A study by Peters et al. (274) confirmed the importance of depth of invasion in predicting survival. Thus, the pathologist who examines a fallopian tube that contains carcinoma is recommended to provide information on the depth of invasion, the presence of lymphatic or capillary space involvement, and the degree of histologic differentiation.

DIAGNOSIS AND CLINICAL EVALUATION

Approximately 75% to 85% of patients with epithelial ovarian cancer are diagnosed at the time when their disease has spread throughout the peritoneal cavity. Several organizations, including the Gynecologic Cancer Foundation, the Society of Gynecologic Oncologists, and the American Cancer Society, released a consensus statement on the symptoms of ovarian cancer in June 2007. It urges women to seek medical attention if they have new and persistent symptoms of bloating, pelvic or abdominal pain, difficulty eating, or early satiety, or urinary urgency or frequency. These symptoms were found to be much more likely to occur in women with ovarian cancer than in the general population. Such symptoms are, however, vague and associated with many other conditions. However, they have been reported to be more recent and of greater severity and frequency in women with the disease than in women without (275). Fatigue, indigestion, back pain, pain with intercourse, constipation, and menstrual irregularities were also noted by ovarian cancer patients, but were equally common in the general population. There is, however, no evidence that detection based on these factors will shift diagnosis early enough to affect mortality.

The diagnosis of early-stage ovarian cancer (when the tumor is still confined to the pelvis) usually occurs by palpation of an asymptomatic adnexal mass during a routine pelvic examination. However, the vast majority of palpable adnexal masses are not malignant and, in premenopausal women, ovarian cancer represents less than 5% of adnexal neoplasms. In these women, the ovarian enlargement is usually due to either follicular or corpus luteum cysts. The vast majority of these functional cysts will regress in one to three menstrual cycles and, consequently, the initial approach to management

for a palpable adnexal mass less than 8 cm in size in a premenopausal woman is to repeat the pelvic examination and imaging studies in 1 to 2 months.

In contrast, an adnexal mass in a premenarchal or postmenopausal woman, particularly when complex, has a higher likelihood of being a malignant tumor, and surgical exploration is usually indicated.

Ultrasonography is frequently used to aid in the evaluation of adnexal pelvic masses. Features that are more frequently associated with malignancy include irregular borders, multiple echogenic patterns due to the presence of solid elements with prominent papillary projections, dense multiple irregular septa, and bilateral tumors. Other radiographic techniques, including computed tomography (CT) scans and magnetic resonance imaging (MRI), are not routinely necessary for preoperative evaluation of ovarian cancer but may provide useful information. The CT scan may provide additional evidence of the exact size of liver and pulmonary nodules, as well as abdominal and pelvic masses, which can be used to monitor the response of therapy. CT scans are also currently used to evaluate para-aortic and pelvic adenopathy.

Positron emission tomography (PET) utilizes a differential in metabolic activity between benign and malignant cells using the radiopharmaceutical 2-[¹⁸F]fluoro-2-deoxy-D-glucose (¹⁸FDG). Some studies have suggested that PET/CT imaging is useful in the differential diagnosis of ovarian cancer (276), and it may have a role in detecting residual or recurrent disease (277).

The use of other radiographic studies is dependent upon the results of the initial physical examination and the presence of patient symptoms. Brain scans and bone scans are unnecessary unless suggested by the patient's symptoms; metastases to these sites are extremely uncommon, particularly at the time of diagnosis. Barium studies of the gastrointestinal tract are not routinely indicated in premenopausal women unless there is occult blood in the rectum or symptoms to suggest intestinal obstruction. In postmenopausal women, in whom there is a higher likelihood that colorectal carcinoma is producing symptoms similar to those which can be observed with ovarian cancer, barium enema and proctoscopy may be useful in the differential diagnosis. Because of the association of ovarian cancer with breast cancer and because metastatic breast cancer can produce intra-abdominal carcinomatosis as well, mammography is often performed to exclude the presence of primary breast cancer. A Pap smear should be obtained, although ovarian cancer cells are unlikely to exfoliate through the uterus to the cervix, and their presence is associated with advanced stage.

The preoperative evaluation of patients with suspected ovarian carcinoma should include a determination of the serum CA-125 level. CA-125 has proven to be the most useful, currently available marker for epithelial ovarian cancer, primarily because of its utility in monitoring the results of therapy. CA-125 determinants are glycoproteins, with molecular weights from 220 to >1,000 kD. OC-125 is a murine monoclonal antibody that recognizes the antigenic determinants of CA-125. A double-determinant immunoradiometric assay has been developed against these CA-125 determinants. It has been demonstrated that <1% of normal nonpregnant women have serum CA-125 levels >35 U/mL. In contrast, 80% to 85% of patients with epithelial ovarian cancer have elevated serum levels (278). The serous histologic subset of epithelial ovarian cancer has the highest incidence of elevated CA-125 levels (>85%), whereas mucinous tumors are associated with a low incidence of abnormally elevated serum CA-125 levels.

In postmenopausal women with asymptomatic pelvic masses, an elevated serum CA-125 (>65 U/mL) had a sensitivity of 97% and a specificity of 78% for ovarian cancer (279). In contrast, in premenopausal women, there is a higher prevalence of nonmalignant conditions that can produce elevated serum CA-125 levels (e.g., pregnancy, endometriosis, uterine

fibroids, and pelvic inflammatory disease). In postmenopausal women with an adnexal mass, an elevated CA-125 level indicates the need for prompt surgical exploration, whereas in premenopausal women, additional noninvasive studies as described above are indicated.

SCREENING

No reliable procedures are currently available for the early detection of ovarian cancer. Available potential screening techniques have included pelvic examination (ovarian palpation), ultrasound examinations, CA-125 and other tumor markers, and combined modality approaches. Criteria have been established for useful screening tests (280). Besides being accurate, a screening test should be inexpensive, safe, simple, and tolerable. Successful screening should result in a decrease in site-specific morbidity and mortality from a disease. The usefulness of a test can be assessed by measures of sensitivity, specificity, and positive predictive value. The sensitivity refers to the probability of a positive test when the disease is present, whereas the specificity represents the probability that the test will be negative in the absence of the disease and is a measure of the false-positive rate. The positive predictive value represents the number of diagnostic procedures (i.e., laparotomies) performed in women who do not have the disease for each woman who has ovarian cancer. Mathematically: sensitivity = true positives/(true positives + false negatives); specificity = true negatives/(true negatives + false positives); positive predictive value = true positives/(true positives + false positives).

What constitutes an acceptable positive predictive value for ovarian cancer has not been agreed upon, although some investigators feel that 10% is the minimum level (281). The positive predictive value varies with the incidence of the disease and, consequently, will be markedly affected by the population screened (Fig. 25.28). Assuming 100% sensitivity, a test will have to have a specificity of 99.6% and 90.0% for screening all women over 45 years of age and *BRCA1* mutant gene carriers, respectively, to achieve a 10% positive predictive value.

FIGURE 25.28. The incidence of ovarian cancer in various population groups with different risks for ovarian cancer and the specificity required of screening tests to achieve a positive predictive value (PPV) of 10%. Source: Jacobs I. Genetic, biochemical, and multimodal approaches to screening for ovarian cancer. *Gynecol Oncol* 1994;522-527.

Pelvic Examinations

The detection of an asymptomatic pelvic mass on routine physical examination may identify an ovarian carcinoma before abdominal dissemination, but there are no data on the frequency with which ovarian cancer is detected in asymptomatic women on the basis of an annual pelvic examination. Furthermore, there is no evidence that ovarian cancer detected in asymptomatic women on the basis of an abnormal pelvic examination alters morbidity or mortality. Thus, although frequent pelvic examination continues to be a common recommendation for women past the age of 40 years, its benefit as a screening procedure for ovarian cancer has not been established.

Ultrasonography

Transabdominal ultrasonography is a screening procedure that is easy to perform, has a good patient acceptability, and is essentially free of complications. However, ultrasonography is not sufficiently specific for use as a routine screening procedure. In a prospective study of 5,479 self-referred asymptomatic women undergoing annual transabdominal ultrasonography at King's College Hospital in London (282), five patients with primary ovarian cancer (three with LMP tumors) were identified from a total of 15,977 scans, of which 338 (2.3%) were initially abnormal. Of note, 326 laparotomies were performed to diagnose these five cases. An additional four patients were found to have metastatic ovarian cancer. Although the apparent detection rate was 100%, the false-positive rate was 2.3%, and the specificity was 97.7%. The odds that an abnormal transabdominal ultrasound indicated the presence of primary ovarian cancer were 1 in 67.

Transvaginal sonography has been proposed as a more specific alternative to abdominal sonography as a screening test (283,284) because of increased resolution capable of detecting minimal morphologic changes in the ovary. Transvaginal ultrasonography also does not require any patient preparation. At the University of Kentucky, 3,220 asymptomatic postmenopausal women were so screened (283,284). Surgery was performed in 44 women with ovarian abnormalities, with the following findings: two stage I ovarian cancers (one granulosa cell and one epithelial carcinoma); one stage IIIB ovarian cancer; and 41 benign pathologies, including 21 serous cystadenomas. Thus, the sensitivity was 100%, specificity 98.7%, and positive predictive value 6.7% (i.e., 15 laparotomies were needed to find one ovarian cancer). These investigators have proposed that removal of cystadenomas may also decrease the risk of ovarian cancer since, based upon their histologic review, they feel that such tumors may be precursors of invasive epithelial cancers.

Transvaginal ultrasonography has been combined with Doppler flow studies (285,286) in an effort further to improve the accuracy of sonography and reduce the unacceptably high rate of false-positive results that currently have been reported with ultrasonography alone. Such a procedure detects intra-ovarian vascular changes, which principally are neovascularization and changes in impedance of blood flow that may help discriminate benign from malignant tumors. Initial results have demonstrated that morphologically normal ovaries show no neovascularization. Similarly, benign masses lacked neovascularization and had a pulsatility index markedly different from invasive ovarian cancers (even early-stage disease), which had clear evidence of neovascularization and marked differences in pulsatility index. Unfortunately, Doppler technology did not improve diagnostic accuracy when the transvaginal sonogram assessed both tumor volume and wall structure (morphology index [MI]) (286). Four hundred forty-two ovarian tumors were assigned a score of 0 to 10 based on increasing volume

and morphologic complexity. Doppler flow studies were performed on 371 of these tumors. Only one malignancy was found in 315 tumors with an MI less than 5, whereas there were 52 malignancies in 127 tumors with an MI ≥ 5 . The positive predictive value was 0.409. The addition of Doppler flow indices to MI did not improve the accuracy of predicting malignancy.

CA-125 Screening

Approximately one half of women with stage I and stage II ovarian cancer have serum CA-125 levels >65 U/mL (287). In a group of 915 Roman Catholic nuns, when the upper limit of normal for CA-125 was raised to 65 U/mL, only 0.5% of women past the age of 50 years had elevated tests (288). As previously noted, false-positive test results have been reported in a number of nonmalignant gynecologic conditions, such as peritonitis, pancreatitis, renal failure, and alcoholic hepatitis. Owing to the high false-positive rate relative to the low incidence of epithelial ovarian cancer, a single CA-125 assay is not useful in detecting early-stage disease. In a large study from Sweden, serum CA-125 levels were measured annually in 5,550 women over the age of 40 years (289). In women who had CA-125 levels >30 U/mL, surveillance was undertaken with sequential CA-125 levels every 3 months, and pelvic examinations and transabdominal ultrasounds were performed every 6 months. If the CA-125 doubled or was >95 U/mL at the time of screening, or if an adnexal mass was detected by either ultrasound or pelvic examination, the patients underwent a laparotomy. One hundred seventy-five women were found to have elevated CA-125 levels, and six ovarian cancers were detected clinically or sonographically (two stage IA, two stage IIB, and two stage III). Three women with normal CA-125 levels developed ovarian cancer. For women less than 50 years old, a CA-125 value >35 U/mL had a specificity of 97% compared to 99% for women more than 50 years of age. Specificity was increased to 99.8% for both groups if the serum CA-125 level was set at 95 U/mL.

It is hoped that sequential measurements of CA-125 levels over a period of time can lead to substantial improvement of screening programs. The risk of ovarian cancer algorithm (ROCA) calculates the risk of ovarian cancer for an individual comparing each individual serial CA-125 level to the pattern in known cases of ovarian cancer and controls. The result is presented as the individual's estimated risk of having ovarian cancer during the year following the test. Currently, ROCA is being evaluated in a large United Kingdom screening trial as well as in a small pilot study of 2,400 high-risk women in the United States. Preliminary results of the U.S. pilot trial, in which CA-125 was measured every 3 months, suggested that among 2,343 women enrolled between 2001 and 2006, nine cancers were detected. Three were prevalent (found at first screen, one early and two late stage), three had not yet been found by screening and were incidentally found at the time of prophylactic salpingo-oophorectomy, and three were found as a result of screening, two early and one late stage (290). Full publication is awaited, but the early results do not suggest that even intensive CA-125 screening in high-risk women will catch all ovarian cancers at an early stage.

Multimodal Screening

The NCI-sponsored Prostate, Lung, Colorectal, and Ovarian (PLCO) Cancer Screening Trial enrolled over 74,000 women aged 55 to 74 from 1993 through 2000 at ten screening sites throughout the United States. Women were randomly assigned to either the intervention arm, which included baseline measurements of CA-125 levels and transvaginal ultrasonography

followed by annual CA-125 readings for 5 years and transvaginal ultrasounds (TVUs) for 3 years, or an observation arm. Baseline screening in the 28,816 women randomized to screening who received at least one test detected 29 neoplasms (26 ovarian, 2 fallopian, and 1 primary peritoneal) (291). Nine were of low malignant potential. Only two of the invasive cancers were stage I; one of these was a granulosa cell tumor. Five hundred seventy surgical procedures, including 325 laparotomies, were performed. The authors calculated the positive predictive value for invasive cancer of an abnormal CA-125 as 3.7%, of an abnormal transvaginal ultrasound as 1.0%, and of having both tests abnormal as 23.5%. However, if only subjects in whom both tests were abnormal had been evaluated, 12 of the 20 invasive cancers would have been missed. Participants will be followed for a minimum of 13 years. A large English study examined a single screening with the sequential continuation of serum CA-125 and ultrasonography in 22,000 volunteers without a family history of ovarian cancer (292). If the serum CA-125 level was ≥ 30 U/mL in the initial determination, women underwent abdominal ultrasonography. If that was abnormal they underwent laparotomy. Forty-one women underwent surgery, and 11 had ovarian cancer: two stage IA, one stage IB, one stage IIA, and seven stage III or IV. Eight of the 21,959 women who had a negative screen developed ovarian cancer. In this study, the positive predictive value was 26.8% for ovarian cancer of all stages (these numbers do not include two women with fallopian tube carcinoma and one with abdominal carcinomatosis of uncertain origin). Seven women who did not have an elevated CA-125 (and one with a CA-125 of 80 who declined abdominal ultrasound) presented with ovarian cancer within the next 22 months. Of these, five had a stage I tumor and three had a stage III tumor.

Based on these results, the same group of investigators performed a pilot randomized trial of screening in 22,000 postmenopausal women aged 45 years or older (293). Women randomized to screening underwent three annual screens that involved measurement of serum CA-125 levels, pelvic ultrasonography if the CA-125 was elevated, and referral to a gynecologist if there was an increased ovarian volume on sonography. In the screened group, there were 468 women with elevated CA-125 levels; 29 were referred for a gynecologic opinion, and cancer was detected in 6 of these women with 23 false-positive screening results. The positive predictive value was 21%. During the 7-year follow-up of this study, an additional 10 women were identified with ovarian cancer in the screened group and 20 in the control group. The median survival for women with cancer in the screened group was 73 months and in the control group was 42 months ($p = 0.0112$). However, the number of deaths from cancer did not significantly differ between the two groups. These results demonstrate that a multimodality approach to screening is feasible. Based on these results, a large-scale screening trial has begun, termed the United Kingdom Collaborative Trial of Ovarian Cancer Screening (UKCTOCS). This is a randomized trial with a control group undergoing no screening, a multimodal group undergoing annual screening with serum CA-125 as the primary test and ultrasound as a secondary test, and an ultrasound-only group undergoing annual screening with an ultrasound as the primary test and repeat ultrasound in 6 to 8 weeks as a secondary test. An estimated 200,000 women are expected to enroll up until 2010, and ovarian cancer mortality will be assessed 7 years later.

These preliminary studies using serum CA-125 levels, pelvic examinations, and ultrasonography have demonstrated that ovarian cancer can be detected in asymptomatic women. However, these procedures are associated with a significant false-positive rate such that an unacceptably large number of negative laparotomies would result if each "positive" screening test resulted in surgical exploration aimed at diagnosing early ovarian cancer. Since a surgical procedure is required to

diagnose ovarian cancer, there is a defined morbidity and mortality associated with screening. When the positive predictive value is below 10%, more harm (complications of unnecessary laparotomy) than good (diagnosing early-stage ovarian cancer) may come to a screened population. Furthermore, in a review of uncontrolled trials of ovarian cancer screening (294) in 36,208 women, 29 cases of ovarian cancer were identified, but only 12 (41%) were stage I. Survival is unlikely to be significantly affected by an earlier diagnosis of advanced-stage disease. Until the completion of the large randomized trials described above, the recommendations of the NIH Consensus Conference against routine screening of the general population remain in effect (62).

Even in women with a positive family history of ovarian cancer, there is no evidence that screening can affect mortality from this disease. In 1,502 asymptomatic women who were screened by transvaginal ultrasonography and who had at least one close relative with ovarian cancer, seven ovarian cancers (three of LMP) were found (295). Screening is also not established to be of value in high-risk women such as those who have two first-degree relatives with ovarian cancer or who are carriers of the *BRCA1* or *BRCA2* gene. The U.K. Familial Ovarian Cancer Screening Study (UKFOCSS) is currently accruing. Despite the lack of evidence for benefit of screening high-risk women, it seems prudent to follow them with pelvic and ultrasound examinations with serum CA-125 determinations on a regular basis until/unless they elect a prophylactic oophorectomy.

SURGICAL STAGING

Our understanding of the early natural history and patterns of spread of epithelial ovarian cancer forms the basis for a rational system for staging the disease and for the surgical management of apparent early ovarian cancer. The widely used FIGO staging system, revised in 1985, is presented in Table 25.7 (296).

The stage, defined as the extent of disease at the time of diagnosis, can be determined only following exploratory laparotomy and thorough evaluation of all areas at risk. Operations on women with a pelvic or adnexal mass that may represent ovarian cancer should generally be carried out through a vertical abdominal incision to allow access to the upper abdomen, which is difficult to visualize through a low transverse incision. On entering the abdomen, aspiration of ascites or peritoneal lavage should be performed to obtain specimens for cytologic examination. Separate specimens should be obtained from the pelvis, right and left paracolic gutters, and the undersurfaces of the right and left hemidiaphragms. An encapsulated adnexal mass should be removed intact, if possible, since rupture and spillage of malignant cells within the peritoneal cavity will increase the patient's stage and may adversely affect her prognosis. Adhesions should be noted and biopsied since they may represent occult areas of microscopic disease. If frozen section indicates the presence of ovarian cancer, a complete abdominal exploration should be carried out, including evaluation of all intestinal surfaces. Any suspicious areas should be biopsied. Omentectomy and random peritoneal biopsies should be performed. Aortic lymph node sampling (Fig. 25.29) should also be performed. Several reports (268,297) have demonstrated that the pelvic lymph nodes are involved by ovarian cancer at the same frequency as are para-aortic nodes and suggest the need for routine pelvic node sampling as well. The technique for surgical staging of apparent early ovarian cancer is summarized in Table 25.8.

Standardized protocols are used to record the specific details of operative and pathologic findings that have prognostic and therapeutic bearing on treatment and natural history. When a rigorous staging laparotomy is performed, a substantial number of patients initially felt to have localized disease will be up-staged. Young et al. (298) reported on ovarian cancer patients believed to have stage I or II disease following initial surgery who underwent repeat staging procedures. Almost a third

TABLE 25.7

CARCINOMA OF THE OVARY: FIGO NOMENCLATURE (RIO DE JANEIRO, 1988)

Stage I	Growth limited to the ovaries
IA	Growth limited to one ovary; no ascites present containing malignant cells. No tumor on the external surface; capsule intact
IB	Growth limited to both ovaries; no ascites present containing malignant cells. No tumor on the external surfaces; capsules intact
IC ^a	Tumor either stage IA or IB, but with tumor on surface of one or both ovaries, or with capsule rupture, or with ascites present containing malignant cells, or with positive peritoneal washings
Stage II	Growth involving one or both ovaries with pelvic extension
IIA	Extension and/or metastases to the uterus and/or tubes
IIB	Extension to other pelvic tissues
IIC ^a	Tumor either stage IIA or IIB, but with tumor on surface of one or both ovaries; or with capsule(s) rupture; or with ascites present containing malignant cells or with positive peritoneal washings
Stage III	Tumor involving one or both ovaries with histologically confirmed peritoneal implants outside the pelvis and/or positive retroperitoneal or inguinal nodes. Superficial liver metastases equals stage III. Tumor is limited to the true pelvis, but with histologically proven malignant extension to small bowel or omentum
IIIA	Tumor grossly limited to the true pelvis, with negative nodes, but with histologically confirmed microscopic seeding of abdominal peritoneal surfaces, or histologically proven extension to small bowel or mesentery
IIIB	Tumor of one or both ovaries with histologically confirmed implants, peritoneal metastasis of abdominal peritoneal surfaces, not exceeding 2 cm in diameter; nodes are negative
IIIC	Peritoneal metastasis beyond the pelvis >2 cm in diameter and/or positive retroperitoneal or inguinal nodes
Stage IV	Growth involving one or both ovaries with distant metastases. If pleural effusion is present, there must be positive cytology to allot a case to stage IV. Parenchymal liver metastasis equals stage IV

^aIn order to evaluate the impact on prognosis of the different criteria for allotting cases to stage IC or IIC, it would be of value to know if rupture of the capsule was spontaneous or caused by the surgeon, and if the source of malignant cells detected was peritoneal washings or ascites.

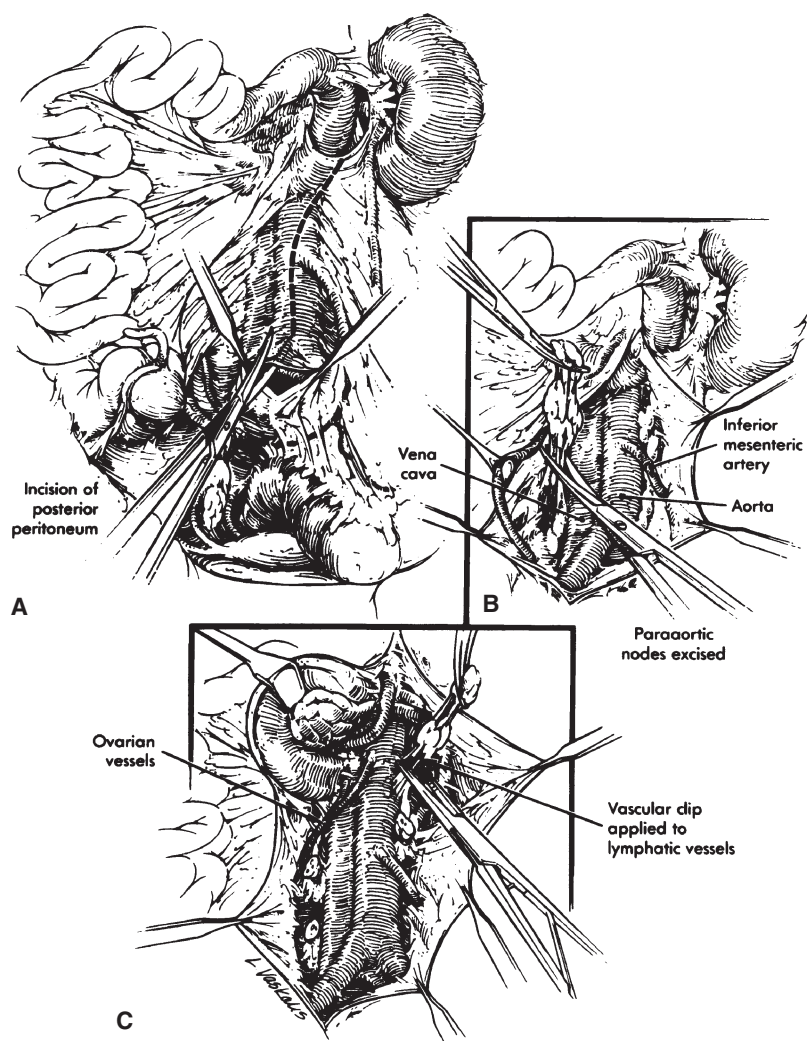

FIGURE 25.29. Para-aortic node dissection for staging of apparent early ovarian cancer.

(31%) of these women were upstaged following the second procedure (Table 25.9), and 77% of the upstaged patients actually had stage III disease. Before referral, only 25% of patients had an initial surgical incision that was adequate for proper staging. Similarly, McGowan et al. (299) examined the completeness of surgical staging in 291 women with ovarian cancer and concluded that 46% had been inadequately evaluated. When staging was performed by gynecologic oncologists, 97% of patients were properly staged as compared to 52%

and 35% of cases operated on by obstetricians/gynecologists and general surgeons, respectively. These observations underscore the critical importance of having an experienced physician involved in the surgical staging of all patients with ovarian cancer.

The importance of meticulous staging cannot be overemphasized, since postoperative therapy is based upon anatomic stage,

as well as other factors, discussed in the section on therapy below. In the past, inadequate surgery often led to understaging and subsequent inadequate postoperative therapy in a significant proportion of ovarian cancer patients. For example, patients were frequently treated with pelvic irradiation at a time when they already had distant, undetected metastases outside the radiation ports. A 1997 report from the NCI's SEER database indicated that only about 10% of American women with apparent early-stage ovarian cancer had received appropriate surgical staging and recommended postoperative therapy (273).

Although ovarian cancer is surgically staged primarily on the basis of the anatomic sites of disease documented at laparotomy, stage IV disease may be documented by cytologically positive pleural fluid or fine-needle aspiration of supraclavicular adenopathy. The majority of patients will have advanced-stage disease (FIGO stages III to IV) after careful staging. The stage distribution is depicted in Table 25.1.

Staging of Fallopian Tube Carcinoma

Because fallopian tube carcinoma has the propensity to spread intra-abdominally, the most widely accepted staging system used in this malignancy is a modification of the FIGO surgical staging of ovarian carcinoma. In 1992, FIGO formally established a staging classification for fallopian tube cancer.

Scully et al. (189,195) have pointed out deficiencies in the current FIGO staging schema for fallopian tube carcinoma. The definition of stage 0 is inappropriate since *in situ* carcinoma is described as a tumor limited to the tubal mucosa—a structure that is composed of lamina propria as well as epithelium. Similarly, stage I tumors are described as tumors that extend into the submucosa—a structure that does not exist in the fallopian tube. Based on careful examination of the histology coupled with outcome in their large series of patients, Alvarado-Cabrero et al. (189) have proposed a modification to the FIGO staging (Table 25.10). This modification corrects the nomenclature and emphasizes the prognostic impact of invasion into the muscular wall.

Prognostic Factors

Surgery accurately stages a patient and allows the evaluation of a series of clinicopathologic variables that are often used to select postoperative therapy. These prognostic factors are discussed below.

Tumor Stage

The 5-year survival of patients with epithelial ovarian cancer is directly correlated with the tumor stage (Fig. 25.30). However, there have been major differences in survival reported for

TABLE 25.10

MODIFIED FIGO STAGING FOR FALLOPIAN TUBE CARCINOMA^a

Stage 0:	Carcinoma <i>in situ</i> (limited to tubal epithelium ^b)
Stage I:	Growth limited to tube
Stage IA:	Growth limited to one tube without extension through or onto serosa, ascites containing malignant cells, or positive peritoneal washings
Stage IA-0 ^c :	Growth limited to one tube with no extension into lamina propria ^b
Stage IA-1 ^c :	Growth limited to one tube with extension into lamina propria ^a but no extension into muscularis
Stage IA-2 ^c :	Growth limited to one tube with extension into muscularis
Stage IB:	Growth limited to both tubes without extension through or onto serosa, ascites containing malignant cells, or positive peritoneal washings
Stage IB-0 ^c :	Growth limited to both tubes with no extension into lamina propria ^b
Stage IB-1 ^c :	Growth limited to both tubes with extension into lamina propria, ^b but no extension into muscularis
Stage IB-2 ^c :	Growth limited to both tubes with extension into muscularis
Stage IC:	Tumor either stage IA or IB but with extension through or onto tubal serosa or with ascites containing malignant cells or with positive peritoneal washings
Stage I(F):	Tumor limited to fimbriated end of tube(s) without invasion of tubal wall
Stage II:	Tumor involving one or both fallopian tubes with pelvic extension
Stage IIA:	Extension and/or metastasis to uterus and/or ovaries
Stage IIB:	Extension to other pelvic tissues
Stage IIC:	Tumor either stage IIA or IIB with ascites containing malignant cells or with positive peritoneal washings
Stage III:	Tumor involving one or both fallopian tubes with peritoneal implants outside pelvis, including superficial liver metastasis, and/or positive retroperitoneal or inguinal nodes. Tumor limited to pelvis except for histologically proven extension to small bowel or omentum
Stage IIIA:	Tumor grossly limited to pelvis with negative nodes but with histologically confirmed microscopic seeding of abdominal peritoneal surfaces
Stage IIIB:	Tumor involving one or both fallopian tubes with grossly visible, histologically confirmed implants of abdominal peritoneal surfaces, none >2 cm in diameter. Lymph nodes are negative
Stage IIIC:	Abdominal implants >2 cm in diameter and/or positive retroperitoneal or inguinal nodes
Stage IV:	Growth involving one or both fallopian tubes with distant metastases including parenchymal liver metastases. If pleural effusion is present, fluid must be positive cytologically for malignant cells

^aAs suggested by Alvarado-Cabrero et al (189).

^bModification in terminology.

^cModifications to accommodate subsets of tumors that otherwise cannot be assigned a stage or to distinguish among subsets that may differ in their associated prognosis.

FIGURE 25.30. Carcinoma of the ovary; patients treated in 1996 to 1998. Survival of FIGO stage. *Source:* Heintz AP, Odcino F, Maisonneuve P, et al. Carcinoma of the ovary. *Int J Gynecol Obstet* 2003;83:135–166.

patients with the same FIGO stage, reflecting the inadequacy of early staging procedures that led to the frequent understaging of patients. Whereas early studies reported 5-year survivals for patients with stage I disease of approximately 60% to 80%, current studies utilizing a comprehensive staging laparotomy demonstrate that some subsets of patients with stage I disease have a 90% 5-year survival (273). Similarly, initial studies of patients with stage II disease reported the range of 5-year survival from 0% to 40%. However, stage II disease frequently is upstaged to stage III disease, particularly when patients present with large-volume disease in the pelvis. The small number of patients who are found to have stage II disease following completion of a comprehensive laparotomy have a 5-year survival rate of approximately 80%. Patients with stage III disease have 5-year survival of approximately 15% to 20%, whereas patients with stage IV disease have less than a 5% 5-year survival (300).

Volume of Residual Disease

The volume of residual disease following cytoreductive surgery is directly correlated with survival (301–308). Patients who have been optimally cytoreduced have a 22-month improvement in median survival compared to those patients undergoing less than optimum resection. In these retrospective analyses of the importance of residual volume upon survival, the size of the largest residual mass, and not the total number of lesions, has been believed to be the primary factor correlating with prognosis. Yet, the number of residual masses may be an important prognostic factor as well (309,310). Patients who have only a single residual mass following cytoreductive surgery have a significantly greater chance of achieving a surgically confirmed complete remission compared with those patients with multiple small nodules even though each nodule is less than 2 cm in size. Randomized trial data confirming the importance of debulking surgery in the survival of patients with advanced disease, however, is lacking, and such trials are not likely ever to be performed. It is possible that there are underlying biologic features that distinguish those tumors for which optimal cytoreduction is feasible from those for which it is not.

Histologic Subtype and Grade

In general, the histologic type has less prognostic significance than the other clinical factors, such as stage, volume of disease, and histologic grade. But this is confounded by a high correlation between histologic type, stage, and grade. In some

series, patients with mucinous adenocarcinomas have an overall better survival in comparison to endometrioid or serous adenocarcinomas. These findings reflect the rarity with which high-grade mucinous adenocarcinoma of the ovary is diagnosed. Few poorly differentiated tumors of advanced stage can clearly be identified as mucinous adenocarcinomas; patients with those tumors so identified have a 5-year survival rate near 0%. Similarly, endometrioid carcinoma also has been suggested to have a better prognosis than serous adenocarcinoma, as well as presenting with a lower histologic grade and clinical stage. Again, poorly differentiated endometrioid carcinomas cannot be differentiated with ease from poorly differentiated serous tumors and are generally classified as serous. Well-differentiated endometrioid carcinomas are, therefore, proportionally more common, which may account for the overall better prognosis for endometrioid than for serous tumors. Some analyses have suggested that ovarian clear cell adenocarcinoma may be more aggressive than the other common epithelial malignancies on a stage-for-stage basis (311). However, as discussed below, not all data support this, and it is possible that clear cell and mucinous tumors are less sensitive to chemotherapy but not faster growing.

The histologic grade of the tumor is a particularly important prognostic factor in patients with early-stage disease. As will be discussed, stage I patients with well- or moderately well-differentiated tumors have a greater than 90% 5-year survival when treated with surgery alone (312). In contrast, patients with stage I disease with poorly differentiated tumors have a significantly worse survival, and postoperative therapy is indicated. In advanced-stage patients treated with cisplatin-based chemotherapy, most studies have failed to demonstrate a significant correlation between histologic grade and survival (301). This may reflect variable degrees of intraobservational and interobservational variation in grading of ovarian tumors (313,314). In addition, different grading systems have been used at different institutions. It should also be recognized that grade 1 advanced-stage tumors are relatively uncommon. Gershenson et al. reported on a group of low-grade stage II-IV serous ovarian carcinomas, noting that they occurred at a younger age (median 43 years) and were associated with prolonged survival, consistent with the hypothesis that they are in a continuum with borderline serous tumors (95).

Surgical Prognostic Factors

Controversy remains about the prognostic importance of other surgical observations (315–317). Tumor size, bilaterality, and ascites without cytologically positive cells are not considered to be of prognostic significance in patients with early-stage disease. However, tumor spillage, capsular penetration, and cytologically malignant ascites (FIGO stage IC) are generally believed to be associated with a worse prognosis.

Prognostic Value of CA-125 Levels

The prognostic significance of preoperative and postoperative CA-125 levels has been established (318). Serum levels of CA-125 generally reflect volume of disease. Whereas prechemotherapy CA-125 levels have been shown on univariate analysis to be of prognostic significance, on multivariate analysis, they are usually not an independent prognostic factor owing to their association with volume of disease (318). In addition, high CA-125 levels may predict for unresectability and an inferior survival. Postoperative CA-125 levels appear to have greater prognostic significance. In a multivariate analysis, postoperative CA-125 levels were of independent prognostic significance in patients with or without residual disease (319).

Controversy also remains regarding the prognostic accuracy of the rate of decline of serum CA-125 levels and the absolute levels after one to three cycles of chemotherapy.

In one study, a level greater than 100 U/mL after the third cycle of treatment was associated with a median survival of 7 months compared to a 50% 5-year survival for patients with a CA-125 level of 10 U/mL or less (320). In another study, there was a marked difference in prognosis for patients who had a greater than sevenfold decrease in CA-125 levels 1 month after chemotherapy compared to those with a lesser reduction (318). In a multicenter study from England, the predictive value of CA-125 levels after the third cycle of chemotherapy was confirmed (320). However, the false-positive rate for accurately predicting progression was 19%. The investigators in this study concluded that, although CA-125 levels are useful for predicting group outcomes, they do not have the predictive power to guide treatment decisions in individual patients. Consequently, although CA-125 levels are frequently drawn before each course of therapy, if the patient shows clinical improvement, treatment should be continued despite the level of CA-125. If there is no change clinically, and if the CA-125 level markedly increases, changing treatment is a consideration. However, if there is no clinical change but the CA-125 is dropping or is not changing, treatment with the same regimen should continue.

An elevated CA-125 has also been increasingly used as an indicator of progression following completion of chemotherapy. Clinical trial groups have established criteria for progression of disease based on elevations of CA-125 levels or the observance of physical or radiographic evidence of disease. The use of serum CA-125 levels to initiate second-line therapy will be discussed subsequently.

TREATMENT CONSIDERATIONS

The selection of therapy for patients with epithelial ovarian tumors is based upon anatomic stage and the previously described clinicopathologic features. Therapeutic options may include cytoreductive surgery, chemotherapy, radiation therapy, or a combination of these modalities. However, most patients with advanced ovarian cancer are not cured with these treatments. Clinical trials are evaluating new treatment approaches in virtually all stages of ovarian cancer in an effort to define more effective treatments, and patients should be encouraged to participate in these studies.

Early-Stage Ovarian Cancer

Prognosis in Early-Stage Disease

Survival by FIGO stage in surgically staged patients is shown in Figure 25.30. About one third of patients present with stage I or II epithelial ovarian cancer (Table 25.1). As noted above, both the incidence of and survival rates for early-stage disease vary, particularly in older publications, depending on (a) whether or not patients have been completely staged, and (b) whether borderline tumors (tumors of low malignant potential), which were not recognized as a separate entity by FIGO until 1971 and by the World Health Organization until 1973) are reliably excluded. From 4% to 25% of patients with apparent stage I ovarian cancer will have nodal involvement when lymph nodes are pathologically examined; the risk for lymph node involvement correlates with histology (higher risk with serous and clear cell types) and grade (higher risk with higher grade). The issue regarding borderline tumors is illustrated by a well-known early GOG trial that randomized women with early-stage disease to observation versus melphalan from 1976 to 1986. Although the design of the trial was to exclude borderline tumors, one third of the patients were declared to have tumors of borderline malignancy after central pathologic review (312).

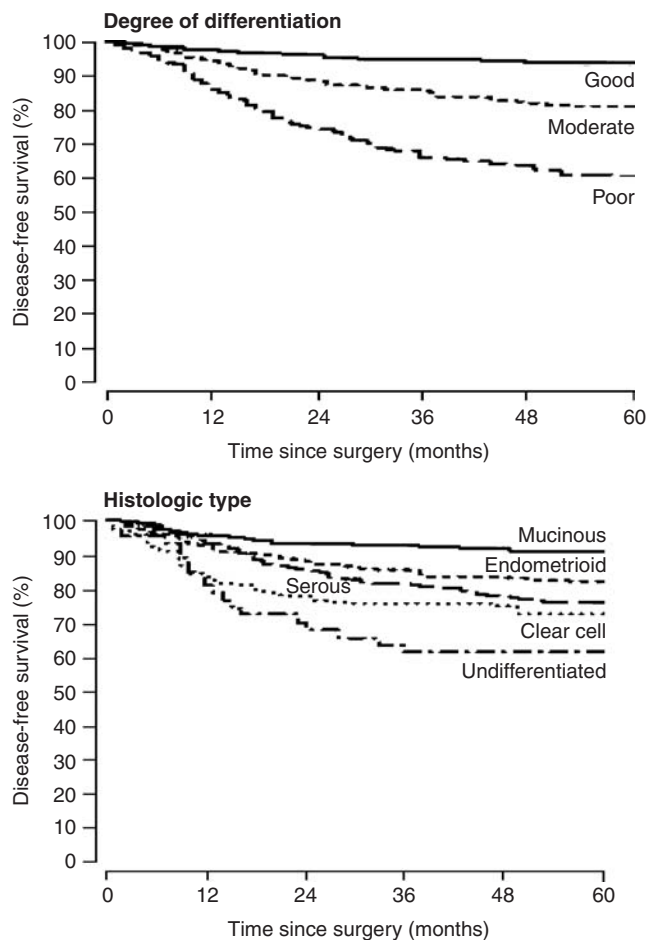

FIGURE 25.31. Actuarial disease-free survival according to prognostic variable. Source: Vergote I, De Brabanter J, Fyles A, et al. Prognostic importance of degree of differentiation and cyst rupture in stage I invasive epithelial ovarian carcinoma. *Lancet* 2001;357:176–182.

Vergote et al. performed a large retrospective study using an international database of over 1,500 women with stage I invasive epithelial ovarian cancer to identify the most important prognostic variables in patients with stage I disease. Routine para-aortic and pelvic lymphadenectomy were not performed, but palpable nodes were sampled. The overall actuarial 5-year survival was 83% (disease-free survival 80%). As seen in Figure 25.31, women with mucinous tumors did best with a 5-year disease-free survival of 91% versus 82% for endometrioid, 76% for serous, 73% for clear cell, and 62% for undifferentiated histologies (321). However, histologic type was not independently prognostic. Multivariate analysis identified degree of differentiation as the most powerful prognostic indicator of disease-free survival: moderately versus well differentiated (hazard ratio [HR] 3.13), poorly versus well differentiated (HR 8.89). This translates into a 5-year disease-free survival of 94% for grade 1 tumors, 81% for grade 2 tumors, and 61% for grade 3 tumors. The other significant factors were rupture before surgery (HR 2.65); rupture during surgery (HR 1.65); FIGO stage IB versus IA (HR 1.70); and age (HR 1.02 per year). None of the following was of prognostic value when the effects of these additional factors were accounted for: histologic type, dense adhesions, extracapsular growth, ascites, FIGO stage (1988), and site of the tumor. It should be pointed out that ascites was defined as in the FIGO 1973 classification (i.e., ascites in the opinion of the surgeon was pathologic or clearly exceeded normal amounts, or malignant cells were detected on peritoneal cytology).

Although the literature has emphasized the importance of thorough intraoperative exploration (staging) in patients with disease apparently localized to the ovaries, scant recognition has been made of the semantic difficulty presented by the concept of “extension to other pelvic (equals stage II disease) or abdominal (equals stage III disease) organs.” No problem exists when the surgeon encounters discrete implants separate from the primary tumor or when solid tumor is found growing into adjacent structures. However, more often, apparently benign adherence of a cyst to adjacent structures, in the absence of metastatic implants or obvious direct tumor extension, is found. There is a considerable body of evidence suggesting that such “benign” adherence, when it is dense, is associated with a relapse risk equivalent to stage II, and that these patients should be considered not as having stage I but rather stage II disease (322). Adherence is considered to be dense when so described by the surgeon, when sharp dissection was required to mobilize the tumor, when a raw area was left in the place of adherence, or when cyst rupture resulted from dissecting the adhesions free. Some clinical trials have advanced the stage of nonmetastatic but densely adherent tumors to stage II (171). However, as noted, the recent large retrospective international study failed to identify dense adhesions as an independent prognostic factor and adhesions are not used by the GOG to “upgrade” apparent stage I patients without histologic confirmation of disease.

The importance of grade is not merely that it predicts occult disease (more patients with presumed stage I grade 3 disease have lymph node involvement than do patients with presumed stage I grade 2 disease). Grade remains an important prognostic factor in surgically staged patients. In surgically staged patients from the FIGO database the overall 5-year survivals are similar to those described above, being 87%, 82%, and 69% for stage I grade 1, 2, and 3 tumors, respectively. For patients with stage II disease, the corresponding survivals were 84%, 67%, and 63% (323). As noted above, histologic grade and type have both been associated with a variable degree of interobserver consistency. One publication from 1984 reported that interobserver agreement was 66% in assigning grade and 66% in assigning histologic type (324).

A recent report analyzing data from 600 surgically staged (including lymphadenectomy) FIGO stage I epithelial ovarian cancer patients proposed that preoperative serum CA-125 was prognostic. The series included patients who did and did not receive chemotherapy. Overall 5-year survival was 88%. The only independent predictors for overall survival were preoperative serum CA-125 ≥ 30 U/mL (HR 2.7) and age at diagnosis >70 years (HR 2.6). Clear cell and mucinous tumors had somewhat lower preoperative CA-125 levels (325).

Future studies will focus on molecular prognostic markers in early-stage disease, to better determine which tumors have such a good prognosis that no adjuvant therapy is needed, and which will be sensitive to chemotherapy.

Surgical Therapy for Early-Stage Ovarian Carcinoma

The optimal surgical procedure for all epithelial ovarian carcinomas is removal of the uterus along with both fallopian tubes and ovaries. Complete surgical staging, as described above, is also indicated in most circumstances. In the younger patient who wishes to retain her childbearing potential and who appears to have a curable cancer (i.e., a localized tumor with favorable histology), it may be appropriate to preserve the uterus and other ovary if a wedge biopsy of this ovary confirms the absence of disease. However, there is a risk that women undergoing such a procedure may have a higher recurrence rate, and completion of the more standard operation is indicated following childbearing.

Postoperative Observation for Stage I Ovarian Carcinoma

The data sets discussed above include patients treated with a variety of adjuvant therapies. Three prospective observational studies have been published in which patients did not receive further therapy after surgery and borderline tumors were excluded.

Investigators at the Royal Marsden Hospital (326) prospectively observed all patients with stage I disease (not necessarily adequately surgically staged) referred to their institution from 1980 to 1994 following surgery only. Thirty percent of the deaths in the 10 years following diagnosis were from causes other than ovarian cancer. Sixty-one (31%) of 194 patients relapsed at a median of 17 months (range, 6 months to 15.7 years). At a median observation time of 54 months, the 5-year disease-free survival rates were 87%, 65%, and 62% for stage IA, IB, and IC disease and 90%, 85%, and 45% for grade 1, grade 2, and grade 3 tumors. Clear cell histology was not predictive of relapse.

The National Cancer Institute of Canada (NCIC) recruited 82 patients (68 evaluable) with FIGO stage I ovarian carcinoma. Patients were surgically staged; lymph node biopsies were recommended but not required. With a median follow-up time of 4 years, only 3 patients with disease progression were identified (2 had clear cell tumors of a total of 16 with clear cell tumors on study) and 1 patient died of disease. Very few of the patients in this series had grade 3 ($n = 3$) disease (327).

Finally, a multicenter Dutch trial followed 67 evaluable patients with early-stage well-differentiated ovarian cancer for a median of 50 months. Only 24 patients had complete surgical staging. Five-year disease-free survival for patients with complete surgical staging was 100%; for the remaining patients it was 88% (four recurrences total) (328).

Adjuvant Therapy of Early-Stage Disease

Although the benefits of chemotherapy in advanced-stage ovarian cancer have been well demonstrated, they have been much harder to show in early-stage disease. The number of patients available is smaller and the prognosis better than with more advanced-stage disease, making adequately powered randomized trials difficult to complete. Much of the published literature is old. The thoroughness of staging in the trials has been variable and has raised questions about whether the benefit of chemotherapy is seen only in less well-staged patients, presumably because their risk of recurrence is higher due to a percentage of occult stage IIIC disease. In addition, early-stage epithelial ovarian cancer is composed of a rather different mix of grades and histologies than advanced-stage disease, in particular a much larger percentage of low-grade, mucinous, and clear cell carcinomas and a smaller percentage of serous carcinomas. Nearly 90% of tumors that extend to the pelvic peritoneum, omentum, or beyond are grades 2 and 3. In contrast, 72% of tumors stages I to IIA are grade 1 (329). The FIGO data from 1996 (Table 25.11) report that serous histology accounts for 67% of stage IIIC carcinomas versus only 23% of stage IA carcinomas; mucinous histology accounts for 38% of stage IA carcinomas versus 7% of stage IIIC carcinomas (309). This is of concern because advanced-stage mucinous (330) and clear cell (331) carcinomas of the ovary appear to have a poorer response rate to front-line chemotherapy than serous carcinomas. However, histology has not yet been demonstrated to be of importance in predicting benefit from chemotherapy in early-stage disease.

External Beam Radiotherapy. Early randomized trials of pelvic radiotherapy were small and included patients without surgical staging. However, they suggested that pelvic radiotherapy compared to observation, while reducing the rate of

TABLE 25.11

HISTOLOGY AND STAGE IN OVARIAN CANCER

	IA (n = 550) (%)	IIIC (n = 1,793) (%)
Serous	23	67
Mucinous	38	7
Endometrioid	19	14
Clear cell	10	4

relapse in the pelvis, had no impact on overall recurrence rate or survival because relapses occurred throughout the peritoneal cavity (332). Interest turned to abdominopelvic radiotherapy (whole abdominal radiotherapy [WAR]) after Dembo from the Princess Margaret Hospital in Canada published results of a study randomizing 147 patients with incompletely staged IB, II, or III optimally debulked ovarian cancer to pelvic radiotherapy plus WAR to pelvic radiotherapy followed by chlorambucil. Among those with less than 2 cm or no residual disease, there was a statistically significant benefit in 10-year overall survivors favoring the WAR group (78% vs. 51% 5-year survival) (333). However, two subsequent small, randomized cooperative group trials of the NCIC and the Danish Ovarian Cancer Group (DACOVA) failed to show superiority of combining pelvic radiotherapy with WAR versus combining pelvic radiotherapy with cyclophosphamide or melphalan (334–336). In addition, investigators at the M. D. Anderson Cancer Center randomized 156 patients with FIGO stage I, II, or III disease to melphalan alone versus abdominopelvic radiotherapy, and found similar relapse-free survival for either treatment in women with stage I or stage II disease (337).

The late effects of WAR include asymptomatic basal pneumonitis or fibrosis detectable in 15% to 20% of patients on radiographic films. This results from the necessity of including 1 to 2 cm of lung field in the radiation portal in order to adequately encompass the leaves of the diaphragms. With upper abdominal doses of 2250 to 2500 cGY in 20 to 22 fractions, about 50% of patients will develop transient elevations of alkaline phosphatase from hepatic irradiation a few months after radiation therapy. Fewer than 1% of patients develop jaundice or ascites (338).

Late gastrointestinal toxicity, particularly obstruction requiring surgical correction, is the complication concerning most investigators. The frequency and severity are dependent on the total dose of radiation, the dose per fraction, and the extent and number of previous operations. There appears to be an increased risk of late complications if lymph node sampling was performed as part of the initial operation. Generally, about 10% to 15% of patients may report some diarrhea or persistent bloating related to particular dietary intolerance, but frank malabsorption is extremely rare. In four studies with almost 1,100 patients in total, 5.6% (range, 1.4% to 14%) of the patients required bowel surgery for late treatment-associated complications of radiation. In these collected series, less than 0.5% (four patients) died as a result of radiation-induced bowel damage.

No large trial has directly compared WAR to platinum-based chemotherapy in women with early-stage ovarian carcinoma; one very small trial showed a trend for superiority of

chemotherapy (339). However, given the technical expertise required for and potential long-term bowel toxicity of this type of therapy, the difficulty in combining WAR with chemotherapy, and the fact that a trial in endometrial cancer suggested superiority of chemotherapy over WAR (340), it is not likely that this modality will be studied further in this situation. Given that pelvic radiotherapy can decrease local relapse, it is possible that the addition of pelvic radiotherapy to chemotherapy would improve disease control in some patients, such as those with bulky stage II disease. However, no studies have addressed this issue.

Intraperitoneal Radiocolloid Therapy. Since transcoelomic spread is the main route of dissemination of ovarian cancer, the intraperitoneal (IP) instillation of radiocolloids, which deliver high doses of radiation to the peritoneal surfaces, would seem intuitively attractive. Most trials have used colloids labeled with a radioactive isotope of phosphorus, ^{32}P , which is a pure beta emitter (short penetration electrons). Difficulties include the fact that experimental data show that the radiation dose distribution of the peritoneal surface is quite variable and unpredictable. Penetration of useful doses of radiation does not occur beyond 2 to 3 mm depth, and dose to lymph nodes, retroperitoneum, or nodules larger than 2 mm thick is negligible. When intraperitoneal ^{32}P is given together with pelvic radiotherapy, the risk of bowel toxicity has been reported to be unacceptable.

There have been no randomized trials of ^{32}P against a no-treatment control arm in early-stage ovarian cancer, although a randomized comparison of ^{32}P versus observation did not show any decrease in the risk of relapse or improve survival in patients with more advanced-stage disease who had a surgically confirmed complete remission (341). Nonetheless, a number of early trials randomized women between chemotherapy and intraperitoneal ^{32}P .

Chemotherapy. An early GOG trial (312) randomized 141 women with high-risk early-stage disease (stage IA or IB grade 3, stage IC any grade, or stage II optimally debulked) to ^{32}P versus oral melphalan. With a median follow-up of over 6 years, the 5-year disease-free survival in both groups was 80%; 5-year overall survival was 81% with melphalan and 78% with ^{32}P . Four patients receiving ^{32}P underwent surgery for bowel obstruction; no tumor was identified. Six of the patients assigned to receive ^{32}P did not receive it, in five of the cases because of difficulties with intraperitoneal catheter placement. Technical issues with IP catheter problems were consistent issues in trials of IP ^{32}P , and remain an issue for administration of intraperitoneal therapy today. One of the patients on the melphalan arm developed myelodysplastic syndrome, and one developed acute myelogenous leukemia. Patients with clear cell tumors had worse outcomes in this trial, and it is for this reason that all patients with clear cell tumors, regardless of grade, were included in subsequent GOG trials for high-risk, early-stage disease.

Randomized trials of cisplatin-based chemotherapy in early-stage ovarian cancer are summarized in Table 25.12. While individual trial results vary somewhat, as a group they have shown fairly consistent improvement in disease-free survival for chemotherapy, with the ICON1 trial also demonstrating a benefit in overall survival.

The Norwegian Radium Hospital performed a trial randomizing 347 women with completely resected stages I, II, or III ovarian cancer to either intraperitoneal ^{32}P or six cycles of single-agent cisplatin (50 mg/m²). There was no significant difference in 5-year actuarial survival rates. However, late bowel complications occurred more often in patients treated with ^{32}P (9% vs. 2%) (342).

A multicenter group in Italy (Gruppo Interregionale Collaborativo in Ginecologia Oncologica; GICOG) randomized 152 women with stage IC ovarian cancer to intraperitoneal ^{32}P

versus six cycles (50 mg/m²) of single-agent cisplatin (343). While 5-year disease-free survival was significantly improved with chemotherapy (85% vs. 65%), 5-year overall survival was not significantly different (81% vs. 79%). The risk of dying after relapse appeared to be greater for patients receiving cisplatin: 11 of 12 patients who relapsed after cisplatin had died of their disease at the time of data analysis versus 18 of 26 after ³²P.

The GOG performed a trial of intraperitoneal ³²P versus three cycles of cisplatin (100 mg/m²) plus cyclophosphamide (1,000 mg/m²) in 251 evaluable patients with unfavorable early-stage disease (stage IA or IB grade 3 or clear cell tumors, or stage IC or stage II disease of any grade or histology) (344). The 10-year recurrence rate was 29% lower (72% vs. 65%) and the death rate was 17% lower for patients receiving chemotherapy, but these differences were not statistically significant. However, based on the better progression-free interval with chemotherapy and the technical problems associated with IP therapy (three patients experienced bowel perforation during insertion of the IP catheter) it was felt that chemotherapy should be the future standard for women with high-risk, early-stage disease. Women with clear cell tumors did not fare

worse on this trial; even after adjusting for stage (most of the clear cell tumors were stage I), the recurrence rate of clear cell tumors was similar to that of patients with grade 1 tumors.

Several trials have also randomized early-stage patients to chemotherapy versus observation.

A Nordic Cooperative Ovarian Cancer Group (NOCOVA) study randomizing women to no adjuvant therapy versus six cycles of adjuvant carboplatin was closed prematurely because of poor accrual (345). Although the confidence intervals were wide, no difference in disease-free or overall survival between the treatment groups was observed. In another small study, the GICOG, randomized 83 women with stage IA or IB grade 2 or grade 3 disease to observation versus six cycles of cisplatin and observed a significant benefit in disease-free survival but no difference in overall survival (343).

The only clear demonstration of a survival benefit in the treatment of early-stage ovarian cancer comes from two large European trials (the combined ACTION and ICON-1 trials), which together randomized 923 patients with early-stage disease to receive either platinum-based chemotherapy or no initial adjuvant treatment. Results of a preplanned combined analysis

FIGURE 25.32. Kaplan-Meier curves for overall survival in early-stage ovarian cancer patients treated with adjuvant chemotherapy (solid line) and no adjuvant chemotherapy (dotted line). *Source:* Trimbos JB, Parmar M, Vergote I, et al. International Collaborative Ovarian Neoplasm Trial 1 and Adjuvant Chemotherapy in Ovarian Neoplasm Trial: two parallel randomized phase III trials of adjuvant chemotherapy in patients with early-stage ovarian carcinoma. *J Natl Cancer Inst* 2003;95:105–112.

indicated a statistically significant improvement in both disease-free survival and overall survival with adjuvant platinum-based therapy (Fig. 25.32). Neither tumor grade nor histologic cell type predicted for relative benefit from treatment. However, even these trials have left uncertainty about the benefit of chemotherapy in a woman with comprehensively staged early-stage disease. In the one third of patients on the ACTION trial with optimal surgical staging there was no benefit to treatment. However, this was a retrospective subset analysis, and this subset of patients was not large enough for the result to reach statistical significance (346–348).

The discrepancy between the benefits in disease-free survival and benefits in overall survival seen in several of the randomized chemotherapy trials has been suggested to result from increased salvage rates for chemotherapy in patients who recur after observation or intraperitoneal ^{32}P . In a GCOG trial randomizing women to chemotherapy versus no adjuvant therapy, 1 of 7 women who relapsed after adjuvant chemotherapy was alive at the time of reporting, whereas 6 of 14 who relapsed after observation were still alive (343). Investigators at the Royal Marsden Hospital examined the salvage rate after relapse in their series of prospective observation for patients with stage I disease (326). Sixty-one (31%) of 194 patients relapsed at a median of 17 months (range, 6 months to 15.7 years), and 55 of these received platinum-based chemotherapy at the time of relapse. Progression-free survival at 5 years after relapse was 24%. Interestingly, although clear cell histology was not predictive of relapse, it was a poor prognostic factor for survival after relapse (349).

Duration of Chemotherapy for Early-Stage Disease. The GOG randomized 427 eligible patients with unfavorable early-stage disease to receive either three or six cycles of carboplatin (Area under the curve [AUC] 7.5)/paclitaxel (175 mg/m²) chemotherapy. Overall 5-year survival was 84% for stage I disease and 73% for stage II disease, and did not differ by treatment regimen (HR 1.02; 95% CI, 0.662 to 1.57; $p = 0.94$). Adjusting for initial FIGO stage and tumor grade, the recurrence rate was 25% lower for patients getting six cycles (relative hazard 0.761, 95% CI, 0.512 to 1.13; $p = 0.18$). The statistics of the study were designed to capture only very large differences in recurrence; there was an 85% chance of identifying a treatment regimen as active if it reduced the recurrence rate by 50%.

Although surgical staging was required, 126 patients did not have a documented complete staging procedure. The estimated recurrence benefit of six cycles of chemotherapy among patients having a complete staging procedure was slightly less (HR 0.796 vs. 0.660 for those not completely staged), but there was no significant evidence of heterogeneity in the treatment effect. Toxicity was increased with six cycles of chemotherapy; in particular grade 3 or 4 neurotoxicity was seen in 11% of patients versus only 2% on the three-cycle arm (350). Based on the lack of survival benefit and the increased toxicity with six cycles of chemotherapy, the GOG conducted a subsequent trial in the same patient population randomizing women to either three cycles of carboplatin (AUC 6)/paclitaxel (175 mg/m²) or three cycles of the same regimen followed by weekly paclitaxel 40 mg/m² for 24 weeks. Results of this study are pending.

At this time it is recommended that patients with comprehensively staged stage IA or IB grade 1 epithelial ovarian cancer receive no postoperative chemotherapy. Patients with grade 3 or stage IC disease have a relapse risk of at least 20%, and this can be reduced with platinum-based chemotherapy. Paclitaxel/carboplatin for three to six cycles is the usual treatment in the United States. It is hoped that future data will better address which women with early-stage ovarian cancers actually derive benefit from therapy.

Early-Stage Fallopian Tube Carcinomas

Unlike ovarian carcinoma, in which two thirds of patients present with advanced-stage disease, about half of patients with fallopian tube carcinoma are diagnosed in stage I or II (351). A review of eight series published over the past decade confirms the preponderance of early-stage disease in fallopian tube carcinoma (192,196,198,200,254). Of 558 patients, 33% were stage I, 33% were stage II, and 34% were stage III or IV. Prognosis of early-stage disease has been reported to be dependent on depth of invasion of the tumor into the fallopian tube (201). Some older series described high recurrence rates in early-stage disease, in particular one series in the radiation oncology literature which reported local recurrence rates of 35% and 70% in untreated stage I and stage II disease (196). However, most recent data have suggested that the survival for

women with fallopian tube cancer is similar or superior to that of women with ovarian cancer when standardized for stage (351–353). No meaningfully sized series to inform about benefits of treatment exist. Radiotherapy including whole abdominal irradiation, intraperitoneal ^{32}P , and pelvic/para-aortic nodal radiotherapy has been used. As advanced-stage fallopian tube carcinomas appear to respond to platinum-based therapies in a manner similar to that of ovarian carcinomas, adjuvant chemotherapy is currently used for early-stage fallopian tumor in most situations.

Management of Borderline Tumors

Borderline (low malignant potential; LMP) tumors comprise 10% to 20% of ovarian malignancies, and most are of serous or mucinous histology. Their histology is discussed in detail above in the section on pathology. Serous borderline tumors are more common than mucinous borderline tumors in the United States, but mucinous borderline tumors are more common in Japan (354). Numerous large series attest to their good prognosis (97,355,356). Unlike invasive epithelial ovarian cancer, approximately 75% to 80% of borderline tumors are diagnosed in early stages. Even when they present with more advanced-stage disease, they progress very slowly. A review of borderline tumors entered into the NCI SEER database between 1988 and 1997 (when SEER stopped collecting data on ovarian borderline tumors) showed 10-year relative survivals of 99% for stage I, 98% for stage II, 96% for stage III, and 77% for stage IV disease (357). Given the good prognosis, no postoperative treatment is indicated for early-stage borderline tumors. Borderline tumors are particularly likely to affect young women (Fig. 25.2), in whom therapeutic decisions regarding fertility-sparing, premature hormonal deprivation, and adjuvant chemotherapeutic treatments are particularly pertinent.

Surgery is the cornerstone of treatment for early-stage borderline ovarian tumors of LMP. It is important to note that the same principles of surgical staging detailed earlier in this chapter with regard to invasive cancers apply equally to borderline tumors. Since many women with borderline tumors are in the childbearing years, the efficacy and safety of conservative surgery have been important. There is no evidence that a conservative surgical approach has an adverse effect on survival in patients with stage I borderline tumors of borderline (358). Even though patients treated with a unilateral oophorectomy have a higher recurrence rate than patients treated with a total hysterectomy and bilateral oophorectomy, effective surgery for recurrent disease leads to equivalent survival. Whether even more conservative surgery (e.g., cystectomy) has an adverse impact on survival remains a subject of debate. Although cystectomy may increase the recurrence rate, it may not have an adverse effect on survival. However, in order to avoid recurrences and still maintain fertility, there appears to be little, if any, disadvantage to performing a unilateral oophorectomy. In patients who present with stage II borderline tumors, a total abdominal hysterectomy and bilateral salpingo-oophorectomy with appropriate staging of the peritoneal cavity is recommended.

Chemotherapy is not indicated for stage I or II borderline tumors.

Serous Borderline Tumors

Approximately 5% to 10% of early-stage serous borderline tumors will ultimately recur. Recurrences can present 10 to 15 years after the initial diagnosis, making long-term follow-up necessary (and raising the question as to whether the relapses represent new primary disease). In one report of 160 stage I serous borderline tumors, 11 patients developed recurrent tumor at a median of 16 years after initial surgery (range, 7 to

39 years), and 8 died of the disease (359). It has been proposed that the majority of recurrences among serous borderline tumors are attributable to the subset with micropapillary histology, and that these have a higher frequency of invasive implants (103). This emphasizes the need for careful surgery in this subset of tumors. This is to be distinguished from the rare group of borderline tumors that exhibit stromal microinvasion; focal microinvasion (less than 3 to 5 mm) does not appear to have prognostic importance (360), and this subset can be managed in the same way as typical borderline tumors.

The optimal adjuvant treatment of more advanced-stage recurrent disease is unknown. The very long natural history of borderline tumors makes prospective clinical trials difficult. Tumors with invasive implants (the minority) have a worse prognosis than those with noninvasive implants, but longer follow-up will reveal more recurrences in patients with more indolent disease. Seidman and Kurman reported on a review of 97 reports including 4,129 patients and noted that after 7.4 years of follow-up, the survival of patients with noninvasive peritoneal implants was 95.3% as compared with 66% for those with invasive implants. Lymph node involvement did not appear to portend a particularly dire prognosis, and was associated with a 98% survival rate at 6.5 years (97).

The M. D. Anderson group retrospectively identified 39 patients with ovarian serous borderline tumors with invasive implants. At a median follow-up of 111 months, 12 (31%) had progressed or recurred with median time from diagnosis to recurrence of only 24 months (361). They also reviewed 80 cases of stage II-IV ovarian serous borderline tumors with noninvasive implants (362). Fifty received postoperative chemotherapy. Thirty-five (44%) developed recurrences, 10% within 5 years, 19% between 5 and 10 years, 10% between 10 and 15 years, and 5% more than 15 years after primary resection. The only statistically significant feature associated with recurrence was the presence of a micropapillary/ciribriform pattern, although this pattern was present in only 26% of the cases that recurred.

Although their very slow growth would seem to predispose them to resistance to traditional cytotoxic agents, serous borderline tumors are not completely chemotherapy resistant. Gershenson et al. reported on a series of patients with metastatic serous borderline ovarian tumors who had macroscopic residual disease after initial surgery, received chemotherapy, and subsequently underwent second-look laparotomy. Three of 20 (15%) patients with noninvasive implants (363) and 4 of 7 (57%) patients with invasive peritoneal implants had a response to chemotherapy (361). Barakat et al. summarized several series in which second-look surgery was performed to document response to initial platinum-based therapy and found that 6 of 23 patients (26%) with macroscopic residual disease had complete responses (364). However, the effect of treatment on survival is very uncertain. Surgery is often used as sole primary treatment for women with serous borderline tumor of the ovary with noninvasive implants, for whom 5-year survivals are 94% to 95% (365), and chemotherapy is often used in women with invasive implants. Aneuploidy has also been reported to predict for poor survival but appears to be related to the presence of invasive implants (366). However, there is no clear evidence that chemotherapy can decrease relapse rates or improve survival in any subset of patients.

Recurrences of serous borderline tumors may be histologically similar to the original tumor or can be invasive tumors, usually of low grade. In the M. D. Anderson series of borderline tumors with noninvasive implants described above, 2 of the 35 recurrences were not histologically examined. Six were recurrent borderline tumors, and the patients with these recurrences were all alive without evidence of disease 7 to 14 years after surgery. Twenty-seven patients had low-grade serous carcinomas at the

time of recurrence, and 20 of these died of disease between 3 and 25 years after surgery (362). Crispens et al. reported that of 49 patients with recurrent borderline serous tumors, 73% of the recurrences were low-grade carcinomas, and that optimal cytoreduction in this group was associated with improved survival. Thirty-six percent of women with progressive or recurrent serous borderline tumors died of their disease. Six complete responses and four partial responses in 45 evaluable patients (22% response rate) were reported with use of a platinum/taxane-based regimen. One patient had a partial response to leuprolide, and one had a partial response to pelvic irradiation. Given the fact that women may live a very long time with advanced-stage borderline tumors, even those recurring as low-grade invasive serous carcinomas, use of chemotherapy should be judicious, and use of agents such as oral etoposide with a propensity to cause leukemia should be avoided. Over 90% of serous borderline ovarian tumors are estrogen-receptor positive (367), and there are case reports of major responses to tamoxifen (367), leuprolide (368), and anastrozole (369). The effect of antiangiogenic or other newer targeted agents on these tumors is not known. There is a high frequency of *BRAF* mutations in borderline serous tumors (370), and agents directed against this or other genetic alterations may be of interest.

Mucinous Borderline Tumors

The pathology and classification of mucinous borderline tumors are covered earlier in this chapter. Most mucinous borderline ovarian tumors are stage I and present as large unilateral ovarian masses; bilaterality suggests the possibility of metastatic tumor from another site. Appendectomy and evaluation of the GI tract should be performed to rule out a primary gastrointestinal tumor. Mucinous tumors need to be sampled thoroughly to avoid missing an area of invasion. However, as with serous borderline tumors, microinvasion is not thought to have prognostic significance. Risk of recurrence for stage I mucinous borderline tumors of either the more typical intestinal type or the less common endocervical type is very low, with metastatic rates of 0% to 7%. For many years pseudomyxoma peritonei was thought to result from ovarian borderline tumors, but pathologists now believe that most ovarian tumors associated with pseudomyxoma peritonei are metastatic from primary neoplasms of the appendix (153). High-stage pure borderline mucinous tumors are exceedingly uncommon.

Advanced Epithelial Ovarian Cancer

Cytoreductive Surgery

Despite decades of effort aimed at improving methods of early detection and diagnosis, the majority of cases of cancer of the ovary are not diagnosed until the disease has spread beyond the ovary. Often, patients with advanced disease will present with an abdomen distended with ascites and obviously bulky tumor masses in the pelvis and upper abdomen. For most human solid tumors, aggressive surgical resection is justified only if all known tumor can be removed, rendering the operation potentially curative. For epithelial cancer of the ovary, however, there is substantial theoretical and clinical support for the concept that debulking, or cytoreduction, of large tumor masses can be beneficial to the patient even in the absence of complete tumor removal. Griffiths (371) has reviewed the theoretical basis for cytoreductive surgery. Removal of bulky tumor masses in a patient with advanced ovarian cancer may improve the patient's comfort, reduce the adverse metabolic consequences of the tumor, and enhance the patient's ability to maintain her nutritional status. Such effects are likely to increase her ability to tolerate the intensive chemotherapy that is required. Perhaps,

more importantly, removal of large tumor masses may enhance the response of the remaining tumor to chemotherapy. Large tumor masses with a relatively poor blood supply may provide a pharmacologic sanctuary where viable tumor cells can escape exposure to adequate concentrations of cytotoxic drugs. Additionally, such poorly vascularized masses may have a low growth fraction (i.e., a larger proportion of cells in the nonproliferating [G_0] phase of the cell cycle) when they are relatively insensitive to the effects of cytotoxic drugs.

In 1968, Munnell (372), who introduced a concept of the "maximum surgical effort" for ovarian cancer, reported an improved survival in patients who had a "definitive operation" compared to "partial removal" or "biopsy only." In 1969, Delclos and Quinlan (373) reported 25% versus 9% survival in stage III ovarian cancer patients when disease was cytoreduced surgically to "nonpalpable" versus "palpable." Griffiths (371) was the first to accurately quantify residual disease following primary surgery and to correlate this with survival in a group of 102 patients receiving chemotherapy (single-agent melphalan) for stage II or III ovarian cancer. Using a multiple linear regression model, he found that survival duration was significantly related to residual tumor size, and he reported a median survival of 39 months for patients with no residual tumor compared to 12.7 months for patients with residual tumor >1.45 cm in maximum diameter. He also noted an important limitation of cytoreductive surgery: Extensive resection of tumor bulk with failure to remove all masses >1.5 cm in diameter did not influence survival.

In 1978, Young et al. (374) reported the first randomized trial of multiagent nonplatinum chemotherapy versus single-agent alkylating therapy of advanced ovarian cancer, showing that patients reduced to "optimal disease" were more likely to achieve a complete clinical response, as well as a pathologic complete response. Other investigators utilizing platinum-based regimens have also supported the role of primary cytoreductive surgery. Omura et al. (375), reporting a GOG study comparing two cisplatin-based regimens, found a statistically significant difference in progression-free interval, survival, and proportion of patients achieving negative second-look laparotomy in those with no gross residual disease compared to those with gross residual ≤ 1 cm. In clinical trials in which the percentage of patients who were optimally cytoreduced was reported, the median survival for optimally cytoreduced patients was 39 months as compared to 17 months for those not optimally cytoreduced. In addition, Fuks et al. (375a) and Dembo (332) have reported beneficial effects of primary cytoreduction when radiation is used following surgery.

More recently, several investigators have published results supporting the role of primary cytoreduction. Hoskins et al. (376), analyzing GOG data, reported on the effect of residual disease size on survival after primary cytoreductive surgery. The patient population studied was relatively homogeneous because it included only patients with suboptimal residual disease according to the GOG definition (>1 cm). This removes an important source of bias present in most prior studies since patients found to have only small-volume disease (or debulked to very small-volume disease) are excluded. Among their study group of 294 patients, they noted a statistically significant improvement in survival in patients who had 1- to 2-cm residual disease as compared to those with >2-cm residual disease ($p < 0.01$). These data, when combined with data from GOG protocol 52, in which patients with stage III or IV disease had optimal (<1 cm) residual disease, provide a striking example of the prognostic importance of the extent of residual disease (Fig. 25.33) (376). Eisenkop et al. (377), in a small study, found a survival benefit to the complete elimination of all visual peritoneal implants using such modalities as CO₂ laser, argon-beam coagulator, and the cavitron ultrasonic surgical aspirator. Retrospective reports confirm that aggressive primary

FIGURE 25.33. Survival time by initial abdominal tumor description (except omentum). Source: Hoskins WJ, McGuire WP, Brady MF, et al. The effect of diameter of largest residual disease on survival after primary cytoreductive surgery in patients with suboptimal residual epithelial ovarian carcinoma. *Am J Obstet Gynecol* 1994;170:974–980.

(and secondary) cytoreductive operations are associated with minimal morbidity and mortality when performed by experienced surgeons (378). The National Institutes of Health Consensus Development Conference on Ovarian Cancer held in April 1994 concluded that “aggressive attempts at cytoreductive surgery as the primary management of ovarian cancer will improve the patient’s opportunity for long-term survival” (Final Statement, NIH Consensus Development Conference on Ovarian Cancer, Bethesda, 1994) (62).

None of the above reports represents randomized clinical trial data, and it is not likely ever to be feasible to conduct a randomized trial testing the value of aggressive debulking surgery. It has been suggested that patients who present with small-volume disease that is optimally cytoreduced following hysterectomy with bilateral salpingo-oophorectomy and omentectomy have disease that is biologically less aggressive than do patients who are anatomically cytoreduced to the same amount of residual disease but require a maximal tumor reduction with removal of bulky disease throughout the peritoneal cavity. For example, in a study from Roswell Park Cancer Institute, it was demonstrated that cytoreductive surgery was successful in debulking 87% of patients with stages III and IV disease to less than 2-cm residual tumor masses (379). The percentage of patients in this study who were optimally cytoreduced was markedly higher than the 17% to 40% successful debulking rate reported in many other series. However, only 30% of patients in this study achieved a complete remission with chemotherapy even though only 13% of the patients had any residual mass greater than 2 cm after debulking surgery. Furthermore, progression-free survival was only 29% at 3 years. These results suggest that, in addition to

the volume of disease, other unknown biologic factors influence survival in patients with advanced disease.

The current FIGO staging system subdivides stage III disease into three groups, based upon the volume of disease before any attempt at surgical debulking (Table 25.7).

Stage IV ovarian cancer patients present special considerations with regard to cytoreduction. Most of the studies supporting cytoreductive surgery have included both stage III and stage IV patients but have not analyzed them separately. Four retrospective studies that have examined the prognostic significance of optimal debulking in stage IV ovarian cancer have all shown a statistically significant improvement in survival in patients with small-volume residual tumor (Table 25.13) (380–383). Based on these data, it seems reasonable to attempt cytoreduction in medically fit patients with stage IV disease if optimal residual disease is achievable.

The actual percentage of patients with advanced ovarian cancer who can successfully be cytoreduced remains to be established. The percentage of patients optimally cytoreduced has ranged from 87% to 17% in different studies in the literature, with a mean of 35%. This wide range is due to several factors in addition to the skill and experience of the surgeon. There has not been universal agreement as to the size of residual masses that place the patient in the “optimal” category. Furthermore, the patient populations may not be comparable with regard to volume of disease at surgery or are not controlled for surgery prior to referral to the investigator.

Preoperative Chemotherapy/Interval Cytoreduction

Since many patients cannot be successfully cytoreduced at initial surgery, the benefit of a brief induction course of chemotherapy prior to debulking surgery has been explored. Two to three cycles of chemotherapy substantially increase the percentage of patients who will be successfully cytoreduced. Several studies (384,385) have provided retrospective comparisons of advanced-stage patients treated with neoadjuvant chemotherapy compared to patients treated with surgery followed by chemotherapy. All have demonstrated the feasibility of neoadjuvant chemotherapy. Everett et al. (386) reported on a retrospective series of 98 patients with initial chemotherapy and 102 with initial surgery. Patients who received initial chemotherapy were more likely to have stage IV and grade 3 disease. Interestingly, there was no difference in surgical morbidity between the groups (as a neoadjuvant approach would generally seem attractive for patients who are ill enough that aggressive primary surgery is risky). Optimal cytoreduction was achieved in 86% of patients who received initial chemotherapy versus 54% of patients who received initial surgery. Optimal cytoreduction but not treatment choice was statistically associated with median survival. However, initial surgery was associated with a

longer progression-free interval. There are currently two randomized trials under way of neoadjuvant chemotherapy versus surgical debulking followed by chemotherapy (EORTC-55971, UK CHORUS). Results will be very interesting.

There is conflicting evidence from two large prospective, randomized trials whether interval debulking can improve survival in certain patients with advanced ovarian cancer (387,388). In a multicenter trial conducted by the EORTC (388), patients with suboptimal (>1 cm) disease remaining after primary cytoreduction were treated with three cycles of cyclophosphamide and cisplatin. Those without progression were randomized to interval debulking surgery and additional chemotherapy versus additional chemotherapy alone. With approximately 150 patients randomized to each arm, patients undergoing the interval debulking showed a statistically significant improvement in both progression-free interval and median survival (Fig. 25.34A). The interval surgery was generally well tolerated.

More recently, the GOG has reported the results of protocol 152, a prospective, randomized trial of interval secondary cytoreduction in patients with advanced ovarian cancer with

suboptimal residual disease (387). Five hundred fifty patients were enrolled in this study within 6 weeks of initial surgery. After three cycles of paclitaxel and cisplatin, patients without evidence of tumor progression were randomized to receive either secondary cytoreduction and three additional cycles of chemotherapy or chemotherapy alone. At the time of the report, median progression-free survival and overall survival for the interval cytoreduction group were 10.5 months and 33.9 months, respectively, compared to 10.7 months and 33.7 months for the chemotherapy-alone group. The overall survival for the two groups is shown in Figure 25.34B.

Several possibilities have been advanced to explain the difference in outcome between the GOG and European studies, both large prospective, randomized trials. Probably most important of these is the difference in the training and experience of the surgeons involved. In the GOG trials, both the initial and interval cytoreductive operations were performed almost exclusively by trained gynecologic oncologists, whereas in the EORTC trial the initial surgery was most often done by general gynecologists. As a result, residual disease following primary surgery measured <5 cm in about two thirds of the GOG patients as compared to one third of the patients in the EORTC trial. Following chemotherapy, residual disease >1 cm was found in 56% of the GOG patients versus 65% of the European patients. This resulted in a higher likelihood of successful cytoreduction in the EORTC trial, with conversion from suboptimal to optimal residual tumor in 45% of patients as compared to 36% in the GOG trial.

Additionally, the chemotherapeutic regimen used in the GOG trial, paclitaxel and platinum, may have reduced the benefit of interval cytoreduction relative to the EORTC trial, which used a platinum and cyclophosphamide combination. Differences in outcome may also be related to differing post-treatment surveillance and to the availability of more effective second-line therapies since the EORTC trial completed accrual in May 1993. It is of interest to note that the similar median and overall survivals in both arms of the GOG trial were substantially longer than those reported in the best (interval cytoreduction) arm of the EORTC trial.

The available evidence from the prospective trials of interval cytoreduction suggests that, although this technique should not be a routine management strategy, certain selected patients may benefit depending on the aggressiveness of the initial cytoreductive surgery, the geographic distribution and size of the remaining disease, and the response to the initial several cycles of chemotherapy.

Postoperative Chemotherapy

Surgery is rarely curative for women with advanced-stage ovarian carcinoma, even when there is no residual disease. Many chemotherapy agents have some activity against ovarian cancer, and a great deal of effort has been spent on trying to optimize adjuvant chemotherapy regimens to improve survival. A recent meta-analysis of 198 trials involving 38,440 women suggested that the regimen that best prolonged survival is a platinum and taxane combination with intraperitoneal administration; this resulted in a 55% relative risk reduction for mortality as compared with nonintraperitoneal monotherapy containing neither platinum nor taxane (389). The most standard regimen in the United States currently is six cycles of postoperative intravenous (IV) paclitaxel/carboplatin; areas of uncertainty exist not only regarding use of neoadjuvant therapy, but regarding the role of single-agent carboplatin, use of intraperitoneal chemotherapy, and use of maintenance taxane therapy.

Platinum Use. Platinum agents represent the most active group of chemotherapy agents in the treatment of ovarian cancer. The GOG performed the largest comparative trial of a platinum-containing regimen versus a non-platinum-containing regimen in

the pretaxane era (390). Two hundred twenty-seven patients with advanced ovarian cancer were randomized to receive doxorubicin/cyclophosphamide treatment with or without the addition of cisplatin. Complete response rate (51% vs. 26%) and median overall survival (15.7 vs. 9.7 months) both were superior for the cisplatin-containing regimen. The meta-analysis of Kyrgiou et al. confirmed that platinum-based combination or monotherapy produces a survival benefit compared to non-platinum-based therapy. A relatively small increased risk of secondary leukemia has been identified in ovarian cancer patients treated with platinum-based chemotherapy (389). However, the clinical benefits of platinum treatment outweigh the risks.

Choice of Platinum Agent. As discussed in Chapter 15 (Principles of Chemotherapy in Gynecologic Cancer), the early trials of platinum in ovarian cancer all used the first available platinum agent, cisplatin, which is associated with troublesome nausea/vomiting, neurotoxicity, and nephrotoxicity. Carboplatin, while more myelotoxic, is otherwise substantially better tolerated than cisplatin. Multiple randomized trials comparing carboplatin to cisplatin in ovarian carcinoma have been performed, and meta-analyses have confirmed that there is no difference in efficacy between the two agents (391). Three trials have specifically compared the combination of intravenous cisplatin plus paclitaxel to intravenous carboplatin plus paclitaxel, and noninferiority for carboplatin/paclitaxel versus cisplatin/paclitaxel has been convincingly demonstrated (392–394). In general, carboplatin is the first-line platinum agent in the treatment of ovarian cancer in the United States. However, as discussed below, there are no randomized data showing that intraperitoneal carboplatin produces benefits similar to those seen with intraperitoneal cisplatin, and cisplatin remains the standard platinum drug for intraperitoneal administration.

Oxaliplatin, a third-generation platinum agent that produces an unusual cold-triggered neurotoxicity, is FDA approved in the United States for use in colon cancer. It has a theoretical benefit in activity against tumors that exhibit mismatch repair deficiency and preclinical data suggested that cell lines resistant to cisplatin might be sensitive to oxaliplatin (395). However, there is no clinical evidence of non-cross resistance with other platinum agents; a GOG trial of oxaliplatin in women with platinum-resistant tumors revealed negligible activity (396). A small ($n = 177$) randomized trial comparing oxaliplatin/ cyclophosphamide to cisplatin/cyclophosphamide as first-line therapy in women with ovarian cancer showed no difference in progression-free or overall survival between the two treatment groups (397).

Platinum Dose and Dose Intensity. To date no evidence supports the use of doses of cisplatin above 50 to 100 mg/m² every 3 weeks or carboplatin AUC 5 to 7.5 every 3 weeks. An influential early meta-analysis of over 60 published trials showed a correlation between dose intensity of cisplatin and observed response rate, but the correlation held only over a range of doses lower than those used in clinical practice today (398).

Numerous prospective clinical trials have compared different platinum doses and dose intensities over a clinically relevant range, and the majority of these have shown no benefit for higher dose or greater dose intensity (399–401). The largest was the GOG trial that tested dose intensity while keeping the total dose fixed. Four hundred fifty-eight patients with bulky stage III or stage IV disease were randomized to receive either eight cycles of cisplatin (50 mg/m²) plus cyclophosphamide (500 mg/m²) every 3 weeks or four cycles of cisplatin (100 mg/m²) plus cyclophosphamide (1,000 mg/m²) every 3 weeks. There was no difference between the regimens in response rate or survival (401). The outlier among the studies was a randomized Scottish trial that compared cyclophosphamide 750 mg/m² plus cisplatin either 50 mg/m² or 100 mg/m² every 3 weeks for six cycles, and found a better response rate, progression-free survival, and overall survival on the high-dose arm (402). Nonetheless, because

neurotoxicity was still evident in patients treated with the higher dose of cisplatin 4 years after chemotherapy, investigators recommended that the dose of cisplatin not be increased beyond 75 mg/m² (400). No other reasonably sized trial has supported importance of cisplatin dose intensity or total dose beyond six cycles (see Prolongation of Primary Therapy/Consolidation/Maintenance below). Randomized trials have also failed to show benefit for escalated doses of carboplatin, although they produce less neurotoxicity than high doses of cisplatin. Danish investigators randomized patients with advanced-stage ovarian cancer to receive cyclophosphamide 500 mg/m² with carboplatin at an AUC of either 4 or 8. There was no difference in either surgically confirmed complete remission rate or overall survival (403). Very high doses of carboplatin requiring hematopoietic stem cell support have also been tested in ovarian cancer without any evidence of benefit (404).

Despite all of the above, as discussed below under Addition of a Taxane to Platinum Chemotherapy, doubt about the optimal dose of platinum for front-line use persists. Perhaps a subset of patients or ovarian cancers exists for which different doses would be appropriate. The Scottish clinical trials group has launched a large trial (SCOTROC4) of single-agent carboplatin in women who do not desire platinum/taxane combination therapy or in whom such therapy is contraindicated. Patients are randomized to a flat carboplatin dose or a dose that is individually escalated in each patient.

Addition of a Taxane to Platinum Chemotherapy. In the 1980s a great deal of excitement was generated by the demonstration that single-agent paclitaxel had substantial activity against platinum-resistant ovarian cancer. Initial trials of paclitaxel used prolonged infusion durations to reduce the incidence of acute hypersensitivity reactions. A GOG trial tested single-agent paclitaxel at 200 mg/m² given intravenously over 24 hours with growth factor support in 43 patients with recurrent, persistent, or progressive ovarian cancer during or after a platinum-based chemotherapy. The overall response rate was 37% with 18% complete responses (405). Twenty-seven of the patients were platinum resistant, and the response rate to paclitaxel in this group was 33%. When premedication with corticosteroids and histamine blockers was found to prevent most hypersensitivity reactions, shorter infusion durations were also tested. In an influential trial performed by a group of European and Canadian collaborators 391 eligible patients were randomized in a 2 × 2 factorial design to receive paclitaxel as either a 3-hour or a 24-hour infusion at a dose of either 135 mg/m² or 175 mg/m² every 3 weeks. Shorter infusions were found to be safe and to result in less myelosuppression but more neurotoxicity (406). There was a slight increase in time to progression (TTP) for patients who received the higher dose (19 weeks vs. 14 weeks; response rate 20% vs. 15%) and 175 mg/m² over 3 hours became the accepted dose in patients with recurrent disease.

A number of randomized trials were rapidly launched comparing platinum-based regimens with and without taxane in the first-line treatment of ovarian cancer. The four largest studies are summarized in Table 25.14. The results of the first two of these trials completed (GOG 111 and OV-10) clearly demonstrated that combination chemotherapy with paclitaxel and cisplatin prolongs both progression-free and overall survival as compared with cyclophosphamide/cisplatin (407,408). In GOG 111, which treated women with suboptimally debulked or stage IV cancer using a paclitaxel dose of 135 mg/m² over 24 hours, the median overall survival was 37 months for those treated with paclitaxel and cisplatin as compared with 25 months for those receiving cyclophosphamide and cisplatin (407). Similar results were found in the more inclusive (stage IIB-IV) European trial, although it produced 18% grade 3 neurotoxicity in the paclitaxel-containing arm (vs. 4% neurotoxicity in the GOG trial), as paclitaxel was used at a dose of 175 mg/m² (with the possibility of escalating to 200 mg/m²) over 3 hours (408).

TABLE 25.14

RANDOMIZED TRIALS ± TAXANE IN FIRST-LINE CHEMOTHERAPY FOR OVARIAN CANCER

Author (year)	N	Eligibility	Regimens	Median PFS	Median OS
McGuire (1996) (Ref 407) GOG 111	386	Suboptimal III Any IV	Cisplatin 75 mg/m ² + paclitaxel 135 mg/m ² /24 hr	18 mo	38 mo
			vs. Cisplatin 75 mg/m ² + cyclophosphamide 750 mg/m ²	vs. 13 mo <i>p</i> < 0.001	vs. 24 mo <i>p</i> < 0.001
Piccart (2000) (Ref 408) OV-10	680	IIB-IV	Cisplatin 75 mg/m ² + paclitaxel 175 mg/m ² /3 hr	15.5 mo	36 mo
			vs. Cisplatin 75 mg/m ² + cyclophosphamide 750 mg/m ²	vs. 11.5 mo <i>p</i> = 0.0005	vs. 26 mo <i>p</i> = 0.0016
Muggia (2000) (Ref 409) GOG 132	614	Suboptimal III Any IV	Cisplatin 75 mg/m ² + paclitaxel 135 mg/m ² /24 hr	14 mo	26 mo

			vs. Carboplatin AUC 6 or	16 mo <i>p</i> = NS	36 mo <i>p</i> = NS
			Cyclophosphamide 500 mg/m ² + cisplatin 50 mg/m ² + doxorubicin 50 mg/m ²		

Note: AUC, area under the curve; NS, not significant; OS, overall survival; PFS, progression-free survival; RR, response rate; mo, months.

The other two trials did not clearly support the addition of paclitaxel to front-line therapy. The GOG trial compared single-agent paclitaxel to single-agent cisplatin to the combination in the same subgroup of patients treated in GOG 111 (409). The response rate to single-agent paclitaxel in patients with measurable disease was significantly lower than to either of the platinum-containing regimens (42% vs. 67%, *p* < 0.01). However, the difference in median durations of overall survival (30.2, 25.9, and 26.3 months for patients randomized to cisplatin, paclitaxel, and the combination) was not statistically significant. Single-agent therapies were discontinued more frequently (cisplatin because of toxicity or patient refusal [17%] and paclitaxel because of progression [20%]) compared to combination chemotherapy in which 7% of patients discontinued because of toxicity and 6% because of disease progression. The relative hazard of first progression or death was significantly greater among those randomized to paclitaxel when compared with either of the cisplatin-containing regimens, but did not differ significantly between the two cisplatin regimens. Since overall survival was similar in the three arms, and the combination regimen had a better toxicity profile than single-agent cisplatin at 100 mg/m², the investigators concluded that the combination of cisplatin and paclitaxel should remain the preferred therapy. They speculated that the lack of benefit for the combination arm related to the fact that almost 50% of patients began subsequent treatment prior to overt clinical progression, presumably on the basis of a rising CA-125. The first nonprotocol treatment for those randomized to cisplatin included paclitaxel 52% of the time, and for women randomized to paclitaxel it included cisplatin or carboplatin 69% of the time. By way of contrast, paclitaxel was seldom used as salvage therapy in GOG 111 because of its limited availability at the time, and while 48% of patients in the cisplatin/cyclophosphamide arm of OV-10 crossed over to

paclitaxel as first salvage treatment, it appears that they did so after overt clinical progression. The results of GOG 132 have raised the question of whether appropriately designed sequential therapy would be as effective as combination therapy. An Eastern Cooperative Oncology Group (ECOG) study of single-agent doxorubicin versus single-agent paclitaxel versus the combination for women with metastatic breast cancer had built in crossover at the time of progression, and showed that the combination produced more toxicity and a higher response rate, but no improvement in overall survival (410). However, no trial has formally tested the question of sequential versus concomitant agents in the treatment of ovarian cancer. Moreover, it is noteworthy that the response rate to single-agent cisplatin 100 mg/m² in GOG 132 was the same as that to the combination therapy (which used a cisplatin dose of 75 mg/m²), again raising uncertainties about the role of platinum dose in the treatment of ovarian cancer.

ICON3, a large multinational trial which randomized women with stage I-IV disease to carboplatin/paclitaxel chemotherapy versus single-agent carboplatin or CAP (cisplatin/doxorubicin/cyclophosphamide) chemotherapy found no superiority for the taxane-containing combination in either progression-free or overall survival (hazard ratio for overall survival 0.98; 95% CI, 0.87 to 1.10) (411). About a third of patients on carboplatin in the control group went on to receive a taxane at some stage, mostly after the disease had progressed. The results of this trial also appear to contradict those of OV-10 and GOG 111, and the explanation remains unclear. It has been suggested that cisplatin/cyclophosphamide is an inferior control arm to optimal dose single-agent platinum. However, a trial comparing cisplatin 50 mg/m² to cisplatin 50 mg/m² plus cyclophosphamide 650 mg/m² repeated every 4 weeks for six cycles did not show any difference between treatment groups (412). ICON3 included

stage I/II patients, a group in which, as discussed above, it has been very difficult to demonstrate the benefit of any chemotherapy, and in which the differences between different chemotherapy regimens might be blunted. However, they made up only about 20% of the study population and statistical analysis of ICON3 did not reveal any heterogeneity of treatment effect when analyzed by stage, cell type, grade, or country of origin.

Alternate Taxanes/Taxane Schedules. The Scottish Gynaecological Cancer Trials Group compared a docetaxel-containing primary regimen to a paclitaxel-containing primary regimen (412a). One thousand seventy-seven women with stage IC-IV ovarian or primary peritoneal carcinoma were randomized to six cycles of carboplatin AUC 5 and either docetaxel 75 mg/m² or paclitaxel 175 mg/m². At a median follow-up of 23 months, there was no difference in progression-free (15 months for docetaxel, 14.8 months for paclitaxel) or overall survival (2-year overall survival 64% for docetaxel and 69% for paclitaxel). This was confirmed in a subsequent report with longer follow-up. Docetaxel was associated with less neurotoxicity (11% vs. 30% grade \geq 2 neurosensory toxicity) and more myelotoxicity (11 patients vs. 3 patients with neutropenic fever). This represents an attractive option for patients with or at risk for neurotoxicity.

A formulation of paclitaxel as protein-bound nanoparticles (ABI-007, Abraxane) has been approved for use in breast cancer in the United States. It has shown activity in ovarian cancer, but randomized trials of its use in front-line therapy have not been performed.

Given the slightly superior response rates observed for more prolonged infusion of a given dose of paclitaxel in the European-Canadian trial, interest in very prolonged infusion schedules was stimulated. The GOG completed a trial (GOG 162) randomizing women with ovarian cancer to cisplatin 75 mg/m² plus paclitaxel 135 mg/m² administered as either a 24- or a 96-hour infusion. There was no difference in overall or progression-free survival (413).

GOG investigators performed a randomized trial of a 24-hour infusion of paclitaxel at different doses in previously treated patients with advanced disease (414). For 271 patients with measurable disease, high-dose paclitaxel (250 mg/m² plus granulocyte colony-stimulating factor [G-CSF]) gave a higher response rate than the lower dose of 175 mg/m² (36% vs. 27%). However, progression-free survival and overall survival were similar. The median duration of overall survival was 13.1 months and 12.3 months for paclitaxel 175 and 250 mg/m², respectively. Despite cytokine support, high-dose paclitaxel is associated with increased platelet toxicity, anemia, neurotoxicity, and gastrointestinal toxicity, and there appears to be, at best, a modest dose-response effect for paclitaxel in previously treated patients. A subsequent prospective, randomized trial in previously untreated advanced ovarian cancer patients compared two different doses of paclitaxel (175 vs. 225 mg/m²), with all patients receiving carboplatin at an AUC of 5. No improvement in survival was reported for the higher-dose paclitaxel regimen (415).

Fennelly et al. (416) performed a phase 1 pharmacologic study of paclitaxel administered weekly in patients with relapsed ovarian cancer. Maximum tolerated dose was 80 mg/m² in this heavily pretreated group of patients. Partial responses were observed in 30% of assessable patients including patients with progressive disease on a standard 3-week paclitaxel schedule. Weekly paclitaxel was associated with less toxicity, particularly alopecia. Subsequent phase 2 trials have reported response rates of 32% to 47% for weekly paclitaxel in platinum-refractory patients (417,418). Current and future trials will address the role of weekly paclitaxel in front-line therapy.

Addition of a Third Agent to Front-Line Chemotherapy. There are no data that addition of any third cytotoxic agent to front-line chemotherapy of ovarian cancer improves outcomes, despite an immense amount of investigation of this strategy.

Doxorubicin produces single-agent response rates of 20% to 30% in women with chemotherapy-naïve ovarian cancer. In the pretaxane era, two meta-analyses suggested that there was benefit to the addition of doxorubicin to cisplatin/cyclophosphamide therapy. The large ICON2 trial therefore randomized 1,526 patients with stage I-IV ovarian cancer to either single-agent carboplatin AUC 5 or CAP (cyclophosphamide 500 mg/m² plus doxorubicin 50 mg/m² plus cisplatin 50 mg/m²). There was no evidence of a difference in survival between the two therapies (HR for survival 1.00) (419). Subsequently two large randomized studies tested the addition of epirubicin to paclitaxel/carboplatin therapy, and neither found any benefit for the addition of anthracycline (420).

Topotecan also seemed a reasonable candidate to improve results with first-line therapy of ovarian cancer. Topotecan has efficacy very similar to that of paclitaxel against ovarian cancer in women naïve to both agents; a large randomized trial reported a response rate of 20.5% for topotecan 1.5 mg/m²/day \times 5 and 13.2% for paclitaxel 175 mg/m² every 3 weeks (421). Moreover, there is some non-cross resistance between paclitaxel and topotecan. One hundred ten patients crossed over to the alternative drug as third-line therapy; 13.1% of topotecan-treated patients responded to paclitaxel and 10.2% of paclitaxel-treated patients responded to topotecan. Three hundred twenty-six patients with stage III/IV ovarian cancer were randomized to six cycles of either carboplatin/paclitaxel every 21 days or the same combination plus IV topotecan 1 mg/m² days 1 to 3 every 21 days. There was no difference in response rate (RR of 84% on carboplatin/paclitaxel vs. 94% for the triplet) or median TTP (70.4 and 71.8 weeks, respectively). There was more anemia with topotecan (23.3% vs. 9.4% of courses required transfusions) (422).

After a substantial number of preliminary studies to establish safe regimens for administering three drugs without unduly compromising the dose of any one agent, particularly platinum, an international multiarm randomized study was led by the GOG (GOG 182-ICON5) to definitively answer whether triplet cytotoxic chemotherapy improves survival (423). A total of 4,312 advanced-staged ovarian cancer patients were randomized to carboplatin/paclitaxel or carboplatin/paclitaxel combined with gemcitabine, liposomal doxorubicin, or topotecan. Progression-free survival ranged from 15.4 to 17.5 months across the four treatment arms, with an HR of 0.94 to 1.07, which was not statistically different among any of the combination regimens studied.

Recent interest has focused on the role of combining some of the newer molecular targeted agents with chemotherapy. The most promising agent to date has been bevacizumab, a monoclonal antibody targeting vascular endothelial growth factor (VEGF). It has produced single-agent response rates in the range of 15% to 20% in the setting of recurrent ovarian cancer, and has improved survival when combined with chemotherapy in the treatment of colon cancer and lung cancer. Two trials have been launched, a placebo-controlled three-arm trial in the GOG (GOG 218; Fig. 25.35), which separately tests the value of bevacizumab in combination with carboplatin/paclitaxel chemotherapy and the value of bevacizumab as consolidation/maintenance after primary therapy, and a two-arm trial (ICON7; carboplatin/paclitaxel vs. carboplatin/paclitaxel with concomitant and consolidation bevacizumab) with no placebo in the European cooperative groups.

Intraperitoneal Chemotherapy. Intraperitoneal (IP) chemotherapy provides a means by which high concentrations of drugs and long durations of tissue exposure can be attained at the peritoneal surface. As intraperitoneal progression of disease remains the major source of morbidity and mortality in ovarian cancer, it is a theoretically attractive approach in the treatment of this disease. Many chemotherapeutic agents, including those used for the treatment of ovarian cancer such as cisplatin, carboplatin, topotecan, and paclitaxel have been tested for feasibility with

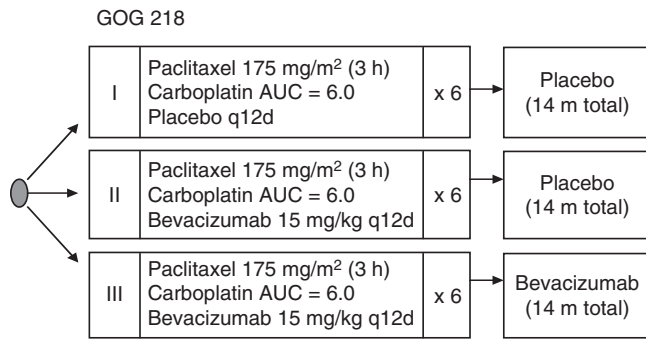

FIGURE 25.35. Design of GOG 218 with incorporation of bevacizumab, concurrently with primary chemotherapy and as maintenance until there is evidence of disease. *Source:* Personal communication, Robert Burger.

intraperitoneal administration. Larger or less water-soluble molecules will stay longer in the peritoneal cavity, and have a higher peritoneal cavity-to-plasma concentration ratio (sometimes referred to as “pharmacologic advantage”), but may not get into the bloodstream. The direct penetration of chemotherapy agents into tumor masses is limited to 1 to 2 mm from the tumor surface. Early work by Los et al., using a rat intraperitoneal tumor model, found that the concentration of cisplatin at the periphery of tumor nodules was higher after IP administration of cisplatin, but the concentration at the center of the nodules was identical after IP and IV administration (424). Hence (a) the theoretical benefit is only for very small tumor volumes, and (b) agents that do not reach therapeutic systemic levels when given by the intraperitoneal route need to be administered intravenously as well. Cisplatin has a 10- to 20-fold pharmacologic advantage when given intraperitoneally. For a given dose of cisplatin, peak concentrations are higher with IV cisplatin, and this has resulted in somewhat decreased toxicity in a randomized comparison of the same doses of cisplatin given intraperitoneally versus intravenously, including less hearing loss and neuromuscular toxicity (425). However, the amount of cisplatin recovered in the urine, reflecting total systemic exposure, is similar regardless of whether the administration is intravenous or intraperitoneal. Similarly, carboplatin given IP at an AUC of 6 has been shown to give an AUC in the peritoneal cavity about 17 times higher than that of carboplatin given intravenously while producing a very similar serum AUC (426). Paclitaxel, on the other hand, has a pharmacologic advantage of about 1,000, and significant levels persist in the peritoneal cavity 1 week after drug administration. However, the dose that can be given is limited by abdominal pain, and serum paclitaxel concentrations detected in patients treated with intraperitoneal paclitaxel at feasible doses are low (427).

Surgical Considerations for Intraperitoneal Chemotherapy. The three methods of obtaining access to the peritoneal cavity that have been examined are single-use percutaneous catheters, semipermanent percutaneous catheters, and implanted subcutaneous port and catheter systems. Reported complications for all catheters include intestinal injury, catheter blockage, and infections involving the peritoneal cavity or the abdominal wall. The implanted subcutaneous port and catheter systems have the advantages of a lower risk of infection and better patient acceptance. In one large single institutional series, Davidson et al. (428) analyzed data on 249 catheters placed in 227 patients. No injuries occurred at the time of catheter placement. Significant complications occurred in 17.6% of patients, including catheter blockage (8.8%) and infection (8.8%). In eight patients, late erosion of the catheter into the intestinal lumen was noted. Recommendations from this study concluded that catheters should not be placed at the time of colon surgery because of a possible increase in the risk of infection, and that intraperitoneal chemotherapy should not be administered until

7 to 14 days following catheter placement to allow time for wound healing. Strict aseptic technique should be used when catheters are accessed.

In a publication from GOG 172, which randomized patients with optimal stage III ovarian cancer to IV versus IP chemotherapy, Walker et al. reported on the IP catheter outcomes in 205 patients allocated to the IP arm (429). One third of patients on that trial discontinued IP therapy primarily related to catheter-related problems including infection in 21 women, catheter blockage in 9, catheter leak in 3, access problems in 5, and drainage per vagina in 1.

The evidence suggests that implanted subcutaneous port and catheter systems have an acceptable level of morbidity for delivery of intraperitoneal therapy. The major technical impediment to successful intraperitoneal therapy is the formation of adhesions within the peritoneal cavity, which leads to catheter blockage and poor distribution of drugs instilled into the cavity. Recent experience suggests that catheters designed for intravenous use may be used for intraperitoneal chemotherapy. The smaller diameter of the IV catheter, together with the absence of side holes, may produce fewer intraperitoneal adhesions as compared to the catheters designed for IP use. Guidance on the selection and placement of catheters is available on the GOG Web site, www.GOG.org.

Clinical Use of IP Therapy for Ovarian Cancer. In January 2006, the NCI issued a clinical alert suggesting the use of intraperitoneal cisplatin chemotherapy in women with optimally debulked ovarian cancer (430). A meta-analysis of eight trials comparing intraperitoneal to intravenous platinum-based chemotherapy (all but one used cisplatin) showed an average 21.6% decrease in the risk of death (hazard ratio 0.79; 95% CI, 0.70 to 0.89). As the expected median duration of survival for women with optimally debulked ovarian cancer receiving standard treatment is approximately 4 years, this size reduction in death rate was estimated to translate into about a 12-month increase in overall median survival. The power of this analysis was based primarily on the survival benefits for intraperitoneal chemotherapy observed in each of the three relatively large randomized trials summarized in Table 25.15 (425,431,432).

Despite these results, intraperitoneal therapy has not yet been consistently adopted for the treatment of women with optimally debulked ovarian cancer in the United States, and has not been widely adopted internationally. There are several reasons for this.

First, intraperitoneal therapy, as used in the reported trials, is technically demanding. Administration of paclitaxel over 24 hours, which is necessary to reduce the neurotoxicity when paclitaxel is combined with cisplatin, is inconvenient and, if it requires hospitalization, expensive. Use of IP catheters is not routine in many oncology practices, and is associated with a number of complications, as discussed above. In the report by Armstrong et al. (431), only 42% of patients on the IP arm received the six planned cycles of intraperitoneal therapy due either to cisplatin related toxicities or catheter problems. It has been suggested that icodextrin, which has a clinical record of use as an exchangeable peritoneal dialysis solution in humans, can reduce adhesion formation in a rat model of intraperitoneal chemotherapy (433). A trial using intraperitoneal 5-FU in 4% icodextrin in patients with colon cancer showed the regimen to be safe, but problems with peritoneal access still occurred in 20% of patients (434).

Second, all of the large randomized studies used cisplatin in both the intraperitoneal and intravenous arms, whereas carboplatin, which is less toxic and easier to administer, has become the standard intravenous platinum agent in the treatment of ovarian cancer. It has even been suggested, based on nonsignificant trends in two of the randomized trials comparing cisplatin/paclitaxel to carboplatin/paclitaxel, that the cisplatin/paclitaxel regimen is inferior to carboplatin/paclitaxel in optimally debulked patients, and that IP therapy must be compared to intravenous carboplatin/paclitaxel before it

TABLE 25.15

SELECTED RANDOMIZED TRIALS OF INTRAPERITONEAL VERSUS INTRAVENOUS CHEMOTHERAPY IN OPTIMALLY DEBULKED OVARIAN CANCER

Author (year)	N	Regimens	Median PFS	Median OS	Comments
Alberts (1996) (Ref 425)	546	IV cyclophosphamide 600 mg/m ² plus IP cisplatin 100 mg/m ² × 6 vs. IV cyclophosphamide 600 mg/m ² plus IV cisplatin 100 mg/m ² × 6	N/A	49 mo vs. 41 mo <i>p</i> = 0.02	<2 cm residual disease permitted; 58% of patients in both groups completed 6 cycles of cisplatin
Markman (2001) (Ref 432)	462	IV carboplatin AUC 9 × 2 followed by IV paclitaxel 135 mg/m ² /24 hr plus IP cisplatin 100 mg/m ² × 6 vs. IV paclitaxel 135 mg/m ² /24 hr plus IV cisplatin 75 mg/m ² × 6	28 mo vs. 22 mo <i>p</i> = 0.01	63 mo vs. 52 mo <i>p</i> = 0.05	18% of patients on IP arm got ≤2 cycles of IP therapy
Armstrong (2006) (Ref 431)	416	D1 IV paclitaxel 135 mg/m ² /24 hr D2 IP cisplatin 100 mg/m ² D8 IP paclitaxel 60 mg/m ² vs. D1 IV paclitaxel 135 mg/m ² /24 hr D2 IV cisplatin 75 mg/m ²	24 mo vs. 19 mo <i>p</i> = 0.027	67 mo vs. 50 mo <i>p</i> = 0.0076	49% of patients received ≤3 cycles of IP therapy

Note: IP, intraperitoneal; OS, overall survival; PFS, progression-free survival; mo, months.

can be adopted (435). Although intraperitoneal carboplatin can be safely used and appears to have favorable pharmacokinetics (pharmacologic advantage combined with good systemic drug exposure), there is no clinical trial evidence that it will provide the same survival benefits as intraperitoneal cisplatin.

Finally, the heterogeneity and toxicity of the intraperitoneal regimens used have left some confusion as to what the most important elements of the ideal IP therapy regimen are, and which could be modified to improve safety and tolerability while maintaining efficacy. For example, the Markman et al. trial used two cycles of carboplatin AUC 9 (as “chemical debulking” prior to starting intraperitoneal therapy), which resulted in significant hematologic toxicity and difficulty delivering the IP regimen (432). The Armstrong et al. trial incorporated both IP cisplatin and IP paclitaxel. Despite these uncertainties, a potential 1-year survival advantage is certainly meaningful, and the option of intraperitoneal therapy should be discussed with healthy patients who have optimally debulked ovarian cancer.

It is possible that intraperitoneal therapy might benefit women other than those with initially optimally debulked disease. It is of note that the Alberts trial (perhaps the cleanest test of intraperitoneal therapy in that all variables were the same in both arms except the route of cisplatin administration) permitted accrual of women with up to 2 cm of residual disease. Benefit of therapy was not influenced by extent of residual disease (*p* = 0.93 for interaction of treatment and residual disease, microscopic vs. ≤0.5 cm vs. >0.5 to 2 cm) (425). Other groups that might stand to benefit are those with an excellent response to intravenous treatment after three cycles or those who have only minimal disease remaining after interim debulking surgery. However, no randomized trials have addressed these scenarios. One small trial did test IP cisplatin as consolidation therapy. The EORTC randomized women with a pathologic complete remission to front-line platinum-based therapy to no further therapy versus four cycles of intraperitoneal cisplatin at 100 mg/m². The trial closed due to poor accrual with less than half of its planned accrual. After a median follow-up of 8 years, the hazard rates for progression-free survival (PFS) and overall survival (OS)

were 0.89 (95% CI, 0.59 to 1.33) and 0.82 (0.52 to 1.29). These results were felt to be suggestive of a treatment benefit but insufficient to change practice (436).

Use of Neuroprotectants. As discussions of cisplatin and paclitaxel above make obvious, neurotoxicity is one of the most bothersome long-term side effects of current therapy for ovarian cancer. Reporting of neurotoxicity is notoriously variable, depending both on the scale used and the awareness of the investigator. The intraperitoneal regimen (IV paclitaxel plus IP paclitaxel plus IP cisplatin) used by Armstrong et al. reported 19% grade 3/4 neurotoxicity. In GOG 132 the rate of grade 3/4 neurotoxicity for six cycles of carboplatin/paclitaxel chemotherapy was 5% (10% grade 2). A group of Italian investigators reported on long-term neurologic evaluations on 120 ovarian cancer patients treated with a front-line carboplatin AUC 5/paclitaxel 175 mg/m²-based regimen. There was a 15% chance of residual neurotoxicity 6 months after the completion of chemotherapy (437). One potential neuroprotectant commercially available is amifostine (WR-2721). Two hundred forty-two patients with advanced ovarian cancer were randomized to receive six cycles of cyclophosphamide (1,000 mg/m²) plus cisplatin (100 mg/m²) with or without amifostine (910 mg/m² 15 minutes prior to chemotherapy). There was a clear reduction in neutropenia requiring hospitalization (*p* = 0.005) and in nephrotoxicity (defined as a ≥40% reduction in creatinine clearance, *p* = 0.004). However, the reduction in neurotoxicity, while statistically significant, was less impressive; 29 versus 35 patients experienced grade 2 neurotoxicity and 9 versus 15 experienced grade 3 neurotoxicity. The trial was not powered to detect any potential loss of anti-tumor activity; however, median survival time was the same (31 months) in both arms. Infusion-related hypotension was the major toxicity observed (438).

No adequately sized studies have studied amifostine with paclitaxel-based therapy or with the lower amifostine doses currently used (which produce less hypotension). However, a placebo-controlled, randomized phase 2 study in which patients were treated with either carboplatin/paclitaxel or carboplatin/paclitaxel/epirubicin found worse nausea and vomiting with

amifostine (740 mg/m²); Common toxicity criteria (CTC) graded sensory neuropathy was improved with amifostine, but there were almost no differences in patient-reported motor or sensory symptoms (439). Other potential neuroprotectants, such as vitamin E or glutamine, have not been tested in the setting of ovarian cancer. Early identification of neurotoxicity and dose reduction or switching to a less neurotoxic agent remain the best-established ways to manage this side effect.

Prolongation of Primary Therapy/Consolidation/Maintenance. Many women with ovarian cancer have an excellent response to first-line chemotherapy, but most will nonetheless relapse and die of their disease. Approximately two thirds of patients with advanced ovarian cancer will achieve a clinical complete remission following chemotherapy, that is, have no evidence of disease on physical examination or in radiographic studies together with a serum CA-125 in the normal range. One third of all patients with advanced ovarian cancer will be free of disease at a second-look laparotomy following primary cisplatin-based therapy. The most important prognostic factor that influences the likelihood of achieving a surgically confirmed complete remission is the volume of disease at the time chemotherapy was initiated. Patients who have suboptimally debulked disease have a four- to fivefold decreased likelihood of achieving a complete remission as compared to those patients who were optimally cytoreduced. In addition, patients with large-volume disease who do achieve a complete remission have a higher likelihood of a subsequent relapse than do patients with small-volume disease (440). Among all patients who have a surgically documented complete remission, at least 50% will recur and die of their disease.

Further therapy after a clinical complete remission would clearly be warranted for many women if an effective treatment could be found. However, no trials of consolidation or maintenance therapy have produced any survival benefit to date.

Whole Abdominal Radiotherapy After Chemotherapy. Nonrandomized data have suggested that consolidative radiotherapy may be curative in a small percentage of patients with small-volume residual disease after primary chemotherapy. For example, Petit et al. recently reported on long-term (median 14 years) follow-up of consolidative whole abdominal radiotherapy (WAR) in a series of 106 stage III patients who had no (33%) or less than 1 cm (46%) residual disease after primary therapy, or who were debulked to less than 1 cm at the time of second-look surgery (21%) (441). Radiation was stopped for acute toxicity in 11 patients. Long-term toxicities included radiation enteritis in 21 patients with 9 patients requiring surgery for bowel obstruction. Four deaths were related to enteritis complications. Overall survival at 5 and 10 years was, respectively, 53% and 36%.

Several very small, randomized trials have examined the role of consolidative WAR after primary chemotherapy. Bruzzone et al. (442) randomly assigned patients who had minimal or no residual disease after chemotherapy to WAR or three more cycles of chemotherapy. The study was stopped after only 41 patients had accrued, because disease progression had been observed in 55% of patients treated with radiation versus 29% of those treated with additional chemotherapy ($p = 0.08$). Lambert et al. (443) randomized 117 patients with residual disease of 2 cm or less after secondary cytoreduction to WAR or five additional courses of carboplatin. There was no statistical difference in disease-free or overall survival between the two arms. Kapp et al. randomized 64 women with a complete clinical response after primary surgery and chemotherapy to WAR versus no further therapy (444). No second-look laparotomy was performed. Patients who had WAR had a significantly better 5-year survival than patients who had chemotherapy alone (59% vs. 33%, $p = 0.03$). Most recently the Swedish-Norwegian Ovarian Cancer Study Group (445) randomly assigned 98 patients who received four courses of cisplatin/anthracycline

chemotherapy and had a pathologic complete response (CR) at second-look surgery to no further therapy, continued chemotherapy with cisplatin/anthracycline to ten courses total, or whole abdominal radiotherapy. Progression-free survival was significantly better (5-year PFS, WAR = 56%, chemotherapy = 36%, control = 35%, $p = 0.032$) and overall survival trended toward better in the group receiving WAR. No benefit for WAR was observed in a separate group of patients with microscopic residual disease, who were randomized to chemotherapy versus WAR. Late grade 3 bowel complications occurred in 10% of patients receiving WAR. In general, the studies of abdominopelvic radiotherapy after chemotherapy have reported higher complication rates than studies of abdominopelvic radiotherapy alone, which has dampened enthusiasm for further investigation of consolidative WAR (446). It has been suggested that there is cross-resistance between platinum chemotherapy and irradiation, as human ovarian cancer cell lines with acquired resistance to cisplatin develop relative radiation resistance *in vitro* (447). As discussed above, a randomized trial conducted by the GOG of ³²P versus observation after pathologic complete response to primary therapy was negative (341).

Consolidative/Maintenance Chemotherapy. Three small, randomized trials of prolonged duration of primary therapy have been conducted. Investigators at Memorial Sloan-Kettering Cancer Center in New York randomized 78 women to five versus ten cycles of CAP (cyclophosphamide, doxorubicin, cisplatin) chemotherapy (448). Danish investigators randomized women to 6 versus 12 cycles of CAP chemotherapy (449). North Thames investigators randomized women to five versus eight cycles of single-agent platinum therapy (450). None of these studies showed a survival benefit, and all showed more toxicity with prolonged therapy.

Like use of a third cytotoxic agent in front-line combination therapy, use of a third cytotoxic agent for consolidation therapy has not proven effective to date. Two large trials of four cycles of consolidative topotecan after primary chemotherapy have both been negative. A randomized phase 3 trial performed by the AGO-OVAR and the GINECO together randomized 1,308 patients with previously untreated FIGO stage IIB-IV ovarian cancer to six cycles of carboplatin/paclitaxel followed by surveillance or four cycles of topotecan (1.25 mg/m² IV days 1 to 5 on a 3-week schedule) (451). Complete response was not required to proceed to topotecan therapy. There was no difference in median PFS (18.2 months for topotecan vs. 18.5 months for control) or OS (43.1 months for topotecan vs. 44.5 months for control). A similar phase 3, multicenter Italian trial (452) randomized 273 patients to observation versus topotecan 1.5 mg/m² days 1 to 5 every 21 days for four cycles after primary carboplatin/paclitaxel chemotherapy. PFS did not differ between the treatment arms (18.2 months for topotecan vs. 28.4 months for controls). Consolidation therapy with epirubicin also failed to improve survival in patients who achieved a clinical complete remission following platinum-based induction therapy (453). As discussed above, the EORTC tested intraperitoneal cisplatin in women with a pathologic complete remission and found hazard rates for PFS and OS relative to observation of 0.89 and 0.82 (436).

Two small prospective trials of high-dose consolidation therapy with hematopoietic stem cell support have both been negative. In the larger trial a collaboration of French and Italian investigators randomized women in remission after front-line chemotherapy to either three further cycles of conventionally dosed carboplatin or a single high-dose cycle (carboplatin 1,600 mg/m² plus cyclophosphamide 6,000 mg/m²) with peripheral stem cell support. No survival benefit was observed for the women receiving high-dose therapy (453a, 453b).

The most promising trial of maintenance therapy to date was a Southwest Oncology Group (SWOG)/GOG trial randomizing women in clinical complete remission to either 3 or 12 cycles of

FIGURE 25.36. Progression-free survival of patients treated with either 3 monthly cycles or 12 monthly cycles of paclitaxel as maintenance therapy of advanced-stage ovarian cancer who were in a clinical complete remission after platinum/paclitaxel-based chemotherapy.

intravenous paclitaxel 175 mg/m² every 4 weeks (454). The trial was halted by its data and safety monitoring board after a planned interim efficacy analysis at a point when there was a statistically significant improvement in time to progression but no difference in overall survival between the treatment arms (PFS 28 vs. 21 months, one sided $p = 0.0035$) (Fig. 25.36). Because insufficient patients to detect a survival difference had been randomized at the time the study was stopped ($n = 262$), and because patients receiving 3 cycles of therapy were allowed the option of crossing over to 12 cycles, a survival comparison will not be possible. In addition, the neurotoxicity observed was so substantial, even though patients with >grade 1 neurotoxicity were excluded from the trial, that the dose of paclitaxel on the study had been modified to 135 mg/m² every 4 weeks. However, not very many patients had accrued to this dose at the time of study closure, and they were not included in the analysis, so the effect of this dose reduction on therapy efficacy is uncertain. An unplanned retrospective subgroup analysis suggested a trend toward survival benefit in the group of patients who started maintenance therapy with a CA-125 level of less than ten (455). A preliminary report on results of an Italian trial randomizing women in complete remission after front-line therapy to observation or six cycles of paclitaxel 175 mg/m² every 3 weeks showed no benefit in either progression-free or overall survival (456). The GOG is attempting to confirm the beneficial results it observed with a larger study randomizing women after clinical complete remission to one of three arms: no further therapy, paclitaxel 135 mg/m² every 4 weeks for 12 cycles, or Xyotax (a microparticle-bound paclitaxel) 135 mg/m² every 4 weeks for 12 cycles. This trial currently has overall survival as the endpoint.

Maintenance With Noncytotoxic Agents. Noncytotoxic agents such as interferon, a monoclonal antibody targeting CA-125 (oregovomab) (457), radioimmunoconjugates, and matrix metalloproteinase inhibitors have also all been tested in randomized trials with no survival benefit. The SWOG randomized 70 evaluable patients to six doses of 50 million IU of intraperitoneal interferon alpha versus observation after pathologic complete remission to primary therapy. There was no difference in progression-free survival between the two groups (435). A trial of subcutaneous interferon was also negative (458). No improvement in progression-free or overall survival was observed following a single intraperitoneal administration of 90Y-conjugated antimucin antibody in a large phase 3 trial, although intraperitoneal recurrences were decreased (459,460). Other current maintenance trials include a trial being conducted by the EORTC of the epithelial growth factor receptor (EGFR) tyrosine kinase inhibitor, erlotinib, and the ongoing trials of maintenance anti-VEGF monoclonal antibody described above.

Implications of Clear Cell and Mucinous Histology

It has long been realized that ovarian cancers of serous histology appear to be more chemotherapy sensitive than other histologic subtypes. For example, in an analysis of multiple different agents used in published phase 2 trials, serous histology (vs. all other histologies) was reported to be one of the most important factors predicting a response to second-line therapy (461). A review of all patients entered into advanced-stage GOG ovarian cancer trials from 1976 to 1982, when response was commonly surgically assessed, revealed no negative second-look laparotomies among women with clear cell or mucinous histology (462).

Clear Cell Carcinomas

Advanced clear cell carcinomas are unusual in the United States. Clear cell carcinoma is more common in Japan, where it accounts for about 20% of epithelial ovarian carcinomas (463). Women of Japanese descent living in the United States continue to have a higher incidence of clear cell carcinoma than is found in Western countries or other Asian countries (464). Even in Japan, early-stage clear cell carcinoma is more common than advanced-stage clear cell carcinoma; in one review, stage I made up 39% of clear cell disease, stage II 13%, stage III 30%, and stage IV 6% (465). As discussed above (Adjuvant Therapy of Early-Stage Disease), the implications of clear cell histology in early disease are not clear; in some reports it seems to portend a high risk of recurrence, and in others it appears to have little prognostic significance. However, it has become increasingly clear that advanced-stage clear cell tumors, which make up only a small percentage of advanced-stage ovarian cancers in the United States, may not respond well to platinum chemotherapy. As early as 1996, Goff et al. reported that 52% of stage III clear cell tumors of the ovary versus 29% of serous tumors progressed clinically while on primary platinum chemotherapy (466). Sugiyama et al. reported a response rate for clear cell carcinomas to primary platinum-based therapy of only 11% (467). The Hellenic Cooperative Oncology Group (331) reviewed patients with advanced clear cell carcinoma of the ovary treated on protocols from 1987 and 2003 ($n = 35$), and compared them to serous tumors treated on the same trials. Response rates were 45% versus 81% ($p = 0.008$) and median survival was 25.1 months versus 49.1 months ($p = 0.141$). The difference in response was significant; the difference in survival was not, and not all series have reported inferior survival even in advanced stages of disease (468). Ho et al. reported that patients with pure advanced clear cell carcinoma had a much worse prognosis (median survival, 11 months) than patients with mixed clear cell and other histologic types (median survival, over 48 months) (469). Similar results have been reported in the setting of recurrent disease. Investigators from M. D. Anderson published a retrospective review of 51 patients treated at their institution for recurrent clear cell carcinoma. Among those with platinum-sensitive disease, only 2 (9%) of 22 patients had a partial response to retreatment with carboplatin and paclitaxel; none of 29 patients given second-line therapy for platinum-resistant disease responded (470).

Unfortunately, the realization that these tumors may be resistant to platinum does not automatically indicate a superior option. Some authors have proposed that clear cell carcinomas have a low proliferation rate, and therefore general resistance to chemotherapy (471). However, Cloven et al. reported that human clear cell tumors (at variable times during therapy) sent for commercial testing for drug resistance had lower rates of extreme drug resistance to paclitaxel, doxorubicin, and cyclophosphamide than papillary serous

tumors (472). An *in vitro* study (473) suggested that paclitaxel and irinotecan were effective against three of five clear cell cancer cell lines, whereas cisplatin was effective against only one. Shimizu et al. reported that irinotecan/mitomycin C chemotherapy produced a response rate of 52% against platinum-resistant clear cell and mucinous carcinomas (473a). Some (463,469) but not all (465) authors have suggested that the response rate might be higher with taxane-containing regimens; all the series are exceedingly small. A multinational phase 3 study for stage I-IV clear cell carcinoma of the ovary has been launched by the Japanese Gynecologic Oncology Group (JGOG). Women are randomized to therapy with either carboplatin/paclitaxel or cisplatin/irinotecan.

Interestingly, multiple reports suggest that women with clear cell carcinomas are more likely to have a thromboembolic event. Goff et al. noted that 42% of patients with stage III clear cell tumor had deep venous thrombosis (DVT) or pulmonary embolus (PE) versus 18% of patients with serous tumors (466); another more recent retrospective study reported that 27.3% of patients with clear cell carcinoma had a DVT or PE versus only 6.8% of patients with other histologies (474).

Molecular studies suggest a different profile for clear cell carcinomas. For example, they have been reported to have high levels of hepatocyte nuclear factor-1 beta (HNF-1 beta) (475) and high levels of ABCF2, which belongs to the ATP-binding cassette gene superfamily, and is highly expressed in nonresponders to chemotherapy (476). In addition, gene expression profiling suggests that clear cell tumors have a very different profile than other epithelial ovarian cancers, one which could not be statistically distinguished from clear cell carcinomas originating in other tissues, including endometrium and kidney (477).

Mucinous Tumors

Early-stage mucinous tumors tend to be low grade and have a good prognosis. Advanced-stage mucinous tumors are uncommon in the United States. They respond poorly to chemotherapy and are associated with a short survival. Investigators from the Royal Marsden Hospital reviewed all patients with stage III or IV mucinous epithelial ovarian cancer ($n = 27$, 19 with measurable disease) treated with first-line platinum-based therapy at their unit between 1992 and 2001 and compared them to controls with nonmucinous epithelial ovarian cancer (478). The response rate for patients with measurable mucinous cancer was 26% with one complete response; 63% of patients experienced disease progression while on platinum-based chemotherapy. The response rate for the controls with measurable disease was 65% ($p = 0.009$ for response). Median overall survival was 12 months versus 37 months ($p < 0.001$). Specific trials for patients with advanced-stage mucinous tumors, possibly using chemotherapeutic agents directed against gastrointestinal tumors, are being considered by the GOG.

Primary Peritoneal Carcinoma

As described in the section above on pathology of serous carcinomas, serous carcinomas may present as diffuse carcinomatosis of the peritoneal cavity with minimal or no involvement of the ovaries or fallopian tubes ("small ovary syndrome") and may be seen in women who have had prior surgical removal of their ovaries and fallopian tubes. This presentation is referred to as primary peritoneal serous carcinoma (PPSC). Up to 18% of laparotomies performed for presumed ovarian carcinoma are felt to be PPSC on final pathology review (479). CA-125 levels will be elevated in most patients with PPSC. In the older literature these were often misclassified as peritoneal mesotheliomas. Typically, mesotheliomas will express mesothelial markers such as calretinin or cytokeratin 5/6, which are rarely

expressed in PPSC; CA-125 and S100 are common in PPSC and are rarely expressed on mesothelioma (480). The epithelium of the ovary and the peritoneal lining are histologically the same, and factors that induce ovarian epithelium to undergo malignant degeneration may have the same effect on the peritoneal lining. As discussed above, women who carry the *BRCA1* mutation are at increased risk for the development of primary peritoneal cancer (481). The risk of primary peritoneal carcinoma for *BRCA1* carriers after prophylactic oophorectomy is unknown but is estimated to be from 1% to 10% (482).

The GOG performed a retrospective case-control study of patients with PPSC and suboptimal cytoreduction, comparing them to patients with ovarian carcinoma with suboptimal cytoreduction. Both groups were treated with cisplatin and cyclophosphamide. Median overall survival and disease-free interval of the two groups appeared very similar (483). Current treatment recommendations for women with PPSC are the same as for women with stage III ovarian carcinoma, and women with PPSC are eligible for most ovarian cancer clinical trials. Peritoneal cancers with nonserous histologies similar to other subtypes of ovarian cancer (mucinous, endometrioid) may also be encountered. They are less common and optimal therapy is not known.

Fallopian Tube Carcinoma

Series of results of chemotherapy for advanced-stage fallopian tube carcinoma are small. It has recently been suggested that many serous tumors thought to be of ovarian or primary peritoneal origin may, in fact, be of fallopian tube origin. In general, advanced-stage fallopian tube carcinomas are treated in the same manner as advanced-stage ovarian cancers and have similar survival. A recent retrospective case-control study reported by Moore et al. identified 96 women with stage IA to IV fallopian tube carcinoma and two ovarian carcinoma controls for each patient with fallopian tube cancer matched by age, stage, and residual disease ($n = 190$). All patients underwent primary surgery with lymph node dissection followed by platinum/taxane combination chemotherapy. Forty-six of the women with fallopian tube cancer had early-stage (I/II) disease. Five-year overall survival for patients with early-stage fallopian tube carcinoma was 95% and for patients with early stage ovarian cancer it was 81%. Among women with advanced-stage (III/IV) disease, median time to recurrence and overall survival were 8.7 months and 32 months for patients with fallopian tube cancer and 7.2 months and 30 months for women with ovarian cancer (484).

Second-Look Laparotomy and Laparoscopy

In the past, patients with advanced ovarian cancer frequently underwent abdominal explorations after induction chemotherapy to assess whether or not residual disease remained. However, although surgery is the most accurate way to assess the response to therapy, there is no evidence that any type of routine surgical procedure after initial chemotherapy prolongs overall survival. The term *second-look laparotomy* has been incorrectly used to refer to several distinctly different types of surgery. These include secondary operations to resect known residual or recurrent disease and secondary operations performed for relief of cancer-related symptoms, such as intestinal obstruction. In current usage, the term should be reserved for a systematic surgical exploration in asymptomatic patients who have completed a planned course of chemotherapy for ovarian cancer.

In 1966, during an era when single-agent alkylating therapy for advanced ovarian cancer was standard, Rutledge and Burns (485) reported on 288 patients treated with melphalan and asked the question: Should laparotomy be used more often when a patient has an unusually good response to determine whether the drug should be discontinued? In their report, 28 patients underwent surgery for this reason; 12 had no tumor detected. The investigators felt that “good response to the drugs is the reason for laparotomy,” but pointed out that patients with a negative re-exploration may relapse, as did two in their series (486). Interest in second-look laparotomy as a means of determining when chemotherapy could be discontinued was stimulated during the 1970s, when reports began to appear linking the long-term use of alkylating agents to the development of acute leukemia (486,487).

With the introduction of platinum-based chemotherapy in the mid to late 1970s and the use of aggressive primary debulking, up to 50% of patients treated with chemotherapy for advanced cancer had no clinically detectable tumor at the completion of their chemotherapy. Since it was known that many of these women harbored occult residual cancer, a number of investigators tested noninvasive methods of detecting such disease. Imaging techniques such as CT, sonography, MRI, and PET are generally unable to detect intraperitoneal tumor masses smaller than 1 cm and, in fact, may miss larger masses (488). Some investigators (489) have suggested that the cytologic analysis of peritoneal fluid obtained by culdocentesis may be a means of assessing response in women under treatment for ovarian cancer. The accuracy of this technique in detecting residual disease is quite low, however. In a study of 96 women re-explored for ovarian cancer who had multiple cytologic washings taken at the time of laparotomy, only 34% of patients with biopsy-proven gross intraperitoneal disease had positive washings (490). In patients with only microscopic disease, 28% had positive washings.

Several groups have used laparoscopy as an alternative to second-look laparotomy. In 1981, Berek et al. (491) reported 119 consecutive laparoscopic examinations performed in 57 patients. Fourteen percent of their patients had major complications requiring laparotomy, most of which involved bowel perforation. At the NCI, laparoscopy was routinely used to assess response to chemotherapy (492). In their series, no patient required a surgical exploration because of a laparoscopy complication. In 66 restaging laparoscopies, residual tumor was found in 33 (50%) and provided the only evidence for disease in 24 cases (36%). These latter patients were spared an unnecessary second-look laparotomy. However, if the laparoscopy was negative, residual disease was documented in 55% of patients at laparotomy.

More recently, the group from the Memorial Sloan-Kettering Cancer Center has reported their experience with the use of laparoscopy for second-look evaluation in 150 patients with advanced ovarian cancer following chemotherapy (493). The majority of patients (87%) had stage III or IV disease at initial surgery; the remainder had stage II disease or were unstaged. Eighty-two patients (54%) had optimal cytoreduction at the time of their initial surgery. All patients had completed primary chemotherapy and were clinically disease-free based on imaging studies and CA-125 levels at the time of second look. Sixty-nine patients (46%) were found to have pathologically negative second looks; thus, the rate of positive second-look evaluations was 54%. The rate of conversion to laparotomy was 18 of 150 (12%). In three cases, this was secondary to bowel injury; one patient sustained a bladder injury; the remainder of conversions to laparotomy was for secondary cytoreduction. There was only one case in which the patient was found to have extensive adhesions and laparoscopy was abandoned. The overall rate of major complications was 2.7%. Although long-term follow-up is not available, the rate of negative evaluations and the rate of

recurrences in patients with negative second looks appear to be equivalent to those described in studies of second-look assessment by laparotomy.

Even with a normal serum CA-125 level, a significant number of patients in clinical complete remission will have residual disease at laparotomy. Rubin et al. (494) measured CA-125 levels at the time of secondary surgery in 96 ovarian cancer patients, all of whom had had documentation of an elevated CA-125 level at the time when the tumor was first diagnosed and were therefore “marker positive.” Persistent disease was found in 62% of patients who had a normal CA-125 level at the time of surgery. These findings have been confirmed in other studies (495). Consequently, if the primary purpose of the second-look laparotomy is to determine whether the patient has residual ovarian cancer, an elevated CA-125 level makes such a procedure unnecessary.

A second-look laparotomy itself is intended as a thorough re-exploration of the peritoneal cavity and selected retroperitoneal structures. Immediately prior to surgery, a pelvic examination under anesthesia is performed. Cystoscopy and proctoscopy may be useful in symptomatic patients or in those with prior tumor involvement of the bladder or lower gastrointestinal tract.

The abdomen should be entered through a generous vertical excision, extending from the pubic symphysis to well above the umbilicus. If obvious tumor is found, frozen-section confirmation should be obtained. The goal of the operation becomes removal of as much tumor as possible. If no obvious tumor is found, the surgeon must undertake a meticulous, systematic search for areas of occult tumor. Saline washings are obtained from multiple sites within the peritoneal cavity, usually including the pelvis, both paracolic gutters, and the undersurfaces of both hemidiaphragms. All adhesions should be lysed and portions submitted for histologic analysis since adhesions often form at the site of tumor nodules. The upper abdomen should be explored carefully, with any suspicious areas biopsied. The residual omentum should be palpated, as should the aortic lymph nodes. The intestines must be carefully examined. A thorough exploration of the pelvic cavity is performed. Throughout this evaluation, particular attention should be paid to areas where residual disease was left at the initial operation. If suspicious areas are identified, frozen-section confirmation should be obtained and areas of tumor resected as completely as possible.

If no tumor is identified, a series of biopsies is performed from areas that may harbor occult disease. The stumps of the infundibulopelvic ligaments, which carry the ovarian blood and lymphatic supplies, should be identified in the retroperitoneum and biopsied. Other surgical pedicles in the pelvis should be examined and biopsied if suspicious. If the uterus was not removed at the initial operation, hysterectomy should be performed. Peritoneal biopsies should be taken from multiple sites within the abdominal cavity, including the pelvis, paracolic gutters, and both hemidiaphragms. Some have suggested the use of a laparoscope or sterile proctoscope to facilitate inspection of the diaphragms. Any remaining areas of omentum should be removed. Many surgeons remove the appendix if present. Para-aortic and pelvic lymph nodes should be thoroughly sampled. A second-look operation at which no tumor is identified will take several hours and will produce 20 to 30 individual biopsy specimens.

In previous years, there have been many published series on second-look laparotomy. Table 25.16 summarizes several reports in which about 55% of the patients with no clinical evidence of disease were found to have cancer present at re-exploration (496). These findings are a clear indication of our current inability to identify persistent cancer by noninvasive means.

Several clinical and histologic factors have been shown to relate to the likelihood of tumor being found at the time of second-look laparotomy. The most important factors are stage and the volume of tumor remaining following initial cytoreductive

TABLE 25.16**FINDINGS AT SECOND-LOOK LAPAROTOMY FROM 71 COMBINED SERIES**

Finding	Number	%
No tumor found	2,417	47
Tumor found	2,773	53
Total	5,190	100

surgery. As shown in Table 25.17, patients with stage III and IV disease had a substantially lower proportion of negative second-look operations than did those with stage I and II, 33% versus 70% to 80%, respectively.

The amount of residual disease remaining following the initial operation for ovarian cancer is also a major determinant of the likelihood of disease being found at the time of second-look laparotomy. Table 25.18 summarizes pooled data on 1,797 patients, providing information on the relationship of the extent of residual disease following primary surgery to findings at second look. Patients with suboptimal residual disease after primary surgery had only a 23% likelihood of a negative second look as compared to 50% for those with optimum residual and 72% in those with no known residual tumor. Many series have included stage I patients in their analysis of the effect of residual disease on findings at second-look laparotomy. As all stage I patients would be included in the no-residual-disease group, this would account, in part, for the improved prognosis of this group. Even considering this bias, there seems to be a strong correlation between extent of residual disease and the likelihood of finding disease at re-exploration.

The histologic grade of the tumor, as distinct from the cell type, has been shown to be a significant prognostic factor, although it has been suggested that, in advanced-stage patients treated with platinum-containing chemotherapy, grade may be of less importance. Numerous series have correlated the surgical findings at a re-exploration with tumor grade (Table 25.19). Earlier series demonstrated a stronger relationship between grade and second-look findings, perhaps because more of the patients in these series were treated with chemotherapeutic regimens that did not contain platinum. Overall, women with poorly differentiated tumors seem to have a somewhat lower chance of having a negative second-look laparotomy, although

it should be remembered that these data are not controlled for other important prognostic variables, including stage and the amount of residual tumor.

Second-look laparotomy is a highly invasive diagnostic procedure that results in significant expense, discomfort, and time in the hospital for the patient; however, it is associated with little serious medical morbidity. Although many reports on second-look surgery have not discussed complications, among seven major series published since 1980 that specifically report complications, no deaths were seen in 682 operations (376). The most common complications were infections of the surgical wound (6.3%), the urinary tract (5.6%), and the lungs (2.8%).

The finding of large-volume residual tumor carries a grave prognosis. In some series, when survival is reported separately for patients with gross tumor, approximately 80% died within 3 years of second-look laparotomy. Patients who have only microscopic disease detected at second look fare considerably better. Copeland et al. (497) reported on 50 patients with microscopic disease followed for a median of 40 months from second look. Survival rates were 96% and 71% at 2 and 5 years, respectively.

Because even the most carefully performed second-look operation may miss microscopic areas of tumor, and because ovarian cancer may occasionally spread beyond the areas assessed at surgery, a negative second-look operation is not synonymous with cure of cancer. Papers reporting the incidence of recurrence following negative second-look laparotomy have often included patients treated with different chemotherapeutic regimens for variable durations and followed for relatively short periods of time. This has made the true incidence of and the risk factors for recurrence following negative second-look laparotomy difficult to determine. In an

old review that included 12 reports published from 1980 to 1986, it was calculated that the overall recurrence rate was 18%, including 10.9% in stages I and II and 26% for patients with stage III or IV disease (316). In 1988, Rubin et al. (498) reported a 50% risk of recurrence following a negative second-look laparotomy in patients treated with platinum-based chemotherapy. A multivariate analysis demonstrated that stage, histologic grade, and extent of residual disease remaining after primary cytoreduction were significant predictors of recurrence following a negative second look.

These results have been substantiated in the multicenter setting. In the GOG trial of intraperitoneal ³²P versus observation after negative second-look laparotomy, 64% of patients relapsed at a median follow-up of 63 months (341); in the EORTC trial of intraperitoneal cisplatin versus observation after negative second-look laparotomy, 52% of patients had relapsed with a median follow-up of 8 years (436).

There is presently no evidence that any type of additional therapy can improve survival in patients who do achieve a surgically confirmed complete remission, or that introducing further treatment earlier for patients who have residual disease without clinical signs or symptoms is of benefit. There is also no evidence that second-look laparotomy *per se* is a therapeutic procedure (499). Although there are no prospective trials in which patients in a clinical complete remission have been randomized either to a second-look operation or to medical follow-up, retrospective studies comparing the survival of patients who underwent a second-look laparotomy versus patients in whom a second-look was not performed have failed to show any difference in survival. Consequently, most gynecologic oncologists no longer consider second-look laparotomy a routine procedure in patients who achieve a complete remission.

An alternative to second-look laparotomy is second-look laparoscopy. A second-look laparoscopy is usually performed as a same-day procedure with patients being discharged home the day of surgery or 1 day postoperatively. With modern laparoscopic techniques, a second-look laparoscopy provides excellent visualization and access to the peritoneal and extraperitoneal spaces where ovarian cancer may be detected. The laparoscopic approach is associated with less operating time, fewer complications, less blood loss, fewer or less costly hospital charges, and shorter hospitalization than laparotomy. The majority of cases can be completed by the laparoscopic approach, with approximately 10% to 15% of cases requiring conversion to laparotomy to complete the procedure satisfactorily. If a second-look operation is planned, the laparoscopic approach should be considered as the initial step as it may provide all the necessary information and avoid the potential morbidity and hospitalization associated with the open approach.

Data from GOG protocol 158, comparing carboplatin and paclitaxel versus cisplatin and paclitaxel in optimal residual stage III ovarian cancer patients, have a bearing on the issue of second-look laparotomy (394). Although not randomly allocated to a second look, almost 400 patients (50%) in this study elected the procedure. Approximately half of them had no evidence of disease at second-look laparotomy. Patients with residual disease at the second look underwent a variety of treatments with the majority of patients receiving more systemic chemotherapy with paclitaxel and carboplatin. There was no difference in progression-free or overall survival between the patients electing second-look laparotomy and those declining the procedure and treated only at the time of clinical progression. The group with the pathologically documented complete remission had better overall survival than the group with residual disease at the second look. Consequently, the potential value of a second-look surgery to identify patients who could benefit from immediate treatment of residual disease was not substantiated in this study. Given the fact that many of these patients who had optimal residual disease following their initial surgery had

no disease or only small-volume disease found at the second look, relatively few, if any, would be expected to benefit from secondary cytoreduction during the operation. The usefulness of a second-look laparotomy to assess the results of therapy accurately in the setting of a clinical trial is unequivocal. However, in a nonclinical trial situation, there appears to be little justification for a second-look laparotomy merely to obtain prognostic information. If, on the other hand, therapeutic decisions will be based upon findings at second look, such a procedure may be justified. However, the patient must be aware that there is no evidence that any form of subsequent therapy has been shown to significantly prolong survival. These observations are consistent with the recommendations from the 1994 NIH Consensus Conference.

As second-look procedures are not commonly performed, recent reports have explored the prognostic use of stratifying CA-125 levels within the normal range at completion of chemotherapy. Juretzka et al. found that patients with a CA-125 of less than or equal to 12 U/mL at the completion of primary chemotherapy had median overall and progression-free survivals of 5.8 years and 2.8 years versus 3.7 years and 1.7 years for those with a CA-125 of greater than 12 U/mL (500).

Follow-Up of Patients in Remission

Most patients with ovarian cancer who enter a clinical complete remission have been followed with a combination of pelvic examinations, computerized abdominal tomograms, and monitoring of serum CA-125 levels. However, none of these has been shown to decrease symptoms or improve survival. Unlike the situation in general screening, rise in CA-125 after primary treatment for ovarian cancer is fairly specific, particularly if a confirmatory test is obtained. One older study reported the median lead time to clinical progression from a doubling of CA-125 above the upper limits of normal was 63 days (501). However, a significant proportion of patients (approximately 30%) may have lead times of greater than 6 months. How early salvage therapy should be started in this situation remains controversial. On the one hand, general belief is that treatment is likely to be more effective when disease burden is smaller. On the other hand, second-line chemotherapy is not curative, and many women, once started on salvage chemotherapy, will be on chemotherapy for the rest of their lives. In Europe, the Medical Research Council (OV-05) and the European Organization for the Research and Treatment of Cancer (EORTC 55955) have completed accrual to a phase 3 trial in which women with clinical response to first-line platinum therapy are followed with serial CA-125 levels and are randomized to initiate treatment at the time of biochemical recurrence versus waiting until the time of clinical evidence of recurrence. Results should help determine if there is any benefit to starting treatment earlier. In addition, the GOG has conducted a randomized trial comparing tamoxifen to thalidomide for the therapy of women who have CA-125 marker elevation but no measurable recurrence of disease; results should be available soon.

In premenopausal women with ovarian cancer, the initial staging and cytoreductive laparotomy results in a surgical castration. Consequently, these women frequently experience hot flashes, and those who do achieve long-term survival are at increased risk for osteoporosis. There is epidemiologic evidence (described above) that estrogen replacement therapy slightly increases the risk of developing ovarian cancer *de novo*, and antiestrogens, such as tamoxifen, may produce tumor shrinkage in a small subset of women with advanced ovarian cancer. However, one small randomized, controlled trial (502) has reported that estrogen replacement therapy has no detrimental effect on disease-free or overall survival in

women with ovarian cancer. The risks of deep venous thrombosis must be weighed against the symptomatic benefits. Short-term use of estrogen replacement therapy, particularly in symptomatic women who were premenopausal prior to their surgery for ovarian cancer, is reasonable.

Uses of CA-125 in Ovarian Cancer Treatment

As discussed above, the current usefulness of CA-125 for screening is limited, in part because many stage I ovarian cancers are not associated with an elevated serum level of CA-125, and a variety of nonmalignant conditions can elevate CA-125, particularly in premenopausal women. It is clear that CA-125 nadir after completion of primary therapy has prognostic value, but as there are no clinical interventions known to improve outcomes for those women who do not have a low nadir. CA-125 is widely used to monitor for cancer recurrence, as described above.

CA-125 may also be useful to monitor the effectiveness of second-line chemotherapy, decreasing the need for supplementing imaging. A number of studies have created CA-125 response definitions, such as 50% or 75% decline to qualify as a response (503). These have been compared to radiographic outcomes, suggesting that they may be similar to standard response criteria (504), may overestimate response compared to WHO criteria (505), or may be better at predicting prognostic outcomes compared to response evaluation criteria in solid tumors (RECIST) (506). In general these criteria have been developed to assist in providing clinical trial outcomes data, not as guidance for treatment of individual patients. False-positive rates (i.e., CA-125 is decreasing, but disease is clearly progressing) are 2% to 3% and false-negative rates (i.e., disease is responding but CA-125 is not decreasing) are about 20% with platinum/paclitaxel therapy (504). The false-positive rate would be higher if more minor decreases in CA-125 were used to indicate clinical benefit. Particular caution should be used in discontinuing a therapy prematurely based solely on rise in CA-125. Sabbatini et al. reported that only half of patients who eventually had a CA-125 decline with liposomal doxorubicin therapy had a decline prior to the second cycle of therapy (507). Removal of ascites will affect CA-125 levels; renal dysfunction does not (508).

TREATMENT OF PERSISTENT/ RECURRENT DISEASE

Secondary Cytoreductive Surgery

The benefit of secondary cytoreductive operations in ovarian cancer, at the time of second-look laparotomy or otherwise, has not been clearly demonstrated. Since about one half of patients who do undergo second-look laparotomy will have disease found, and in about 80% of these patients macroscopic disease will be present, approximately 40% of all patients having second-look laparotomy are candidates for secondary cytoreduction. Technically, secondary cytoreduction can be accomplished, with reported success rates ranging from 24% to 84% (509–512). There is less information available, however, on the effect of secondary cytoreduction on survival. Chambers et al. (513) concluded that residual tumor size following secondary cytoreduction did not influence survival after comparing 23 patients with microscopic residual disease and 6 with macroscopic disease. Luesley et al. (511) found no survival benefit in patients cytoreduced to microscopic disease compared to patients with residual macroscopic disease or small-volume gross residual disease. On the other hand,

Podratz et al. (514) reported an actuarial 4-year survival rate of 55% in patients with microscopic residual disease compared to 19% for those with macroscopic disease. In a series reported by Hoskins et al. (510), patients cytoreduced to microscopic residual disease at the time of the second look had a 5-year survival of 51%. This was similar to the survival of patients found to have only microscopic disease at the second look, and was significantly better than the survival in patients left with gross disease. Lippman et al. (515) examined the effect of extensive tumor resection at second-look laparotomy on survival for patients with >2 cm gross residual disease. Patients undergoing optimum resection (<2 cm residual tumor) had a significantly better survival than those undergoing suboptimal resection, suggesting that there is a survival benefit associated with optimal cytoreduction at second-look laparotomy.

Segna et al. (512) reported on 100 patients with advanced ovarian cancer initially treated with cisplatin-based therapy who were explored at the time of recurrence. Sixty-one percent of patients were left with optimal (<2 cm) disease after secondary cytoreduction. These patients had a significant improvement in their median survival compared with patients with suboptimal residual disease (27 vs. 9 months, $p = 0.0001$).

More recently, Salani et al. (516) reported on 55 patients who underwent secondary cytoreduction for recurrent epithelial ovarian cancer after a complete response to initial chemotherapy, at least a 12-month interval from initial diagnosis to recurrence, and in whom preoperative imaging studies showed five or fewer sites of recurrence. Complete macroscopic cytoreduction was achieved in 41 patients (74.5%). Independent predictors of overall survival were a diagnosis-to-recurrence interval of 18 months or greater, only one to two sites of recurrence on preoperative imaging, and no macroscopic residual disease after the secondary surgery.

In a recent review article on secondary cytoreductive surgery for recurrent ovarian cancer, Hauspy and Covens (517) examined 17 publications on the subject, and concluded that patients with favorable characteristics such as a long disease-free interval, good performance status, and a single or few small intra-abdominal sites of recurrence may benefit from secondary cytoreduction. It appears that, in patients whose tumors remain sensitive to chemotherapy, cytoreduction to small-volume disease prior to secondary chemotherapy can be of benefit. The GOG is currently conducting a trial assessing the value of secondary cytoreductive surgery in the setting of platinum-sensitive disease.

Second-Line Chemotherapy

Ovarian cancer that is resistant to primary chemotherapy or recurs at some point after primary chemotherapy is generally not curable. Nonetheless, a group of women with recurrent disease will have tumors that remain very sensitive to chemotherapy, and will clearly benefit from further treatment. Eisenhauer et al. analyzed results for 704 patients who had recurrence or persistent disease after primary platinum-based therapy and were treated on a variety of second-line chemotherapy trials (461). Independent predictors of response to second-line therapy were bulk of disease less than 5 cm, fewer sites of disease, and serous histology. Time to recurrence since primary therapy, when analyzed as a continuous variable, was not independently prognostic, and was closely correlated with tumor size. However, time to recurrence from completion of primary platinum-based chemotherapy is clinically readily available and quantifiable, and has come into common use as the primary means of predicting which patients are most likely to benefit from further treatment, in particular from further platinum-based treatment. In 1991 Markman et al. published results of an influential retrospective review of 72 patients who had

responded to an initial platinum-based therapy and were subsequently retreated with a platinum-based regimen (518). Response rate for women with a “platinum-free interval” of 5 to 12 months was 27%, for 13 to 24 months was 33%, and for over 24 months was 59%. Women who had a greater than 24-month interval with no therapy (as opposed to just no platinum-based therapy) had a 77% response rate with a 32% rate of surgical complete remission. The terms “platinum resistant” and “platinum refractory” are used somewhat variably in the literature, and are sometimes subdivided into “primary” and “secondary” platinum resistance, which may have different implications for survival or benefit to future therapies. Perhaps the most common usage is to define “platinum-resistant” tumors as those with a treatment-free interval of less than 6 months since previous platinum therapy. The GOG defines ovarian cancers with progression on platinum-based therapy as “platinum refractory,” those that recur less than 6 months after completion of platinum-based therapy as “platinum resistant,” and those that recur more than 6 months after completing treatment with a platinum-based regimen as “platinum sensitive” (short for “potentially platinum sensitive”). In general, tumors resistant to platinum are more resistant to any cytotoxic agent. Women with primary platinum-refractory therapy have a very poor prognosis, and response to any subsequent treatment is unlikely. Patients with a complete response to second-line platinum therapy will usually have a shorter time to recurrence after the second treatment regimen than after the first (519), and recurrent ovarian cancers eventually become resistant to platinum and all other therapies.

While the categories of “platinum sensitivity” are useful shorthand predictors of likelihood of response to further treatment, and are practical for designing and reporting clinical trials to estimate whether similar groups of patients are being studied across studies, they must be combined with clinical judgment in selecting therapy in individual cases. For example, a woman with stage I clear cell carcinoma that recurs with diffuse disease 7 months after completion of adjuvant chemotherapy probably had no response to treatment at all, and her cancer will likely be refractory to further therapy. On the other hand, a woman with suboptimally debulked stage IV serous carcinoma that responds completely to primary chemotherapy and has a rise in CA-125 five months later probably has chemotherapy-sensitive disease and is very likely to have some tumor shrinkage with a second line of treatment. The effects of prolonged consolidation therapy on future disease sensitivity have not been well studied, and are likely to vary with the agent used. Women who have tumors that repeatedly respond to a variety of therapies can sometimes be retreated with an agent to which their tumor had previously developed resistance after sufficient time has elapsed. For example, Kavanagh et al. published results describing 3 women with less than a complete response to primary platinum therapy who had a subsequent response to taxane therapy and over a year since their previous platinum therapy who then obtained a partial response to single-agent carboplatin (520). Finally, survival and sensitivity to treatment may sometimes be separable issues, and this should be taken into account in therapy planning. A few ovarian cancers (borderline tumors being one end of the spectrum) will be unresponsive to treatment but slow growing and associated with relatively longer survival.

General principles of treating recurrent disease include:

1. Although platinum-sensitive tumors are more sensitive than platinum-resistant tumors to any cytotoxic agent tested to date, most data suggest platinum compounds are the most active single agents in women with platinum-sensitive recurrent disease.
2. Platinum-based combinations produce superior response rates and progression-free survival compared with single-agent platinum therapy in women with platinum-sensitive

disease; the effect on overall survival is less certain. In women with platinum-resistant disease, combination therapy has never been shown to provide any benefit.

3. No agents except possibly taxanes have consistently produced response rates over 20% in women with platinum-resistant disease.
4. Treatment must be recognized as primarily palliative, and decisions about treatment regimens should include patient convenience and toxicity as well as efficacy.

Single Agents in Platinum-Sensitive Disease

Response rates in multicenter trials testing single-agent cisplatin or carboplatin in women with platinum-sensitive disease are 30% to 50% (521,522), and, as discussed above, tend to be higher in women with a longer platinum-free interval. Response rates in multicenter trials to single-agent paclitaxel, topotecan, or liposomal doxorubicin in platinum-sensitive disease have generally been in the range of 20% to 30% (521,523), although one randomized phase 2 study comparing single-agent paclitaxel to a cyclophosphamide, doxorubicin, cisplatin combination therapy in women with platinum-sensitive disease reported a response rate of 45% for single-agent paclitaxel (vs. 55% for the platinum-based combination) (524). It is always difficult to compare activity of agents across trials because of bias as to which patients are entered on the various studies and variation in the rigidity of determination of response and progression-free interval. There are few randomized data comparing single-agent platinum compounds to other single agents in women with platinum-sensitive disease. The EORTC randomized 86 women to either single-agent paclitaxel or single-agent oxaliplatin. Responses among the 63 platinum-resistant patients were 5 out of 31 (16%) for paclitaxel and 2 out of 32 (6%) for oxaliplatin. Responses among the platinum-sensitive patients were 2 out of 10 (20%) for paclitaxel and 5 out of 13 (38%) for oxaliplatin (525).

Repeated courses of carboplatin therapy place patients at risk for hypersensitivity reactions. The incidence in patients treated with seven or more cycles of platinum-based therapy (typically the second dose of the second regimen) has been reported to be 27% (526). These reactions occur during drug infusion and are associated with flushing, nausea, and hypertension. Atypical hypersensitivity reactions, occurring after drug infusion, have also been described (527). A number of desensitization protocols have been published and appear to be generally effective (528); moreover, not all patients allergic to carboplatin will be allergic to cisplatin. However, the reactions are frightening and may be fatal, and desensitization protocols are time consuming for the patient and decrease the convenience of carboplatin therapy. Routine use of diphenhydramine premedication has been reported to produce a non-significant decrease in reaction rate (529).

Platinum-Based Combination Therapy in Platinum-Sensitive Disease

Results of several retrospective analyses of carboplatin/paclitaxel combination therapy in women with platinum-sensitive disease showed strikingly high response rates of 70% to 90% (530,531), and raised the question of whether combination therapy was superior to single-agent therapy in this setting. There have now been several randomized trials comparing platinum-based combination therapy to single-agent platinum therapy (Table 25.20) (521,522,524,532,533,534). As a group they show a superior response rate and superior progression-free survival with combination therapy. Results regarding overall survival are conflicting. Only the ICON4/AGO-OVAR-2.2, a combined analysis of two parallel trials comparing paclitaxel

plus platinum to “conventional platinum-based chemotherapy” (71% received single-agent carboplatin, 17% cisplatin/doxorubicin/ cyclophosphamide, and 12% other nontaxane platinum-based regimens), showed convincing survival benefit; the absolute improvement in overall survival was 5 months (from 24 months to 29 months) (534). Seventy-five percent of patients entered had a treatment-free interval of more than 12 months. The rate of grade 2 or greater neuropathy on the combination arm was 20%. Only about 40% of the patients had received prior taxane therapy, and this has raised concerns about the generalizability of the results (although there was no significant statistical interaction between survival benefit and prior taxane therapy). This trial also does not in any way address the question of whether sequential therapy might produce the same overall survival results as combination therapy. It was noted that only 31% of patients in the nontaxane arm received taxane therapy at the time of progression.

It is interesting that the ICON4 trial showed superior survival with a platinum/taxol combination compared to single-agent platinum in women with relapsed disease, whereas the ICON3 trial conducted by the same investigators showed no advantage with the addition of paclitaxel to front-line therapy. It is possible that the recurrent group of tumors, albeit noncurable, are overall more chemotherapy sensitive than the group of tumors initially presenting, as the majority of completely resistant to therapy will not have survived to recur. Hence the differences between combination and single-agent therapy will be more obvious. However, there may be other unexplained factors as well.

The GCIC trial randomizing women to carboplatin and to carboplatin plus gemcitabine was not powered to show an overall survival difference; however, despite a superior response rate and progression-free interval with combination treatment, there is no evidence of a trend to survival benefit (530). There were no differences in quality of life scores between the two arms of that trial; the primary difference in toxicities was increased hematologic toxicity of the combination regimen, with 27% versus 8% grade 3/4 anemia, 70% versus 12% grade 3/4 neutropenia, and 35% versus 11% grade 3/4 thrombocytopenia.

As with front-line therapy, it could be hypothesized that combination therapy in the second-line setting will not produce any overall survival when compared to an appropriately designed sequential regimen, and may well produce more toxicity. The argument could be made that combination therapy is appropriate even if there is no survival benefit since (a) there would be more likely resolution of symptoms (if there are any symptoms to resolve); (b) improved quality of life due to decreased anxiety during the time of nonprogressing disease might overcome any decreased quality of life due to increased toxicity (not proven); (c) most convincingly, if a complete response is obtained, there would be higher likelihood of a meaningful period of time off chemotherapy (as the majority of patients in the United States are not given prolonged chemotherapy holidays in the presence of visible disease). It should be kept in mind that only a minority of patients achieve a complete response even with combination therapy; CR rate was 14.6% to the gemcitabine/carboplatin combination in the GCIG trial, and 27% to carboplatin/

paclitaxel in the GEICO trial. Nonetheless, platinum-based combinations have become the usual treatment in the United States for women who relapse more than 12 months after the completion of primary therapy, with single-agent therapy usual in women who have an initial treatment-free interval of less than 6 months, and individualized decisions in those with a 6- to 12-month treatment-free interval.

Treatment of Platinum-Resistant Disease— Randomized Trials of Nonplatinum Chemotherapy

Several phase 3 randomized trials have been informative in guiding our treatment of platinum-resistant disease, although several of them also included women with platinum-sensitive tumors (Table 25.21). Together they show that response rates to conventional single-agent therapy in this group of women are about 10%, median progression-free survival is about 3 to 4 months, and median overall survival is 9 to 12 months.

In 1997 ten Bokkel Huinink et al. published a trial performed before paclitaxel was a part of standard front-line therapy. Patients who progressed during or after platinum-based therapy received either topotecan 1.5 mg/m² daily for 5 days or paclitaxel 175 mg/m². Overall response rates were 20.5% and 13.2% in the topotecan and paclitaxel group, respectively ($p = 0.138$). Response rates in the platinum-resistant subgroup were 13% for topotecan and 7% for paclitaxel. Twenty-five percent of patients treated with topotecan experienced neutropenic fever, and 25% had grade 4 thrombocytopenia. A large number of patients (110) crossed over to the alternative drug as third-line therapy. Thirteen percent of topotecan-treated patients responded to paclitaxel and 10% of paclitaxel-treated patients responded to topotecan (535).

Another phase 3 trial in women who were platinum pretreated but paclitaxel naïve has been reported in abstract form only (536). O'Byrne et al. randomized women to paclitaxel versus liposomal doxorubicin; the trial is underpowered as it stopped early when paclitaxel became commercially available. No significant differences between the agents were seen in either platinum-sensitive or platinum-resistant patients.

Topotecan and pegylated liposomal doxorubicin were compared in a phase 3 trial of 474 women who did not respond to or progressed after first-line platinum-based therapy. The majority had received prior paclitaxel. Patients were randomized to

topotecan 1.5 mg/m² days 1 to 5 every 3 weeks versus liposomal doxorubicin 50 mg/m² every 4 weeks (523). Overall response rates to liposomal doxorubicin and topotecan were 20% and 17%; in the platinum-resistant group they were 12% and 7%. Progression-free survival for platinum-resistant patients was 9 weeks for liposomal doxorubicin and 14 weeks for topotecan; overall survivals were 36 weeks and 41 weeks. At final analysis, there was an 18% reduction in the risk of death for patients treated with liposomal doxorubicin (537). However, this was observed primarily in women with platinum-sensitive disease; survival with the two agents was similar in platinum-refractory disease. This trial confirmed that there are a small number of patients with platinum-refractory disease who have relatively prolonged survival. The 3-year survival for women with platinum-refractory disease treated with liposomal doxorubicin was 13.8% (9.5% for topotecan). Twenty-two percent of patients treated with liposomal doxorubicin experienced grade 3 palmar-plantar erythrodysesthesia. Seventy-seven percent of patients on topotecan experienced grade 3/4 neutropenia and 28% had grade 3/4 thrombocytopenia.

A small trial randomized 234 women who had recurred within 12 months of initial platinum-based therapy (median 3 months) to single-agent paclitaxel versus epidoxorubicin plus paclitaxel (537). The response rate was 37% for the combination and 47% for single-agent paclitaxel; median survival was 12 months and 14 months, respectively.

Mutch et al. (538) compared pegylated liposomal doxorubicin 50 mg/m² every 4 weeks to gemcitabine 1,000 mg/m² on days 1 and 8 every 21 days in 195 women with platinum-resistant or refractory ovarian cancer. One or two prior chemotherapy regimens were permitted, and platinum resistance was defined according to exposure to the most recent platinum-based regimen. Response rates were 6.1% for gemcitabine and 8.3% for liposomal doxorubicin; progression-free and overall survivals were similar for the two regimens. One hundred thirty patients crossed over to the alternate therapy; the response rate in those who crossed over to gemcitabine was 7.6%; in those who crossed over to liposomal doxorubicin it was 4.7%. Liposomal doxorubicin was associated with more grade 2/3 mucositis (16%) and palmar-plantar erythrodysesthesia (20%); gemcitabine was associated with more grade 3/4 neutropenia (38%), fatigue (11%), and nausea and vomiting (12%). Four patients in each arm experienced febrile neutropenia.

Agents Useful in Treatment of Platinum-Resistant Disease

A list of agents with some activity in the treatment of platinum-resistant recurrent ovarian cancer is shown in Table 25.22. Taxanes, liposomal doxorubicin, topotecan, and gemcitabine have been studied in randomized trials, as discussed above. They are discussed in slightly more detail below. Hexamethamelamine (altretamine) is an older alkylating agent with the advantages (patient convenience) and disadvantages (inappropriate for patients with episodic or partial small bowel obstruction, limited availability for patients without good insurance coverage for outpatient medication) of an oral therapy. It is rarely used, as it produces significant amounts of neuropathy, nausea, and vomiting. A GOG phase 2 trial of single-agent hexamethamelamine in women with platinum-resistant ovarian cancer demonstrated a 10% response rate and a 21% rate of grade 3 emesis (539). Oral etoposide, a topoisomerase II inhibitor, is better tolerated and may be slightly more active; however, it is leukemogenic, which has limited enthusiasm for attempts to incorporate it into front-line therapy. Interestingly, IV etoposide appears to have minimal activity in women with pretreated ovarian cancer. Ifosfamide has produced response rates of 10% to 20%, but the toxicities, hematologic and neurologic, are excessive compared to those of other available agents, and it is also rarely used (540). Response rates were not noticeably better in women who had not received a prior alkylating agent (i.e., cyclophosphamide). Irinotecan is associated with substantial diarrhea and nausea (541), which can be particularly troublesome in ovarian cancer patients with some pre-existing level of bowel dysfunction; it will hopefully be better tolerated as part of the ongoing front-line international trial for clear cell carcinoma. Epothilones are a group of investigational antitubulin agents with activity against platinum-refractory ovarian cancer. However, they cause neuropathy, and their eventual place in the armamentarium against ovarian cancer remains to be established.

Hormonal therapies such as tamoxifen and antiangiogenics such as bevacizumab are discussed below. Response rates to hormonal treatment by modern standards are hard to gauge, as most of the trials are quite old; however, it does appear that selected patients may respond and toxicities are minimal. Antiangiogenics appear very promising in the treatment of ovarian cancer. None, including bevacizumab, are currently FDA approved for the treatment of ovarian cancer, all are exceedingly expensive, and bevacizumab has been associated

with a number of toxicities, including an increased number of bowel perforations.

Taxanes. Although in most parts of the world, taxane therapy is part of front-line treatment for ovarian cancer, taxanes remain very useful in treating recurrent disease. Both weekly paclitaxel (542,543) and docetaxel (544) have shown response rates of 20% to 30% in women who recurred within 6 months of primary platinum-taxane-based combination therapy. Weekly paclitaxel is particularly useful, as it tends to be less myelotoxic than many other regimens.

Interest in the use of weekly paclitaxel had been stimulated by results in women with metastatic breast cancer in whom weekly paclitaxel at a dose of 80 mg/m² per week produced less myelosuppression and a superior response rate and overall survival when compared to a schedule of 175 mg/m² per week (545). However, the same superiority has not yet been documented in ovarian cancer. Rosenberg et al. randomized 208 patients with pretreated ovarian cancer to every-3-week paclitaxel at 200 mg/m² per week or weekly paclitaxel at a dose of 67 mg/m² per week (with the goal to have similar total doses of paclitaxel in the trial arm). There was no difference in efficacy between the two arms, but less toxicity (other than fingernail toxicity) in the weekly arm (546). This paclitaxel dose, however, is lower than the 80 mg/m² most commonly used in current therapy. Weekly administration of paclitaxel has resulted in about a 20% objective response rate in ovarian cancer patients with clinically defined resistance to platinum and standard every-3-week paclitaxel (543).

ABI-007 is a newer taxane with the advantage that it does not require steroid premedication to avoid hypersensitivity reactions. However, its activity in patients resistant to platinum/paclitaxel therapy remains to be defined.

Topotecan. Topotecan, a topoisomerase I inhibitor, is FDA approved for the treatment of recurrent ovarian cancer, and as discussed above, is as effective as or more effective than paclitaxel or liposomal doxorubicin in women with platinum-resistant disease. However, the FDA-approved schedule of 1.5 mg/m² daily × 5 every 3 weeks is not a convenient regimen and has proved more myelosuppressive than most treating physicians deem reasonable in the palliative setting. Lower starting doses of 1.0 to 1.25 mg/m² are more commonly employed, although their efficacy is not as well documented. Individuals at increased risk for myelotoxicity include those with impaired renal function, older age, extensive prior therapy, or prior pelvic irradiation.

Weekly bolus topotecan has been shown to have some activity in a number of small trials, and has come into common use (547). The maximum tolerated dose (MTD) in phase 1 studies was 4 mg/m² with dose-limiting toxicities of anemia, chronic fatigue, and gastrointestinal distress. However, there are no data showing that the weekly schedule is as effective as the daily × 5 schedule. A preliminary report presented on a randomized phase 2 trial of topotecan 4 mg/m² 3 weeks out of 4 versus topotecan 1.25 mg/m² daily × 5 in women with platinum-resistant ovarian cancer showed a numerically lower response rate for the weekly schedule (2 of 28 vs. 5 of 21 for the daily × 5 regimen) (548).

As shown in Table 25.21, Gore et al. randomized women who had failed one prior platinum-based regimen to oral topotecan (which is not currently available) or IV topotecan 1.5 mg/m² per day every 21 days. The authors separated out response rates for platinum-refractory (progressive or stable disease during primary chemotherapy) and platinum-resistant disease (initial response but relapse within 6 months of completing chemotherapy; these two categories are combined in the table). For women with platinum-refractory disease, the response to IV topotecan was 5%; for those with platinum-resistant disease it was 11% (549).

Liposomal Doxorubicin. Liposomal doxorubicin is also FDA approved for the treatment of recurrent ovarian cancer. The every-4-week schedule of administration is convenient, and the lack of alopecia is attractive to patients. However, the high incidence of palmar-plantar erythrodysesthesia is unappealing for a palliative regimen. Markman et al. published a nonrandomized phase 2 trial suggesting that there was only a 12% incidence of grade 2 and no grade 3 palmar-plantar erythrodysesthesia when the starting dose was lowered from 50 mg/m² to 40 mg/m². The response rate was 9%; all patients were platinum/paclitaxel resistant with a median of two prior regimens (550).

Gemcitabine. As discussed above, gemcitabine has modest activity in the treatment of recurrent ovarian cancer. Based on experimental models, it was hypothesized that combining gemcitabine with cisplatin might reverse platinum resistance. Cisplatin-resistant cells upregulate nucleotide excision repair complexes, which are thought to be inhibited by gemcitabine. Preclinical models suggested synergy between cisplatin and gemcitabine in platinum-resistant cell lines. However, while some early clinical reports appeared promising, a multicenter GOG trial of the combination as second-line therapy in women with platinum-resistant ovarian cancer reported a response rate of only 16% (551).

Hormonal Therapy

The ovary is an endocrine organ. There is evidence (discussed above) for the role of endocrine factors in the etiology of ovarian cancer, and ovarian cancers frequently express estrogen and progesterone receptors. Multiple attempts have therefore been made to treat ovarian carcinoma with hormonal therapy, including progestins, antiestrogens, and gonadotropin-releasing hormone (GnRH) analogs. The response rates generally are quite low, in the range of 10% (552). It seems clear that some patients respond, but there are no good means of selecting them. Many of the trials were performed decades ago, before steroid receptor analysis was available, and the role of steroid receptors in predicating response of ovarian carcinomas to hormonal therapy remains unclear. Of note, over 90% of serous borderline ovarian tumors are estrogen-receptor positive (367), and there are case reports of major responses to tamoxifen (553,554), leuprolide (368), and anastrozole (369).

Progestins/Antiprogestins

As discussed above, progesterone appears to play a protective role in the etiology of ovarian cancer. The protective role of pregnancy may be due to the tenfold increase in maternal circulating progesterone levels as well as suppression of ovulation. Combination oral contraceptive formulations with high progestin potency appear to be associated with a greater reduction in ovarian cancer risk than those with low progestin potency. In addition, overexpression of progesterone receptor (PR) has been found to be a favorable prognostic factor in women with invasive ovarian cancer. The most commonly reported progestins in the treatment of gynecologic malignancies are medroxyprogesterone acetate and megestrol acetate. A review of 13 trials of 10 patients or more (432 patients total) revealed a major response rate of 7.2%, with stable disease in 10.9%. Progestins have well-documented activity in the treatment of recurrent endometrial carcinoma, and it has therefore been hypothesized that they will have activity in the endometrioid subset of ovarian cancers, which tend to express high levels of progesterone receptors. One series of 43 patients with ovarian endometrioid carcinoma using medroxyprogesterone acetate as first-line therapy postsurgery or postradiotherapy

was reported in 1982. Eighty-four percent of the patients had well-differentiated disease. Forty-one of them underwent second-look laparotomy after 6 to 8 months of therapy. Twenty-three had evidence of tumor regression and eight had no evidence of disease. Tumor regression was observed in 68% of the 31 cancers that were positive for both estrogen receptor (ER) and PR and in none of the cancers that did not express either receptor (553). In one phase 2 study of megestrol acetate in 36 platinum-refractory ovarian cancer patients, three complete responders were observed; all had tumors of endometrioid histology (554).

RU486 (mifepristone) is a synthetic antiprogestin that competitively binds the progesterone receptor (as well as the glucocorticoid receptor) and inhibits ovarian cancer cell growth *in vitro*. One phase 2 trial using RU486 in the treatment of platinum-resistant ovarian cancer patients has been reported with a 26.5% response rate, including one complete response of over 3 years' duration (555). Seven of the nine responders had grade 3 tumors. Rash was the primary treatment-limiting toxicity.

Estrogen Therapy/Estrogen Progestin Combinations

Diethylstilbestrol (DES), which was formerly used to treat endocrine-response breast cancer, has also been tested in the management of ovarian cancer, based on the hypothesis that it would inhibit gonadotropin production. One series published in 1963 reported on 14 ovarian carcinoma patients treated with 15 to 30 mg DES daily. There were two objective responses lasting more than a year and two patients with disappearance of ascites and an increased sense of well-being (556).

Estrogens and tamoxifen have the ability to upregulate progesterone receptor expression, and have therefore been used to try to improve the benefit observed with progestin therapy. Two trials treated women with sequential ethinyl estradiol 50 µg per day and medroxyprogesterone acetate 200 mg per day with response rates of 14% and 17% (557,558). Some patients required dose reduction of the ethinyl estradiol because of severe nausea. Two trials have also treated women with sequential tamoxifen and progestins; no responses were observed (559,560).

Tamoxifen

Tamoxifen is a selective estrogen receptor modulator (SERM) with estrogen agonist activity on some tissues (such as bone) and antagonist activity on breast cancers. One review of 18 trials including 648 patients testing tamoxifen in the treatment of advanced ovarian cancer found an overall 13% response rate (561). There was marked heterogeneity in the response rates, suggesting that selection bias (for unknown factors) may be very important. A randomized controlled trial comparing tamoxifen to triptorelin showed no responses in either arm (562). The relationship between hormone receptor status and response to tamoxifen (or other hormonal therapy) is not clear. In the 1980s the GOG conducted a trial of tamoxifen 20 mg po bid (twice the dose commonly used in the treatment of breast cancer) in 105 women with previously treated ovarian cancer. There was an overall 17% response rate, including 13% complete responses. Eight of the nine patients achieving a complete response had elevated levels of estrogen receptor (563). However, the difference in response by estrogen receptor status was not statistically significant. It has been suggested that tamoxifen might be an appropriate therapy for women with small-volume asymptomatic recurrences. The GOG has completed a randomized trial comparing tamoxifen to thalidomide for the therapy of women who have CA-125 marker elevation but no measurable recurrence of disease, and results should be available soon.

GnRH Agonists

GnRH receptors are expressed on about 80% of ovarian cancers. A summary of 12 published trials using GnRH agonists in women with recurrent ovarian cancer noted an overall 5.7% response rate and a disease stabilization rate of 21% with only one complete responder (552). In the largest trial, which was conducted by the EORTC, there were no responders among 68 evaluable patients. One report suggested that responses may be more frequent in low-grade tumors. As low-grade ovarian cancers may respond less well to chemotherapy, and as GnRH agonists have very low toxicity in postmenopausal women, they are a reasonable option for this group of tumors. Like other hormonal therapies, they may also be active against stromal tumors. Of 12 patients treated in four reports of the use of GnRH agonists for ovarian granulosa cell tumors, there were 4 patients with a partial response and 4 with stable disease (552).

GnRH antagonists cause rapid suppression of gonadotropin secretion without the initial gonadotropin release caused by GnRH agonists. There has been one trial of the GnRH antagonist cetrorelix in 17 patients with ovarian or müllerian carcinoma refractory to platinum chemotherapy. Three patients (18%) experienced a partial remission (564).

Aromatase Inhibitors

The major source of estrogen (principally estrone) in postmenopausal women is aromatization of androstenedione in the skin and adipose tissues. Commercially available third-generation aromatase inhibitors include anastrozole, letrozole, and exemestane. Five phase 2 trials of aromatase inhibitors have reported 7 major responses among 179 patients with measurable disease by RECIST (Response Evaluation Criteria in Solid Tumors) criteria (4%) and 16 CA-125 responses among 124 patients with CA-125 evaluable disease (13%) (552). One report suggested that higher ER, lower HER2, and higher EGFR were associated with CA-125 stable or responsive disease (565).

Androgen/Antiandrogen Therapy

About half of ovarian cancers have been reported to express the androgen receptor (552). As discussed above (under Pathogenesis) there is also some epidemiologic evidence supporting a role of androgens in the genesis of ovarian cancer. Two studies of androgen therapy did not report any objective responses (566). Two small studies of the nonsteroidal antiandrogen flutamide noted response rates of 4.3% and 8.7% and disease stabilization rates of 8.7% and 28%.

Front-Line Chemohormonal Therapy

Most of the trials of single-agent hormonal therapy have been in pretreated patients. There have been several small negative randomized studies comparing chemohormonal therapy to chemotherapy in patients with previously untreated advanced disease. Schwartz et al. treated 100 patients with the combination of doxorubicin plus cisplatin. Half were randomized to concomitant tamoxifen. There was no difference in overall or progression-free survival between the groups (567). Similarly, Emons et al. enrolled 135 patients to a prospective double-blinded, randomized trial comparing chemotherapy with chemotherapy plus triptorelin (568). There was no difference between the groups in response, survival, or time to disease progression. Finally, a small randomized trial of 71 patients showed no differences between chemotherapy and chemotherapy plus medroxyprogesterone acetate (569).

SELECTED ISSUES IN PALLIATIVE CARE

Palliative Radiotherapy

Radiation therapy as a palliative modality in ovarian cancer is often neglected, but may be very useful if the sole or dominant symptomatic problem for the patient is localized to a site and volume that may be safely encompassed in a radiation field. For example, a fixed pelvic mass eroding the vaginal mucosa causing bleeding, pain, or bowel or bladder dysfunction may occur without obvious disseminated symptomatic peritoneal disease. Tumor regression or symptomatic relief can often be obtained in these situations from local irradiation. Similarly, radiation may be employed to treat localized masses elsewhere in the abdomen, such as the retroperitoneal nodes. Palliative irradiation may also be useful for extra-abdominal disease, particularly supraclavicular or inguinal node masses and bony or brain metastases.

Limited data are available from the literature concerning the palliative efficacy of radiation therapy in these settings (570–572). Using large single-fraction irradiation, one to three fractions of 10 Gy, investigators at the M.D. Anderson Cancer Center reported overall response rates of 55% and 71% among ovarian cancer patients palliated for pain and bleeding, respectively. However, 6 of 42 patients so treated did develop severe bowel radiation injury that may be attributable to the large fractions employed. Another report of palliative radiation therapy used after initial management with cisplatin-containing regimens documented that radiation therapy produced a mean symptom-free interval of 8.5 months in a group of patients with a median survival of 19.5 months (572). A study from Fox Chase Cancer Center (570) reported the use of fractionated palliative irradiation in 33 patients with symptomatic ovarian cancer in 47 irradiated sites. For the entire group, complete palliative response was seen in 51% of patients, and overall palliative responses occurred in 79%. The median duration of palliation was 4 months, which reflected palliation until death in 90% of cases. Vaginal or rectal bleeding was controlled in 90% and 85%, respectively, and pain relief occurred in 83%. A range of radiation doses was employed, but it is unclear whether patients with better performance status received the higher doses. Palliation was improved in those with higher Karnofsky performance status and in those who received biologically effective doses (BED) of at least 44 Gy (e.g., 35 Gy in 14 fractions). In a recently reported study from the Memorial Sloan-Kettering Cancer Center, variable doses of palliative irradiation were given to a group of 33 patients with platinum-refractory disease who had not previously received paclitaxel. Complete subjective or objective responses were observed in 70% (571). Firm recommendations on the optimal dose for palliation cannot be made; none of the papers provides sufficient detail to do a multivariate analysis of factors predictive of the observed palliative response. Also, the palliative dose fractionation schemes employed do not allow the construction of a dose-response curve. However, it is clear that durable palliation may be achieved with local radiation therapy for ovarian cancer recurring after cisplatin-based chemotherapy, particularly in patients with good performance status.

Palliative Surgery for Obstruction

For the majority of women with ovarian cancer, the disease eventually progresses within the abdominal cavity. Such tumor growth often produces compromise of the intestinal lumen, leading to intestinal obstruction that requires hospitalization for intravenous hydration and decompression of the intestinal

tract. Since these patients generally have no impairment of other vital organ systems, they are often completely alert and in little or no pain. If conservative measures fail to result in relief of the obstruction, the patient and her physician must then confront a difficult decision: prolonged in-hospital (or at-home) intravenous hydration and gastric decompression, or an attempt at surgical relief of the obstruction. In making this decision, one must consider a number of factors, including the patient's overall physical condition, the current status of her cancer and future therapeutic options, the site of the intestinal obstruction, and the extent of her prior therapy, including prior surgical procedures, intraperitoneal chemotherapy, and radiation therapy. A number of investigators have attempted to identify clinical factors that would allow selection of patients unlikely to benefit from surgery for intestinal obstruction so that these women might be saved exploration. Krebs and Goplerud (574) identified a series of variables, including advanced age, poor nutritional status, the presence of palpable tumor masses, the presence of ascites, and a history of previous radiation therapy to the pelvis or whole abdomen, that were associated with a poor outcome. Other studies (515) have reported that the serum albumin level, nutritional status, and the amount of residual ovarian cancer at the completion of bowel obstruction surgery were significantly associated with postoperative survival. On the other hand, in one study (575), no clinical features could be identified that would predict operability or survival following surgery. These differences may be accounted for, in part, by variation in patient selection and preoperative and postoperative care.

The site of intestinal obstruction in ovarian cancer patients is most commonly the small intestine. If the patient is felt to be an operative candidate, consideration should be given to the use of preoperative total parenteral nutrition to improve the patient's nutritional status and decrease the risk of perioperative complications related to malnutrition. Total parenteral nutrition is generally not indicated in patients in whom no surgery is planned. In a series of 54 operations performed for intestinal obstruction in ovarian cancer patients, Rubin et al. (576) reported that the site of obstruction was in the small intestine in 44%, the large intestine in 33%, and involved both small and large intestines in the remaining 22% of cases. A definitive surgical procedure for relief of obstruction was performed in 79% of the patients in this series; the remaining patients were explored and judged to be inoperable. Among the patients undergoing a definitive procedure, about 80% were discharged from the hospital with restoration of intestinal function sufficient to allow a regular or low-residue diet. The mean postsurgical survival among these patients was 6.8 months. In a more recent report from the Memorial Sloan-Kettering Cancer Center (577), the investigators retrospectively reviewed all patients undergoing surgery for intestinal obstruction due to recurrent ovarian cancer from 1994 to 1999. During the study period, 68 operations were performed on 64 patients. The mean time from original diagnosis of ovarian cancer to obstruction was 2.8 years. Surgical correction (intestinal surgery performed for relief of obstruction) was attained in 57 of 68 (84%) cases. Successful palliation (the ability to tolerate a regular or low-residue diet at least 60 days postoperatively) was achieved in 71% of cases in which surgical correction was possible. The rate of major surgical morbidity was 22%. There was one death from pulmonary embolus and one from peritonitis. Two other deaths occurred because of progression of disease, for an overall perioperative mortality rate of 6%. Postoperative chemotherapy was administered in 45 of 57 (79%) cases in which surgical correction was possible. The median survival of the entire cohort was 8 months. If surgery resulted in successful palliation, median survival was 11.6 versus 3.9 months for all other patients. Although survival is relatively brief, by restoring intestinal function, at least

temporarily, these patients can leave the hospital and enjoy an improved quality of life for their remaining months. In the absence of criteria that clearly predict operability, survival, and quality of life following surgery for intestinal obstruction in ovarian cancer patients, an active surgical approach should remain a management option. For patients who are deemed to be unsuitable for surgical exploration or found to be inoperable at exploration, gastrostomy, which can usually be accomplished percutaneously, offers a more comfortable alternative to prolonged nasogastric drainage (577).

Management of Ascites

Ascites is a common finding at the time of initial presentation in patients with advanced ovarian cancer. Generally, ascites does not produce any significant discomfort or respiratory embarrassment. Although the fluid may reaccumulate in the days following initial surgery, once chemotherapy is begun, it usually resolves quickly. In the occasional patient in whom massive ascites causes respiratory compromise, either before or after surgery, paracentesis may be performed safely for temporary relief prior to the initiation of chemotherapy. Cruikshank and Buchsbaum (578), using hemodynamic monitoring, showed that large quantities of ascites can be rapidly removed from ovarian cancer patients without untoward effects. This also appears to have little significant effect on serum proteins. The failure of ascites to resolve after the initiation of chemotherapy or its reappearance later in the course of treatment is an indication of lack of response to treatment and a grave prognostic sign.

Although the majority of patients with advanced ovarian cancer will eventually experience progression of disease, most do not develop clinically significant ascites. For those who do, therapeutic options are limited. Instillation of bleomycin into the peritoneal cavity as a nonspecific sclerotic agent has been reported but has been minimally effective in ovarian cancer (579,580). Experience with implanted peritoneovenous shunts has been poor, with a significant rate of blockage and the risk of embolization and implantation of tumor cells (581). In the absence of effective therapy for the patient's underlying cancer, it is usually not currently possible to control ascites other than on a temporary basis. The potential anti-ascites effects of the antiangiogenic agents are intriguing. An ongoing double-blind randomized trial is testing the effectiveness of single-agent intravenous VEGF trap for the control of ascites in women who have failed all other therapy for ovarian cancer. A preliminary abstract reported on nine patients (three with colon cancer, three with breast cancer, two with uterine cancer, and one with ovarian cancer) who had ascites that had reaccumulated within 2 weeks of paracentesis and were treated with a single dose of intraperitoneal bevacizumab monthly. No patient had a major antitumor response, but no patient had reaccumulation of ascites within 2 months (582).

NEW DIRECTIONS

Molecular Targeted Therapies

The group of newer targeted therapies with the most promise in the treatment of epithelial ovarian cancer to date is the antiangiogenic agents. None of the other available agents has shown appreciable activity, even though ovarian cancers express a number of the putative targets.

Agents Targeting Angiogenesis

Angiogenesis is crucial in the development of many cancers, including ovarian cancer. The most clinically advanced

antiangiogenic therapeutics target vascular endothelial growth factor and its receptors, and a few of these are discussed below. Many other antiangiogenic agents are in various stages of development, and are of interest for the treatment of ovarian cancer. Most currently available anti-VEGF and anti-VEGF receptor (VEGFR) agents share (to a varying degree) a tendency to cause hypertension, and appropriate monitoring and treatment of blood pressure is critical to the safe use of these drugs.

Anti-VEGF Agents. Elevated vascular endothelial growth factor (VEGF or VEGF-A) expression occurs in all stages of ovarian cancer and is associated with poor prognosis, including shorter survival. In addition, VEGF (which is also known as vascular permeability factor) overexpression is directly associated with the production of ascitic fluid.

Bevacizumab is a humanized anti-VEGF monoclonal antibody that is currently FDA approved in the United States for the treatment of advanced colon cancer in combination with chemotherapy. Prospective trials have reported activity of single-agent bevacizumab against pretreated ovarian cancer to be in the range of 15% to 20%. The GOG evaluated single-agent bevacizumab in 63 patients who had one to two prior regimens of cytotoxic chemotherapy. The overall response rate was 21% with a median response duration of 10 months (583). Twenty-five of 62 patients had a progression-free survival (PFS) of ≥ 6 months. Cannistra et al. evaluated 44 patients with platinum-resistant disease that progressed after second-line topotecan or liposomal doxorubicin. The overall response rate was 16% (7 out of 44) (584). Another trial evaluated the combination of bevacizumab and metronomic (daily low-dose) oral cyclophosphamide. Fifty-six percent of patients were progression-free at 6 months and the overall response rate was 24% (585).

There has been caution in rapidly introducing bevacizumab into clinical use because (a) like many other newer anticancer agents, it is exceedingly expensive, and (b) it appears to cause an increased rate of bowel perforation. The study of Cannistra et al. described above closed early due to the higher than expected number of gastrointestinal perforations (5 out of 44), 1 of which was fatal. This led the NCI to alert investigators via an investigational new drug (IND) action letter dated October 4, 2005, of the risk of gastrointestinal perforation in ovarian cancer patients treated with bevacizumab (586). Despite this risk, the responses seen in heavily pretreated women and the durability of some of the responses observed have raised considerable interest in the treatment of ovarian cancer with bevacizumab. As discussed above, two randomized trials are currently testing the addition of bevacizumab to first-line therapy, one in the GOG (GOG 218) (Fig. 25.35) and one in the European Cooperative Group (ICON7). In the GOG trial bevacizumab/placebo is not given until the second cycle of chemotherapy to allow for adequate postoperative healing, and patients with any evidence of bowel obstruction are excluded. An early safety analysis was part of the study design, and the data and safety monitoring board did not recommend early stopping of the trial.

Another anti-VEGF agent of interest, which is not currently commercially available, is VEGF-Trap. VEGF-Trap is a high affinity soluble decoy receptor that comprises portions of the extracellular domains of both VEGFR-1 and VEGFR-2. Preliminary clinical trial reports suggest it has some activity against ovarian cancers that are platinum resistant (587). Preclinical data suggest that VEGF-Trap inhibits ascites in animal models, and it is currently being tested for the control of ascites in ovarian cancer patients who have failed other available treatments.

VEGF Receptor Tyrosine Kinase Inhibitors. VEGF actions are mediated through binding to receptor tyrosine kinases, including VEGFR-1(Flt-1) and VEGFR-2(KDR; whose murine form is known as Flk-1). Both are found predominantly on the surfaces of vascular endothelial cells. Numerous small molecule

inhibitors of VEGF receptor tyrosine kinase are in clinical development. Many of these also inhibit other kinases of relevance, such as platelet-derived growth factor (PDGF) receptors. Single-agent phase 2 trials of sorafenib, sunitinib, and AZD2171 are under way or completed, and results are awaited with interest.

Thalidomide. Thalidomide is an interesting agent with documented activity in the treatment of erythema nodosum leprosum and multiple myeloma. Its mechanism of action is not well understood; it possesses both antiangiogenic and immunomodulatory properties. Complications are generally dose related and include somnolence, constipation, neuropathy, and thrombosis. An initial phase 2 trial including 19 patients with ovarian cancer showed no responses (588), but subsequent studies have documented CA-125 decreases and up to 18% partial responses in heavily pretreated ovarian cancer patients, with some of the responses lasting over a year (589,590). A phase 2 trial of the thalidomide derivative lenalidomide in 20 patients produced no major responses and only 4 patients with stable disease for 6 months or more. However, this was a particularly heavily pretreated group of patients with a median of five prior chemotherapy regimens (591). The GOG is currently conducting a randomized trial comparing tamoxifen to thalidomide for the therapy of women who have CA-125 marker elevation but no measurable recurrence of disease.

Agents Targeting Human Epidermal Growth Factor Receptor Family

The human epidermal growth factor receptor (HER) family comprises four transmembrane receptors, HER-1 (also called EGFR), HER-2 (HER2/neu, the target of trastuzumab), HER-3, and HER-4. The HER-1, -2, and -4 proteins are transmembrane tyrosine kinases that are autophosphorylated after homo- or heterodimerization, triggering a series of downstream events that ultimately affect cellular proliferation and survival. HER-3 does not possess tyrosine kinase activity, but can dimerize with other HER proteins. HER-1, -3, and -4 require ligand binding to dimerize; HER-2 has no known ligand, and can adopt a fixed conformation resembling a ligand-activated state, making it constitutively available for dimerization in the absence of a ligand (592). HER receptors are overexpressed or dysregulated in a variety of solid tumors, and a number of monoclonal antibodies and small molecule tyrosine kinase inhibitors of this pathway have been approved for use in different solid tumors. However, with the exception of HER2 gene amplification in breast cancer, molecular predictors of tumor response to these agents have been elusive. EGFR overexpression is no longer believed to accurately predict for response to the anti-EGFR monoclonal antibodies in colon cancer. While mutations in the tyrosine kinase domain of EGFR may predict response of lung cancers to the EGFR tyrosine kinase inhibitors (593), there also appears to be benefit in patients whose lung cancers do not have such a mutation. Results of immunohistochemical staining for EGFR in epithelial ovarian cancer tumor samples have varied widely, with detectable expression reported in 19% to 92% (594). Most studies suggest that dysregulation of EGFR in ovarian cancer is associated with worse survival. However, therapy targeting EGFR or HER2 has had minimal activity against ovarian cancers to date.

EGFR Tyrosine Kinase Inhibitors. As a group, the EGFR tyrosine kinase inhibitors tend to cause acneiform rash and diarrhea. It has been suggested that development of a rash predicts for longer survival with EGFR tyrosine kinase inhibitor treatment across tumor types. Several phase 2 trials using single-agent anti-EGFR small molecule tyrosine kinase inhibitors in women with pretreated ovarian cancer have been reported. Gordon et al. used single-agent erlotinib to treat 34 patients with refractory (up to three prior regimens with disease progression within 6 months of most recent therapy) EGFR-positive disease

(594). Two of 34 patients achieved a partial response (PR) (6%). Neither responder had strong EGFR expression; both had grade 2 rash. Patients with any grade rash had a significantly longer survival than those without (9.9 vs. 3.6 months, $p = 0.009$). The GOG reported on a phase 2 trial of gefitinib in women with up to two prior regimens and a platinum-free interval of less than 12 months (595). One of 27 evaluable patients (4%) had an objective partial response with a progression-free survival time of about 27 months. Forty-two percent of patients had EGFR expression (1+ or higher); exploratory analysis suggested an association between EGFR expression and progression-free survival. Grade 3 skin toxicity was also associated with improved progression-free survival. Only one of the 25 tumors examined had a mutation in exons 18-21 of the *EGFR*; this was in the patient with a partial response. The investigators also sequenced exons 18-21 of the *EGFR* in 32 additional cases of invasive epithelial ovarian cancer; one mutation was found. Two other phase 2 trials of gefitinib, one of which combined it with tamoxifen, reported no clinical responses (596,597).

The EORTC/GCIG is currently conducting a phase 3 trial of erlotinib for 2 years versus observation in women with responding or stable disease after first-line platinum-based therapy.

Anti-EGFR Monoclonal Antibodies. Cetuximab is an anti-EGFR monoclonal antibody FDA approved in the United States for the treatment of colon cancer. A phase 2 trial of cetuximab in women with pretreated ovarian cancer and was stopped after first stage as it produced only one response among the first 25 women treated (598). A phase 2 trial of matuzumab (EMD72000), a humanized anti-EGFR monoclonal antibody, produced no responses in 37 women with platinum-resistant EGFR-positive ovarian cancer (599).

Anti-HER2 Monoclonal Antibodies. Trastuzumab is an anti-HER2 monoclonal antibody approved for the treatment of breast cancer. The best predictor for response to trastuzumab in breast cancer patients appears to be tumor amplification of the HER2 gene. This is clinically tested by fluorescent *in situ* hybridization (FISH). Immunohistochemical staining for HER2 overexpression appears to be less predictive. HER2 overexpression has been reported in 11% to 30% of primary ovarian carcinomas, but in a higher percentage of women with metastatic or recurrent disease, including some in whom the primary tumor did not overexpress HER2 (600). In a phase 2 trial of trastuzumab conducted by the GOG only 11.2% of women with progressive or recurrent ovarian cancer had tumors that stained 2+ or 3+ for HER2 (601). Among women whose cancers were HER2 2+ or 3+, only 7.3% had a major response to trastuzumab (one CR, two PR). Gene amplification was not assessed in this study.

Pertuzumab is a monoclonal antibody that binds to an epitope on HER2 distinct from the trastuzumab-binding site, and prevents dimerization of HER2 with other receptors. HER2 amplification or overexpression does not appear to be necessary for antitumor activity. A randomized phase 2 trial testing two different doses of pertuzumab enrolled heavily pretreated ovarian cancer patients (median of five prior chemotherapy regimens). Five of 123 patients treated had a partial response. Where possible, fresh tumor biopsies were obtained for development of predictive testing, and there was a trend to improved progression-free survival for women with phospho-HER2+ tumors (602). Preliminary results of a subsequent trial that randomized women with platinum-resistant disease to gemcitabine or gemcitabine plus pertuzumab showed a 5% response rate for gemcitabine versus 14% for the combination (603).

Other Targeted Agents

Imatinib is a receptor tyrosine kinase inhibitor with potent activity against *abl* (including the *bcr-abl* fusion protein found in chronic myelogenous leukemia [CML]), platelet-derived

growth factor receptor, and *c-kit*. It is FDA approved in the United States for use in the treatment of CML and gastrointestinal stromal tumors (GIST, many of which have gain-of-function *c-kit* mutations). While numerous reports have suggested that many ovarian carcinomas express *c-kit* and its ligand, stem cell factor (SCF), and they may also express platelet-derived growth factor receptor (PDGFR) (604,605), trials of imatinib in ovarian cancer have not reported any activity to date (604,606,607).

Src tyrosine kinase has been found to be overexpressed in both mouse and human ovarian cancer cells as well as in human primary ovarian cancers, and trials of *src* inhibitors, such as dasatinib, are planned or under way in ovarian cancer. Likewise, abnormalities of the PI3K/Akt pathway are common, and agents affecting this pathway, such as the mTOR inhibitor temsirolimus, are being tested in ovarian cancer.

Immunologic Therapies

It has long been known that immune therapies, such as IL2, have some activity in the treatment of ovarian cancer. Immune therapy has been of particular interest in ovarian cancer since the provocative observation by Zhang et al. that among patients in clinical complete remission the presence of intratumoral T cells was a strongly favorably prognostic factor (Fig. 25.37) (608). CD3+ tumor-infiltrating T cells were detected within tumor cell islets in 102 of 186 tumors (54.8%). The 5-year survival rate was 38% for patients whose tumors contained T cells compared to 4.5% for patients without tumor-infiltrating T cells. While clinical results of immune therapy have been disappointing to date, vigorous investigation of a large number of immune strategies has continued, and these have recently been reviewed (609). Several phase 3 trials are planned or ongoing.

Oregovomab is a murine monoclonal antibody that binds with high affinity to circulating CA-125. The oregovomab-CA-125 complex is processed by antigen-processing cells, such as macrophages and dendritic cells. CA-125-specific antibodies, T-helper cells, and cytotoxic T cells (CTLs) are subsequently produced, demonstrating both a humoral and cellular response. This is referred to as an “anti-idiotypic vaccine” approach. In a randomized, placebo-controlled trial, 145 patients with stage III

FIGURE 25.37. Kaplan-Meier curve for duration of survival according to presence or absence of intratumoral T cells in 173 patients with stage III or IV epithelial ovarian cancer. Source: Zhang L, Conejo-Garcia JR, Katsaros D, et al. Intratumoral T cells, recurrence and survival in epithelial ovarian cancer. *N Engl J Med* 2003;348:203–213.

or IV epithelial ovarian cancer received intravenous oregovomab at first clinical remission (457). There was no overall difference in time to progression between the two groups. However, in a retrospective analysis, it was found that for a subgroup of patients (≤ 2 cm of residual tumor at debulking, CA-125 ≤ 65 U/mL before third cycle, and CA-125 ≤ 35 U/mL at entry), time to progression for those receiving oregovomab was significantly better (24 vs. 10.8 months). Using the eligibility criteria of the subgroup, the investigators have completed enrollment to the phase 3 Immunotherapy Pivotal Ovarian Cancer Trials I and II with 354 patients. These results should be available soon.

Another anti-idiotypic monoclonal antibody is abagovomab (formerly ACA-125). An international, multicenter, randomized phase 3 trial of abagovomab versus placebo in stage III or IV epithelial ovarian cancer patients, with an accrual goal of 870 patients, began accruing patients in 2007 under the direction of the Arbeitsgemeinschaft Gynäkologische Onkologie group and the Cooperative Ovarian Cancer Group for Immunotherapy. Eligible patients have completed standard debulking and platinum with taxane-based chemotherapy (intravenous or intraperitoneal) and are in complete remission. The end points of this study are progression-free and overall survival.

Another vaccine trial planned is a phase 3 randomized study of a multivalent antigen-KLH construct by investigators at Memorial Sloan-Kettering Cancer Center for patients with epithelial ovarian cancer in second complete remission with progression-free survival as the study end point.

Other New Directions

Aberrant DNA methylation is a frequent epigenetic event in ovarian cancer and represents an additional source of potential molecular markers. Wei et al. (610) investigated CpG island hypermethylation across stages III and IV ovarian tumors. Hierarchical clustering revealed two tumor groups with distinctly different methylation profiles. The duration of progression-free survival after chemotherapy was significantly shorter for patients whose tumors contained high levels of concurrent methylation compared to patients whose tumors had lower tumor methylation levels. These data suggest that CpG island methylation is associated with early disease recurrence after chemotherapy. The differential methylation hybridization assay they developed also identified a group of CpG island loci that are potentially useful as epigenetic markers for predicting treatment outcome in ovarian cancer patients. Demethylating agents and histone deacetylase inhibitors are currently being studied in ovarian cancer.

Additional large-scale studies are in progress to correlate the gene expression profiles in patients with advanced ovarian cancer and survival. Such analyses may identify patients with advanced-stage disease in whom standard therapy is likely to be ineffective and who may be candidates for experimental treatments. Differential gene expression profiles will also be essential in the identification of novel molecular targets.

CHAPTER 26 ■ OVARIAN GERM CELL TUMORS

DANIELA E. MATEI, HELEN MICHAEL, ANTHONY H. RUSSELL, AND DAVID M. GERSHENSON

INTRODUCTION

Significant improvements in the management of ovarian germ cell tumors have been achieved during the past two decades. The development of more effective chemotherapy regimens is clearly the leading cause for improved outcome for these patients. In addition, advancements in other disciplines led to the development of a more precise surgical staging system, improved radiographic imaging, more sophisticated pathology techniques, as well as improved supportive care and symptom control. A substantial majority of patients with ovarian germ cell tumors are long-term survivors and suffer minimal morbidity from treatment. Fertility-sparing surgical procedures enable a large proportion of young women with ovarian germ cell tumors to preserve their reproductive potential. These results illustrate the value of collaboration between different specialties (surgery, medical oncology, pathology, imaging).

PATHOLOGY

The current World Health Organization (WHO) classification of ovarian germ cell tumors includes dysgerminoma, yolk sac tumor, embryonal carcinoma, polyembryoma, nongestational choriocarcinoma, mixed germ cell tumors, and teratomas (immature, mature, and monodermal types) (1). Primitive germ cell tumors account for 2% to 3% of all ovarian cancers and occur usually in young women. The peak age incidence for development of these tumors is the early 20s. The pathology of these neoplasms is discussed in the same order as the listing in the current WHO classification.

Dysgerminoma

Dysgerminoma represents the most common ovarian malignant germ cell tumor (2). Most dysgerminomas are seen in patients with a normal karyotype, but dysgerminoma is the most frequent ovarian neoplasm in patients with gonadal dysgenesis. Five percent to 10% are associated with gonadoblastomas in sexually maldeveloped patients. Most dysgerminomas occur in normal females who usually present with abdominal enlargement, a mass, or pain due to torsion. About 10% of dysgerminomas are bilateral on gross examination and another 10% have microscopic involvement of the contralateral ovary. Association with gonadoblastoma increases the risk of bilateral involvement by dysgerminoma.

On gross examination, dysgerminomas are usually large, white to gray, fleshy, lobulated masses that usually have no more than very focal areas of hemorrhage or necrosis on cut section.

Abundant hemorrhage, necrosis, or cystic areas in a well-fixed tumor should raise the question of a mixed germ cell tumor. Microscopically, dysgerminomas display nests and cords of primitive-appearing germ cells with clear to eosinophilic cytoplasm and prominent cytoplasmic borders (Fig. 26.1). Nuclei are enlarged but they are not pleomorphic. Mitoses may be numerous, and the number of mitotic figures does not have any therapeutic or prognostic significance. Nests of tumor cells are separated by fibrous trabeculae that contain lymphocytes and, sometimes, granulomas. Syncytiotrophoblast cells are present in about 3% of dysgerminomas.

Dysgerminomas contain cytoplasmic glycogen that can be demonstrated with a periodic acid-Schiff (PAS) stain. These tumors display diffuse staining for placenta-like alkaline phosphatase (PLAP), usually with accentuation of the cytoplasmic membrane. Positive staining of dysgerminomas for c-kit (3) and the nuclear transcription factor OCT 3/4 (4) is helpful in confirming this diagnosis. Dysgerminoma is the only ovarian germ cell tumor that displays c-kit staining (5). Both dysgerminoma and embryonal carcinoma stain for OCT 3/4. In contrast to embryonal carcinoma, dysgerminoma does not stain for CD30. Syncytiotrophoblast cells present in dysgerminomas display human chorionic gonadotropin (hCG) staining. In contrast to choriocarcinoma, the syncytiotrophoblast cells in dysgerminomas are not admixed with cytotrophoblast cells. Dysgerminomas do not produce alpha fetoprotein (AFP), a finding that may be helpful in distinguishing them from the solid variant of yolk sac tumor. Optimal and prompt fixation of the surgical specimen facilitates the correct diagnosis. Poor fixation can result in artifacts that mimic embryonal carcinoma and yolk sac tumor histology.

Yolk Sac Tumor

Yolk sac tumor (endodermal sinus tumor) is the second most common ovarian germ cell tumor, accounting for 22% of ovarian germ cell tumors studied at the Armed Forces Institute of Pathology (AFIP) (2,6). These tumors grow very rapidly, often becoming clinically evident in less than one month.

Ovarian yolk sac tumors are typically large and unilateral, although metastasis to the opposite ovary may occur. These tumors have a smooth external surface unless rupture or invasion into surrounding structures has occurred. On cut section, these neoplasms are tan to gray, with abundant hemorrhage and necrosis. They may be partially solid, but they usually contain cysts that vary in size from a few millimeters to several centimeters in diameter. The cut surface appears mucoid, slimy, or gelatinous. Yolk sac tumor (6) displays many different histologic patterns (7). The most common microscopic

FIGURE 26.1. Dysgerminoma. This neoplasm has nests of cells with clear cytoplasm and enlarged hyperchromatic nuclei. Fibrous septae containing lymphocytes separate nests of tumor.

pattern in primary ovarian tumors is the reticular or microcystic pattern (Fig. 26.2). The tumor has a mesh-like pattern and it displays a network of flattened or cuboidal epithelial cells with varying degrees of atypia. The endodermal sinus (festination) pattern contains Schiller-Duval bodies (Fig. 26.3) that have a central capillary surrounded by connective tissue and a peripheral layer of columnar cells. These structures are situated in cavities lined by yolk sac tumor cells. When present, Schiller-Duval bodies are diagnostic of yolk sac tumor. Other less common variants of yolk sac tumor include hepatoid, polyvesicular vitelline, enteric, endometrioid, solid, parietal, and mesenchymal patterns. Most patterns of yolk sac tumor may contain eosinophilic hyaline globules that are PAS positive and diastase resistant. These globules may be seen in non-germ cell tumors and they are not specific for yolk sac tumor. They do not contain AFP. Yolk sac tumors generally display cytoplasmic staining for cytokeratin and AFP, although the parietal pattern of yolk sac tumor typically does not contain AFP. Therefore, serum AFP is a useful marker for yolk sac tumor, although a negative serum AFP does not exclude the disease. Chemotherapy has resulted in the appearance of AFP-negative parietal yolk sac tumor after eradication

FIGURE 26.2. Reticular pattern of yolk sac tumor. There is a mesh-like arrangement of cuboidal tumor cells.

FIGURE 26.3. Schiller-Duval bodies, papillary structures with central blood vessels, are seen in the endodermal sinus pattern of yolk sac tumor.

of AFP positive patterns of the tumor (8). Enteric glands in yolk sac tumor may be carcinoembryonic antigen (CEA) positive. Some types of yolk sac tumor need to be differentiated from endometrioid and clear cell tumors of the ovary. Germ cell tumors usually occur in younger patients than epithelial ovarian tumors, but the lack of staining for cytokeratin 7 and epithelial membrane antigen supports a diagnosis of yolk sac tumor (9) in controversial neoplasms.

Embryonal Carcinoma

Embryonal carcinoma is rarely seen in the ovary, in contrast to its frequent occurrence in the testis. Only 14 cases were identified during a period of 30 years at the AFIP (10), and there have been no recent large series of these tumors. Embryonal carcinoma of the ovary is usually associated with yolk sac tumor in mixed germ cell tumors. On gross examination, embryonal carcinoma characteristically displays areas of hemorrhage and necrosis. Microscopically, this tumor is composed of very crowded cells that display overlapping nuclei in paraffin sections. The nuclei are very pleomorphic and they contain large, prominent nucleoli. The mitotic rate is high in these tumors. Glandular, solid, and papillary patterns may be seen. Vascular invasion is common. Embryonal carcinoma stains positively for PLAP, pancytokeratin (AE1/AE3 and CAM 5.2), CD30, and OCT 3/4. In contrast to seminoma, embryonal carcinoma does not display c-kit staining. Some embryonal carcinomas display focal AFP positivity that may represent partial transformation to yolk sac tumor. Syncytiotrophoblast cells may be present. They produce hCG, but they are not accompanied by admixed cytotrophoblast cells unless choriocarcinoma is also present.

Polyembryoma

Polyembryoma is a very rare malignant ovarian tumor (2). In the few cases reported, the embryoid bodies characteristic of this germ cell tumor have coexisted with other germ cell tumor types. The microscopic appearance of embryoid bodies (11) with an embryonic disc separating a yolk sac and an amniotic cavity may actually be due to an admixture of yolk sac tumor and embryonal carcinoma.

FIGURE 26.4. Choriocarcinoma. This ovarian neoplasm is extremely hemorrhagic.

Choriocarcinoma

Primary nongestational ovarian choriocarcinoma is rare (12). It is most often seen as a component of mixed germ cell tumors of the ovary (13,14). Choriocarcinomas display abundant hemorrhage and necrosis on gross examination (Fig. 26.4). Microscopically, these neoplasms show a plexiform pattern composed of an admixture of syncytiotrophoblast and cytotrophoblast cells (Fig. 26.5). Syncytiotrophoblastic giant cells have abundant eosinophilic to amphophilic cytoplasm that contains multiple atypical, hyperchromatic nuclei. Cytotrophoblast cells are round and often have well-defined cell borders, clear to lightly eosinophilic cytoplasm, and single, atypical nuclei. Numerous mitoses are present. Choriocarcinoma spreads by blood vessel invasion that is easy to identify in these tumors. Cytotrophoblast cells do not produce hCG. Syncytiotrophoblast cells are formed from cytotrophoblast cells, and syncytiotrophoblast does produce hCG. Choriocarcinoma may also stain for cytokeratins, epithelial membrane antigen, and carcinoembryonic antigen. Nongestational choriocarcinoma must be distinguished from gestational choriocarcinoma because the former

FIGURE 26.5. Choriocarcinoma. Syncytiotrophoblast cells have dark cytoplasm and multiple atypical nuclei. Cytotrophoblast cells have lighter cytoplasm and single atypical nuclei. Both cell types are admixed in choriocarcinoma. Areas of hemorrhage and necrosis are common.

has a worse prognosis and requires more aggressive therapy. Identification of paternal genetic material indicates that the tumor is of gestational origin (15).

Mixed Germ Cell Tumors

Mixed germ cell tumors of the ovary contain two or more different types of germ cell neoplasm, either intimately admixed or as separate foci within the tumor (13,14). They are much less common in the ovary than in the testis. They accounted for only 8% of malignant ovarian germ cell tumors accessioned at the AFIP over a period of 30 years (13).

Malignant mixed germ cell tumors are large, unilateral neoplasms, but the gross appearance on the cut surface depends on the particular type of germ cell tumor present. The most common germ cell tumor element in the AFIP series was dysgerminoma (80%), followed by yolk sac tumor (70%), teratoma (53%), choriocarcinoma (20%), and embryonal carcinoma (13%) (13). The most frequent combination has been dysgerminoma and yolk sac tumor. Syncytiotrophoblast may occur either as a component of choriocarcinoma or as isolated cells in other germ cell tumor elements. The diagnosis and prognosis of malignant mixed germ cell tumors depend on adequate tumor sampling in order to detect small areas of different types of germ cell tumor. Thorough sampling is essential because the types of tumor identified may affect therapy and prognosis.

Teratomas

Teratomas are germ cell tumors that contain tissue derived from two or three embryonic layers. Teratomas are subclassified according to whether the tumor elements represent mature or immature tissue types. In addition, monodermal and highly specialized teratomas are composed of a predominance of one tissue type such as thyroid tissue (struma ovarii). This discussion of the pathology of ovarian tumors will address predominantly mature and immature teratomas in adult women. In contrast to other ovarian germ cell tumor types, ovarian teratomas do not contain 12p amplification (16,17). Ovarian teratomas apparently arise by parthenogenesis.

Most teratomas are mature cystic teratomas that contain differentiated tissue components such as skin, cartilage, glia, glandular elements, and bone. Any tissue type present in adults may be represented in teratomas. The widest variety of tissue types is characteristically identified in a nodule in the wall of the cystic neoplasms. Mature cystic teratomas represent benign neoplasms unless they contain a somatic malignancy such as squamous carcinoma, papillary thyroid carcinoma, or other non-germ cell tumors arising in differentiated elements of the teratoma.

Immature teratomas in adult women, in contrast to mature cystic teratomas, are uncommon tumors. They represent about 3% of all ovarian teratomas, but immature teratomas are the third most common form of malignant ovarian germ cell tumors. Very limited amounts of immature tissue occurring in mature cystic teratomas does not seem to alter the prognosis of those tumors (18), but immature tissue in solid teratomas represents a malignant tumor that can disseminate and metastasize.

Most immature ovarian teratomas are unilateral neoplasms, although they can metastasize to the opposite ovary and they can also be associated with mature teratoma in the opposite ovary. Immature teratomas are predominantly solid tumors, but they may contain some cystic areas. The cut surface of immature teratomas is soft and fleshy or encephaloid in appearance (Fig. 26.6). Areas of hemorrhage and necrosis are common. Microscopically, these tumors contain a variety

FIGURE 26.6. Ovarian immature teratoma. The neoplasm is predominantly solid and has a soft, encephaloid appearance.

of mature and immature tissue components. The immature elements almost always consist of immature neural tissue in the form of small, round blue cells focally organized into rosettes and tubules (Fig. 26.7). There is a correlation between disease prognosis and the degree of immaturity in the teratoma. The three-tiered grading system is still the one most often used (19). Grade 1 neoplasms display some immaturity, but the immature neural tissue does not exceed in aggregate the area of one low-power field (40 \times) in any slide. Grade 2 teratomas contain more immaturity, but immature neural tissue occupies no more than an area equal to three low-power fields in any slide. Grade 3 neoplasms contain immature neural tissue that occupies an area greater than three low-power fields in at least one slide (20). Mature tissue is easily identified in grade 1 tumors. It is present to a lesser extent in grade 2 neoplasms and may be absent altogether in grade 3 immature teratomas. The amount of mitotic activity and immature neural tissue with rosettes and tubules also increases with increasing tumor grade. Some authors prefer classifying immature teratomas as either low (grade 1) or high (grades 2 and 3) grade teratomas. In patients whose neoplasm has disseminated beyond the ovary, the grade of the tumor metastasis is important in predicting survival and determining treatment.

FIGURE 26.7. Ovarian immature teratoma. Immature neural tissue forms tubules.

Occasionally, patients may have peritoneal implants that contain only mature tissue, but these mature glial implants may represent host tissue and not actual tumor implants (21). It is extremely important to sample peritoneal disease thoroughly in order that foci of immature teratoma (that may coexist with mature glia) are identified.

A rare, but distinct entity deserves mention. The poorly differentiated small cell carcinoma of the ovary, classically associated with hypercalcemia (22), may have germ cell origin, as suggested by immunostaining for alpha-1-antitrypsin, presence of PAS-positive intracellular globules, presence of foci of intercellular basement membrane material, and focal laminin immunoreactivity (23). These tumors usually occur in young women and are invariably associated with a dismal prognosis (24,25). Treatment with germ cell type chemotherapy regimen is probably justified, although data are scant and inconclusive, given the rarity of such tumors.

Biologically, ovarian germ cell tumors, like testis cancer, are derived from primordial germ cells, which undergo defective meiosis. Karyotypic abnormalities are common and include aneuploidy or chromosomal rearrangements. In contrast, benign teratomas have a normal karyotype. One report notes chromosomal abnormalities in 7% of mature teratomas (26,27). Analysis of centromeric heteromorphisms suggests that 65% to 70% of benign teratomas result from a post-meiosis I type error (homozygotes), while the remaining 30% to 35% are caused by defective meiosis I, as demonstrated by heterozygosity of centromeric markers (26). Among malignant ovarian germ cell tumors, aneuploidy and chromosomal translocations or truncations similar to those encountered in testicular carcinoma have been widely reported (28,29). The presence of an isochromosome 12p (i12p) has been noted in ovarian tumors (30), albeit less commonly than in testis cancer. Other chromosomal aberrations such as loss or gain in chromosomes 1, 11, 12, 16, and X can be identified (31). The association between dysgerminoma and dysgenetic gonads (32) is well recognized and should be managed accordingly, as will be discussed.

CLINICAL FEATURES

Malignant germ cell tumors of the ovary occur mainly in girls and young women. In the University of Texas M. D. Anderson Cancer Center (UTMDACC) series, the age of the patients ranged from 6 to 40 years, with a median age of 16 to 20 years, depending upon histologic type (33).

Signs and symptoms in these patients are rather consistent. Abdominal pain associated with a palpable pelvic-abdominal mass is present in approximately 85% of patients (14,34,35). Approximately 10% of patients present with acute abdominal pain, usually caused by rupture, hemorrhage, or ovarian torsion. This finding is somewhat more common in patients with endodermal sinus tumor or mixed germ cell tumors and is frequently misdiagnosed as acute appendicitis. Less common signs and symptoms include abdominal distention (35%), fever (10%), and vaginal bleeding (10%). A few patients exhibit isosexual precocity, presumably due to hCG production by tumor cells.

In a small percentage of cases, ovarian germ cell tumors occur during pregnancy or in the immediate postpartum period (34). In the series reported by Gordon et al., 20 of 158 patients with dysgerminoma were diagnosed during pregnancy or after delivery (36). Nondysgerminomatous ovarian tumors occur less frequently during pregnancy, but rare cases have been reported (37–40). Marked increase in AFP heralds the presence of a germ cell tumor with yolk sac component. By and large, patients with ovarian tumors diagnosed during pregnancy can be treated successfully, without compromising the health of the fetus. Surgical resection of tumors and

TABLE 26.1**SERUM TUMOR MARKERS IN MALIGNANT GERM CELL TUMORS OF THE OVARY**

Histology	AFP	hCG

chemotherapy have been performed safely in mid and third trimesters. However, rapid disease progression or pregnancy termination/miscarriage have been recorded, especially for nondysgerminomatous tumors (41).

Many germ cell tumors possess the unique property of producing biologic markers that are detectable in serum. The development of specific and sensitive radioimmunoassay techniques to measure hCG and AFP led to dramatic improvement in patient monitoring. Serial measurements of serum markers aid the diagnosis and, more importantly, are useful for monitoring response to treatment and detection of subclinical recurrences. Table 26.1 illustrates typical findings in the sera of patients with various tumor histologic types. Endodermal sinus tumor and choriocarcinoma are prototypes for AFP and hCG production, respectively. Embryonal carcinoma can secrete both hCG and AFP, but most commonly produces hCG. Mixed tumors may produce either, both, or none of the markers, depending on the type and quantity of elements present. Dysgerminoma is commonly devoid of hormonal production, although a small percentage of tumors produce low levels of hCG, if multinucleated syncytiotrophoblastic giant cells are present. The presence of an elevated level of AFP or high level of hCG (>100 U/mL) denotes the presence of tumor elements other than dysgerminoma. Therapy should be adjusted accordingly (see below). Although immature teratomas are associated with negative markers, a few tumors can produce AFP. A third tumor marker is lactic dehydrogenase (LDH), which is frequently elevated in patients with dysgerminoma or other germ cell tumors. Unfortunately, it is less specific than hCG or AFP, which limits its usefulness. CA-125 can also be nonspecifically elevated in patients with ovarian germ cell tumors (42).

SURGERY

Operative Findings

Malignant germ cell tumors of the ovary tend to be quite large. In the UTMDACC series, these tumors ranged in size from 7 to 40 cm, with a median size of 16 cm (14). Predominance of right-sided over left-sided involvement was noted. Bilaterality of tumor involvement (especially true stage IB disease) is exceedingly rare except for dysgerminoma. Bilateral involvement occurs in 10% to 15% of dysgerminoma patients (36,43–46). For nondysgerminomatous tumors, bilateral involvement signifies either advanced disease with metastatic spread to the contralateral ovary or the presence of a mixed germ cell tumor with prominent dysgerminoma component.

Ascites may be noted in approximately 20% of cases. Rupture of tumors, either preoperatively or intraoperatively, can occur in approximately 20% of cases. Torsion of the ovarian pedicle was documented in 5% of patients in the UTMDACC series.

Benign cystic teratoma is associated with malignant germ cell tumors in 5% to 10% of cases. These coexistent teratomas may occur in the ipsilateral ovary, in the contralateral ovary, or bilaterally. Likewise, a pre-existing gonadoblastoma may be noted in association with dysgerminoma and dysgenetic gonads related to a 46,XY karyotype (32,47–49).

Malignant germ cell tumors generally spread in one of two ways: along the peritoneal surface or through lymphatic dissemination. Although the relative frequency of these two principal mechanisms is difficult to discern, it is generally accepted that these neoplasms more commonly metastasize to lymph nodes than epithelial tumors. The high prevalence of inadequate staging procedures makes the true incidence of lymph node involvement uncertain. It is our impression that although still uncommon, malignant germ cell tumors have a somewhat greater predilection than epithelial tumors to metastasize hematogenously to parenchyma of liver or lung. The stage distribution is also very different from that of epithelial tumors. In most large series, approximately 60% to 70% of tumors will be stage I (36). The next most common stage is III, accounting for 25% to 30% of tumors. Stages II and IV are relatively uncommon.

Extent of Primary Surgery

The initial treatment approach for a patient suspected of having a malignant ovarian germ cell tumor is surgery, both for diagnosis and for therapy. After an adequate vertical midline incision, a thorough determination of disease extent by inspection and palpation should be made. If the disease is confined to one or both ovaries, it is imperative that proper staging biopsies be performed (see below).

The type of primary operative procedure depends upon the surgical findings. Because many of these patients are young women, for whom preservation of fertility is a priority, minimizing the surgical resection while ensuring removal of tumor bulk must be thoughtfully balanced. As noted previously, bilateral ovarian involvement is rare, except for the case of pure dysgerminoma. Bilateral involvement may be found in cases of advanced disease (stages II–IV), in which there is metastasis from one ovary to the opposite gonad, or in cases of mixed germ cell tumors with dysgerminoma component. Therefore, fertility-sparing unilateral salpingo-oophorectomy with preservation of the contralateral ovary and of the uterus can be performed in most patients (50–52). If the contralateral ovary appears grossly normal on careful inspection, it should be left undisturbed. However, in the case of pure dysgerminoma, biopsy may be considered, because occult or microscopic tumor involvement occurs in a small percentage of patients. Unnecessary biopsy, however, may result in future infertility due to peritoneal adhesions or ovarian failure. If the contralateral ovary appears abnormally enlarged, a biopsy or ovarian cystectomy should be performed. If frozen examination reveals a dysgenetic gonad, or if there are clinical indications suggesting a hermaphrodite phenotype, then bilateral salpingo-oophorectomy is indicated. However, it is difficult to establish this diagnosis on frozen section. This determination should preferably be made by determining a normal female karyotype preoperatively. If benign cystic teratoma is found in the contralateral ovary, an event that can occur in 5% to 10% of patients, then ovarian cystectomy with preservation of remaining normal ovarian tissue is recommended.

An important problem, albeit rare, is bilateral gonadal involvement in a patient who desires to preserve fertility and

who is a candidate for postoperative chemotherapy. There are no data regarding the ability of chemotherapy to eradicate a primary ovarian tumor. In testis cancer, there are presumptive data suggesting that tumor may persist after chemotherapy in the gonad and that the testis may be a drug sanctuary. In exceptional situations, it may be reasonable to preserve an involved ovary in a patient who will be receiving chemotherapy. However, it is conceivable that ovarian preservation could increase the risk for recurrence in these selected cases. The decision to preserve an involved ovary is difficult and must be made carefully considering the patient's wishes.

The advent of *in vitro* fertilization technology also has an impact on operative management (53). Convention has dictated that if a bilateral salpingo-oophorectomy is necessary, a hysterectomy should also be performed. However, with current assisted reproduction technologies (ART) involving donor oocyte and hormonal support, a woman without ovaries could potentially sustain a normal intrauterine pregnancy. Similarly, if the uterus and one ovary are resected because of tumor involvement, current techniques provide the opportunity for oocyte retrieval from the remaining ovary, *in vitro* fertilization with sperm from her male partner, and embryo implantation into a surrogate's uterus. As the field of ART is evolving, traditional guidelines concerning surgical treatment in young patients with gynecologic tumors have to be thoughtfully adapted to individual circumstances.

Surgical Staging

Surgical staging information is essential for determining extent of disease, providing prognostic information, and guiding postoperative management. A meticulous approach is important for every patient, but is of critical importance for those patients with early clinical disease in order to detect the presence of occult or microscopic metastases. Staging of ovarian germ cell tumors follows the same principles applicable to epithelial ovarian tumors, as described by the International Federation of Gynecologists and Obstetricians (FIGO, Table 26.2). Proper staging procedures consist of the following:

1. Although a transverse incision is cosmetically superior, a vertical midline incision is usually necessary for adequate exposure, appropriate staging biopsies, and resection of large pelvic tumors or metastatic disease in the upper abdomen.
2. Ascites, if present, should be evacuated and submitted for cytologic analysis. If no peritoneal fluid is noted, cytologic washings of the pelvis and bilateral paracolic gutters should be performed prior to manipulation of the intraperitoneal contents.
3. The entire peritoneal cavity and its structures should be carefully inspected and palpated in a methodical manner. We generally prefer to start with the subphrenic spaces and move caudad toward the pelvis. The subdiaphragmatic areas, omentum, colon, all peritoneal surfaces, the entire retroperitoneum, and small intestinal serosa and mesentery should be checked. If any suspicious areas are noted, they should be submitted for biopsy or excised.
4. Next, the primary ovarian tumor and pelvis should be examined. Both ovaries should be carefully assessed for size, presence of obvious tumor involvement, capsular rupture, external excrescences, or adherence to surrounding structures.
5. If disease seems to be limited, i.e., confined to the ovary or localized to the pelvis, then random staging biopsies of structures at risk should be performed. These sites should include the omentum (with generous biopsies from multiple areas) and the peritoneal surfaces of the following sites: bilateral paracolic gutters, cul-de-sac, lateral pelvic walls, vesicouterine reflection, and subdiaphragmatic areas. Any adhesions should also be generously sampled.
6. The para-aortic and bilateral pelvic lymph node-bearing areas should be carefully palpated. Any suspicious nodes should be excised or sampled. If no suspicious areas are detected, these areas should be sampled. There is no evidence that a complete para-aortic and/or pelvic lymphadenectomy is advantageous.
7. If obvious gross metastatic disease is present, it should be excised if feasible, or at least sampled to document disease extent. The concept of cytoreductive surgery is discussed below.

TABLE 26.2

FIGO STAGING OF OVARIAN GERM CELL TUMORS

Stage	Description
I	Tumor limited to ovaries.
IA	Tumor limited to one ovary, no ascites, intact capsule.
IB	Tumor limited to both ovaries, no ascites, intact capsule.
IC	Tumor either stage IA or IB, but with ascites present containing malignant cells or with ovarian capsule involvement or rupture or with positive peritoneal washings.
II	Tumor involving one or both ovaries with extension to the pelvis.
IIA	Extension to uterus or tubes.
IIB	Involvement of both ovaries with pelvic extension.
IIC	Tumor either stage IIA or IIB, but with ascites present containing malignant cells or with ovarian capsule involvement or rupture or with positive peritoneal washings.
III	Tumor involving one or both ovaries with tumor implants outside the pelvis or with positive retroperitoneal or inguinal lymph nodes. Superficial liver metastases qualify as stage III.
IIIA	Tumor limited to the pelvis with negative nodes but with microscopic seeding of the abdominal peritoneal surface.
IIIB	Negative nodes, tumor implants in the abdominal cavity <2 cm.
IIIC	Positive nodes or tumor implants in the abdominal cavity >2 cm.
IV	Distant metastases present.

Note: FIGO, International Federation of Gynecologists and Obstetricians.

The gynecologic literature is replete with examples of inadequate surgical staging. Most patients still undergo initial surgery in community hospitals and are inadequately staged. Upon referral of such a patient to a university or tertiary care center, the oncologist is faced with the dilemma of inadequate staging information. In such cases, postoperative studies including computed tomography (CT) of the abdomen are recommended. If histopathologic and limited anatomic information from the first surgery clearly indicates the use of systemic chemotherapy, it is generally inadvisable to consider re-exploration solely for the purpose of precise staging information. Reoperation to complete comprehensive staging may be appropriate under clinical circumstances where careful surveillance observation after complete staging may be a sensible alternative to chemotherapy.

Cytoreductive Surgery

If widely spread tumor is encountered at initial surgery, it is recommended that the same principles concerning cytoreductive surgery applied in the surgical management of advanced epithelial ovarian cancer be followed. Specifically, as much tumor should be resected as is technically feasible and safe. However, because of their rarity, there is scant information in the literature on the impact of cytoreductive surgery of malignant germ cell tumors.

In a study of the Gynecologic Oncology Group (GOG), Slayton et al. found that 15 of 54 (28%) patients with completely resected disease at primary surgery failed chemotherapy with a combination of vincristine, dactinomycin, and cyclophosphamide (VAC), as opposed to 15 of 22 (68%) patients with incompletely resected disease treated with the same regimen (54). Furthermore, a higher percentage of patients with bulky postoperative residual disease (82%) failed chemotherapy compared to those with minimal residual disease (55%). In a subsequent GOG study reported by Williams et al., patients received the combination regimen of cisplatin, vinblastine, and bleomycin (PVB). In this study patients with nondysgerminomatous tumors and clinically nonmeasurable disease after surgery had a greater likelihood of remaining progression-free than those with measurable disease (65% vs. 34%) (55). In addition, patients who had been surgically debulked to optimal disease had an outcome intermediate between patients with suboptimal disease and those with optimal disease without debulking.

Even with epithelial tumors, the relative influence of tumor biology, surgical skill, and tumor aggressiveness remains uncertain. Germ cell tumors, especially dysgerminomas, are generally much more chemosensitive than epithelial ovarian tumors. Therefore, aggressive resection of metastatic disease in these cases, especially resection of bulky retroperitoneal nodes, is questionable. The surgeon must exercise thoughtful and mature intraoperative judgment when encountering such situations, carefully weighing the risks of cytoreductive maneuvers in the setting of chemosensitive tumors. There is no substitute for surgical experience and a clear understanding of the biologic behavior of these neoplasms. Even in the face of extensive metastatic disease, it is possible to perform a fertility-sparing procedure with preservation of a normal contralateral ovary.

The value of secondary cytoreductive surgery in the management of malignant ovarian germ cell tumors is even less clear than that of primary cytoreductive surgery. Although secondary cytoreduction is of questionable benefit for patients with refractory epithelial ovarian cancer (56,57), germ cell tumors are relatively more chemosensitive than epithelial tumors and more likely to respond to second-line therapy. Therefore, if a patient has an isolated focus of persistent tumor after first-line chemotherapy in an area such as the lung, liver, retroperitoneum,

or brain, then surgical extirpation should be considered before changing chemotherapy regimens. Although this clinical situation is extremely rare, it has been observed in other situations involving chemosensitive tumors, such as gestational trophoblastic disease and testicular cancer.

Unlike testis cancer, the finding of a residual mass after completion of chemotherapy is less common in patients with ovarian germ cell tumors because these women are likely to have considerable tumor debulking at the time of the diagnostic surgical procedure and thus enter chemotherapy with significantly less tumor burden. At completion of chemotherapy, men with nonseminomatous tumors or seminoma may have persistent mature teratoma or desmoplastic fibrosis. In patients with bulky dysgerminoma, residual masses after chemotherapy are very likely to represent desmoplastic fibrosis. Although a number of patients with pure ovarian immature teratomas or mixed germ cell tumors have persistent mature teratoma at the completion of chemotherapy, as documented by second-look laparotomy (58), the majority are left with multiple small peritoneal implants rather than with a dominant mass. However, it is now recognized that occasional patients who have received chemotherapy for immature teratoma or mixed germ cell tumor containing teratoma will have bulky residual teratoma after chemotherapy. The natural history or biologic implications of this finding are not clear. In testis cancer, patients with bulky residual teratoma may experience slow progression of tumor (59) or may develop overtly malignant tumors over time (60–63). There are similar anecdotal reports of progressive mature teratoma in ovarian germ cell tumor patients after chemotherapy (64–66). Considering this information, it seems appropriate to resect persistent masses in patients with negative markers after chemotherapy for germ cell tumors containing immature teratoma. If viable neoplasm is found, additional chemotherapy should be considered. However, if only mature teratoma is resected, observation is generally recommended.

Second-Look Laparotomy

Since 1960, second-look laparotomy was included in the routine management of patients with epithelial ovarian cancer to assess disease status after a fixed interval of chemotherapy. It was only natural that such an approach would be extrapolated to the management of patients with malignant ovarian germ cell tumors. In a review of the experience with second-look laparotomy at UTMDACC, findings were negative in 52 of 53 patients (67). The one patient with positive findings at second-look laparotomy had an elevated AFP level prior to surgery, which accurately predicted residual disease. This patient received subsequent chemotherapy with PVB, entering prolonged remission. Of the patients with negative findings, one woman relapsed 9 months after the negative second-look surgery and subsequently died. Thirteen patients in this series had biopsy-proven evidence of residual mature teratoma (so-called “chemotherapeutic retroconversion”) at second-look laparotomy; treatment was discontinued in all patients and none developed recurrence. Thus, in this series, second-look surgery did not add prognostic information or alter the therapeutic management of patients. The role of second-look surgery is further obscured in the setting of advancement in imaging techniques (CT scanning, positron emission tomography [PET], magnetic resonance imaging [MRI]) and in an era where tumor marker measurements are part of routine care of patients with germ cell tumors.

The GOG experience with second-look laparotomy in ovarian germ cell tumors has been reviewed (58). One hundred and seventeen patients enrolled prospectively on one of three GOG protocols using cisplatin-based chemotherapy after initial surgical staging and cytoreduction (GOG protocols 45, 78, and 90)

underwent second-look surgical procedures. Of these, 45 surgical procedures were performed in patients who received three courses of bleomycin, etoposide, and cisplatin (BEP) after complete tumor resection. In this subgroup, 38 patients had negative findings, 2 patients had immature teratoma, and 5 patients had mature teratoma. One of the patients with residual immature teratoma received further chemotherapy and one did not. Both of them and the rest of the patients are disease-free. One patient with negative second-look surgery findings subsequently relapsed and succumbed to disease. Hence, in the subgroup of patients with completely resected primary ovarian germ cell tumors, the benefit of second-look surgery is nil. In contrast, 72 patients in this series treated with similar chemotherapy had advanced, incompletely resected tumor before beginning adjuvant treatment. In this subgroup, 48 patients did not have teratoma elements in their primary tumor. At second-look surgery, 45 patients had no residual tumor and 3 patients displayed persistent endodermal sinus tumor or embryonal carcinoma. All three of the latter patients are dead despite further treatment. Five patients with negative second-look laparotomies recurred, of which only one was salvaged with chemotherapy. Thus, the value of second-look surgery in patients with incompletely resected germ cell tumors not containing teratoma is arguably minimal. However, in the subgroup of patients with incompletely resected tumors containing teratoma elements (total of 24 patients), second-look surgery had an impact on subsequent management. Of these patients, 16 were found to have mature teratoma at second look, which was bulky or progressive in 7 cases. Four additional patients were found to have residual immature teratoma. Fourteen of the total 16 patients with teratoma and 6 of the 7 women with bulky residual tumor remain disease-free after surgical resection. Therefore, while second-look laparotomy is not necessary in patients with tumor completely resected primarily or in those patients with initially incompletely resected tumor not containing teratoma, clinical benefit can be derived in those patients with incompletely resected primary tumor that contains elements of teratoma (Table 26.3).

Advances in imaging technology, including the advent of PET scanning, may further obviate the need for surgical re-exploration. While PET scan is sensitive for detecting active (malignant) tumor, its usefulness in evaluating residual mature teratoma is more limited (68–71). A positive PET scan in the setting of a residual mass after treatment is highly indicative of viable tumor, and when used in conjunction with traditional radiographic techniques (CT scan, MRI) and tumor marker

determinations, it can predict relapses with accuracy (72). A recent series demonstrates that in patients with residual masses after treatment for seminoma, a positive PET scan is strong evidence that the residual mass contains persistent tumor. In contrast, if the PET scan is negative, the residual mass is very unlikely to contain tumor. The specificity of the PET scan in this situation was 100%, the sensitivity was 80%, and the positive and negative predictive values were 100% and 95%, respectively (73). Although studies using PET scanning in ovarian germ cell tumors are scant, the concepts are very similar and can be extrapolated from the testis cancer literature.

CHEMOTHERAPY FOR OVARIAN GERM CELL TUMORS

Chemotherapy: From VAC to PEB

One of the great triumphs of cancer treatment in the 1970s and 1980s was the development of effective chemotherapy for testicular germ cell tumors (74,75). The lessons learned from prospective, randomized trials in testis cancer have been applied to ovarian germ cell tumors. Presently, the overwhelming majority of patients with ovarian germ cell tumors survive their disease with the judicious use of surgery and cisplatin-based combination chemotherapy. There are many similarities, but also a few important differences between testis cancer and ovarian germ cell tumors.

Historically, the first regimens used successfully for women with ovarian germ cell tumors were VAC (vincristine, dactinomycin, and cyclophosphamide) or VAC-type regimens. Such treatment had curative potential, especially in early-stage disease. However, among patients with advanced disease, the number of long-term survivors after VAC therapy remained under 50%. In the series reported from UTMDACC, although 86% of patients with stage I tumors were cured with VAC, the efficacy of the regimen was significantly less for patients with advanced disease (33). Only 57% of stage II patients and 50% of patients with stage III achieved long-term control. The two patients with stage IV tumors succumbed to disease. Similarly, in a study of the GOG, only 7 out of 22 patients with incompletely resected ovarian tumors achieved long-term disease control after treatment with VAC, as compared to 39 of 54 patients with completely resected tumors (76). In this report, 11 of 15 patients with stage III and both patients with stage IV

disease failed within 12 months of follow-up. These data suggest that VAC chemotherapy was insufficient for the treatment of advanced-stage and/or incompletely resected ovarian germ cell tumors.

Because of the experience gained from the treatment of testicular germ cell tumors demonstrating the superiority of cisplatin-based regimens, new platinum-based regimens were tested in patients with ovarian germ cell tumors. Gershenson et al. reported the efficacy of cisplatin, vinblastine, and bleomycin (PVB) in a small series of patients treated at UTMDACC (77). Among 15 patients, 7 received PVB in the adjuvant setting and 9 received the combination at the time of recurrence. Six of seven patients treated with PVB up front are long-term survivors. Among them, three patients had optimally debulked stage III disease.

Subsequently, the PVB combination was evaluated prospectively in a GOG protocol (GOG 45) (55). In this series, 47 of 89 patients with nondysgerminomatous ovarian tumors (53%) were disease-free with a median follow-up of 52 months. The latest treatment failure occurred at 28 months. Eight other patients had durable remissions with second-line therapy and a few other patients had nonprogressive or slowly progressive immature teratoma. Thus, the 4-year overall survival was approximately 70%. Of note, 29% of patients enrolled in this trial had received prior radiation or chemotherapy, which might have negatively affected the overall outcome. As discussed previously, patients who were debulked to optimal disease fared better than those who were not. Histologic type and marker elevation before treatment were not associated with adverse outcome. However, even among patients with nonmeasurable, and presumably small-volume disease, and without prior treatment, 8 of 30 patients treated with PVB ultimately failed.

In testis cancer, subsequent experience documented that etoposide is at least equivalent to vinblastine and produces improved survival in patients with high tumor volume (75). Furthermore, the use of etoposide in place of vinblastine led to reduced neurologic toxicity, abdominal pain, and constipation. The latter two adverse effects are particularly important for patients with ovarian tumors, as many will have had recent abdominal surgery. These observations led to the evaluation of the combination of bleomycin, etoposide, and cisplatin (BEP; Table 26.4) in patients with ovarian germ cell tumors. In a series from UTMDACC, long-term remissions were recorded in 25 of 26 patients treated with BEP (78). The only patient who succumbed to disease had been incompliant with treatment, monitoring, and follow-up. In this report, four patients with measurable disease after surgery had complete remissions after BEP treatment. This led to a prospective GOG study evaluating BEP in patients with ovarian germ cell tumors (79). The regimen was highly effective, with 91 of 93 enrolled patients being free of disease at follow-up. Based on these data, although BEP and VAC have not been prospectively compared, BEP emerged as the preferred regimen for patients with ovarian germ cell tumors.

The inclusion of cisplatin in the treatment of ovarian tumors resulted indisputably in an improvement in survival and disease control, as shown by the results of GOG studies,

TABLE 26.4**THE BEP REGIMEN^a**

Cisplatin	20 mg/m ² days 1–5
Etoposide (VP-16)	100 mg/m ² days 1–5
Bleomycin	30 units IV weekly

Note: BEP, bleomycin, etoposide, and cisplatin; IV, intravenously.

as well as by other clinical series (80–82). The results of therapy are summarized in Table 26.5.

Differences in Outcome for Patients With Completely Resected Tumors Versus Advanced-Stage Disease

It is clear that several prognostic factors impact the outcome of patients with ovarian germ cell tumors and that there are important differences between testicular and ovarian germ cell neoplasms. Debulking surgery plays a central role in the management of ovarian tumors, but has a less important role in testis cancer. In the hands of an experienced surgeon, the majority of women with ovarian tumors are debulked to minimal and often clinically undetectable disease before starting chemotherapy. Therefore, unlike patients with testis cancer, most women who are candidates for chemotherapy have minimal or no residual disease. However, even in this circumstance, there seems to be little doubt that adjuvant therapy is appropriate in the majority of cases. The anticipated risk of relapse with surgery alone in patients with advanced disease is as high as 75% to 80%. Particularly, patients with embryonal carcinoma, endodermal sinus tumors, and mixed tumors containing these elements are considered to be at very high risk of recurrence without postoperative therapy. This risk can be minimized by the use of adjuvant chemotherapy. In GOG protocol 78, 50 of 51 patients with completely resected ovarian germ cell tumors remained without evidence of disease when three cycles of BEP were given adjuvantly. Other studies using cisplatin-based therapy have given similar results (Table 26.6). The recommended

treatment for most patients (with the exception of patients with grade 1, stage IA immature teratoma or stage IA dysgerminoma) is adjuvant chemotherapy with three courses of BEP. Virtually all patients with early-stage or completely resected disease will survive after careful surgical staging and cisplatin-based adjuvant chemotherapy. More recently, clinical series and observations are beginning to suggest that surveillance with careful follow-up after surgery may be an acceptable alternative for carefully selected patients, as discussed below. Given the fact that surgery followed by chemotherapy is curative for most patients, this course of action should be taken only after very careful consideration. Further studies are needed in this area.

In contrast, most clinical series have shown worse clinical outcome for patients with metastatic disease or with incompletely resected tumors (Table 26.7). Current clinical trials in testicular cancer separate patients with small tumor volume and a resultant excellent prognosis from those with bulky tumor or liver and brain involvement (83). Patients in the former group are usually complete responders to chemotherapy and long-term survivors, whereas only about 50% to 60% of the latter patients are cured. Hence, clinical trials for patients with good prognostic factors investigate shorter or less toxic chemotherapy aiming at minimizing toxicity (84), while preserving efficacy. In contrast, clinical trials for patients with high-risk disease evaluate more intensive chemotherapy regimens with the goal of improving the likelihood of cure (85,86). For instance, high-dose chemotherapy (HDCT) with stem-cell rescue was investigated for patients with high-risk testicular cancer in a multi-institutional clinical protocol (Eastern Cooperative Oncology Group [ECOG] protocol 3894). Patients considered to have high risk for relapse were randomized to receive four cycles of BEP (control arm) versus two cycles of BEP followed by HDCT with autologous stem-cell rescue in the form of two (tandem) courses using carboplatin, etoposide, and cyclophosphamide as a conditioning regimen (experimental arm). The 1-year durable complete response rate was 52% after BEP + HDCT and 48% after BEP alone ($p = 0.53$) (87). The trial disproved the concept that more aggressive chemotherapy in the first-line setting improves outcome of high-risk testicular cancer patients.

This is not the case for patients with incompletely resected or advanced ovarian germ cell tumors. Except for the subgroup of patients with dysgerminoma, there are no identifiable patients who have a sufficiently high cure rate to warrant less intensive therapy. Clinical prognosticators for outcome of malignant ovarian germ cell tumors are stage at diagnosis and increase in tumor markers (88). However, a dependable risk stratification, such as the one used for testis tumors, is not currently in use. Whether this reflects an inherent biologic difference between ovarian germ cell tumors and testis cancer or merely an underestimation of tumor volume because of intraperitoneal spread is not clear.

Management of Residual or Recurrent Disease

The large majority of patients with ovarian germ cell tumors are cured with surgery and platinum-based chemotherapy. However, a small percentage of patients have persistent or progressive disease during treatment or recur after completion of treatment. Like in testis cancer, these treatment failures are categorized as platinum-resistant (progression during or within 4 to 6 weeks of completing treatment) or platinum-sensitive (recurrence beyond 6 weeks from platinum-based therapy).

Most recurrences occur within 24 months from primary treatment. In a series from the UTMDACC, 42 treatment failures were identified among 160 patients with ovarian germ cell tumors treated between 1970 and 1990 (89). Treatment failure in these patients was attributed to inadequate surgery in 14 patients, inadequate radiation in 5 patients, inadequate chemotherapy in 16 patients (underdosing and noncompliance), treatment-related toxicity in 1 patient, and unidentifiable causes in 6 patients. A significant number of patients included in this series had received VAC-based chemotherapy, which might have accounted for the higher than expected rate of recurrence.

Given the high curability rate of ovarian germ cell tumors with primary treatment, the management of recurrent disease represents a complex and often difficult issue, and should preferably be performed in a specialized center. Data to guide the management of patients with recurrent ovarian germ cell tumors are scant and largely extrapolated from the clinical experience with testicular cancer. The single most important prognostic factor in patients with testis cancer is whether or not they are refractory to cisplatin. The likelihood of cure with high-dose salvage therapy in patients who relapse from a complete remission after initial therapy is as high as 60% or more. On the other hand, in patients who are truly cisplatin refractory, the likelihood of long-term survival and cure is significantly less, but fully 30% to 40% of these patients will be long-term survivors. Approximately 30% of patients with recurrent platinum-sensitive testis cancer can be salvaged with second-line chemotherapy (vinblastine, ifosfamide, platinum [VeIP]) (85). However, there is now strong evidence that high-dose therapy with carboplatin, etoposide with or without cyclophosphamide or ifosfamide, and stem-cell rescue is superior to standard dose salvage therapy for these patients (90,91). Generally, in patients who are not cisplatin refractory, one course of standard dose therapy, usually cisplatin, vinblastine, and ifosfamide, is given. If an initial response is seen, then two subsequent courses of high-dose chemotherapy (carboplatin and etoposide) with stem-cell rescue are given (92). A recent report from Indiana University describes this approach among 184 patients with recurrent testicular cancer. At a median follow-up of 48 months, 116 patients were in complete remission. Remarkably, of 40 patients who were platinum refractory, 18 are disease-free after high-dose chemotherapy (93). While this approach has not been prospectively tested in women with recurrent platinum-sensitive ovarian germ cell tumors, because of the small numbers of patients, the concepts are very similar and support the use of high-dose therapy in this setting. Referral to a specialized center for management of recurrent disease is desirable.

Active agents in the setting of recurrence after high-dose chemotherapy include ifosfamide, taxane, and gemcitabine (94–97). In a phase 2 trial from Indiana University, the combination of gemcitabine and paclitaxel induced objective responses in 10 of 31 patients who had recurred after high-dose chemotherapy. Of those, five patients were free of disease at 2 years after treatment (97). Referral for treatment with investigational agents for recurrent, refractory disease is appropriate.

Immediate Toxicity of Chemotherapy

Acute adverse effects of chemotherapy can be substantial and these patients should be treated by physicians experienced in their management. About 25% of patients develop febrile neutropenic episodes during chemotherapy and require hospitalization and broad-spectrum antibiotics (98). Cisplatin can be associated with nephrotoxicity. This adverse event can be avoided by ensuring adequate hydration during and immediately after chemotherapy and by avoidance of aminoglycoside antibiotics. Bleomycin can cause pulmonary fibrosis (98). Pulmonary function testing is frequently used to follow these patients. However, the value of carbon monoxide diffusion capacity to predict early lung disease has been challenged (99). The most effective method for monitoring germ cell tumor patients is careful physical examination of the chest. Findings of early bleomycin lung disease are a lag or diminished expansion of one hemithorax or fine basilar rales that do not clear with cough. These findings can be very subtle but if present mandate immediate discontinuation of bleomycin. It is important to note that randomized trials in good-prognosis testis cancer have suggested that bleomycin is an important component of the treatment regimen, particularly if only three courses of therapy are given (100,101). Other randomized trials have shown that carboplatin is inferior to cisplatin and cannot be substituted for cisplatin without worsening therapeutic outcome (102,103).

Patients with advanced ovarian germ cell tumors should receive three to four courses of treatment given in full dose and on schedule. There is presumptive evidence in testis cancer that the timeliness of chemotherapy may be associated with outcome. Thus, treatment is given regardless of hematologic parameters on the scheduled day of treatment. The impact of the hematopoietic growth factors (granulocyte colony-stimulating factor [G-CSF], granulocyte-macrophage colony-stimulating factor [GM-CSF]) on the management of the myelosuppressive complications of this chemotherapy has not been precisely defined. As most patients will not develop neutropenic fever or infection, hematopoietic growth factors are not routinely necessary (104). It is reasonable to use hematopoietic growth factors to avoid dose reductions for patients with previous episodes of neutropenic fever or in unusually ill patients who are at a higher risk of myelosuppressive complications, or those who received prior radiotherapy. Modern antiemetic therapy, an example of which is shown in Table 26.7, has greatly lessened chemotherapy-induced emesis. By following these guidelines and providing supportive care as indicated, virtually all patients can be treated on schedule, in full or nearly full dose. Chemotherapy-related mortality should be less than 1%. Late effects of chemotherapy are discussed below.

Immature Teratoma

The situation of patients with immature teratoma (IT) is more complex. Immature teratomas are categorized as grade 1, 2, or 3 depending on the amount of immature neuroepithelium in the tumor, based on Kurman and Norris's system (2), which was later modified by Norris (19). Our current appreciation of recurrence risk in these patients is based on an early study by Norris (19). This report demonstrated that prognosis of patients with IT directly relates to tumor grade. Specifically, only 1 of 14 patients with grade 1 IT recurred, while 13 of 26 patients with grade 2 and 3 tumors recurred. This study set the current standard of care for women with stage I teratoma, which is surveillance for grade 1 immature teratoma and adjuvant chemotherapy with three courses of BEP for patients with

grade 2 and 3 tumors (4). However, a significant limitation of the Norris report is the probable underestimation of tumor stage. Hence, in the modern era of complete surgical staging of ovarian neoplasms, it might be appropriate to reconsider the role of routine adjuvant therapy in these patients. Obviously, such an approach must be done with great caution, as surgery followed by adjuvant therapy cures virtually all patients with localized high-grade teratoma. However, it is possible that the risk of relapse is sufficiently low in a defined population of well-staged patients as to warrant clinical observation. This could be accomplished with careful follow-up, such that relapsing patients would be diagnosed with small-volume tumor and cured with subsequent salvage chemotherapy. While some issues are different in testis cancer, a deferral of chemotherapy has been shown to be an appropriate therapeutic alternative for resected stage II tumors and clinical stage I disease. Surveillance for stage I ovarian IT is supported by experience from several groups.

First, an Intergroup study of the Pediatric Oncology Group and the Children's Cancer Group reported that surveillance after complete surgical resection in 41 girls with ovarian immature teratoma was sufficient (105,106). Only one recurrence (which was salvaged with BEP) was noted during 24 months of follow-up. Of note is that in this series, 13 patients had grade 2 and 3 IT, and 10 patients had mixed tumors containing IT plus yolk sac tumor (5).

Second, investigators at Mount Vernon and Charing Cross Hospitals in England have observed 15 patients with stage IA tumors after initial surgical treatment (107). Of these, nine patients had grade 2 or 3 immature teratoma and six had elements of endodermal sinus tumor. There were three recurrences in this series, one of nine in the pure immature teratoma group and two of six in the mixed histology group. Two of these patients were salvaged with chemotherapy and one patient died of pulmonary embolus. Of note is that the patient who died became pregnant 4 months after diagnosis and could not be followed adequately due to her pregnancy.

Third, investigators at the University of Milan reported the clinical outcome in a group of 32 patients with pure ovarian IT followed prospectively (108). In this group, nine patients had grade 2 and 3 stage IA immature teratomas and were treated with surgery and intensive surveillance. Only two recurrences were noted in this group. They consisted of one case of mature teratoma and one case of gliosis. The mature teratoma was resected and the patient with gliosis was followed without treatment. Both patients are alive and well and never received chemotherapy. Furthermore, among four patients with stage IC tumors treated with surgical resection and surveillance, there was one case of gliosis and one recurrence with mature tissue, which was resected (no chemotherapy). All patients are currently free of disease.

When considering these issues, it is important to not overstate the toxicities of adjuvant therapy. In earlier times, chemotherapy-induced emesis was a very significant problem. However, with modern antiemetics such as the 5HT₃ antagonists, emesis is greatly reduced and, while unpleasant, rarely is a major complication of chemotherapy. Acute treatment-related mortality, particularly from bleomycin-related lung disease, is also rare. In GOG protocol 78, there were no toxic deaths among 93 patients. Nonetheless, chemotherapy is certainly unpleasant, produces universal alopecia and occasionally severe emesis, and has a remote risk of serious acute toxicity and drug-induced mortality. Considering this information, it may be appropriate to consider surveillance with careful follow-up in well-staged adult patients with ovarian stage IA immature teratoma. While this concept is supported by evidence derived from the pediatric literature and two small clinical series as discussed, this hypothesis has not been tested prospectively and should be approached with caution.

DYSGERMINOMA

Dysgerminoma is the female equivalent of seminoma. This disease differs from its nondysgerminatous counterparts in several respects. First, it is more likely to be localized to the ovary at the time of diagnosis (stage I). Bilateral involvement is more common, as is its spread to retroperitoneal lymph nodes. While less relevant now than before the era of modern chemotherapy, dysgerminoma is very sensitive to radiation (36,45,109).

Observation for Stage I Tumors

As many as 75% to 80% of dysgerminoma patients used to be considered stage I at diagnosis (44,110). However, with more precise surgical staging, as done currently, the true figure is probably somewhat less. Traditionally, most of these women received postoperative radiotherapy. Given the fact that pelvic radiotherapy is associated with a high incidence of gonadal dysfunction and sterility, an alternative option for low-risk patients who desire to maintain fertility is postsurgical clinical surveillance (111). In a previous era, clinical observation was deemed appropriate for women with tumors less than 10 cm and without contralateral ovarian involvement, while adjuvant radiotherapy was recommended for larger tumors (112). The size-based distinction was subsequently called into question (110,113). In a series reported by LaPolla et al., seven of nine patients with stage IA dysgerminoma followed without postoperative radiotherapy remained disease-free (110). All but one had tumors greater than 10 cm. In another report, among 14 patients with stage IA dysgerminoma treated with surveillance, 5 recurred. Of those, four patients were salvaged with radiation and one was salvaged with radiation followed by chemotherapy. All stage IA patients are alive, free of disease (109). Similarly, Gordon et al. reported that the 5-year survival among 72 patients with stage IA pure dysgerminoma treated conservatively was 95% (36). The recurrence rate in this case series was 17%, with four deaths attributable to disease. However, in this series salvage chemotherapy was offered to only one patient, which may explain the unfavorable outcomes. A report from Mount Vernon and Charing Cross Hospitals quoted two relapses among nine patients with stage IA dysgerminoma treated with observation. Both were cured with salvage chemotherapy (114). A summary of reports using observation after surgery in stage I dysgerminoma is presented in Table 26.8.

Currently, patients with well-staged IA dysgerminoma can be observed after unilateral salpingo-oophorectomy, regardless of the size of the primary tumor, if preservation of fertility is an issue. Careful follow-up is required, because as many as 15% to

25% of patients will experience a recurrence. However, because of the tumor's chemosensitivity, virtually all dysgerminoma patients can be salvaged successfully at the time of recurrence, if adequate follow-up and early detection have been accomplished.

Radiation Therapy

In the past, many stage I patients and all patients with higher stage tumors received radiotherapy. DePalo et al. recommended radiation therapy for all stage I-III patients (44). Radiation therapy was delivered to the ipsilateral hemipelvis (with shielding of the contralateral ovary and the head of the femur) and to the para-aortic nodes. A single field incorporating these areas was used. In either case, the upper limit of the field was set at T10-11. The lower limit of the spinal field was at the L4-5 level. They recommended that all stage IB patients receive postoperative radiation therapy to the whole pelvis and para-aortic nodes. For stage III retroperitoneal disease they offered curative radiation therapy set up in the same fashion as for stage I with the addition of a prophylactic field including the mediastinum and supraclavicular nodes. In the presence of peritoneal involvement, the whole abdomen and pelvis, mediastinum, and supraclavicular nodes were irradiated. They gave 30 Gy (7.5 to 9 Gy per week) as prophylactic irradiation. For curative irradiation, 35 to 40 Gy total dose was given and a boost (10 Gy) was delivered to involved nodes. When irradiating above the diaphragm, DePalo et al. gave 30 Gy 3 to 6 weeks after completion of irradiation below the diaphragm. When irradiating the entire abdominal cavity the fields were similar to those used for epithelial tumors. They gave a total dose of 25 Gy (6 to 7.5 Gy per week). The kidneys were shielded. Similarly, Lawson and Adler reported giving 30 Gy (10 Gy per week) to pelvic and para-aortic fields (115). In their series, only two patients were treated to the whole abdomen, one with moving strip technique and one with open fields. The patient treated with moving strip technique received 22.5 Gy to the whole abdomen and 45 Gy to the pelvis.

Others reported similar treatment plans. Freed et al. gave external pelvic irradiation for disease limited to the pelvis (20 to 30 Gy in 2 to 3 weeks) (116). If the para-aortic nodes were positive histologically or by lymphangiogram, the fields were extended to cover this area. In this case, prophylactic radiation therapy to the mediastinum and supraclavicular nodes was also given. If extranodal spread or intra-abdominal disease was found, total abdominal therapy (25 to 30 Gy in 3 to 5 weeks) with a pelvic boost (15 to 20 Gy in 1.5 to 3 weeks) and para-aortic boost (15 Gy in 2 weeks) were recommended (112,116,117).

Historically, patients with testicular seminoma received prophylactic treatment to the mediastinum. However, over

time this line of reasoning has been challenged (118). Currently, most investigators consider that this form of treatment is obsolete because of the small number of patients who would derive a potential benefit and because of the subsequent reduced tolerance for chemotherapy in this population. Furthermore, considering the recent developments in the field of chemotherapy, it is accepted that primary chemotherapy is equally or more effective than irradiation of extensive normal tissue volumes, and is substantially less likely to compromise salvage therapy when patients relapse after primary therapy. Given that most patients will be cured of their ovarian tumors, and that most patients are young at the time of diagnosis, some consideration should also be given to the delayed carcinogenic effects of intermediate-dose radiation. Although this issue has not been specifically addressed in women with ovarian germ cell tumors, it is logical to extrapolate from the experience of younger women who are frequently successfully treated with radiation for cancer of the uterine cervix, and in whom the risk of second malignancies (both within and remote from the primary radiation fields) is increased 2 or 3 decades following successful initial treatment (119).

Results of radiation therapy are reasonably good. DePalo et al. reported that all 13 stage I patients (12 stage IA and 1 with stage IB) treated with radiotherapy were alive and free of disease with a median follow-up of 77 months (44). The 5-year relapse-free survival for 12 stage III patients was 61.4% and the overall survival was 89.5%. Median follow-up was 67 months. Only one death was reported in this group. Earlier, DePalo et al. reported 100% overall 5-year survival and 90% recurrence-free 5-year survival in 31 stage IA, IB, and IC patients (44). At 4 years, the overall survival was 80% and the recurrence-free survival was 57% in stage III patients. Lawson and Adler reported that 10 of 14 stage I-III patients were alive with a median follow-up of 54 months (115). In this small series there was no correlation between survival and the stage of disease or the size of the primary tumor. Others reported similar results with overall progression-free rates varying between 70% and 90% (Table 26.9) (45,46). However, despite the remarkable radiosensitivity of dysgerminoma, radiotherapy is rarely performed nowadays, since chemotherapy is equally or more effective, less toxic, and less likely to compromise gonadal function.

Chemotherapy

There is an increasing amount of information available about chemotherapy for patients with advanced ovarian dysgerminoma. Dysgerminoma is very responsive to cisplatin-based

chemotherapy, even more so than tumors other than dysgerminoma (78,121). Since 1984, patients with advanced dysgerminoma were eligible for GOG protocols. Patients enrolled in these studies received three to four courses of PVB or BEP. In a combined analysis, 20 patients were evaluated (122). All had stage III or IV disease and most of them had suboptimal (greater than 2 cm) residual tumor. Overall, with a median follow-up of 26 months, 19 of the 20 women were disease-free. Among 11 patients with clinically measurable tumor, 10 had complete responses to chemotherapy. Fourteen patients who underwent second-look laparotomy had completely negative results. Thus, it appears that nearly all patients with advanced dysgerminoma treated with chemotherapy will be durable complete responders.

Considering that patients with stage III dysgerminoma would require extensive radiation and still carry a risk of failure and that such patients probably fare worse with subsequent chemotherapy, it is clear that these patients should be treated primarily with chemotherapy. For most, the preferred adjuvant therapy is BEP. This regimen almost invariably prevents recurrence in nondysgerminomatous tumors and certainly will do so in dysgerminoma. Most patients treated with BEP will retain fertility. An alternative regimen tested by the GOG consists of a 3-day regimen with carboplatin and etoposide. On this protocol, all 39 patients with pure dysgerminoma remained free of disease at a median follow-up of 7.8 years (123). Although highly active, this regimen is not recommended for routine use, because significantly less experience has been accumulated with its use and because of the concern that this regimen is not as effective in tumors containing nondysgerminomatous elements.

The implications of elevated hCG or AFP levels in patients with dysgerminoma should be emphasized. These tumor markers are usually increased in patients with nondysgerminomatous tumors. Therefore, AFP elevation denotes the presence of elements other than dysgerminoma and treatment should be tailored accordingly. An elevated hCG level can occasionally be seen in pure dysgerminoma. This finding should not alter therapy, but prompt reexamination of the tumor specimen to determine whether syncytiotrophoblastic cells are present, or if the tumor contains nondysgerminomatous elements.

In summary, the majority of dysgerminoma patients have stage I disease at diagnosis. These patients can be treated with unilateral salpingo-oophorectomy, and if fertility is an issue, they can be observed carefully with regular pelvic exams, abdominal computerized tomography, and tumor markers including LDH. Fifteen percent to 25% of patients treated with surveillance recur and will require chemotherapy. In patients with more advanced disease, the risk of recurrence is significant

enough to warrant adjuvant treatment. Alternatives are chemotherapy or radiation. For the majority of patients, chemotherapy is the clear choice because of ease of administration, predictable and minimal toxicity, and fertility-sparing properties. Chemotherapy is recommended also for patients with metastatic or incompletely resected tumor and for patients who recur after previous radiotherapy. Radiation might be considered as initial treatment in unusual circumstances, such as older patients or in those with serious concomitant illness that would preclude the use of systemic chemotherapy.

LATE EFFECTS OF TREATMENT

As the prognosis of patients with malignant ovarian germ cell tumors has dramatically improved with the evolution of modern combination chemotherapy, attention is focused on late effects of therapy. There is a considerable body of literature on the late effects of treatment in testicular cancer patients, yet the information available for women with ovarian germ cell tumors remains scant. However, many analogies can be drawn.

Sequelae of Surgery

Young patients with malignant ovarian germ cell tumors undergo at least one, if not multiple, surgical procedures. Although there is no available information on the long-term effects of surgery on these patients, future infertility related to pelvic surgery with subsequent peritoneal and tubal adhesions is well described. Therefore, meticulous surgical technique and avoidance of unnecessary operative maneuvers (e.g., biopsy of a normal contralateral ovary) are required for preventing future complications (50,124,125). Another cause of infertility in this population is unnecessary bilateral salpingo-oophorectomy and hysterectomy. The UTMDACC series includes several patients who underwent surgical sterilization without good indication before referral to their center. It is expected that this phenomenon will be less frequent, as information concerning the outcome of treated patients with ovarian germ cell tumors will be more widely disseminated. In a series from Milan, among 55 patients treated with fertility-sparing surgery, without further chemotherapy, 12 out of 12 patients who attempted conception became pregnant and 12 normal deliveries were recorded (126). Two additional pregnancies occurred in this group and resulted in termination, one of which was due to in-uterus detection of fetal malformation. Recently, Gershenson et al. reported the findings of GOG protocol 9901 (127). Among 132 survivors of ovarian germ cell tumors treated with surgery and platinum-based chemotherapy, 71 patients had fertility-sparing procedures. Of those fertile survivors, 62 (87.3%) maintained menstrual periods and 24 survivors reported 37 successful pregnancies. Although the survivors reported increased incidence of gynecologic problems and diminished sexual pleasure, they also tended to have stronger, more positive relationships with their significant others (127).

As with any group of patients with history of pelvic surgery, patients with malignant ovarian germ cell tumors may develop functional cysts in the residual ovary. Muram et al. reported his experience with 27 patients with ovarian germ cell tumors who underwent unilateral salpingo-oophorectomy and were followed for 12 to 215 months after completion of therapy (128). Of the 18 patients who maintained ovarian function, 13 (72%) developed functional cysts during follow-up. A trial of oral contraceptives and serial ovarian surveillance with sonography is helpful in distinguishing functional cysts from tumor recurrence.

Sequelae of Radiation Therapy

There is limited information about the late effects of radiotherapy in dysgerminoma patients. In a review of the late effects of radiotherapy in patients receiving abdominal therapy for ovarian dysgerminoma at UTMDACC, there was a small increase in reported dyspareunia and the number of bowel movements (111). Somewhat surprisingly, at a median follow-up of 12 years, none of 43 patients treated with radiotherapy developed small-bowel obstruction. No other significant intestinal or bladder problems were recorded. As expected, none of the patients treated with radiation conceived.

Although the late effects of radiotherapy in this population seem to be few with the notable exception of gonadal failure (129), these observations may soon be of only historical interest. As discussed earlier, there has been a strong trend away from radiotherapy and toward chemotherapy as the preferred postoperative therapy of dysgerminoma patients. Concern over preservation of gonadal function has been the driving force behind this transition (43,130).

Sequelae of Chemotherapy

The evolutionary development and refinement of combination chemotherapy have resulted in the cure of a high percentage of patients with chemosensitive tumors, such as lymphomas, testicular cancer, gestational trophoblastic disease, and malignant ovarian germ cell tumors. Within the last few years, several reports have described the long-term effects of chemotherapy in cancer survivors. As expected, most reports refer to the more common lymphomas and testicular cancers.

A recently recognized effect of chemotherapy used for the treatment of germ cell tumors is the risk of secondary malignancies. The epipodophyllotoxins teniposide and etoposide are associated with the development of acute myelogenous leukemia (AML) with certain morphologic and cytogenetic features (131–135). This treatment complication appears to be dose (131,132) and schedule dependent (134). Of 348 male germ cell tumor patients receiving three to four courses of BEP as first-line therapy at Indiana University, 2 developed etoposide-related leukemia. None of 67 patients who received only three courses developed AML (131). Similarly, in the study reported by Pedersen-Bjergaard et al., 5 of 212 patients developed acute leukemia or myelodysplastic syndrome after etoposide therapy (132). However, all patients who developed AML received more than 2,000 mg/m² of etoposide. None of the 130 patients who received less than this dose developed AML. Morphologically, these leukemias are monocytic or myelomonocytic (M4 or M5). Characteristic chromosomal translocations (mostly involving the 11q23 region) are frequently, but not always, present. Leukemia after etoposide treatment occurs within 2 to 3 years compared to alkylating agent-induced AML, which has a longer latency period. Late occurrence of chronic myelogenous leukemia after treatment of testis cancer was reported (136). In the GOG protocol testing the efficacy of BEP in women with ovarian germ cell tumors, one case of AML was recorded among 91 patients treated (79). An additional case of lymphoma was diagnosed during follow-up in this series, yet a correlation between chemotherapy and lymphoproliferative disorders has not been reported to date.

Taking these issues into account, most clinicians consider BEP as the chemotherapy regimen of choice. The incidence of second neoplasms is quite low, particularly in patients receiving low cumulative etoposide doses. The continued use of etoposide over vinblastine is based on its superior efficacy demonstrated in testis cancer (75). Furthermore, vinblastine-induced abdominal pain and ileus are troublesome for some

patients, particularly for those who underwent abdominal surgery, such as women with ovarian germ cell tumors. The risk/benefit ratio continues to favor etoposide over vinblastine.

There also continues to be considerable focus on the long-term effects of chemotherapy on gonadal function. Studies of patients with a variety of cancers suggest that, although ovarian dysfunction or failure is a risk of chemotherapy, the majority of survivors can anticipate normal menstrual and reproductive function (137–139). Factors such as older age at initiation of therapy, greater cumulative drug dose (140), and longer duration of therapy (139) have an adverse effect on future gonadal function. Successful pregnancies after treatment with combination chemotherapy have been well documented in other types of malignancies, including Hodgkin's disease, non-Hodgkin's lymphomas, and leukemia. There are similar reports in patients with malignant ovarian germ cell tumors (126,141–144).

In a review of the UTMDACC series (141), 27 (68%) of 40 patients who had retained a normal contralateral ovary and uterus maintained regular menses consistently after completion of chemotherapy, and 33 (83%) were having regular menses at the time of follow-up. Of 16 patients who had attempted to become pregnant, 12 were successful. One patient had an elective first-trimester abortion and the other 11 patients bore 22 healthy infants over time, none of which had a major birth defect. In a series from Milan, among 169 patients with ovarian germ cell tumors, 138 underwent fertility-sparing surgery, and of these 81 underwent adjuvant chemotherapy (126). After treatment, all but one woman recovered menstrual function and 55 conceptions were recorded. Forty normal full-term babies were delivered. There were four babies with congenital malformations, one in a patient who did not receive chemotherapy and three in women who had received chemotherapy (the difference was not statistically significant).

Although limited reports are available concerning other late effects of chemotherapy in patients with ovarian germ cell tumors (145,146), there are several articles on this topic involving patients with testicular cancer (147–152). In male patients who received cisplatin-based combination regimens, principally PVB, late toxicities included high-tone hearing loss (147), neurotoxicity (147,150,152), Raynaud's phenomenon (148,152), ischemic heart disease (152,153), hypertension (152), renal dysfunction (152), and pulmonary toxicity (149,151). Fortunately, despite these observations, most patients have excellent overall health and functional status (151). Indeed, in a prospective study of immediate chemotherapy versus observation and chemotherapy at the time of relapse in patients with early-stage testis cancer, the patients treated with chemotherapy had only an increased incidence of paresthesias compared to the patients who were monitored without chemotherapy (154). Hypertension, cardiac disease, and stroke were rare and of similar incidence in chemotherapy-treated and untreated patients at a median follow-up of 5.1 years. Interestingly, the late effects of treatment are more pronounced among children receiving treatment for germ cell tumors (145). Specifically, neurotoxicity, growth abnormalities, pulmonary toxicity, and gastrointestinal toxicity have been reported in a higher proportion than in adult patients. The GOG recently completed an analysis evaluating the quality of life and psychosocial characteristics of survivors of ovarian germ cell tumors compared to matched controls. In this analysis, the survivors appeared to be well adjusted, were able to develop strong relationships, and were free of significant depression (155). The impact on fertility was modest or none in patients undergoing fertility-sparing surgeries (127). Overall, these women appeared to be free of any major physical illnesses at a median follow-up of 10 years (Williams SD, personal communication).

SUMMARY

Virtually all patients with early-stage, completely resected ovarian germ cell tumors survive after careful surgical staging and three courses of adjuvant BEP. Furthermore, 50% to 80% of patients with incompletely resected or advanced tumors are expected to be long-term survivors. Current and future clinical trials should address the latter group of patients in an effort to improve therapeutic results. Acute toxicity of treatment is relatively modest. An important, but fortunately unusual late complication of treatment is etoposide-induced leukemia. However, patients receiving the usually administered cumulative dose of etoposide are at low risk for developing AML. Otherwise, late consequences of chemotherapy are limited. Efforts should concentrate on fertility preservation for patients who desire subsequent pregnancies.

The majority of dysgerminoma patients have stage I disease at diagnosis. These patients usually can be treated with unilateral salpingo-oophorectomy and careful postoperative observation without adjuvant treatment. Chemotherapy is offered at the time of recurrence. In patients with more advanced but resected disease, risk of recurrence is significant enough to warrant up-front adjuvant treatment, which for most patients is chemotherapy because of its near universal effectiveness and limited impact on fertility. In patients with incompletely resected tumor or for patients who recur after previous radiation, chemotherapy similar to that given for tumors other than dysgerminoma is appropriate.

Surgery continues to have a pivotal role in the management of all patients with ovarian germ cell tumors. Initial careful surgical staging is important for selection of appropriate subsequent therapy. The role of cytoreductive surgery is under study but the evidence supports its judicious use. However, an operation done strictly for debulking when the diagnosis is established does not seem warranted. Second-look laparotomy is not necessary in patients who have no residual tumor after their initial surgical procedure and who receive adjuvant chemotherapy. This procedure also does not seem warranted in patients with advanced tumors without elements of teratoma. However, patients with incompletely resected tumors containing teratoma elements are likely to benefit from such surgery.

The judicious use of surgery followed by chemotherapy will cure the majority of patients with ovarian germ cell tumors, at the expense of minimal and predictable immediate and late toxicities. In most circumstances fertility can be preserved.

CHAPTER 27 ■ OVARIAN SEX CORD–STROMAL TUMORS

DAVID M. GERSHENSON, LYNN C. HARTMANN,
AND ROBERT H. YOUNG

The intraovarian matrix that supports the germ cells and is covered by the surface epithelium consists of cells originating from the sex cords and mesenchyme of the embryonic gonad. Granulosa cells and Sertoli cells, generally considered to be homologous, are derived from the sex cord cells, whereas the pluripotential mesenchymal cells are the precursors of the theca cells, Leydig cells, and fibroblasts. Neoplastic transformation of these cellular constituents, either singly or in various combinations collectively, results in neoplasms that are termed sex cord–stromal tumors (SCSTs). The classification of the sex cord–stromal tumors provides the template from which this chapter endeavors to stratify and define these tumor entities according to their morphologic characteristics (Table 27.1).

The SCSTs are estimated to account for approximately 7% of all malignant ovarian neoplasms (1). Although SCSTs account for a decreasing proportion of all ovarian malignancies with advancing age, the annual age-related incidence continues to increase through the seventh decade of life (2). Overall, the majority of these tumors are benign or of low malignant potential and are associated with a favorable long-term prognosis. In addition, a significant proportion of SCSTs are diagnosed in patients prior to age 40 years and have the potential to produce a variety of steroid hormones. Hence, adequate knowledge of the natural history of each of these tumors is imperative to diagnose and individualize appropriately definitive surgical and adjuvant therapy.

Sex cord–stromal tumors account for nearly 90% of all functioning ovarian neoplasms (3). With the exception of fibromas, the clinical presentation of patients with SCSTs is frequently governed by the clinical manifestations resulting from the endocrinologic abnormalities. Excessive estrogen production, whether from increased tumor synthesis or peripheral conversion of androgens, influences end-organ responses, which are usually age-dependent and can range from isosexual precocious puberty to menometrorrhagia to postmenopausal bleeding. In addition, the associated risks for endometrial cancer and possibly breast cancer must be recognized (4–6). Conversely, the rapid onset of signs ranging from early defeminization to frank virilization heralds a hyperandrogenic state. Elevated circulating levels of testosterone and/or androstenedione provide strong evidence for the presence of an SCST. Although granulosa cell, theca cell, and Sertoli cell tumors are generally considered to be estrogenic, and Sertoli–Leydig cell and steroid cell tumors are predominantly androgenic, the functional endocrinologic capacities of these tumors are impossible to predict based on their morphologic features. It should also be noted that miscellaneous ovarian tumors, both primary and metastatic, that are not in the

SCST family may be androgenic or estrogenic if their stroma is stimulated to undergo luteinization.

GRANULOSA CELL TUMORS

Although granulosa cell tumors (GCTs) of the ovary were initially described by Rokitansky in 1859 (7), the etiopathogenesis of these neoplasms remains ill defined. At least in part, this is a reflection of the low incidence of GCTs, and hence the limited number of cases witnessed at any single institution. To our knowledge, there are no recognized risk factors for the development of GCTs (4,8). Reproductive factors, including the use of fertility-promoting agents and oral contraceptives, do not correlate consistently with the development of disease. Unkila-Kallio et al. (9) studied a possible link between fertility-promoting agents and GCTs using the nationwide Finnish Cancer Registry. They analyzed the occurrence of GCTs in Finland during the time period 1965 to 1994 against sales statistics for ovulation inducers. In fact, the incidence of GCTs declined by nearly 40% from 1965–1969 to 1985–1994, whereas the use of clomiphene citrate increased 13-fold and that of human menopausal gonadotropin increased 200-fold. Of interest, oral contraceptive use increased fivefold. No hereditary predisposition for any of the sex cord–stromal tumors has been identified (10). Of note, a recent case report described the occurrence of adult GCTs in two first-degree relatives (11). Granulosa cell tumors comprise only 5% of all ovarian malignancies and account for approximately 70% of malignant sex cord–stromal tumors (4–6,12–19). The annual incidence of GCTs in the United States and other developed countries varies from 0.4 to 1.7 cases per 100,000 women (5,6,8,18,20,21). Quirk and Natarajan reported histology-specific age-adjusted ovarian cancer incidence rates that were standardized to the recently adopted year 2000 U.S. standard population (22). They utilized data gathered from the Surveillance, Epidemiology, and End Results (SEER) Program for the years 1992–1999. Out of a total of 23,484 microscopically confirmed cases of primary ovarian cancer, 293 (1.2%) were of sex cord–stromal origin. Although GCTs have been diagnosed from infancy through the tenth decade of life, the peak incidence for these tumors occurs during the perimenopausal decade. The average age at the time of diagnosis in over 750 cases was 52 years (4–6,13,15–18). Considering that GCTs occurring after the third decade of life appear to be histologically distinct in most instances from those occurring in children and younger adults, the clinical and pathologic characteristics for the juvenile and adult GCTs will be addressed separately.

 Leydig cell tumor, nonhilar type
 Steroid cell tumor not otherwise specified

Granulosa Cell Tumors: Adult Type

Adult-type granulosa cell tumors (AGCTs), as histologically described below, account for 95% of all GCTs. The majority of patients will present with one or a combination of the following clinical symptoms: abnormal vaginal bleeding, abdominal distention, and abdominal pain (5,6,15–18,23). The latter symptoms are most frequently attributable to the gross size of the tumor at the time of diagnosis, with the majority exceeding 10 cm in diameter and many exceeding 15 cm (5,16,18). In one series, 12% had ascites at diagnosis (23). In many series, menometrorrhagia, oligomenorrhea, or amenorrhea in premenopausal women or bleeding in postmenopausal women is the most common reason for seeking medical assistance. These and other clinical manifestations such as breast tenderness, uterine myohypertrophy, and endometrial hyperplasia are consistent with the presence of an estrogen-secreting tumor.

The endocrine function of AGCTs, specifically the production of estrogens, has been repeatedly demonstrated by assessment of the end organ, the endometrium, and measurements of peripheral levels of estrogen before and after surgery. In a detailed retrospective analysis of endometrial specimens from patients ($n = 69$) with GCTs, Gusberg and Kardon (24) observed histologic features consistent with unopposed estrogen, including atypical adenomatous hyperplasia in 42% of the evaluated cohort, adenocarcinoma *in situ* (4) in 5%, and invasive adenocarcinoma in 22%. Similarly, Evans et al. (4) noted endometrial hyperplasia in 55% and adenocarcinoma in 13% of their GCT study population. Other investigators have corroborated the high prevalence of glandular hyperplasia and have reported adenocarcinoma frequencies ranging from 3% to 27% (5,6,13,15–18,25,26). Selective ovarian

venous catheterizations during surgery have documented hormonal production, including the secretion of large quantities of estrogen from the ovary harboring the GCT. The return of serum estrogen to physiologic levels after definitive treatment has been witnessed repeatedly. Occasionally, patients with GCTs present with endometrial changes (decidual reaction of the stroma or secretory characteristics of the glands) consistent with tumor production of progesterone (27). Rarely, virilizing changes such as oligomenorrhea, hirsutism, and other masculinizing signs may accompany GCTs (28–30).

Pathology

AGCTs have an average diameter of approximately 12 cm, but a subset, 10% to 15% of the cases, are small and not appreciated on pelvic examination (31). Most characteristically, they are predominantly cystic with numerous locules filled with fluid or clotted blood and separated by solid tissue (Fig. 27.1), or they are solid with large areas of hemorrhage. The solid tissue may be gray-white or yellow and soft or firm. A rare tumor is cystic, usually thin walled, but occasionally thick walled, and multilocular or unilocular (29).

Microscopic examination reveals an almost exclusive population of granulosa cells or, more often, an additional component of theca cells, fibroblasts, or both. The granulosa cells grow in a wide variety of patterns. The better-differentiated tumors usually have microfollicular, macrofollicular, insular, or trabecular patterns. The microfollicular pattern is characterized by numerous small cavities (Call-Exner bodies) (Fig. 27.2) that may contain eosinophilic fluid, one or a few degenerating nuclei, hyalinized basement-membrane material, or rarely, basophilic fluid. The microfollicles are typically separated by well-differentiated granulosa cells that contain scanty cytoplasm and pale, angular or oval, often grooved nuclei arranged haphazardly in relation to one another and to the follicles. The uncommon macrofollicular pattern is characterized by cysts lined by well-differentiated granulosa cells beneath which theca cells are present. The trabecular and insular forms of granulosa cell tumors are characterized by bands and islands of granulosa cells separated by fibromatous or thecomatous stroma. The less well-differentiated forms of the adult granulosa cell tumor typically have a water silk (moiré silk), gyriform, or diffuse (sarcomatoid) pattern alone or in combination. The first two patterns are manifested by parallel undulating or zigzag rows of granulosa cells,

FIGURE 27.2. Granulosa cell tumor, adult type, microfollicular pattern. Several nests of granulosa cells with small oval and angular nuclei enclose multiple Call-Exner bodies.

generally in single file, whereas the diffuse form is characterized by a monotonous, patternless cellular growth. In some adult granulosa cell tumors, the neoplastic cells have moderate to abundant quantities of dense or vacuolated cytoplasm; the term *luteinized granulosa cell tumor* is appropriate when such cells predominate (27). The cells in GCTs usually have round to oval, pale, and often grooved nuclei (Fig. 27.2), but rarely the cells are spindle shaped, resembling a cellular fibroma or low-grade fibrosarcoma; mitotic figures may be numerous, but are rarely atypical. There is usually only mild nuclear atypia, but approximately 2% of tumors contain mononucleate and multinucleate cells with large, bizarre, hyperchromatic nuclei, the presence of which does not appear to worsen the prognosis (32).

Natural History

Adult granulosa cell tumors are low-grade malignancies with a propensity to remain localized and demonstrate indolent growth. Ninety percent are stage I at diagnosis (26). The 10-year survival rate for stage I disease ranges from 86% to 96%; for more advanced disease at diagnosis, 26% to 49% (26). Bilaterality is infrequent (less than 10%) (23). For patients who recur, the median time to recurrence is 6 years. The median survival after recurrence is 5.6 years, consistent with indolent growth features (4,13). Tumor rupture occurred in 22% of a series of 97 cases (23). A unique feature of GCTs is the occurrence of recurrences at extended time intervals from primary therapy, suggesting the presence of persistent occult disease with a very indolent growth rate. Numerous investigators have witnessed recurrences more than a decade after primary treatment (33,34).

Prognostic Factors

The staging system for GCTs is the same as that used for epithelial ovarian cancer (International Federation of Gynecology and Obstetrics, FIGO). Whereas surgical stage has been recognized as the most important prognostic factor for GCTs, tumor size, rupture, histologic subtype, nuclear atypia, and mitotic activity have been correlated with survival with varying degrees of success (8,35,36). As noted above, GCTs are large and therefore prone to rupture. Rupture appears to adversely impact survival in stage I patients, justifying stratification as stage IC (13). However, the prognostic importance of positive cytology and surface involvement is less defined in stage I GCTs (8). Larger, well-characterized series are necessary to clarify these apparent discrepancies. Traditionally, tumor

size was considered to be prognostically significant but appears to lose independent predictability when assessed according to stage (5,14,18,20). Both the increasing degree of nuclear atypia and the increasing mitotic frequency per 10 high-power fields (HPFs) have been correlated inversely with prognosis. Specimens from patients with more advanced disease were associated with a higher grade of atypia and/or more mitotic figures (5,13,14,18). Of note is the observation that nuclear grade, despite its somewhat subjective assessment, has been reported to be a reliable prognostic indicator in stage I cases (13,18). The significance of histologic subtypes and ploidy status has been debated and they appear to be of minimal value. Several investigative groups (4,5,12–14,18) have failed to confirm Kottmeier's (37) report of the prognostic importance of histologic patterns alone in GCTs. Similarly, the reported studies utilizing flow cytometric analysis of DNA content have been inconsistent. Klemi et al. (38) reported a significant survival advantage for patients with tumors demonstrating normal ploidy and/or an S-phase fraction of less than 6%. In contrast, other investigators have suggested that nondiploid GCTs are infrequently encountered (39,40). Chadha et al. (39) observed three of five aneuploid tumors from a sample population of 43 pathologically diagnosed GCTs to be vimentin negative but positive for cytokeratin and epithelial membrane antigen, and therefore cautioned that such highly aneuploid tumors may represent undifferentiated carcinomas. Indeed, it is clear that some series of GCTs in the literature are "contaminated" by the inclusion of undifferentiated carcinomas not otherwise specified or recently recognized entities, such as the large cell carcinoma of hypercalcemic type. Series with unusually large numbers of late-stage or poor-prognosis cases should accordingly be evaluated cautiously.

Investigators have analyzed several potential molecular markers, including p53 status, telomerase, Ki-67, c-myc, and HER2/neu in GCTs (41–45). To date, no molecular marker provides prognostic information for GCTs beyond what is known from stage and histopathologic parameters.

Ala-Fossi et al. stained 30 GCTs for the inhibin subunit. All 24 stage I and II tumors were positive, whereas 4 of 6 stage II to IV tumors were negative. Those that were negative were poorly differentiated and exhibited rapid disease progression. Whether other observers would have accepted these tumors as valid granulosa cell tumors is a concern. Stage was the sole independent prognostic factor (46).

Serum Markers

Recognizing that the majority of patients presenting with advanced GCTs will recur, the identification of a specific serum tumor marker(s) would facilitate early detection of recurrent disease and monitoring of treatment effectiveness (4,5,16,18). As noted above, serum estrogens are generally produced by GCTs and have been utilized as an indicator of disease status (47). Unfortunately, serum estradiol levels are occasionally not elevated, and more frequently are only marginally increased. Hence, they are not ideal for monitoring in a significant number of cases. Several proteins derived from granulosa cells, including inhibin, follicle-regulating protein, and müllerian-inhibiting substance, are readily assayable in serum and forwarded as useful diagnostic monitoring markers (48–56). In a prospective evaluation of 27 patients with GCTs, Jobling et al. (50) demonstrated that serum inhibin levels are typically elevated sevenfold above normal follicular phase levels prior to primary surgical management and can become elevated again several months prior to clinical detection of recurrent disease. In recent years, inhibin and calretinin have become available as markers that can be evaluated immunohistochemically to assist in the diagnosis of GCTs and, for that matter, other SCSTs (57).

Granulosa Cell Tumors: Juvenile Type

Ovarian neoplasms are relatively rare in childhood and adolescence, and when encountered, the majority are of germ cell origin, with only 5% to 7% being SCSTs. The latter, which consists predominantly of the granulosa cell type in this age group, demonstrates a tumor biology that appears to be different from the typical granulosa cell tumor (AGCT) considered above (58). Approximately 90% of the granulosa cell tumors diagnosed in prepubertal girls and in most women less than 30 years of age will be of the juvenile type (JGCT). In a clinicopathologic analysis of 125 cases of JGCT, 44% of the tumors occurred prior to age 10 years and only 3% after the third decade of life (59). The majority of prepubertal patients present with clinical evidence of isosexual precocious pseudopuberty, which may include breast enlargement, development of pubic hair, increased vaginal secretions, advanced somatic development, and other secondary sex characteristics (59–63). Serum estradiol levels were reported as being elevated in 17 of 17 cases of JGCTs and pseudopuberty (61). In addition, elevated levels of serum progesterone (six of ten) and testosterone (six of eight) were likewise observed, as well as suppressed levels of luteinizing hormone and follicle-stimulating hormone. The occasional patient will harbor an androgen-secreting JGCT accompanied by virilization (59,61,62). Although the signs of either precocious pseudopuberty or virilization are dramatic, the most consistent clinical sign at presentation in patients with JGCTs is increasing abdominal girth. Young et al. (59) indicated that in only 2 of 113 nonpregnant patients with JGCTs was the treating physician unable to palpate a mass on abdominal, pelvic, and/or rectal examination. Abdominal pain, dysuria, and constipation may occur. Infrequently, a surgical emergency is encountered following spontaneous rupture or torsion of the enlarged ovary. Juvenile granulosa cell tumors can occur in infants, in whom the prognosis appears to be more favorable than in older individuals (64). Hasiakos et al. describe a recent case of JGCT associated with pregnancy and review the literature (65).

The frequency of bilaterality for JGCTs is estimated to be 5%, similar to AGCTs (66). When stage was assigned based on surgical and histologic parameters, 88% were stage IA, 2% stage IB, 8% stage IC, and 3% stage II. As noted, extraovarian spread is infrequently encountered at exploration, whereas rupture of the tumor is noted in approximately 10% of cases. Ascites contributes to the abdominal distention in 10% to 36% of cases (59,61).

JGCTs have been reported in association with enchondromatosis alone (Ollier's disease) or concomitantly with hemangiomas (Maffucci's syndrome) (61,67–69). Individuals with these relatively uncommon mesodermal dysplasias generally present prior to puberty and frequently develop secondary neoplasms, most commonly sarcomas, after the second decade of life. Juvenile granulosa cell tumors are the next most frequent tumor associated with these disorders and become evident during the first and second decades of life. These observations appear to imply more than coincidental occurrences and suggest a generalized mesodermal dysplasia, perhaps contributing to the pathogenesis of these neoplastic processes. In addition, congenital bilateral JGCTs of the ovary have been reported in leprechaunism, a disease characterized by insulin resistance resulting from an insulin-receptor defect (70).

Pathology

The appearances of JGCTs are similar to the adult form; a solid and cystic neoplasm, in which the cysts contain hemorrhagic fluid, is common (59,60,63). Uniformly solid and uniformly cystic neoplasms are also encountered; the latter may be multilocular or, in rare instances, unilocular. The solid

FIGURE 27.3. Granulosa cell tumor, juvenile type. A nodule of tumor is composed of large cells with abundant cytoplasm and slightly pleomorphic, hyperchromatic nuclei.

component is typically yellow-tan or gray and occasionally exhibits extensive necrosis, hemorrhage, or both.

Microscopic examination typically reveals a predominantly solid cellular tumor with focal follicle formation, but occasionally, a uniformly solid or a uniformly follicular pattern is seen. In the solid areas, the neoplastic cells may be arranged diffusely or as multiple nodules of various sizes. The follicles typically vary in size and shape; Call-Exner bodies are rarely encountered, and the follicles rarely reach the large size of those in the macrofollicular AGCT. The follicular lumens in the juvenile tumor contain eosinophilic or basophilic fluid, which stains with mucicarmine in approximately two of three cases.

The two characteristic cytologic features of the neoplastic juvenile granulosa cells that distinguish them from those of AGCT are their generally rounded, hyperchromatic nuclei, which almost always lack grooves, and their almost invariable moderate to abundant eosinophilic or vacuolated (luteinized) cytoplasm (Fig. 27.3). Nuclear atypia in JGCTs varies from minimal to marked; in approximately 13% of the cases, severe degrees are present. The mitotic rate also varies greatly but is generally higher than that seen in AGCTs, often being five or more per HPF (59,63).

Natural History

In the initial series by Young et al., 98% of 125 patients with JGCTs were less than 35 years of age, and 78% were 20 years or less (59). Notwithstanding the customary presenting complaint of increased abdominal girth and the clinical documentation of a large mass (64% >10 cm), 90% of the JGCTs analyzed by Young et al. (59) were stage IA or IB. The corresponding survival rate for these patients with an average follow-up of 3.5 years was 97%. Included were nine stage IA2 patients with rupture of the tumor, all of whom were alive and free of disease. Patients presenting with associated isosexual pseudoprecocious puberty may have a more favorable prognosis. Assessing 80 such cases accrued from 212 reported JGCTs, only two cancer-related deaths (2.5%) were observed. Presumably, the clinical manifestations lead to early medical intervention and reflect the excellent outcomes (59,61–63).

Although the early symptoms and presentation with localized disease are similar to AGCTs, several behavioral characteristics are notably different when comparing these histologic variants. Although the natural history of the adult form frequently includes a latency period with recurrences remote

from initial diagnosis, the juvenile counterpart is characteristically aggressive in advanced stages and the time to relapse and death of limited duration. Thirteen cases of stage II, III, or IV disease were abstracted from three analyses with a combined sample size of 180 patients (59,61,62). Of these 13 cases, only three patients (23%) were alive when reported, and notably, the recurrences and deaths occurred within a relatively brief interval. In contrast to the AGCTs, recurrences of JCGTs occur early, usually within 3 years of the diagnosis (59,61,63).

Prognostic Factors

Young et al. (59) noted surgical stage to represent the most reliable prognostic indicator. Tumor size, mitotic activity, and nuclear atypia appeared to be significant when tumors were analyzed without regard to stage. However, these parameters lost discriminating value when applied to only stages IA1 and IB1 tumors. In that series, rupture did not correlate with outcome. Schneider et al. reported on a group of 54 sex cord–stromal tumors in children and adolescents from Germany (45 JGCTs and 9 others) (71). They addressed the outcome of patients with “accidental” stage IC disease, defined as violation of the tumor capsule during surgery, versus “natural” stage IC tumors, with preoperative rupture or malignant ascites. Among 12 patients with accidental stage IC disease, there were no recurrences. In contrast, five of the nine patients with natural stage IC disease recurred ($p = 0.001$). Assessment of DNA content via flow cytometry in JGCTs demonstrated that nearly half of such tumors harbored nondiploid patterns (72,73). Jacoby et al. (72) were unable to correlate DNA ploidy or S-phase fraction (SPF) with either stage of disease or prognosis in patients with localized disease. In the series by Schneider et al., mitotic activity correlated with prognosis (71). There were no relapses in 35 patients whose tumors exhibited low or moderate mitotic activity. Among those with high mitotic activity (>19 mitoses per 10 HPFs), approximately half recurred.

Although the information in the literature is limited, the various tumor markers as discussed above for AGCTs would appear to be applicable to JGCTs for the monitoring of advanced disease.

TUMORS IN THE THECOMA-FIBROMA GROUP

Considering that the ovarian stromal cell is the precursor of both fibroblasts and theca cells, pure thecomas and pure fibromas appear to represent extremes in a continuum, with a significant percentage of the tumors having admixtures of lipid-laden, steroid-secreting cells and collagen-producing spindle cells. Nonetheless, the vast majority of tumors in the thecoma-fibroma group are readily subcategorized based on relatively distinct clinical and histologic characteristics. The major subcategories include thecoma, fibroma-fibrosarcoma, and the sclerosing stromal cell tumor.

Thecoma

Theca cell tumors (TCTs), or thecomas (Fig. 27.4), are composed of lipid-laden stromal cells, occasionally demonstrating luteinization, and are almost invariably clinically benign (4,74,75). Thecomas account for approximately 1% of ovarian neoplasms and occur at a more advanced age than other sex cord–stromal tumors. The majority of patients are in their sixth and seventh decades at the time of diagnosis (4,74). Combining two large series totaling over 140 patients, less than 10% presented prior to age 30 years. Notably, the luteinized tumors are an exception to this generalization, with

FIGURE 27.4. Thecoma. The tumor is composed of a mass of clear, vacuolated cells with round to oval nuclei intersected by bands of fibromatous tissue. Source: Reprinted with permission from Morris JM, Scully RE. *Endocrine Pathology of the Ovary*. St. Louis: Mosby; 1958.

30% occurring in women before their fourth decade of life (76). Assessing a compendium of nearly 300 cases, bilaterality occurs with a frequency of approximately 2% and extraovarian spread occurs rarely if at all (4,74,75,77).

The primary presenting signs and symptoms in patients with TCTs are abnormal genital bleeding and/or an abdominal/pelvic mass (74,75,77). The former urges initiation of medical intervention in the majority of postmenopausal patients, whereas an increasing abdominal girth or a palpable mass is more frequently the main presenting complaint of premenopausal patients. Lesion size has been reported to vary from <1 to 40 cm in diameter (74,75,77). Ascites is occasionally encountered.

Thecomas are considered to be among the most hormonally active of the sex cord–stromal tumors. The abnormal bleeding encountered in 60% of patients is presumably attributable to excess estrogen production (74,75). In the series reported by Evans et al. (4), endometrial hyperplasia was observed in 37% of the evaluable patients, and adenocarcinoma consistent with an unopposed estrogen effect was documented in an additional 27%. All the uterine cancers were well differentiated and minimally invasive, but two patients subsequently died of endometrial carcinoma. Other coexisting uterine pathologic findings potentially influenced by elevated circulating estrogen levels included leiomyomata, myohypertrophy, and endometrial polyps. Conversely, Zhang et al. (76) noted that nearly one half of the evaluated luteinized thecomas were either nonfunctional or androgenic, resulting in a relatively significant frequency of masculinization.

An enigmatic tumor that has been considered to be a variant of luteinized thecoma has been associated with sclerosing peritonitis (78). These tumors are often bilateral and frequently have a brisk mitotic rate, but have not been shown to have a metastatic potential. Sclerosing peritonitis has, however, been fatal owing to complications pursuant to it.

Fibroma-Fibrosarcoma

Fibromas represent the most commonly encountered sex cord–stromal tumor, accounting for approximately 4% of all ovarian neoplasms. These endocrine-inert tumors are seldom bilateral and vary in size from microscopic to extremely large masses. Although infrequently diagnosed prior to age 30 years,

fibromas can occur at any age; the average age of diagnosis is the latter half of the fifth decade of life (79). These tumors become more edematous as their size increases, which is frequently accompanied by the escape of increasing quantities of fluid from the tumor surfaces. Ascites is detected in association with 10% to 15% of ovarian fibromas exceeding a diameter of 10 cm (80). Furthermore, 1% of patients develop a hydrothorax in addition to the hydroperitoneum, both resulting from excessive fluid loss from the ovarian fibroma (Meigs' syndrome) (81). Gorlin's syndrome represents an inherited predisposition to the development of ovarian fibromas along with several other abnormalities, the most frequent of which is the appearance of basal-cell nevi at an early age (82).

Although ovarian fibromas are generally considered to be benign lesions, approximately 10% will demonstrate increased cellularity and varying degrees of pleomorphism and mitotic activity. Fibromatous tumors characterized histologically by an increased cellular density and brisk mitotic activity are designated cellular fibromas and are considered to be tumors of low malignant potential, particularly if ruptured or associated with adhesions (83). In contrast, fibrosarcomas are highly malignant neoplasms. These tumors are distinguished by their greater cellular density and, most notably, moderate to marked pleomorphism (84).

Sclerosing Stromal Cell Tumors

Sclerosing stromal cell tumors (SSTs) were initially described by Chalvardjian and Scully (85) in 1973 as a distinct subgroup within the thecoma-fibroma family of ovarian tumors. Accounting for less than 5% of sex cord-stromal tumors, this relatively rare tumor characteristically differentiates itself histologically and clinically from both thecomas and fibromas (86,87). Histologically, the presence of pseudolobulation of cellular areas separated by edematous connective tissue, increased vascularity, and prominent areas of sclerosis are distinguishing features. Clinically, SSTs commonly become manifest during the second and third decades of life, with 80% being diagnosed prior to age 30 years, which is unique among ovarian stromal tumors (88). The signs and symptoms that most commonly necessitate medical evaluation include menstrual irregularities and/or pelvic pain (89). Despite the relatively large tumor size, which ranges from clinically undetectable to 20 cm or more in greatest diameter, ascites is seldom encountered; this further contrasts SSTs from fibromas (89). In contrast to thecomas, SSTs were originally considered to be inactive endocrinologically (85). However, a limited number of cases have been subsequently reported in which steroidogenic activity has been clinically demonstrable (89-92). To date, all SSTs have been clinically benign, and with one exception (93), all have been unilateral. Although a recent report noted an elevated CA-125 level, which the investigators speculated was perhaps nonspecific (94), no specific tumor marker has been identified for SSTs to date.

Natural History

Thecomas, fibromas, and sclerosing stromal tumors are considered to be benign ovarian neoplasms, and any associated morbidity or mortality that would be encountered would be attributed to the treatment modalities or the sequelae of concurrent disease (4,74,77,79,95). Examples of the latter are deaths from endometrial carcinoma resulting from the unopposed estrogen produced by the thecomas (4). Although several cases of "malignant thecomas" have been reported, critical reappraisal of such tumors invariably results in histologic reassignment as sarcomas or diffuse granulosa cell tumors (96). Furthermore, DNA ploidy assessment in both thecomas

and fibromas not infrequently demonstrates aneuploid patterns that do not correlate with prognosis, rendering the significance of these observations questionable (97).

Prognostic Factors

The prognosis for patients diagnosed with cellular fibromas is generally considered to be quite favorable. Recurrences of these tumors of low malignant potential are generally correlated with adherent disease, rupture, or incomplete removal at the time of primary cytoreduction (83). Fibrosarcomas are associated with an extremely poor prognosis, but are fortunately rare.

SERTOLI STROMAL CELL TUMORS

Neoplasms arising in the ovary exhibiting morphologic characteristics similar to those of the testes during various stages of gonadogenesis were recognized and elegantly described by Meyer (98,99). He reasoned that the origin of these tumors was the male blastema and coined the term *arrhenoblastoma*. Considering the functional nature of these male homologs and the varying degrees of associated defeminization and/or masculinization, the term *androblastoma* was also adopted. However, Morris and Scully (100), in 1958, contended that both designations implied masculinization, which is frequently absent, and furthermore facilitated the inclusion of a variety of unrelated androgen-producing ovarian tumors. Therefore, they recommended the adoption of the morphologic designation Sertoli-Leydig cell tumor (SLCT), which also allowed a consistent nomenclature for the general classification of sex cord-stromal tumors of the ovary. The SLCTs include tumors composed of Sertoli cells only, Leydig cells only, and a combination of Sertoli and Leydig cells.

Sertoli Cell Tumors

Sertoli cell tumors are rare, accounting for less than 5% of all SLCTs (88). The average age at presentation is about 30 years, but this lesion can occur at any age. Evidence of estrogen production has been observed in approximately two thirds of the reported cases. Consistent with excess estrogen production, isosexual precocious puberty has been witnessed during the first decade of life, menstrual disorders during the reproductive decades, and postmenopausal bleeding in the decades after the climacteric. Reflecting tumor size (average 9 cm), capsular distention and/or adnexal torsion, and abdominal distention and/or pain are frequent complaints. Pelvic examination generally confirms the presence of the tumor under these circumstances. The frequency with which excessive renin production has been associated with Sertoli cells appears to exceed mere chance (101-103). Evaluation of refractory hypertension and hypokalemia has rarely eventuated in the discovery of a Sertoli cell tumor as the origin of the excess renin. An occasional Sertoli cell tumor has arisen in a patient with the Peutz-Jeghers syndrome (PJS) (104).

Pathology

On gross examination, these rare tumors are typically solid, lobulated, and yellow (88,105). Microscopic examination typically shows hollow or solid tubules lined by cells that usually have relatively bland cytologic features, but rare tumors exhibit moderate to severe nuclear atypia. In most tumors, a tubular pattern predominates, but occasionally a diffuse pattern is conspicuous.

Prognosis

The great majority of these rare tumors have been unilateral stage I lesions. The greater majority of Sertoli cell tumors are well differentiated, and only rare tumors are malignant (88). Excision of the tumor results in prompt resolution of the hyperestrogenic state. (Leydig cell tumors are discussed in the section on steroid cell tumors below.)

Sertoli–Leydig Cell Tumors

SLCTs are extremely uncommon, accounting for less than 0.2% of all ovarian tumors. As implied by their designation, the tumors contain both Sertoli and Leydig cell elements. Many of the clinical characteristics are related to the degree of histologic differentiation and the presence of a retiform pattern and/or heterologous elements (described below). The average patient age at diagnosis is approximately 25 years, with the majority (70% to 75%) of the tumors becoming clinically manifest during the second and third decades of life. Less than 10% occur either prior to menarche or after the climacterium. Patients harboring well-differentiated tumors present at an average age of 35 years, or 10 years later than patients with intermediate or poorly differentiated lesions. Conversely, tumors with retiform patterns are generally detected 10 years earlier than the intermediate and poorly differentiated tumors (106–108). Based on the compiled data from three reported series totaling over 300 patients, the frequency of extraovarian spread of disease at the time of diagnosis is approximately 2% to 3%. In addition, the likelihood of encountering bilateral tumors is even less frequent (106–108).

The most frequent complaints at the time of presentation of these generally healthy adolescents and young adults are menstrual disorders, virilization, and nonspecific symptoms resulting from an abdominal mass. Nearly one half of the patients experience sufficient abdominal pain or discomfort or note abdominal distention or palpate a mass on self-examination to prompt professional assessment. Whereas capsular distention and/or intraleisional hemorrhage or necrosis of the tumor and/or adjacent visceral compression by the tumor account for the associated chronic or intermittent pain, acute abdominal pain necessitating emergency intervention invariably reflects vascular compromise from torsion. While lesion size varies according to histologic differentiation (approximately 5 cm for well-differentiated tumors to >15 cm for poorly differentiated tumors), abdominal, vaginal, and/or rectal examination readily identifies an adnexal mass in approximately 95% of symptomatic patients. The most common premonitory symptoms, namely, menstrual disorders and subtle androgenic manifestations, predate by several months, and less often, by years, the recognition of the overt clinical signs or symptoms. Irregular bleeding, oligomenorrhea, and postmenopausal bleeding, retrospectively, have been attributed to either excess androgens or estrogens. The etiology of the latter is presumably the peripheral conversion of androgens to estrogens or, rarely, from an estrogen-secreting SLCT. Frank virilization occurs in 35% of the patients with SLCTs, and another 10% to 15% have some clinical manifestations consistent with androgen excess. The most frequent androgenic symptom complex encountered includes amenorrhea, voice deepening, and hirsutism. In addition, breast atrophy, clitorimegaly, loss of female contour, and temporal hair recession, for example, are signs of masculinization witnessed in patients with SLCTs (106–108). The prevalence of androgenic manifestations appears to be independent of the degree of histologic differentiation but is observed less frequently in heterologous SLCTs and only occasionally in patients harboring retiform lesions (107,109–112). Although the preoperative diagnosis of SLCT in the absence of androgenic excess may be impossible, this neoplastic entity

should constitute the primary preoperative diagnosis in patients with androgenic manifestations presenting during the second through the fourth decades of life with a unilaterally palpable adnexal mass.

Uncommonly, estrogen manifestations are witnessed in the context of presumed end-organ estrogenic responses, including postmenopausal bleeding and endometrial polyp formation, hyperplasia, and adenocarcinoma. Cautious interpretation of such observations is required, realizing that peripheral conversion of androgens to estrogens may be as plausible as a primary estrogen-secreting SLCT. As expected from the clinical findings, most patients demonstrating signs of defeminization or virilization have elevated plasma testosterone levels (106–108). Whereas plasma androstenedione may occasionally be elevated, the urinary 17-ketosteroids, including dehydroepiandrosterone, are usually normal, with the occasional patient presenting with a slightly elevated level. An elevated testosterone/androstenedione ratio generally suggests the presence of an androgen-secreting ovarian tumor, most likely an SLCT. Recognizing that certain gonadotropin-releasing hormone (GnRH) agonists modulate androgen production by down-regulating gonadotropin levels and through a direct effect on the ovary, Pascale et al. (113) demonstrated successful suppression of testosterone and androstenedione in five virilized women with the administration of GnRH agonists. Their data suggest that androgen-secreting tumors of the ovary appear to be less autonomous than such tumors originating in the adrenal gland. Surgical excision of the SLCTs results in a precipitous drop in androgen levels and, over time, partial to complete resolution of the clinical manifestations associated with androgen excess is observed.

The coexistence of other diseases with SLCTs has been chronicled. The frequency with which thyroid disease is observed in these patients appears to exceed mere chance. Furthermore, several cases of other mesenchymal tumors have occurred in patients with SLCTs, including sarcoma botryoides of the cervix as well as Ollier's disease (107,114). The latter is a rare disease, but it is associated with other sex cord–stromal tumors, specifically JGCTs, as noted above. Finally, a tendency toward familial occurrence appears to exist (107).

Pathology

Gross Features. Sertoli–Leydig cell tumors vary in size from small to huge masses, but most are between 5 and 15 cm in diameter. The majority are solid, often yellow, and lobulated (Fig. 27.5), but many are solid and cystic. Pure cystic tumors are exceptionally rare, in contrast to the situation with granulosa cell tumors. Poorly differentiated tumors tend to be larger than those more differentiated, and contain areas of hemorrhage and necrosis more frequently (107). Tumors with heterologous or retiform components are more often cystic than other tumors in this category (109,110,112,115). The heterologous tumors occasionally simulate mucinous cystic tumors on gross examination, and retiform tumors may contain large edematous intracystic papillae, resembling serous papillary tumors, or may be soft and spongy with varying degrees of cystification (112).

Microscopic Features. Well-differentiated SLCTs are characterized by a predominantly tubular pattern (116). On low-power examination, a nodular architecture is often conspicuous, with fibrous bands intersecting lobules composed of small, round, hollow, or, less often, solid tubules lined by well-differentiated cells and separated by variable numbers of Leydig cells. Rarely the tubules appear pseudoendometrioid (117).

Sertoli–Leydig cell tumors of intermediate and poor differentiation form a continuum characterized by a variety of patterns and combinations of cell types (106–108). Some tumors exhibit intermediate differentiation in some areas and poor differentiation in others, and less commonly, tumors of intermediate

FIGURE 27.5. Sertoli-Leydig cell tumor. The sectioned surface of the tumor is focally lobulated and was yellow in the fresh state.

differentiation contain well-differentiated foci. Both the Sertoli cells and the Leydig cells may exhibit varying degrees of immaturity. In tumors of intermediate differentiation, immature Sertoli cells have small, round, oval, or angular nuclei and generally scanty cytoplasm and are arranged typically in ill-defined masses, often creating a lobulated appearance on low power; solid and hollow tubules, nests, broad columns of Sertoli cells, and, most characteristically, thin cords resembling the sex cords of the embryonic testis are often present (Fig. 27.6). These structures are separated by stroma, which ranges from fibromatous to densely cellular to edematous, and typically contains clusters of well-differentiated Leydig cells (Fig. 27.6). Cysts containing eosinophilic secretion may be present and create a thyroid-like appearance, and follicle-like spaces are encountered rarely. The Sertoli cell and Leydig cell elements, singly or in combination, may contain varying and sometimes large amounts of lipid in the form of small or large droplets. When a significant amount

FIGURE 27.6. Sertoli-Leydig cell tumor, intermediate differentiation. Nests of large Leydig cells (*arrow*) lie among bands of immature Sertoli cells. *Source:* Reprinted with permission from Morris JM, Scully RE. *Endocrine Pathology of the Ovary*. St. Louis: Mosby; 1958.

of the stromal component is made up of immature cellular mesenchymal tissue with high mitotic activity resembling a nonspecific sarcoma, the tumor is poorly differentiated.

Fifteen percent of SLCTs have a substantial retiform component, and are so designated because they are composed of a network of elongated tubules and cysts, both of which may contain papillae, resembling the rete testis (32). This pattern is usually accompanied by other patterns of SLCTs, but sometimes an entire tumor has a retiform pattern.

Heterologous elements occur in approximately 20% of Sertoli cell tumors (113,118). In a series of these tumors, 18% contain glands and cysts lined by moderately to well-differentiated intestinal-type epithelium (113). Mesenchymal heterologous elements, encountered in 5% of Sertoli cell tumors, include islands of cartilage arising on a sarcomatous background, areas of embryonal rhabdomyosarcoma, or both (118).

Natural History

SLCTs display characteristics that differ markedly from their epithelial counterparts, notably in regard to their malignant potential. Despite an average size of approximately 16 cm, only 2% to 3% of SLCTs have demonstrable extraovarian spread at the time of detection. Furthermore, Young et al. (59) identified only 29 clinically malignant cases in their series of 220 SLCTs having variable observation intervals, and they noted an 18% malignancy rate among 164 patients with adequate follow-up. At least in part, the more favorable prognosis reflects the abrupt onset of androgenic manifestations and the early detection of nonspecific symptoms, which promote prompt medical assessment. Nevertheless, the natural history of the malignant variant includes early recurrences, with approximately two thirds becoming evident within 1 year of treatment and only 6% to 7% recurring after 5 years. The abdominal cavity (including the pelvis) and the retroperitoneal nodes are the most frequent sites for recurrences. In addition, the contralateral ovary, lungs, liver, and bone are other reported sites of recurrent metastatic disease. The collective salvage rates in patients with clinically malignant disease are low, with extrapolated estimates being less than 20%.

Prognostic Factors

Stage is the most important predictor of outcome in SLCTs. Fortunately, 97% of SLCTs are reportedly stage I at diagnosis, and less than 20% of these localized tumors become clinically malignant. The most cogent phenotypic prognostic determinant for stage I SLCTs is the degree of histologic differentiation (106–108). Approximately one half of the reported SLCTs are of intermediate differentiation, 10% are well differentiated, 20% are heterologous, and the remainder are poorly differentiated. No extraovarian spread or subsequent recurrences were encountered by Young and Scully (116) among 23 well-differentiated SLCTs. However, approximately 10% of intermediate and 60% of poorly differentiated tumors as well as 20% of heterologous tumors demonstrated clinically malignant behavior (107). The heterologous tumors contain either endodermal elements such as gastrointestinal epithelium and carcinoids or mesenchymal elements including skeletal muscles and/or cartilage. The endodermal elements are typically associated with intermediately differentiated homologous elements and represent 75% of the heterologous SLCTs. Their corresponding prognosis parallels that of the intermediately differentiated homologous tumors. In contrast, heterologous tumors containing mesenchymal elements account for 5% of all SLCTs and invariably coexist with a poorly differentiated homologous component. The clinically aggressive malignant behavior of poorly differentiated heterologous tumors is witnessed in the extremely low survival (107).

Retiform patterns, tumor size, mitotic activity, and tumor rupture appear to increase in frequency as the degree of tumor differentiation decreases (106–108). Approximately 10% of neoplasms express histologic patterns resembling the rete testis. They are more commonly observed in younger patients (average age 15 years) and are generally larger, possibly secondary to the less frequent association of androgenic manifestations and hence a later clinical presentation (109–112). Sertoli–Leydig cell tumors harboring a retiform pattern are associated with a 20% malignancy rate, significantly higher than the 12% nonretiform SLCT rate. Young and Scully (112) noted that 14 of 25 retiform cases were of intermediate differentiation, with 1 demonstrating poorly differentiated homologous histology and 10 exhibiting heterologous elements (3 intermediate and 7 poorly differentiated). Arguably, the less favorable prognosis reflects the frequency of associated heterologous and/or poorly differentiated homologous lesions. This concept is supported by the findings that the majority of the metastatic lesions do not contain retiform patterns (112). However, the adverse characteristics of the retiform component are witnessed when examining tumors of intermediate differentiation. Although only 4 of over 100 reported intermediately differentiated SLCTs were clinically malignant, 3 of the 4 contained retiform patterns (107).

Tumor size, mitotic activity, and tumor rupture have been reported to influence prognosis (106,107). The size, mitotic index, and rupture frequency appear to increase as histologic dedifferentiation increases. Notwithstanding these associations, substratification of intermediate and poorly differentiated lesions according to these parameters identifies significant prognostic differences.

The frequency of androgen excess has been addressed above, with 50% or more of patients diagnosed with SLCTs either directly or indirectly displaying clinical manifestations of hyperandrogenism. Serum testosterone levels are invariably elevated when virilization is present, and selective venous catheterization has documented the ovary as the site of origin (119,120). In addition, immunostaining was positive for testosterone in eight SLCTs analyzed, including a limited number of tumors from patients without clinical signs or symptoms of androgen excess (2,121). The Leydig cells, as anticipated, were shown to be the cell of origin for the synthesis of testosterone. Following cytoreductive surgery, the serum testosterone levels are rapidly cleared from the circulation and have been reported on occasion to increase again as a function of the burden of recurrent metastatic disease.

Other unique secretory products, namely, inhibin and alpha fetoprotein (AFP), have been reported in a limited number of SLCTs and are proteins generally equated with GCTs and germ cell tumors, respectively (110,112,120–122). In addition to GCTs, the Sertoli and Leydig cells have been shown to produce inhibin in testicular tissues, and presumably these same cell types are the site of origin in the SLCTs. Motoyama et al. (122) summarized the literature and reported the 14th case of an elevated serum AFP accompanying SLCTs. A clinically malignant course was appreciated in 43% of the described population, which had a mean age of 16 years. In addition, the majority (57%) was described as having a retiform component, a frequency substantially higher than the 10% usually seen in larger SLCT samples. Perhaps preferential AFP sampling accounts for a portion of this seemingly unusually high frequency in that, histologically, the retiform pattern may be confused with an endodermal sinus tumor, particularly in the absence of clinical androgenic manifestations. The Sertoli and Leydig cells appear to be the cells of origin for AFP within the tumor. Employing immunostaining, Gagnon et al. (121) confirmed that Leydig cells appear to be the predominant site for AFP synthesis, but Sertoli cells are also capable of producing this oncoprotein. Testing four retiform and four nonretiform SLCTs, they

demonstrated a 50% positivity rate in both histologic subtypes. The precise frequency of both inhibin and AFP positivity and their correlation with disease activity await larger confirmatory assessments.

OVARIAN SEX CORD TUMOR WITH ANNULAR TUBULES

In 1970, Scully (66) described a limited series of unique ovarian tumors characterized by either simple or complex ring-shaped tubules and proposed the morphologic designation ovarian sex cord tumor with annular tubules (SCTATs). The distinctive cellular elements of these neoplasms were judged to be histologically representative of an intermediate between Sertoli cell and granulosa cell tumors. Shen et al. (123) reported that SCTATs accounted for 6% of the sex cord tumors treated at their institution. An association with PJS was likewise recognized, and in a subsequent report of 74 cases of SCTAT, Young et al. (124) noted that approximately one in three SCTATs occurred in patients with PJS. Ovarian sex cord tumors with annular tubules occurring in association with PJS are typically small (many microscopic), multifocal, calcified, and bilateral. The average age of presentation is the early to mid portion of the fourth decade of life (124,125). The non-PJS tumors are considerably larger, seldom multifocal or calcified, and invariably unilateral. The average age of these patients is the mid to latter portion of the third decade of life.

Abnormal vaginal bleeding is the most common presenting complaint, including menstrual irregularities during the reproductive era and postmenopausal bleeding during the mature years. Menometrorrhagia followed by prolonged episodes of amenorrhea is commonly experienced in the non-PJS patients. Abdominal pain or discomfort is less frequently encountered but generally accompanies grossly involved adnexa or other incidental pelvic pathology. In addition, the signs and symptoms accompanying intussusception secondary to colonic polyp formation may be manifested in PJS-associated patients. The majority of PJS-associated SCTATs are not detectable via clinical examination and are appreciated unexpectedly during surgical or pathologic assessment. In contrast, the majority of non-PJS SCTATs are palpable on abdominal and/or vaginal examination. Although these tumors are seldom encountered during the first decade of life, isosexual precocity is invariably witnessed when SCTATs are diagnosed in affected children (124–127).

Considering the rarity of both PJS, an autosomal dominant disorder, and SCTAT, the frequency of concurrency of these two processes suggests a potential linkage in their pathogenesis. Approximately 36% of SCTATs are observed in patients with PJS. In addition, 15% of PJS-associated SCTATs also develop adenoma malignum of the cervix, a neoplasm that defies early diagnosis and is associated with a relatively high mortality rate (124,128–130). A recent report of 34 patients with PJS demonstrated a significantly elevated risk (relative risk = 20.3) of breast and gynecologic malignancies in women (131); 1 patient had a Sertoli–Leydig tumor and 3 had sex cord tumors with annular tubules. The PJS gene was mapped to chromosome 19p13.3 (132) and was later identified as a novel serine threonine kinase, STK11 (133). Because of the wide variety of malignancies occurring in individuals with PJS, STK11 is believed to function as a general tumor-suppressor gene.

Contingent on the patient's age, precocious puberty, menstrual irregularities, or postmenopausal bleeding are clinical manifestations of SCTATs, indirectly attesting to their endocrine activity (124–128,130,134,135). These signs of hyperestrogenism and the corresponding effects on the endometrium were readily recognized in the initial description of these unique tumors (58). Numerous reports have confirmed the presence of

endometrial hyperplasia and/or polyp formation, particularly in PJS-associated SCTATs. Although similar signs in endometrial histology can be observed in non-PJS SCTATs, clinical histories of menorrhagia followed by episodes of amenorrhea are more frequently obtained (123–126,134,135). Endometrial sampling in a limited population of such patients has demonstrated a spectrum from atrophic glandular to secretory or decidualized endometrium suggestive of significant levels of progesterone production (123,125,135). Assessment of circulating steroid levels has confirmed the presence of excessive estrogen in essentially all SCTAT cases (123,134–136). However, normal progesterone levels have been observed in PJS-associated tumors, but elevated quantities of progesterone have been documented in non-PJS patients (123,134–136). Shen et al. (123) demonstrated elevated estrogen and progesterone levels (and normal testosterone levels) in two SCTAT patients without PJS having documented glandular atrophy and decidual stromal changes. Utilizing selective ovarian venous sampling, Crain (135) demonstrated a significant progesterone gradient between peripheral and ovarian venous serum in a non-PJS patient with pseudodecidual changes of the endometrium. Complete resolution of the manifestations attributed to these hormonal imbalances has been routinely witnessed with surgical extirpation of the ovarian neoplasm.

Pathology

Grossly, the PJS-associated tumors are solid and yellow. The non-PJS-associated neoplasms may be similar, but in some cases, they are solid and cystic or mostly cystic. This tumor is characterized microscopically by the presence of simple and complex annular tubules (Fig. 27.7). The simple tubules have the shape of a ring, with the nuclei oriented around the periphery and around a central hyalinized body composed of basement membrane material; an intervening anuclear cytoplasmic zone forms the major component of the ring. The more numerous complex tubules are rounded structures made up of intercommunicating rings revolving around multiple hyaline bodies. In patients with PJS, the tumors are typically multifocal and exhibit calcification.

Prognostic Factors

Notwithstanding their histologic similarities, the differences in the natural history and hence long-term prognosis for SCTATs associated with PJS and SCTATs independent of PJS are readily

FIGURE 27.7. Sex cord tumor with annular tubules. Numerous rounded tubules encircle multiple hyaline bodies.

apparent. Those detected in women with PJS are benign. Important in the management of this entity, however, is the recognition that approximately 15% of these patients will harbor an adenoma malignum of the cervix (AMC). As a result of delayed declaration of symptoms, the diagnosis of AMC is frequently made following examination of the hysterectomy specimen. As evident in the recent review by Srivatsa et al. (130), the prognosis for PJS patients with SCTAT and AMC is ominous, reflecting high AMC recurrence rates and refractoriness to treatment.

Based on the compiled data from four reported series totaling 63 patients with SCTATs without clinically apparent PJS, the clinical malignancy rate approximated 20% (123–126). Primary extraovarian extension and/or the recurrence frequency has been correlated with the original tumor size and mitotic activity. The tumor characteristically has a relatively long doubling time, a propensity for lymphatic dissemination, and an aptness to remain lateralized. As the primary ovarian lesion is invariably unilateral, the lymphatic metastases are invariably ipsilateral, extending within the confines from the paraaortic region to the supraclavicular area. The nature of the retroperitoneal metastases generally facilitates surgical resection and repeat cytoreduction. The tumor's indolent growth pattern, coupled with the relative ease of resection, affords patients extended palliation.

Because SCTATs possess characteristics of both granulosa cells and Sertoli cells, tumor markers elicited by either or both cell types might find utility in the diagnosis and surveillance of these tumors as well. The observed increased serum estrogen levels and the corresponding clinical manifestations recognized with SCTATs suggest utility in monitoring hormone levels. Unfortunately, serum estradiol lacks adequate sensitivity, particularly when the residual tumor volume is limited. However, recent reports demonstrate the potential value and sensitivity of two unique secretory proteins as tumor markers for SCTATs. Gustafson et al. (136) illustrated the applicability of monitoring serum inhibin and müllerian-inhibiting substance (MIS) in the management of a patient with advanced, recurrent SCTAT. More recently, Puls et al. (137) likewise reported an excellent correlation between serum inhibin and MIS levels and the clinical status of a patient with SCTAT during chemotherapy administration. The ultimate utility of these tumor markers awaits accrual of sufficient numbers of patients with SCTATs to address adequately sensitivity and specificity issues.

SEX CORD–STROMAL TUMORS, UNCLASSIFIED

This ill-defined group of tumors, which accounts for less than 10% of those in the sex cord–stromal category, comprises those in which a predominant pattern of testicular or ovarian differentiation is not clearly recognizable. Talerman et al. (138) have recently segregated from within this category a group of tumors for which they have proposed the designation “diffuse nonlobular androblastoma.” The six ovarian tumors they reported were mostly estrogenic and had a predominant diffuse proliferation of cells resembling theca cells, granulosa cells, or both, but five of the six cases also contained steroid-type cells and tubules typical of Sertoli cell neoplasia.

Sex cord–stromal tumors may be particularly difficult to subclassify when they occur in pregnant patients because of alterations in their usual clinical and pathologic features (139). Their nature is rarely suggested clinically because during pregnancy estrogenic manifestations are not recognizable, and androgenic manifestations are rare. In one study, 17% of 36 SCSTs that were removed during pregnancy were placed in the unclassified group, and many of those that were classified in the granulosa cell or Sertoli–Leydig cell category had large areas with an indifferent appearance (139).

Gynandroblastoma

Gynandroblastoma is an extremely rare SCST if strict morphologic criteria are followed to establish the diagnosis. Microscopically, these tumors must demonstrate readily identifiable (at least 10%) granulosa cells and tubules of Sertoli cells. Not surprisingly, the corresponding stromal cells, namely, theca and/or Leydig cells, may also be present in varying degrees. Martin-Jimenez et al. (140) recently reviewed the world literature and were able to identify only 17 authenticated cases of gynandroblastoma. Patients presented at an average age of 29.5 years (range 16 to 65 years) with primary symptoms of menstrual disturbances consistent with the predominant functional status of the tumor. Commonly, a hyperandrogenic clinical profile is elicited, but signs and symptoms of excessive estrogens or no endocrine manifestations can be encountered. Amenorrhea, hirsutism, and clitorimegaly are frequently noted in association with elevated testosterone levels. Conversely, the common end-organ responses to hyperestrogenism include menometrorrhagia, postmenopausal bleeding, and endometrial hyperplasia. Although the unilateral masses are typically small, 75% are palpable prior to surgical exploration and are characterized by well-differentiated ovarian and testicular constituent elements. Regardless of the associated hormonal activity, gynandroblastomas are considered to be tumors of low malignant potential. To date, only a single case was reported to have been clinically malignant and resulted in death of the patient (141). Recently, a gynandroblastoma in pregnancy was reported (142).

Steroid Cell Tumors

Steroid cell tumors (SCTs) constitute only 0.1% of all ovarian neoplasms. The predominant components of these tumors are steroid hormone-secreting cells including lutein cells, Leydig cells, and adrenocortical cells. Until recently, the term *lipid cell tumors* was applied to these neoplasms, but Hayes and Scully (143) noted that 25% of such designated tumors did not contain appreciable intracellular fat. Hence, the functional designation steroid cell tumors was suggested and stratified into three subclasses: stromal luteoma, Leydig cell tumor, and steroid cell tumors not otherwise specified. The first two categories are essentially invariably benign, but some in the third group are malignant.

Stromal Luteoma

In 1964, Scully et al. (144) described the stromal luteoma as a distinctive type of steroid cell tumor. These relatively small (<3 cm) tumors are localized within the parenchyma of the ovary and account for approximately 25% of SCTs. They are thought to arise from luteinized stromal cells or their precursors. Histologically, the adjacent ovarian matrix as well as the contralateral ovary demonstrate stromal hyperthecosis in the vast majority of cases. The distinction between nodular hyperthecosis and stromal luteomas has been arbitrarily based on size, with lesions <5 mm being referred to as nodular hyperthecosis. In contrast to stromal hyperthecosis, stromal luteomas are rarely bilateral.

The average age at which stromal luteomas are diagnosed is the latter half of the sixth decade of life, with 80% occurring after the climacterium (143). Considering that the predominant functional profile is estrogenic, the result of either direct tumor secretion or peripheral conversion of androgens, it is not surprising that abnormal vaginal bleeding is the primary complaint. In a series of 25 cases reported by Hayes and Scully (143), information regarding the histologic architecture of the endometrium was known for 17 cases, which included 14 cases of hyperplasia and a single case of a well-differentiated adenocarcinoma of the

endometrium. Conversely, 12% of the patients presented with clinical manifestations of hyperandrogenism. In their analysis, 20% of the tumors were functionally quiescent and were detected incidentally during histologic assessment of surgical specimens processed for a variety of other indications.

Prognostic Factors. Considering the small size and lack of atypical histology, the posttreatment course is benign. To date, we are unaware of a single adverse outcome. Any untoward sequelae related to the stromal luteoma would presumably reflect secondary events from prolonged excessive hormone secretions such as an endometrial carcinoma.

Leydig Cell Tumors

Leydig cell tumors account for only 15% to 20% of SCTs. Histologically, the cellular elements are indistinguishable from lutein cells or adrenocortical cells except for the presence of crystals of Reinke, a requirement based on either light or electron microscopy for definitive diagnosis. Roth and Sternberg (145) subdivided these tumors according to location and possibly the cell of origin, namely, Leydig cell tumors of hilar type versus nonhilar type. Whereas the latter presumably arise from ovarian stromal cells and are extremely rare, the former tumors are located in the hilus of the ovary and encroach on or extend into the ovarian stroma in varying degrees. Other tumors containing features of Leydig cell tumors (such as location in the ovarian hilus or adjacent to nonmedullated nerve fibers, location within a continuum of hilar cell hyperplasia, fibrinoid vascular changes in the tumor, clustering of cells around vessels) but lacking crystals of Reinke are preferably categorized as steroid cell tumors not otherwise specified (146). By combining two reviews (146,147) that summarize the English-language literature prior to and after 1966, 38 Reinke-positive cases affording adequate abstraction were identified. These invariably unilateral tumors are typically small, ranging in size from 0.7 to 15 cm, with a mean of 2.7 cm, and are therefore frequently not detectable via clinical examination or pelvic imaging. Similar to stromal luteomas, the age of diagnosis is 58 years (range, 37 to 86 years), with only a small percentage occurring prior to the climacterium. The initial clinical manifestations are usually consistent with a hyperandrogenic state. Overt signs of virilization are observed in greater than 80% of the patients. These include one or more of the following: hirsutism, acne, deepening of the voice, breast atrophy, clitorimegaly, and male-pattern baldness. In contrast to the frequently dramatic onset and progression of virilization witnessed with SLCTs, ovarian Leydig cell tumors are generally characterized by a more indolent course. Paraskevas and Scully (146) reported an interval of 7 years between recognized onset of signs and symptoms of androgen excess and diagnosis. Analysis of serum androgens demonstrated testosterone to be consistently elevated while urinary 17-ketosteroids were normal or marginally increased. These observations suggest minimal production of androstenedione or dehydroepiandrosterone by these tumors.

Conversely, estrogenic manifestations are occasionally witnessed, such as irregular menses or postmenopausal bleeding (146,147). Pathologic assessment of the uterus may reveal endometrial hyperplasia, polyp formation, and/or carcinoma in the presence or absence of leiomyomata and/or myohyperplasia. Whether the hyperestrogenic features are a result of tumor secretion of estrogens or peripheral conversion of androgens to estrogens remains to be ascertained.

Prognostic Factors. In a review of the English literature through 1988, 38 Reinke-positive cases were accrued and only a single case of a clinically malignant lesion was identified (146,147). Based on tumor size (15 cm) alone, this sole example might be considered to be an outlier. Hence, similar to stromal luteomas, ovarian Leydig cell tumors are essentially benign neoplasms with the primary postsurgical concerns consisting of regression of the androgen-induced alterations.

Generally speaking, significant regression is witnessed, but significant residual sequelae are appreciated in approximately one half of the patients.

Steroid Cell Tumors Not Otherwise Specified

Neoplasms identified as steroid cell tumors but lacking the specific characteristics of stromal luteomas or Leydig cell tumors are collectively classified as steroid cell tumors not otherwise specified (SCTNOS). These tumors constitute the majority of steroid cell tumors and undoubtedly include both Leydig cell tumors and stromal luteomas that fail to meet specific identification criteria already noted. Although serving as a catchment for an undefined percentage of steroid hormone-secreting tumors, as a group, the SCTNOS have nonetheless unique characteristics. The natural history and biology of these tumors are significantly different when compared to Leydig cell tumors or stromal luteomas.

Although the average age at presentation of patients harboring SCTNOS is 43 years (10 to 15 years earlier than stromal luteomas and/or Leydig cell tumors), these tumors have been diagnosed from early childhood to the ninth decade of life (148). In addition, these generally solid yellow tumors are larger than the other SCTs. The average size at diagnosis approximates 8.5 cm (range, 1.2 to 45.0 cm). Furthermore, a higher frequency of bilaterality (5%) in advanced disease is encountered with these neoplasms. In their review of 63 collocated cases, Hayes and Scully (148) reported that 81% of cases had localized disease (stage I), 6% had stage II disease, and 13% had stage III or IV disease. Curiously, they noted the average age (54 years) of patients with advanced disease was 10 years older than the group as a whole. At least in part, these findings reflect the absence of documented advanced malignancies during the first two decades of life.

Clinical signs and/or symptoms of androgen excess ranging from heterosexual precocity in prepubertal girls to amenorrhea, hirsutism, and/or virilization during the reproductive and/or postmenopausal ages prompt the majority of patients to seek medical advice (148,149). Not infrequently, the duration of these androgenic changes may have extended over many years (150). Additional concerns at presentation include increasing abdominal girth reflecting tumor size and, rarely, ascites, abdominal pain, cushingoid symptoms, and irregular uterine bleeding. The latter may represent clinical manifestations of estrogen excess (148,151), which has been suggested to occur at a frequency of 6% to 23%. Whether the source of estrogen is *de novo* synthesis by the tumor or from peripheral conversion of androgens remains to be determined. Isosexual precocious pseudopuberty has been detected in young girls harboring SCTNOS (148,152,153). An additional 10% to 15% of patients are asymptomatic, with tumors being detected incidentally during routine pelvic examination or at the time of hysterectomy or other surgical interventions.

The steroid hormone-secreting capacities of SCTNOS are more diverse than those of most sex cord-stromal tumors. Whereas approximately one in four patients does not demonstrate clinical manifestations of hormonal imbalances, the majority of patients with SCTNOS have evidence of androgen excess (10% to 15% estrogen excess) and a lesser percentage of cortisol excess. These excesses are demonstrable via assessment of end-organ responses and serum/plasma steroid levels. Whereas elevated plasma levels of corticosteroids are typically observed in conjunction with SCTNOS, the number of overt presentations with Cushing's syndrome is limited (152,154-156). However, 17% of the clinically malignant tumors reported by Hayes and Scully (148) were associated with Cushing's syndrome. The serum testosterone and androstenedione levels are invariably elevated, as are urinary 17-ketosteroids; presumably, the latter reflect the level of excess androstenedione production.

FIGURE 27.8. Steroid cell tumor, unclassified. The sectioned surface of the tumor is lobulated and was yellow-orange in the fresh state. This tumor was from a 9-year-old virilized girl.

Pathology.

Gross Features. The tumors are typically solid, well circumscribed, occasionally lobulated (Fig. 27.8), and average 8.4 cm in diameter (148). Approximately 5% are bilateral. They are typically yellow or orange but are occasionally red, dark brown, or black. Necrosis, hemorrhage, and cystic degeneration are occasionally observed.

Microscopic Features. On microscopic examination, the tumor cells are typically arranged diffusely but occasionally grow in nests, irregular clusters, thin cords, and columns. The polygonal to rounded tumor cells have distinct cell borders, central nuclei, and moderate to abundant amounts of cytoplasm that varies from eosinophilic and granular to vacuolated and spongy (Fig. 27.9). In approximately 60% of the cases, nuclear atypia is absent or minimal and mitotic activity is low (less than two mitotic figures [MFs] per 10 HPFs). In the remaining cases, grades 1 to 3 nuclear atypia (Fig. 27.3) is present, usually associated with an increase in mitotic activity (up to 15 MFs per 10 HPFs).

FIGURE 27.9. Steroid cell tumor. The tumor cells are large and rounded and laden with lipid vacuoles. Source: Reprinted with permission from Hayes MC, Scully RE. Ovarian steroid cell tumors not otherwise specified [lipid cell tumors]: a clinicopathologic analysis of 63 cases. *Am J Surg Pathol* 1987;11:835-845.

Prognosis. In contrast to the benign natural history of both ovarian Leydig cell tumors and stromal luteomas, SCTNOS are associated with a relatively high rate of clinical malignancy. In the largest series in the literature, 43% of patients with follow-up of 3 or more years demonstrated extraovarian disease either at primary surgery or during subsequent follow-up (157). Unfortunately, to date, salvage therapy has been abysmal. Multiple factors appear to correlate with the frequency of disseminated disease including age, stage, tumor size, mitotic activity, tumor necrosis, hemorrhage, and symptoms of Cushing's syndrome. The average age of patients with clinical malignancies was 16 years older than patients without metastatic disease and having had 3 or more years of observation. No clinically malignant cases have been reported to date in patients less than 20 years of age. All malignant SCTNOS were reported to measure 7 cm or more in greatest diameter (148). In fact, 78% of all tumors 7 cm or larger were malignant, whereas only 21% of all benign tumors exceeded this dimension. The most cogent determinant correlating with malignant potential was mitotic activity, with 92% of malignant tumors displaying two or more MFs per 10 HPFs. Similarly, in the presence of necrosis, 86% were malignant; if hemorrhage was present, 77% were malignant. In addition, three of four patients (17% of all malignant cases) with recognizable Cushing's syndrome harbored clinically malignant disease (148).

Although the majority of recurrences become clinically manifest within 3 years of diagnosis, Hayes and Scully (148) reported that 22% of recurrences occurred after 3 years and that, in fact, all of these cases occurred after 5 years; the longest interval witnessed was 19 years. Therefore, the duration of posttreatment surveillance should be adjusted accordingly. The only currently available utilizable markers for SCTNOS include the steroid hormones that were elevated prior to definitive treatment.

TREATMENT

The definitive management of sex cord–stromal tumors is dependent on one or more of the following therapeutic determinants: surgical stage, histologic subtype, patient's age and desire for fertility preservation, and various prognostic factors. Surgery alone is sufficient for several SCSTs lacking malignant potential, whereas postoperative adjunctive therapy generally should be considered for patients with advanced disease and Sertoli–Leydig cell tumors with poor differentiation or heterologous elements (158).

Operative Management

Surgery remains the cornerstone of treatment for patients with SCSTs. Definitive therapy for SCSTs commences with an abdominal exploration through an adequate vertical midline incision. Following securing of peritoneal washings for cytologic assessment, inspection and palpation of the viscera are conducted to detect macroscopic disease. Fertility-sparing surgery with unilateral salpingo-oophorectomy seems to be appropriate management for patients with stage IA disease who are desirous of retaining their reproductive potential. In a review of the 1988 to 2001 SEER database, Zhang et al. identified 376 patients with ovarian SCST (159). The survival for the group of 110 patients with stage I–II disease who underwent conservative surgery without hysterectomy was similar to that of patients who underwent standard surgery. For older patients or those with advanced-stage disease or bilateral ovarian involvement, abdominal hysterectomy and bilateral salpingo-oophorectomy are usually indicated. Frozen section examination of the ovarian tumor should be performed to confirm the diagnosis of a sex cord–stromal tumor.

Resection of the ovarian tumor will constitute sufficient therapy for the essentially benign neoplasms, including thecomas; fibromas; gynandroblastomas; stromal luteomas; and Leydig cell, sclerosing stromal, Sertoli cell, and well-differentiated SLCTs. Furthermore, sex cord tumors with annular tubules associated with PJS are also considered to be benign and can be similarly managed, but it is imperative that the endocervix be evaluated and subsequently monitored for the potential development of an adenoma malignum of the cervix. Conversely, histologic confirmation of granulosa cell tumors, intermediate or poorly differentiated Sertoli–Leydig cell tumors, sex cord–stromal tumors with annular tubules (independent of PJS), and steroid cell tumors not otherwise specified will require definitive surgical staging. This includes multiple biopsies from high-yield sites, omentectomy, and pelvic and para-aortic lymph node sampling/dissection, although the benefit of comprehensive staging in those tumors has not been established. However, recent evidence from a retrospective review of the Memorial Sloan-Kettering Cancer Center experience calls into question the necessity of performing a retroperitoneal lymphadenectomy in the absence of any grossly suspicious lymph nodes (160). Of 68 patients with granulosa cell tumors, 16 (24%) underwent a pelvic lymph node sampling, and 13 (19%) also had a para-aortic lymph node sampling at primary surgery or re-staging surgery. All lymph nodes in these cases were negative for metastatic tumor. In addition, of 34 patients with recurrent granulosa cell tumors, 2 recurred in the retroperitoneum only; 2 in the pelvis and retroperitoneum; and 1 in the pelvis, abdomen, and retroperitoneum. Overall, approximately 15% of first recurrences appeared to involve the retroperitoneum.

Following careful surgical staging and in the absence of extraovarian disease, conservation of the uterus and contralateral ovary is reasonable in patients wishing preservation of fertility. However, when electing conservative, fertility-sparing treatment, a thorough curettage must be performed in all patients with estrogen-producing tumors whether they are considered to be benign or potentially malignant (4). If fertility is not an issue or if extraovarian spread of disease is documented, a hysterectomy and residual salpingo-oophorectomy should be performed. Although no scientific evidence exists pertaining to the efficacy of cytoreduction in SCSTs, based on the benefits observed with their epithelial counterparts, we endorse an aggressive maximum effort at primary surgery if metastatic disease is encountered. The value of secondary tumor reduction continues to be controversial but appears to be meritorious in the more indolent tumor types such as GCTs and SCTATs (those not associated with PJS). Repeat cytoreduction frequently affords these patients extended palliation. It is therefore mandatory that the surgeon have adequate familiarity with the natural history of the various SCSTs and the technical expertise to facilitate optimal surgical management.

Postoperative Management and Management of Recurrent Disease

Granulosa Cell Tumors (Adult)

The vast majority of women with stage I disease have an excellent prognosis after surgery alone and do not require adjuvant therapy. For those with stage IC disease, consideration can be given to adjuvant therapy on an individualized basis. Most women presenting with stages II to IV disease would be advised to have postoperative therapy depending on their individual characteristics.

Whereas some investigators have reported improved outcomes in patients treated with adjuvant radiation therapy, other investigators have found no clear value to the use of

adjuvant radiation therapy (4,6,16,161). Because of the rarity of granulosa cell tumor, it is difficult to conduct prospective trials in these patients. Two retrospective reports provide some data on the use of radiotherapy. Savage et al. reviewed the courses of 62 women treated for adult GCTs at the Royal Marsden Hospital from 1969 to 1995 (162). Thirty-eight (61%) had stage I disease. Eleven of the stage I patients had adjuvant pelvic radiation. The 10-year disease-free survival of these patients was 77% versus 78% for stage I patients treated with surgery alone. Unfortunately, neither complete surgical staging information nor the features that led to the selection of patients for adjuvant radiation was provided. For eight patients with inoperable disease (or residual disease postoperatively), radiation resulted in complete responses in four (50%) that lasted 16 months to 5 years.

Wolf et al. reported on 34 patients with GCTs treated with radiation at the M. D. Anderson Cancer Center, 14 of whom had measurable disease (161). Six of the 14 (43%) had a clinical complete response. Three of the responders were alive without evidence of disease 10 to 21 years after radiation.

The Gynecologic Oncology Group (GOG) has reported the largest series of women with ovarian SCSTs treated with chemotherapy. They used four cycles of cisplatin, bleomycin, and etoposide (BEP) (163). Eligible patients had incompletely resected stage II to IV or recurrent disease. Seventy-five patients entered but 18 were ineligible because of incorrect histology or disease status. Of the 57 eligible patients, 41 had recurrent disease and 16 had primary disease. Thirty-nine had gross residual disease following surgery. Forty-eight had GCTs, seven had SLCTs, one had a malignant thecoma, and one had an unclassified SCST. This chemotherapy combination was considered to be active, with 11 of 16 primary-disease patients and 21 of 41 recurrent-disease patients remaining progression free at a median follow-up of 3 years. Recognizing the prolonged natural history of these tumors, longer follow-up of this cohort will be important. The regimen was fairly toxic, with two bleomycin-related fatalities among the first six patients treated with the initial bleomycin dose of 20 U/m² (maximum 30 U) weekly for 9 weeks. The bleomycin dose was then reduced (20 U/m² every 3 weeks × four cycles) with no mention of further toxicity. Grade 4 myelotoxicity occurred in 61% of the patients. The value of bleomycin in the treatment of this tumor type remains in question (164).

Gershenson et al. (165) also reported on the use of BEP in a group of nine women with poor-prognosis SCSTs of the ovary (seven had metastatic disease). The median progression-free survival was 14 months, with a median survival time of 28 months. These investigators, in the same publication, describe activity with paclitaxel in patients with granulosa cell tumors who have failed platinum-based therapies. In an earlier series, Gershenson et al. (157) found that cisplatin, doxorubicin, and cyclophosphamide were shown to have activity in the treatment of metastatic ovarian stromal tumors, including two Sertoli-Leydig cell tumors. The overall response rate was 63% in this series.

The management of patients with recurrent disease must be individualized. Given the characteristic indolent growth pattern of GCTs, with long disease-free intervals, surgical resection of disease recurrence is often the initial step in the management of appropriate patients. Pecorelli et al. treated 38 patients with advanced (n = 7) or recurrent (n = 31) GCTs with cisplatin, vinblastine, and bleomycin (PVB) on a prospective trial through the European Organization for Research and Treatment of Cancer (EORTC) (166). Of the seven women who presented with advanced disease (stages II to IV), one was alive and disease-free at 81 months. Five died between 4 and 12 months after the start of PVB, and another was alive with disease at 2 months. Among the 31 women with recurrent disease, 7 were alive without further evidence of disease from 24 to 81 months from the start of PVB. Consistent with the indolent course

observed with GCTs in some women, another 11 women were alive with disease at a mean of 45 months from the start of PVB (median 39 months).

The wisdom of using a germ cell-like regimen for stromal tumors is questionable. Uygun et al. reported on a small series of 11 women with recurrent GCTs (167). Most had cyclophosphamide, Adriamycin (doxorubicin), and cisplatin (CAP) in the adjuvant setting. Four were treated with cyclophosphamide and cisplatin for recurrence and survived 35 to 73 months after recurrence.

Recently, there has been increasing interest in the use of taxanes in SCSTs. A case report documented a dramatic response to paclitaxel in a patient with a GCT 2 years following cessation of platinum-based therapy (168). Subsequently, Brown et al. reported a retrospective review of the M. D. Anderson Cancer Center experience with taxane therapy in 44 patients with newly diagnosed or recurrent SCSTs (169). Eleven patients received paclitaxel and a platinum drug for newly diagnosed SCST; all were alive at the time of the study, with a median follow-up of 52 months. Of 37 patients treated with a taxane for recurrent SCST, 7 had no measurable disease after secondary cytoreductive surgery, and 30 had measurable disease. The response rate in the latter cohort was 42%. In a follow-up study, Brown et al. retrospectively compared the efficacy and side effects of taxanes, with or without platinum, to the combination of BEP (170). The outcomes of the two groups were similar, but the side effects associated with the BEP regimen appeared to be greater. The authors concluded that taxane and platinum chemotherapy warrants further investigation in SCSTs. The GOG is currently conducting a phase 2 trial of paclitaxel in women with stromal tumors with measurable disease (GOG protocol 187)—either previously untreated or recurrent. In addition, a GOG randomized phase 2 study of paclitaxel and carboplatin versus BEP in patients with SCSTs is planned in the near future.

Considerable rationale exists for the utilization of hormone-based approaches in GCTs. A proportion of these tumors express steroid hormone receptors (171). Responses of GCTs, occasionally long term, to medroxyprogesterone acetate and to GnRH antagonists have been reported (172–176). Fishman et al. (177) treated six patients with recurrent or persistent GCTs with monthly intramuscular injections of leuprolide acetate. Four patients had received prior cisplatin-based chemotherapy. Five patients had evaluable disease: two had partial responses and three had stable disease. The leuprolide was well tolerated.

Granulosa Cell Tumors (Juvenile)

Calaminus et al. (178) reported the outcome of 33 patients with JGCTs—24 treated with surgery alone and 9 with surgery and cisplatin-based chemotherapy. There have been six relapses, with 60 months median follow-up: 2 of 20 stage IA, 2 of 8 stage IC, and 2 of 5 stage IIC to IIIC. Three patients with stage IIC to IIIC disease treated with adjuvant cisplatin-based therapy remain disease free at 46 to 66 months after diagnosis. Furthermore, Powell and Otis (179) reported short-term disease control in two teenagers with stage III JGCTs following surgery and cisplatin-based chemotherapy.

German investigators published their 15-year experience (1985 to 2000) with 54 sex cord-stromal tumors in children and adolescents (71). Forty-five were JGCTs. Twelve received adjuvant chemotherapy for stages IC to IIIC disease. BEP and cisplatin, etoposide, and ifosfamide (PEI) were the most commonly used regimens. Six patients remained in remission after adjuvant chemotherapy from 15 to 106 months later. A seventh developed a contralateral JGCT 10 years after her initial primary tumor. Five of the 12 have recurred, 3 of whom died 16 to 28 months from diagnosis.

Powell et al. have reported a patient with long-term disease-free survival following salvage chemotherapy for recurrent JGCT (180). The patient had presented with stage IIIc disease initially treated by resection of all gross disease followed by carboplatin and etoposide for six cycles. She recurred 13 months later with limited disease in the liver and a mass at the inferior aspect of the spleen. She underwent gross total resection followed by six cycles of bleomycin and paclitaxel. She was disease-free 44 months later, delivering a normal baby at cesarean section.

Sertoli–Leydig Cell Tumors

Therapy for those few individuals presenting with high-stage SLCTs, as well as for individuals with recurrent disease, must be individualized. The effectiveness of radiation therapy is unknown (108). Reports exist of responses to vincristine, actinomycin D, and cyclophosphamide (VAC) and cisplatin, doxorubicin, and cyclophosphamide (157,181). Schneider et al. reported three patients with SLCTs who were treated with platinum-based chemotherapy (71). One patient with stage IC disease with intermediate differentiation received two cycles of the combination of cisplatin and etoposide and was disease free at 47 months. Two other patients, both of whom had stage IC poorly differentiated SLCTs, were dead of tumor at 7 and 19 months after receiving either BEP or PEI. Given the functional hormonal nature of many of these neoplasms, consideration could also be given to some form of hormonal manipulation, such as luteinizing hormone–releasing agonists or antagonists (182).

Sex Cord Tumor With Annular Tubules

Given the rarity of this tumor, the collective experience with systemic therapy for SCTATs is scant. Their endocrine activities suggest that the tumors may retain responsiveness to perturbation of gonadotropin levels. A recent case report documents a complete response to etoposide, bleomycin, and cisplatin in a patient with recurrent SCTAT (137).

MOLECULAR PATHOGENESIS

Our current knowledge regarding various autocrine and endocrine regulatory mechanisms influencing ovarian function, the overexpression of inhibin in several SCSTs, the alterations in ovarian steroidogenesis, and the changes in circulating gonadotropin levels in SCSTs provide several probable clues regarding the pathogenesis of these tumors. Investigations to date exploring the interactive regulatory mechanisms of inhibin, activin, follistatin, and follicle-stimulating hormone (FSH) have predominantly utilized GCTs. Follicle-stimulating hormone provides a fundamental regulatory role in the differentiation processes of granulosa cells during the early stages of follicle development. Specifically, FSH stimulates cell proliferation (mitosis), increases the availability of cell-surface prolactin and luteinizing hormone receptors, and induces aromatase activity, resulting in increased estradiol production. Other growth-regulatory factors such as insulin-like growth factor and epidermal growth factor modulate these actions, including the enhancement of the mitogenic effects of FSH. In addition, FSH secretion from the anterior pituitary is modulated in part by the serum levels of inhibin, activin, and estrogens and/or androgens.

Inhibin, a heterodimeric glycoprotein hormone composed of an alpha-subunit and one of two beta-subunits, is secreted by the granulosa cells of the ovary (183). Inhibin A consists of alpha and beta A; inhibin B, alpha and beta B. Petraglia et al.

(184) studied the molecular form of inhibin in adult GCTs and epithelial ovarian cancers. Serum inhibin B was dramatically increased in eight of nine patients with GCTs. Inhibin A was slightly increased in all patients. Its major physiologic function is to inhibit the secretion of FSH by the anterior pituitary gland (185). Inhibin is expressed in excessive quantities by GCTs. Although it maintains its regulatory function pertaining to FSH suppression, it appears to be ineffective in controlling estrogen production and cell proliferation within the gonad. Robertson et al. have recently reviewed the various serum-based assays for inhibin (186).

Activin, also a peptide hormone of ovarian granulosa cell origin, is composed of two beta subunits that are identical to those of inhibin. In contrast to inhibin, activin stimulates the secretion of FSH, induces the production of estradiol while having a negative impact on progesterone production, and serves as a promoter of differentiation of granulosa cells (185).

Several investigative teams are pursuing studies to elucidate the underlying genetic and biologic changes that give rise to sex cord–stromal tumors, especially granulosa cell tumors. Lin et al. performed comparative genomic hybridization of a set of 37 adult-type granulosa cell tumors (36 primaries, 1 recurrence) obtained from five hospitals in Taiwan (187). All patients had stage I disease except for one stage III patient with limited disease at initial diagnosis. Twenty-two (61%) of the 36 primary tumors had chromosomal imbalances. The nonrandom changes included loss of 22q in 31% of tumors, gain of chromosome 14 in 25% of tumors, and gain of chromosome 12 in 14% of tumors. Monosomy 22 frequently coexisted with trisomy 14. High-level amplification, as can be seen in many aggressive carcinomas, was not detected in any of these granulosa cell tumors. Findings were similar to those reported by Mayr et al. (188). As a sole abnormality, trisomy 12 has also been found in fibromas and fibroepitheliomas, in addition to granulosa cell tumors (189,190). Menczer et al. looked for HER2/neu expression in 12 granulosa cell tumors and saw no immunohistochemical staining (191). An Austrian group looked at the immunohistochemical expression of the HER family of receptors—HER1 (EGFR), HER2, HER3, and HER4—in 38 adult granulosa cell tumors and two of the juvenile type (192). Thirty-one cases (77.5%) were positive for at least one of the receptors (EGFR, HER3, or HER4). None of the 40 cases showed a positive reaction for HER2. Twenty-six of 40 (65%) showed reactivity for EGFR. HER3 and HER4 expression were observed in 18 (45%) and 23 (57.5%) tumors, respectively. Kusamura et al. also looked for HER2 expression in 18 granulosa cell tumors: all cases were negative (193). They also showed a markedly low likelihood of immunohistochemical staining for p53 and low proliferative indices in these tumors.

Chu et al. examined the estrogen receptor isoform gene expression in a small series of granulosa cell tumors and serous cystadenocarcinomas of the ovary (four of each) (194). They saw widespread expression of estrogen receptor (ER)-alpha in both tumor types but at relatively low levels, similar to or less than what is seen in the endometrium. ER-beta expression in the granulosa cell tumors, however, was several-fold higher than that of ER-alpha. Fuller and Chu have provided an informative review of various signaling pathways that are important in the regulation of growth, differentiation, and apoptosis of normal granulosa cells, which may contribute to the molecular pathogenesis of GCTs (195). Because of the important role of the insulin-like growth factor (IGF) system in development of the dominant follicle, and its contribution to epithelial ovarian cancer, Alexiadis et al. characterized the expression of several components of the IGF system in a series of nine granulosa cell tumors (196). Interestingly, pregnancy-associated plasma protein-A expression was highest in the granulosa cell tumors. PAPP-A is a metalloproteinase synthesized by granulosa cells, the activity

of which leads to increased IGF bioavailability. Anttonen et al. studied samples from a cohort of 80 GCT patients from the University of Helsinki and examined several growth regulatory factors known to be important in normal granulosa cell function, including anti-müllerian hormone, inhibin alpha, and GATA transcription factors (197). They found a correlation between high GATA-4 expression and higher likelihood of recurrence.

The natural history of sex cord–stromal tumors is uniquely different from that of their epithelial counterparts and provides an intriguing tumor model. The vast majority of these neoplasms are characteristically of low malignant potential. They are typically unilateral and remain localized, retain hormone-secreting functions, and infrequently develop recurrences, many of which are delayed. In contrast, a small percentage of otherwise phenotypically similar tumors demonstrate a more virulent course and are generally refractory to therapy. The SCST subtypes display a bimodal age distribution, notably with JGCTs, SSCTs, SLCTs, and SCTATs occurring predominantly during the first three decades of life. Furthermore, the association of these tumors with several uncommon congenital disease entities, such as enchondromatosis, leprechaunism, and PJS, occurs at frequencies that exceed mere chance. Uniquely, several of these functioning neoplasms, including AGCTs, JGCTs, SLCTs, and SCTATs, overexpress growth-regulatory substances including inhibin, müllerian-inhibiting substance, and follicle-regulating protein. Given the limited number of ovarian SCSTs available for study, our current understanding of the mechanism of oncogenesis in these tumors is understandably limited.

SUMMARY

The principal problem related to the study of SCSTs and the development of effective therapy is their rarity. Although this interesting group of tumors has been studied extensively from a histologic standpoint, there are surprisingly few features that distinguish tumors that are more likely to recur or have aggressive behavior, and much of the information is conflicting.

Surgery remains the cornerstone of treatment for patients with SCSTs. Furthermore, for young patients desirous of fertility preservation, fertility-sparing surgery is possible in a large proportion related to the propensity of these tumors to be unilateral and nonmetastatic. Patients who appear to have a worse prognosis and for whom postoperative therapy would appear to be indicated include those with metastatic SCSTs of any histotype and those with stage I poorly differentiated Sertoli–Leydig cell tumors. For patients with SCSTs confined to the ovary, postoperative therapy is not recommended. For those with stage IC disease, the issue of postoperative therapy is unresolved.

Standard postoperative treatment consists of platinum-based chemotherapy. The BEP regimen is currently the most popular combination. However, this is a relatively toxic regimen; hence, the interest in alternative combinations, such as taxane/platinum chemotherapy. However, more study of this latter combination is warranted. An upcoming GOG study should help resolve this issue.

Beyond platinum-based chemotherapy, there is no consensus concerning recommended second-line or salvage therapy. Hormonal medications clearly have some degree of activity in granulosa cell tumors. In addition, there is probably a limited role for radiation. This gap in our armamentarium underscores the need for novel target-based therapeutics developed through the study of the genes and pathways involved in the pathogenesis of these neoplasms.

CHAPTER 28 ■ MOLAR PREGNANCY AND GESTATIONAL TROPHOBLASTIC NEOPLASMS

ROSS S. BERKOWITZ AND DONALD P. GOLDSTEIN

Molar pregnancy and gestational trophoblastic neoplasms (GTN) comprise a group of interrelated diseases including complete and partial molar pregnancy, invasive mole, placental-site trophoblastic tumor (PSTT), and choriocarcinoma (CCA) that have varying propensities for local invasion and metastasis. GTN are one of the rare human malignancies that are highly curable with chemotherapy even with widespread metastases (1–4). Although GTN most commonly follow a molar pregnancy, they may develop after any gestation. Important advances have been made in the diagnosis, treatment, and follow-up of patients with molar pregnancy and GTN over the past 5 years. This chapter reviews these advances and discusses basic principles in the management of patients with molar pregnancy and persistent GTN.

EPIDEMIOLOGY

The reported incidence of GTN varies dramatically in different regions of the world (5). The frequency of molar pregnancy in Asian countries is seven to ten times greater than the reported incidence in North America or Europe (6). Whereas hydatidiform mole occurs in Taiwan in 1 per 125 pregnancies, the incidence of molar gestation in the United States is about 1 per 1,500 live births. Variations in the incidence rates of molar pregnancy partly result from differences between reporting hospital-based versus population-based data. Jeffers et al. (7), reporting a study from Ireland where all products of conception from first- and second-trimester abortions were referred for pathologic examination, found the incidence of complete and partial mole was 1:1,945 and 1:695 pregnancies, respectively.

The high incidence of molar pregnancy in some populations has been attributed to socioeconomic and nutritional factors. We have observed in a case-control study that the risk for complete molar pregnancy progressively increases with decreasing levels of consumption of dietary carotene (vitamin A precursor) and animal fat (8). Parazzini et al. (9) also reported from Italy that low carotene consumption was associated with an increased risk of molar gestations and their sequelae. Global regions with a high incidence of vitamin A deficiency correspond to areas with a high frequency of molar pregnancy. Vitamin A deficiency in the rhesus monkey produces degeneration of the seminiferous epithelium with production of primitive spermatogonia and spermatocytes (10). Dietary factors such as carotene may therefore partly explain the regional variations in the incidence of complete molar pregnancy.

The risk of having a complete hydatidiform mole (CHM) also increases with advanced maternal age (6). Women older than age

40 years have a five- to tenfold greater risk of having a complete molar gestation. In fact, one out of three pregnancies in women over 50 years of age are molar and the risk of developing GTN is significantly increased as well. Ova from older women may be more susceptible to abnormal fertilizations.

The risk for both complete and partial molar pregnancy (partial hydatidiform mole [PHM]) is increased in women with a history of prior spontaneous abortion and infertility (11). Compared with women with no previous miscarriage, the risk for complete and partial mole was 3.1 and 1.9, respectively, among women with two or more prior miscarriages. Difficulty in conception or infertility problems were associated with an odds risk of 2.4 and 3.2, respectively, for complete and partial mole.

Certain epidemiologic features of complete and partial molar pregnancy differ markedly. Parazzini et al. (12) reported that the risk for partial mole was not associated with maternal age. Additionally, the risk for partial mole has been reported to be associated with the use of oral contraceptives and a history of irregular menstruation, but not with dietary factors (13). Therefore, in contrast to CHM, the risk for partial mole appears to be associated with reproductive history rather than dietary factors.

The risk for CCA and GTN has been observed in a case-control study to be related to hormonal factors (14). Women with light menstrual flow and menarche after the age of 12 years were noted to be at increased risk for CCA. Additionally, Palmer et al. (15) reported that the prior use of oral contraceptives was associated with an increased risk for CCA.

Immunobiology

The remarkable curability of GTN may be partly attributable to a host immunologic response to paternal antigens expressed on trophoblastic cells (16). The prognosis of patients with gestational CCA has been related to the intensity of lymphocytic and monocytic infiltration at the tumor-host interface (17). Because the lymphocytes and macrophages that infiltrate gestational CCA are probably exposed to paternal antigens and oncoproteins, the immune cells may become activated. Immunologically active cells may promote the regression of GTN through their release of cytokines. Cytokines have been reported to inhibit the proliferation of CCA cells *in vitro* and to increase the human leukocyte antigen (HLA) expression of CCA cells *in vitro*, thereby increasing immunogenicity (18–20).

It has been theorized that the development and progression of persistent GTN may be favored by histocompatibility

between the patient and her partner. If the patient and her partner are histocompatible, the trophoblastic tumor that bears paternal antigens may not be immunogenic in the maternal host. The intensity of the host's immunologic response may depend upon the immunogenicity of the trophoblastic tumor. However, histocompatibility between the patient and her partner does not appear to be a prerequisite for the development or persistence of GTN (21,22). The HLA system may, however, influence the clinical course of rapidly progressive and fatal GTN. Tomoda et al. (23) reported that drug-resistant CCA was associated with increased histocompatibility between the patient and her partner. Similarly, Morgensen et al. (24) observed that histocompatibility between patients and partners was associated with a greater risk of metastatic disease.

Because all chromosomes in a CHM are paternal in origin, a CHM is a complete allograft and may stimulate a vigorous immunologic response by the maternal host. There is evidence for both a cellular and humoral immune response to CHM. As compared with normal placentas, molar implantation sites have a fivefold increased infiltration by helper T cells (25). Circulating immune complexes have also been measured in patients with CHM and have been noted to increase as the patient entered gonadotropin remission (26).

Circulating immune complexes in patients with complete moles have been demonstrated to contain paternal HLA antigen (27). The maternal host with a complete mole is therefore sensitized to paternal HLA. The distribution of HLA antigen in molar chorionic villi has been determined by immunofluorescence assays (28). HLA A, B, and C antigens were detected on the stromal cells of molar chorionic villi but not on the villous trophoblast. However, the molar villous fluid that bathes the stromal cells does not contain soluble HLA antigen (29). The maternal host may therefore be sensitized to paternal HLA antigen when the villous trophoblast layer is disrupted and HLA-positive villous stromal cells are released into the maternal circulation.

Molecular Pathogenesis

Several growth factors and oncogenes have been studied in molar tissues and CCA (11). Increased expression of p53 and *c-fms* has been observed in CHM and increased *ras* and *c-myc* RNA has been measured in CCA (30–32).

We have investigated the expression of various growth factors and oncogenes in normal placenta, complete and partial mole, and CCA (33,34). Complete mole and CCA were characterized by overexpression of *c-myc*, *c-erbB2*, and *bcl-2* and these oncoproteins may be important in the pathogenesis of GTN. Expression of *c-fms* protein did not differ between normal placenta and GTN. CHM and CCA were also characterized by increased expression of p53, *p21*, *Rb*, and *Mdm2*. The p53 gene was studied to detect any mutation in 22 complete moles and 11 CCAs that had increased expression of p53. Because only one nonsense mutation in p53 was detected by polymerase chain reaction analysis, it is likely that the overexpressed p53 protein was wild type. Although studies have identified increased expression of several growth factors in GTN, the precise molecular pathogenesis has not been determined (35).

It was observed that the level of expression of epidermal growth factor receptor (EGFR) in CCA and the syncytiotrophoblast and cytotrophoblast of CHM was significantly greater than the expression of EGFR in syncytiotrophoblast and cytotrophoblast of placenta and PHM (36). This observation was consistent in both immunohistochemical and *in situ* hybridization studies. In CHM, strong expression of EGFR and *c-erbB3* in the extravillous trophoblasts was significantly associated with the development of postmolar tumor. The EGFR-related family of oncogenes may be important in the pathogenesis of GTN.

Extracellular proteinases such as matrix metalloproteinases (MMPs) are thought to be important in modulating both cell-matrix interactions and the degradation of the basement membrane necessary for invasion and metastasis. CCA exhibits significantly stronger expression of MMP-1 and MMP-2 and decreased expression of tissue inhibitor of MMP-1 (TIMP-1) than the syncytiotrophoblast of complete and partial mole and normal placenta (37). The increased expression of MMP-1 and MMP-2 and decreased expression of TIMP-1 in CCA may contribute to the invasiveness of choriocarcinoma cells.

Certain genes are normally expressed on either the maternal or paternal allele, and this occurrence is described as parental imprinting. Modification of parental imprinting has been associated with tumor formation, and CHMs and CCAs have relaxation of parental imprinting (38). Relaxation in parental imprinting may be important in the pathogenesis of GTN.

cDNA microarray analysis has been utilized to study differential gene expression in GTN. Kim et al. investigated differential gene expression in CHMs as compared to normal placenta and identified 91 upregulated genes and 122 downregulated genes (39). The differentially expressed genes need to be further studied to determine which may play an important role in the biology of GTN. Vegh et al. studied differential gene expression in CCA as compared to normal placenta using cDNA expression assay. CCA cells have marked downregulation of heat shock protein-27, which may contribute to the marked sensitivity of this tumor to chemotherapy (40).

Studies of loss of heterozygosity have been performed to identify potential tumor suppressor genes that may be important in the pathogenesis of GTN. Matsuda et al. demonstrated homozygous deletions of one or more markers in the 7p12-q11.23 region of seven of eight CCA cell lines indicating that deletion in this region may be important in the pathogenesis of this malignancy (41). In contrast, Ahmed et al. (42) did not identify significant loss of heterozygosity in chromosome 7 in a series of 12 choriocarcinomas. Furthermore, Burke et al. (43) reported no detectable deletions on 7q11.2 and 8p12-p21 in 14 cases of GTN after CHM. Molecular biologic studies continue to try to identify the key genetic events that are critical in the pathogenesis of GTN.

MOLAR PREGNANCY

Pathologic and Chromosomal Features

Hydatidiform moles may be categorized as either complete or partial based upon gross morphology, histopathology, and karyotype (Table 28.1). CHMs have no identifiable embryonic or fetal tissues. The chorionic villi have generalized swelling and diffuse trophoblastic hyperplasia and the implantation-site trophoblast has diffuse, marked atypia (Fig. 28.1) (44,45). Complete moles usually have a 46,XX karyotype, and the molar chromosomes are derived entirely from paternal origin (46). Most complete moles appear to arise from an anuclear empty ovum that has been fertilized by a haploid (23X) sperm, which then duplicates its own chromosomes (47). Whereas most complete moles have a 46,XX chromosomal pattern, approximately 10% of complete moles have a 46,XY karyotype (48). The 46,XY complete mole arises from fertilization of an anuclear empty ovum by two sperm. Whereas chromosomes in the complete mole are entirely of paternal origin, the mitochondrial DNA is of maternal origin (49).

Recent reports have shed light on the rare occurrence of familial recurrent hydatidiform mole (FRHM), which is characterized

TABLE 28.1

COMPLETE VERSUS PARTIAL MOLAR PREGNANCY: HISTOPATHOLOGIC AND CHROMOSOMAL FEATURES

	Complete mole	Partial mole
Fetal or embryonic tissue	Absent	Present
Hydropic swelling of villi	Diffuse	Focal
Trophoblastic hyperplasia	Diffuse	Focal
Scalloping of chorionic villi	Absent	Present
Trophoblastic stromal inclusions	Absent	Present
Implantation-site trophoblast	Marked atypia	Mild atypia
Karyotype	46, XX (mainly); 46, XY	Triploid, 69, XXY, 69, XYY

FIGURE 28.2. Photomicrograph of a partial hydatidiform mole demonstrating varying-sized chorionic villi with focal swelling and focal trophoblastic hyperplasia. (Magnification $\times 50$)

by recurrent complete hydatidiform moles of biparental, rather than the more usual androgenetic, origin. Although the specific gene defect in these families has not been identified, genetic mapping has shown that in most families the gene responsible is located in a 1.1 Mb region on chromosome 19q13.4 (50). Mutations in this gene result in dysregulation of imprinting in the female germ line with abnormal development of both embryonic and extraembryonic tissue. Subsequent pregnancies in women diagnosed with this condition are likely to be CHM. Molar pregnancies in women with FRHM are associated with consanguinity and have a risk of progressing to GTN similar to that of androgenetic CHM.

During the 1960s and 1970s, CHMs were primarily diagnosed in the second trimester. However, currently, most patients with complete moles are diagnosed in the first trimester both in the United States and abroad (51–53). The pathologic characteristics of a first-trimester complete mole are different from the classic features in the second trimester. Mosher et al. (54) compared pathologic findings of 23 current complete moles (1994 through 1997; mean gestational age, 8.5 weeks) with 20 historic complete moles (1969 through 1975; mean gestational age, 17 weeks). Histologically, current complete moles had a smaller mean maximal villous diameter

FIGURE 28.1. Photomicrograph of a complete hydatidiform mole showing chorionic villi with generalized swelling and diffuse trophoblastic hyperplasia. (Magnification $\times 20$)

(5.7 vs. 8.2 mm), less circumferential trophoblastic hyperplasia (39% vs. 75%), more primitive villous stroma (70% vs. 10%), and less global necrosis (22% vs. 54%). Currently, complete moles are often characterized by subtle morphologic alterations that may result in their misclassification as partial moles or nonmolar spontaneous abortions. Similarly, Keep et al. (55) described that early complete moles were characterized by focal trophoblastic hyperplasia, minimal villous cavitation, and a hypercellular primitive stroma.

PHMs are characterized by the following pathologic features: (a) varying-sized chorionic villi with focal swelling and focal trophoblastic hyperplasia; (b) focal, mild atypia of implantation-site trophoblast; (c) marked villous scalloping and prominent stromal trophoblastic inclusions; and (d) identifiable fetal or embryonic tissues (Fig. 28.2) (56). Partial moles generally have a triploid karyotype, which results from the fertilization of an apparently normal ovum by two sperm (57). Lawler et al. (58) and Lage et al. (59) reported that 93% and 90%, respectively, of partial moles were triploid. When fetuses are identified with partial moles, they generally have stigmata of triploidy including growth retardation and multiple congenital anomalies. Genest et al. (60) reviewed 19 putative nontriploid PHMs using standardized histologic diagnostic criteria and repeat flow cytometry, and none of these cases on re-evaluation was convincingly a nontriploid partial mole. Nontriploid partial moles may not exist.

Early diagnosis and intervention has made the pathologic diagnosis of CHM challenging because the characteristic histologic features have become more subtle. Recently biomarkers have emerged that take advantage of imprinted genes to distinguish CHM from other entities. Because CHM results from diandry, paternally imprinted gene products, which are normally expressed only from maternally derived chromosomes, should be absent. Studies have recently shown that immunohistochemistry for p57 (paternally imprinted, maternally expressed gene products) is useful for confirming the diagnosis of CHM (61). Nuclei of decidua (maternally derived tissue) and extra villous trophoblast of all types of gestations stain positively for p57. Almost all complete moles have absent (or near absent) villous stromal and cytotrophoblastic nuclear activity for p57, while all other types of gestations (including partial moles) show nuclear reactivity in more than 25% of villous stromal and cytotrophoblastic nuclei. Fisher et al. (62) have shown that maternal chromosome 11 is retained in the rare cases of CHM exhibiting p57 staining.

Presenting Signs and Symptoms

Complete Hydatidiform Mole

The clinical presentation of a CHM has changed dramatically over the past two decades. Whereas CHM was usually diagnosed in the second trimester in the 1960s and 1970s, the diagnosis of CHM is now generally made in the first trimester (63). Earlier diagnosis is most likely attributable to the availability of accurate and sensitive tests for human chorionic gonadotropin (hCG) and the widespread use of ultrasound. The diagnosis of CHM is now often made before the classic clinical signs and symptoms develop. Soto-Wright et al. (53) investigated the clinical presentation and outcome of patients with CHM at the New England Trophoblastic Disease Center (NETDC) between 1988 and 1993 as compared with patients between 1965 and 1975.

Vaginal Bleeding. Vaginal bleeding is the most common presenting symptom in patients with CHM, occurring in 89% to 97% of cases (63–65). Retained blood may undergo oxidation and prune juice–like fluid may leak from the endometrial cavity. Molar chorionic villi may separate from the decidua and disrupt vessels, leading to the distension of the endometrial cavity by large volumes of retained blood. Because bleeding used to be prolonged, occult, and considerable, 54% of our patients used to present with anemia (hemoglobin <10 g/100 mL). Vaginal bleeding continues to be the most common presenting symptom, occurring in 84% of our current patients. However, anemia was present in only 5% of our current patients with complete mole.

Theca Lutein Ovarian Cysts. The reported frequency of theca lutein ovarian cysts depends upon the method of diagnosis. Ultrasonography detected theca lutein ovarian cysts (>5 cm in diameter) in 23 (46%) of 50 patients with molar pregnancy (66). However, clinical examination detected theca lutein ovarian cysts in 26% of patients with molar pregnancy (67). Although theca lutein cysts are generally 6 to 12 cm in diameter, they may enlarge to more than 20 cm in size. They are usually multicystic and bilateral and contain serosanguineous or amber-colored fluid. Although theca lutein cysts are usually detected at the time of presentation, they may develop rapidly after molar evacuation.

Theca lutein cysts are detected exclusively in patients with very high serum hCG levels and result from hyperstimulation of the ovaries by high circulating levels of hCG (68). Other signs of ovarian hyperstimulation may infrequently develop, including ascites and pleural effusion. Theca lutein cysts generally resolve over an interval of 8 weeks (67).

Torsion or rupture of theca lutein ovarian cysts occurs infrequently. Kohorn (69) reported that 3 (2.3%) of 127 patients with molar pregnancy developed torsion of ovarian theca lutein cysts. Similarly, Montz et al. (67) noted that only 2 of 102 patients with theca lutein cysts developed torsion or rupture. If patients develop severe symptoms of pelvic or abdominal pressure or pain, theca lutein cysts may be decompressed by ultrasound-directed or laparoscopic aspiration (70). Ovarian rupture or torsion may also be managed by laparoscopy.

Excessive Uterine Size. Uterine size was excessively enlarged as compared with gestational age in about 38% to 51% of patients with complete moles (44,64,65). Both retained blood and chorionic tissues may expand the uterine cavity. Excessive uterine enlargement is commonly associated with markedly elevated hCG values from trophoblastic proliferation and overgrowth. Among current patients at the NETDC, excessive uterine size was diagnosed at presentation in only 28% of patients.

Hyperemesis Gravidarum. Hyperemesis requiring antiemetic therapy used to develop in 20% to 26% of patients with complete moles (44,69). Hyperemesis was associated with excessive

uterine enlargement and high hCG values. High circulating levels of estrogen have been proposed as a cause of hyperemesis (71). Although hyperemesis used to be a common problem, only 8% of our current patients present with hyperemesis.

Preeclampsia. Preeclampsia used to be observed in 12% to 27% of patients with complete moles (64,72). Preeclampsia primarily developed in patients with excessive uterine size and high hCG levels. Eclamptic convulsions developed rarely. In contrast, between 1988 and 1993, only 1 of 74 patients with CHM presented with preeclampsia at the NETDC.

Hyperthyroidism. Laboratory evidence of hyperthyroidism commonly used to be present in patients with complete moles. Galton et al. (73) reported that all 11 patients with CHM had elevated thyroid function tests before molar evacuation. Hyperthyroidism occurred almost exclusively in patients with very high hCG values. There are conflicting data whether hCG is a thyroid stimulator in patients with molar pregnancy. Amir et al. (74) found no significant correlation between serum hCG levels and free T_4 and T_3 index values in 47 patients with complete mole. Similarly, Nagataki et al. (75) found no correlation between free T_4 and hCG in ten patients. However, highly purified hCG may have intrinsic thyroid-stimulating activity, and some studies do report correlations between serum levels of hCG and total T_4 and T_3 (76).

Patients with poorly controlled or untreated hyperthyroidism may develop thyroid storm at the time of anesthesia induction and evacuation. Thyroid storm may be characterized by hyperthermia, delirium, coma, atrial fibrillation, and cardiovascular collapse. The diagnosis of thyroid storm must be made clinically so that treatment can be promptly instituted and not await the return of laboratory confirmation. Many of the cardiovascular and metabolic complications of thyroid storm may be prevented or reversed by the administration of beta-adrenergic blocking agents. A pulmonary artery catheter may be helpful to guide fluid replacement and to monitor cardiovascular status.

Between 1988 and 1993, none of our 74 patients with complete moles had clinical evidence of hyperthyroidism. However, during the past decade, one patient with a complete mole and a pre-evacuation hCG level of 1.4 million mIU/mL developed clinical and laboratory evidence of hyperthyroidism and required beta-adrenergic blockers to treat tachyarrhythmia.

Respiratory Insufficiency. Twigg et al. (77) observed that 12 (27%) of 44 patients with a CHM of at least 16-weeks size developed pulmonary complications. Respiratory insufficiency used to develop in 2% of our patients with complete moles (72). Pulmonary compromise was generally observed in patients with excessive uterine size and high hCG levels—the same group of patients who are at risk for preeclampsia and hyperthyroidism. During the past decade, none of our patients with complete moles developed respiratory failure.

Patients may present with anxiety, confusion, tachypnea, and tachycardia in the recovery room after molar evacuation. Pulmonary insufficiency is multifactorial and results not only from embolization of molar tissue to the pulmonary vasculature, but also the cardiovascular complications of thyroid storm, preeclampsia, and massive fluid replacement. Chest radiography may show bilateral pulmonary infiltrates, and auscultation of the chest usually reveals diffuse rales. Arterial blood gases may indicate respiratory alkalosis and hypoxia. With appropriate cardiovascular and respiratory support, the signs and symptoms of respiratory distress usually resolve within 72 hours. However, it is vital to recognize that some patients may require mechanical ventilation to provide adequate oxygenation.

Partial Hydatidiform Mole

Patients with PHM usually do not present with the classic clinical features that are characteristic of a CHM. These

patients generally present with the signs and symptoms of missed or incomplete abortion. Eighty-one patients were followed with partial moles at the NETDC between January 1979 and August 1984 (78). Excessive uterine size and preeclampsia were detected in only three and two patients, respectively. Szulman and Surti (56) and Czernobilsky et al. (79) reported that only 9 (11%) of 81 and 2 (8%) of 25 patients with partial moles had excessive uterine enlargement. Preeclampsia was reported in both studies in only 4% of patients. None of our patients had prominent theca lutein ovarian cysts, hyperthyroidism, or hyperemesis. The diagnosis of partial mole is usually made after histologic review of curettage specimens. In contrast to CHM, the gestational age at diagnosis and presenting symptoms of PHM have not appreciably changed in recent years (80).

Ultrasonography and Diagnosis of Hydatidiform Mole

Ultrasonography is a sensitive and reliable technique for detecting CHM. Because of marked swelling of the chorionic villi, a complete mole produces a characteristic vesicular sonographic pattern. However, it may be difficult to distinguish an early complete mole from degenerating chorionic tissues, since small molar chorionic villi in the first trimester may be difficult to visualize on ultrasound. However, despite smaller chorionic villi, ultrasound is still able to detect most first-trimester complete moles (81). An elevated hCG measurement at the time of sonography may help to differentiate an early complete mole from a missed abortion (82).

Ultrasonography may also contribute to the diagnosis of PHM. Two sonographic findings are significantly associated with the diagnosis of partial mole: focal cystic changes in the placenta and a ratio of the transverse to anteroposterior dimension of the gestational sac >1.5 (83). Changes in the shape of the gestational sac may be part of the embryopathy of triploidy. When both findings were present, the positive predictive value for partial mole was 87%. On rare occasions, the sonogram will show the presence of a fetus with multiple congenital anomalies associated with a focally hydropic placenta. Naumoff et al. (84) also reported that partial moles may exhibit cystic spaces within the placenta with a growth-retarded fetus.

hCG Measurement and Diagnosis of Hydatidiform Mole

Patients with CHM commonly have markedly elevated pre-evacuation hCG levels. Menczer et al. (85) reported that 30 (41%) of 74 patients with complete moles had pre-evacuation hCG values greater than 100,000 mIU/mL. Similarly, Genest et al. (86) noted that 46% of 153 patients with complete moles who were managed at the NETDC between 1980 and 1990 had pre-evacuation hCG levels above 100,000 mIU/mL. The measurement of markedly elevated hCG values is therefore suggestive of the diagnosis of complete mole.

Patients with PHM less commonly present with markedly elevated hCG values. Czernobilsky et al. (79) reported that only 1 of 17 patients with partial moles presented with a urinary hCG value $>300,000$ mIU/mL. Likewise, we noted that only 2 of 30 patients with partial moles at the NETDC presented with hCG levels $>100,000$ mIU/mL (78).

Complete and partial moles also differ in their levels of free β - and α -subunits of hCG. Whereas complete moles have higher levels of percentage free β -hCG, partial moles have higher levels of percentage free α -hCG (87,88). The mean

ratios of percentage free β -hCG to free α -hCG in complete and partial moles are 20.9 and 2.4, respectively.

Natural History of Molar Pregnancy and Prognostic Factors

CHMs are well recognized to have the potential for developing uterine invasion or distant spread. Following molar evacuation, uterine invasion and metastasis occur in 15% and 4% of the patients, respectively (89). Although complete moles are now being diagnosed earlier in pregnancy, the incidence of postmolar tumors has not been affected (52,53).

Whereas the incidence of postmolar tumor is reported from 18% to 29% in the United States, the incidence of postmolar GTN in Western Europe is reported from 8% to 10% of patients (2,64,69,90–94). Most centers in the United States define postmolar persistent GTN by the presence of a re-elevation or persistent plateau in hCG for at least 3 consecutive weeks. However, the definition of persistent disease does vary among American centers (95). The criteria for persistent GTN in Western Europe have been more stringent than American definitions. At the Charing Cross Hospital in London, the criteria for postmolar persistent tumors were (a) hCG $>20,000$ IU/L more than 4 weeks after evacuation; (b) progressively rising hCG levels, with a minimum of three rising values over 2 to 3 weeks; (c) metastasis to the liver, kidney, brain, or gastrointestinal tract; (d) metastasis to lung larger than 2 cm in diameter or three or more in number; or (e) persistent hCG level 4 to 6 months after evacuation. The use of less stringent diagnostic criteria for postmolar tumors in the United States is partly motivated by the concern that some patients may be lost to follow-up. Among 333 recent patients with molar pregnancy at our center, 122 (37%) patients did not complete the entire hormonal follow-up and 13 (4%) patients were lost to follow-up without attaining even one undetectable hCG value (96). Furthermore, Massad et al. (97) observed that among 40 indigent women with molar pregnancy, 33 (82%) did not fully comply with hCG follow-up and 5 (13%) were lost to follow-up before remission.

We reviewed 858 patients with CHM to identify factors that predispose to postmolar tumors (63). At the time of presentation, 41% of the patients had the following signs of marked trophoblastic proliferation: (a) hCG level $>100,000$ mIU/mL; (b) uterine size greater than gestational age; and (c) theca lutein cysts >6 cm in diameter. After evacuation, 31.0% of these patients developed uterine invasion and 8.8% developed metastases. The risk for persistent tumors is considerably less for patients who do not present with signs of marked trophoblastic growth. Following molar evacuation, only 3.4% of these patients developed invasion and 0.6% developed metastases. Similarly, Curry et al. (64) and Morrow (98) reported postmolar tumors in 57% and 55% of patients, respectively, with excessive uterine size and theca lutein ovarian cysts. Therefore, patients with CHM who exhibit markedly elevated hCG levels and excessive uterine size are at increased risk of developing postmolar tumors, and are categorized as “high risk.”

An increased risk of postmolar GTN has also been observed in women older than age 40 years. Tow (99) and Xia et al. (100) reported that 37% and 33%, respectively, of women more than 40 years old with complete molar pregnancy developed persistent tumors. In women over age 50 years, postmolar tumors were reported to have developed in 56% of patients (101). Complete moles in older women are more frequently aneuploid, and this may be related to their increased potential for local invasion and metastasis (102).

Patients with repetitive molar pregnancy are also at increased risk of developing persistent tumors in their later

episodes of molar gestation. Between June 1965 and December 2001, we treated 34 patients with repeat molar gestations at the NETDC (103). Postmolar tumors developed following their first mole in 4 (20%) of 20 complete moles and in none of 14 partial moles. However, postmolar tumors developed following the second mole in 8 (44.4%) of 18 complete moles and 2 (12.5%) of 16 partial moles. Parazzini et al. (104) also reported a threefold increased risk of postmolar tumors in patients with repetitive molar disease.

The risk for persistent GTN has been reported to be increased in CHM with marked trophoblastic hyperplasia and atypia, high free β -hCG levels, and heterozygous genotype. However, data concerning these three potential prognostic variables are inconsistent and conflicting (58,86,87,104–109).

The risk of developing GTN following PHM has been reported from 0% to 11%. Hancock et al. (110), summarizing the data from ten centers, reported that 73 of 7,155 patients (1.0%) required chemotherapy after evacuation of a partial mole. In a series of 240 patients who were followed for PHM at the NETDC, 16 (6.6%) developed nonmetastatic GTN (111). Only one of these patients presented with the classic signs and symptoms of molar disease including excessive uterine enlargement, theca lutein ovarian cysts, and high hCG levels. Fifteen (94%) patients were thought to have a missed abortion before evacuation. Our patients with partial moles who developed persistent disease did not have clinical features that distinguished them from other patients with partial moles. Flow cytometric studies of partial moles that developed persistent tumors showed a triploid pattern in 11 (85%) of 13 cases with interpretable histograms (112). A recent update of our experience with partial moles found that 22 of 390 patients (5.6%) developed GTN, and that pre-evacuation clinical symptoms did not distinguish those patients at risk for persistence (113).

Multiple Conceptions With Molar Pregnancy and Coexisting Fetuses

Twin pregnancy consisting of a CHM and a coexisting fetus has been estimated to occur in 1 per 22,000 to 100,000 pregnancies (114). We have reported our experience with 8 cases of twin pregnancy with complete mole and a coexisting fetus and reviewed 14 additional published cases by other researchers (115). Furthermore, we described one case of a partial mole coexisting with a normal fetus and placenta. As compared with singleton complete moles, twin pregnancies consisting of complete moles and coexisting fetuses have higher pre-evacuation hCG levels, have larger uteri, and are diagnosed later in pregnancy (116–118). GTN developed in 12 (55%) of 22 cases and 5 (22.7%) had metastatic tumor. Limited information is available to guide antenatal management of multiple gestations with complete moles and coexisting fetuses. These pregnancies are at risk for hemorrhage and preeclampsia. However, no patient died from obstetric or neoplastic complications, and five fetuses survived and no anomalies were detected. The increased availability of ovulation-induction drugs may result in more multiple gestations involving a molar pregnancy. While patients should be advised of the potential risks of neoplastic and obstetrical complications, it is appropriate in many cases to carefully monitor the course of the pregnancy in the hope that delivery at viability can be accomplished.

Surgical Evacuation

After diagnosing a molar pregnancy, the patient should be carefully evaluated to identify the potential presence of medical complications including preeclampsia, electrolyte imbalance, hyperthyroidism, and anemia that might complicate surgical

evacuation. The patient is first stabilized and then a decision must be made concerning the most appropriate method of evacuation.

If the patient no longer desires to preserve fertility, hysterectomy may be performed. Prominent theca lutein ovarian cysts may be aspirated at the time of surgery. Patients should be counseled that although hysterectomy eliminates the risks of local invasion, it does not prevent metastasis.

Suction curettage is the preferred method of evacuation regardless of uterine size in patients who desire to preserve fertility (119,120). As the cervix is being dilated, the surgeon may encounter brisk uterine bleeding due to the passage of retained blood. Shortly after commencing suction evacuation, uterine bleeding is generally well controlled and the uterus rapidly regresses in size. If the uterus is larger than 14-weeks size, one hand should be placed on top of the fundus and the uterus should be massaged to stimulate uterine contraction. When suction evacuation is thought to be complete, a sharp curettage should be performed to remove any residual chorionic tissue. Patients who are Rh negative should receive Rh immune globulin at the time of evacuation because Rh D factor is expressed on trophoblast.

Role of Prophylactic Chemotherapy

The use of prophylactic chemotherapy at the time of molar evacuation remains controversial (121). However, several investigators have reported that chemoprophylaxis reduces the risk of postmolar tumor (91,122).

Kim et al. (123) performed a randomized, prospective trial of chemoprophylaxis in patients with complete mole. Chemoprophylaxis significantly reduced the incidence of postmolar tumor from 47% to 14% in patients with high-risk complete moles. However, chemoprophylaxis did not significantly influence the occurrence of persistent tumors in patients with low-risk complete moles. Similarly, Limpongsanurak (124) demonstrated in a double-blind randomized, controlled trial that actinomycin D (ACT D) reduced postmolar tumor in patients with high-risk complete moles from 50.0% to 13.8%.

We have also reported that prophylactic ACT D reduces the risk of persistent GTN in patients with high-risk complete moles (89). Only 10 (11%) of 93 patients with high-risk complete moles developed postmolar tumor after prophylactic ACT D. Chemoprophylaxis failure more commonly occurred in patients with markedly elevated hCG values. Prophylactic chemotherapy may be of benefit in patients with high-risk complete moles, particularly when hormonal follow-up is unavailable or unreliable.

Hormonal Follow-Up

After molar evacuation, all patients must be followed with hCG measurements to ensure remission. Patients should be followed with weekly hCG values until they are normal for 3 weeks and then monthly values until they are normal for 6 months. After achieving nondetectable hCG levels, the risk of relapse appears to be very low (113,125). In fact, several recent studies have confirmed that after obtaining a nondetectable serum hCG level, the risk of developing GTN following molar evacuation approaches zero (113,126). As more data is published it is possible that hCG follow-up can be safely abbreviated.

It is also possible to utilize hCG regression curves to develop criteria that determine a patient's risk of developing GTN or achieving remission after molar evacuation. Growdon et al. (127) observed that an hCG level of >199 mIU/mL in the 3rd through 8th week following partial molar evacuation was associated with at least a 35% risk of GTN. Similarly, Wolfberg et al.

(128) reported that postevacuation hCG levels could be used to predict both GTN and remission within a few weeks of molar evacuation in a study of 1,029 women diagnosed with CHM between 1973 and 2001. These data demonstrated that within 3 weeks of molar evacuation, more than half the women in the cohort had their risk of GTN modified to either >50% or <9%.

Patients are encouraged to use effective contraception during the entire interval of follow-up. Intrauterine devices should not be inserted until the patient achieves normal hCG levels because of the risk of uterine perforation, bleeding, and infection if residual tumor is present. If the patient does not desire surgical sterilization, she is then confronted with the choice of using either hormonal contraceptives or barrier methods.

The incidence of postmolar tumor has been reported to be increased in patients who used oral contraceptives (129). However, data from the NETDC (130), the Gynecologic Oncology Group (131), and the Brewer Center (130) indicate that oral contraceptives do not increase the risk of postmolar trophoblastic disease. Ho Yuen and Burch (132) also reported that the use of oral contraceptives containing 50 µg or less of estrogen was not associated with an increased risk of postmolar tumor. They speculated that the conflicting data concerning the use of oral contraceptives and the risk of postmolar tumor may be explained by differences in the dosage of estrogen. We therefore believe that oral contraceptives may be safely prescribed after molar evacuation.

GESTATIONAL TROPHOBLASTIC NEOPLASMS

Pathologic Considerations

After a molar pregnancy, persistent GTN may have the histologic pattern of either molar tissue or CCA. However, following a miscarriage or term pregnancy, GTN characteristically has only the histologic features of CCA (133). Gestational CCA does not contain chorionic villi, but is composed of sheets of both anaplastic cyto- and syncytiotrophoblasts. Since tubal moles can metastasize, the histologic pattern of GTN following an ectopic pregnancy can be either molar or CCA.

Placental-site trophoblastic tumor (PSTT) is an uncommon variant of CCA (134). This tumor is composed almost entirely of mononuclear intermediate trophoblast and does not contain chorionic villi. Because PSTTs secrete very small amounts of hCG, a large tumor burden may be present before hCG levels are detectable (135). PSTTs are associated with a higher percentage of free β-hCG, which can contribute to diagnosis (136,137).

Natural History

Nonmetastatic Disease

Locally invasive GTN develops in 15% of patients following evacuation of a complete mole and infrequently after other gestations (89). An invasive trophoblastic tumor may perforate through the myometrium, producing intraperitoneal bleeding, or erode into uterine vessels, causing vaginal hemorrhage (Fig. 28.3). A bulky necrotic tumor may also serve as a nidus for infection.

Metastatic Disease

Metastatic GTN occurs in 4% of patients after evacuation of CHM and infrequently after other pregnancies (89). GTN usually metastasizes as CCA because of its propensity for early vascular invasion with widespread dissemination. The most common metastatic sites are the lung (80%), vagina

FIGURE 28.3. Uterine choriocarcinoma invading and replacing fundal myometrium.

(30%), brain (10%), and liver (10%). Because trophoblastic tumors are perfused by fragile vessels, metastases are often hemorrhagic. Patients may present with signs and symptoms of bleeding from metastases such as hemoptysis, intraperitoneal bleeding, or acute neurologic deficits. Cerebral and hepatic metastases are uncommon unless there is concurrent involvement of the lungs and/or vagina.

Trophoblastic tumors produce four principal radiologic patterns in the lung: (a) pleural effusion, (b) alveolar or snowstorm pattern, (c) discrete rounded densities, or (d) embolic pattern caused by pulmonary arterial occlusion (138–141). Patients may develop pulmonary hypertension in the absence of substantial parenchymal involvement. The extent of pulmonary involvement may differ greatly among centers owing to differences in the frequency of early detection. In Saudi Arabia, Bakri et al. (141) reported that >50% opacification of the lungs, pleural effusion, and more than ten metastases were present in 33%, 48%, and 43% of patients, respectively, with pulmonary involvement. In contrast, in the United States, patients with pulmonary metastases generally have small nodules on chest radiography and infrequently present with prominent respiratory symptoms.

Patients with pulmonary metastases commonly have asymptomatic lesions on chest radiography or may present with dyspnea, chest pain, cough, or hemoptysis. Trophoblastic emboli may cause pulmonary arterial occlusion and lead to right-heart strain and pulmonary hypertension (142). Gynecologic symptoms may be minimal or absent and the antecedent pregnancy may be remote in time. The patient may be thought to have a primary pulmonary disease because respiratory symptoms may be dramatic. Unfortunately, the diagnosis of GTN may only be considered and established after

the performance of a thoracotomy. *The diagnosis of GTN should be considered in any woman in the reproductive age group with unexplained systemic or pulmonary symptoms.*

Early respiratory failure requiring mechanical ventilation may develop in patients with extensive pulmonary involvement. Kelly et al. (143) and Bakri et al. (141) reported 100% mortality in 11 and 8 patients, respectively, with early respiratory failure. However, Vaccarello et al. (144) reported one patient who was cured following mechanical ventilation for respiratory failure. Risk factors for early respiratory failure within 1 month of presentation include >50% lung opacification, dyspnea, anemia, cyanosis, and pulmonary hypertension. With chemotherapy, patients may develop bleeding into metastatic sites and potentially worse pulmonary symptoms and radiologic findings. Importantly, Kelly et al. (143) also noted that reducing the initial dose of chemotherapy did not protect against early respiratory failure and recommended administering intensive chemotherapy at the outset.

Vaginal lesions may present with irregular bleeding or purulent discharge and are most commonly located in the fornices or suburethrally. Vaginal metastases are highly vascular and may bleed vigorously if biopsied. Biopsy of vaginal metastases should be absolutely avoided; the desire to avoid hemorrhage should supersede the interest of obtaining an unequivocal pathologic diagnosis.

Most patients with cerebral metastases are symptomatic and present with vomiting, seizures, headache, hemiparesis, slurred speech, or visual disturbances (145–150). Neurologic symptoms usually result from increased intracranial pressure or intracerebral bleeding. Bakri et al. (147) and Athanassiou et al. (149) reported that 20 of 23 patients (87%) and 66 of 69 patients (96%), respectively, with brain involvement had neurologic complaints. Furthermore, Liu et al. (150) reported that all 34 patients with brain metastases presented with neurologic symptoms.

Patients with liver metastases less commonly present with symptoms that are related to hepatic involvement. Bakri et al. (151) noted that only 5 (26%) of 19 patients with liver metastases presented with jaundice, intra-abdominal bleeding, or epigastric pain. Patients with liver metastases generally presented with symptoms related to pulmonary, vaginal, or cerebral involvement.

TABLE 28.2**FIGO ANATOMIC STAGING FOR GESTATIONAL TROPHOBLASTIC NEOPLASIA**

Stage I	Disease confined to the uterus
Stage II	GTN extends outside of the uterus, but is limited to the genital structures (adnexa, vagina, broad ligament)
Stage III	GTN extends to the lungs, with or without known genital tract involvement
Stage IV	All other metastatic sites

Note: FIGO, International Federation of Gynecology and Obstetrics; GTN, gestational trophoblastic neoplasia.

Staging System

The International Federation of Gynecology and Obstetrics (FIGO) reports data on GTN using an anatomic staging system (Table 28.2). Staging enables a comparable reporting of data, which is critical to allow objective comparison of treatment results (152). Stage I includes all patients with persistently elevated hCG levels and tumor confined to the uterus. Stage II comprises all patients with tumor outside of the uterus but localized to the vagina and/or pelvis. Stage III includes all patients with pulmonary metastases with or without uterine, vaginal, or pelvic involvement. Stage IV patients have far-advanced disease with involvement of the brain, liver, kidneys, or gastrointestinal tract. Patients with stage IV disease are most likely to be resistant to chemotherapy. Stage IV tumors generally have the histologic pattern of CCA and commonly follow a nonmolar pregnancy, with protracted delays in diagnosis and large tumor burdens.

It is also helpful to use prognostic variables to predict the likelihood of drug resistance and to assist in selecting appropriate chemotherapy. The World Health Organization (WHO) has published a prognostic scoring system based on one published by Bagshawe in 1976 (1) that reliably predicts the potential for chemotherapy resistance (Table 28.3). The current

TABLE 28.3**MODIFIED WHO PROGNOSTIC SCORING SYSTEM AS ADAPTED BY FIGO**

Scores	0	1	2	4
Age	<40	>40	—	—
Antecedent pregnancy	Mole	Abortion	Term	—
Interval months from index pregnancy	<4	4–7	7–13	>13
Pretreatment serum hCG (IU/L)	<1000	<10,000	<100,000	>100,000
Largest tumor size (including uterus)	—	3 to <5 cm	>5 cm	—
Site of metastases	Lung	Spleen/kidney	GI	Liver/brain
Number of metastases	—	1–4	5–8	>8
Previous failed chemotherapy	—	—	Single drug	Two or more drugs

Note: Format for reporting to FIGO Annual Report: In order to stage and allot a risk factor score, a patient's diagnosis is allocated to a stage as represented by a Roman numeral: I, II, III, and IV. This is then separated by a colon from the sum of all the actual risk factor scores expressed in arabic numerals, e.g., stage II:4, stage IV:9. This stage and score will be allotted for each patient. FIGO, International Federation of Gynecology and Obstetrics; WHO, World Health Organization.

FIGO staging system combines both anatomic staging and the prognostic scoring system. When the prognostic score is 7 or greater, the patient is considered to be “high-risk” and requires intensive combination chemotherapy for optimal results. In general, patients with stage I disease have a low-risk score and patients with stage IV disease have a high-risk score. Therefore, the distinction between low and high risk primarily applies to stages II and III. The variables that are included in the prognostic score include (a) tumor volume (hCG level, size of metastases, and number of metastases); (b) site of involvement; (c) prior chemotherapy exposure; and (d) duration of disease. In 1965, Ross et al. (153) reported that patients with high hCG levels, prolonged delays in diagnosis, and brain or liver metastases were relatively resistant to single-agent chemotherapy. Hammond et al. (154) further observed in 1973 that patients with prior chemotherapy or an antecedent term pregnancy were also relatively unresponsive to single-agent chemotherapy. Several investigators have since strongly confirmed the importance and reliability of these prognostic factors (155–162).

Choriocarcinoma following term pregnancy has been noted to be a poor-prognosis factor and to have some distinctive clinical features (163–167). We reviewed our experience with post-term CCA at the NETDC from 1964 to 1996 (164). Seven (16%) of 44 patients presented with clinical evidence of maternal-fetal bleeding, resulting in severe anemia and nonimmune hydrops or third-trimester bleeding. Although none of the infants had evidence of metastatic CCA, rare cases of fetal involvement have been reported and generally have resulted in fetal death. The time interval from delivery to diagnosis, sites of metastases, and pretreatment hCG level were all significant risk factors in predicting outcome. All 31 patients with a WHO score ≤ 8 survived, whereas 6 of 13 (46%) patients with a WHO score > 8 died. A recent retrospective multicenter cohort study in the Netherlands of 68 patients with CCA by Lok et al. (167) concluded that although antecedent term pregnancy is considered an adverse prognostic factor in GTN, current survival is comparable to the general survival in high-risk patients with optimal therapy.

Diagnostic Evaluation

The optimal management of a GTN requires a thorough evaluation of the extent of the disease prior to treatment. All patients should undergo a thorough assessment including a complete history and physical examination; a baseline hCG level; hepatic, thyroid, and renal function tests; and chest radiograph. If the chest x-ray is negative a computed tomographic (CT) scan should be obtained. Asymptomatic patients with a normal pelvic examination and negative chest CT are very unlikely to have liver or brain metastases identified by further radiographic studies. However, patients with vaginal or lung metastases and/or a pathologic diagnosis of choriocarcinoma should undergo either a CT scan or magnetic resonance imaging (MRI) scan of the head and abdomen to exclude brain and liver involvement.

Cerebral involvement may also be assessed by measuring hCG levels in the cerebrospinal fluid (CSF). Bagshawe and Harland (168) reported that the plasma/CSF hCG ratio tends to be < 60 in the presence of brain metastases. However, a single plasma/CSF hCG ratio may be misleading because very rapid changes in plasma hCG values may not be promptly reflected in the CSF (169). For example, Bakri et al. (170) observed that the serum/CSF hCG ratio was > 60 in five of ten patients with cerebral involvement.

Pelvic ultrasonography may be useful to detect extensive uterine involvement by trophoblastic tumor and to identify sites of resistant uterine disease (171). However, ultrasound should not be performed merely to document nonmetastatic disease

(172). The sensitivity of ultrasonography may be further enhanced by the use of color flow Doppler as well as the vaginal probe (173–175). Ultrasonography may be helpful to select patients who will benefit from hysterectomy because it can accurately detect an extensive uterine trophoblastic tumor (176).

Management

Stage I

Tables 28.4 and 28.5 review the NETDC protocol for the management of stage I disease and the results of therapy. The selection of treatment is based mainly on the patient's desire to preserve fertility. If the patient no longer wishes to retain fertility, hysterectomy with adjuvant single-agent chemotherapy may be performed as primary treatment. Adjuvant chemotherapy is administered for three reasons: (a) to reduce the likelihood of disseminating viable tumor cells at surgery, (b) to maintain a cytotoxic level of chemotherapy in the bloodstream and tissues in case viable tumor cells are disseminated at surgery, and (c) to treat any occult metastases that may already be present at the time of surgery. Occult pulmonary metastases may be detected by CT scan in about 40% of patients with presumed nonmetastatic disease (177,178). Chemotherapy may be safely administered at the time of hysterectomy without increasing operative complications. Thirty-two patients were treated by primary hysterectomy and adjuvant chemotherapy at the NETDC and all achieved complete remission with no additional therapy.

Single-agent chemotherapy is the preferred treatment in patients with stage I disease who desire to retain fertility. Primary single-agent chemotherapy induced complete remission in 419 (84%) of 502 patients with stage I GTN. The remaining 83 resistant patients subsequently attained remission with either combination chemotherapy or surgical intervention. If the patient is resistant to chemotherapy and wants to preserve fertility, local uterine resection may be considered. When local resection is planned, ultrasound, MRI, arteriography, and/or positron emission tomography (PET) scan may

identify the site of resistant tumor (179,180). Two of our patients who underwent local uterine resection achieved remission, and one of these patients had a later term delivery by cesarean section.

Nonmetastatic PSTT should be treated with primary hysterectomy because this tumor responds poorly to chemotherapy. However, despite its relative resistance to chemotherapy, long-term survivors with metastatic disease have been reported with the use of combination chemotherapy (134,181–184). Papadopoulos et al. (181), in reviewing the clinical experience with 34 patients with PSTT at the Charing Cross Hospital, found that a long interval from the antecedent pregnancy to clinical presentation was the most important prognostic factor. Whereas all 27 patients survived when the interval from the antecedent pregnancy was less than 4 years, all 7 patients died when the time interval exceeded 4 years. Similarly, Lathrop et al. (135) reported in a review of 43 patients that all ten fatal cases of PSTT had a more than 2-year interval from antecedent pregnancy to diagnosis. However, whereas Lathrop et al. reported that the mitotic rate was prognostically important, Papadopoulos et al. also observed that the mitotic rate of PSTT was not related to outcome.

Stages II and III

The NETDC protocol for the management of stage II and III disease and the results of treatment are outlined in Tables 28.6, 28.7, and 28.8. Low-risk patients (prognostic score <7) can be optimally treated with primary single-agent chemotherapy. High-risk patients (prognostic score 7 or above) should receive combination chemotherapy as the primary modality (185).

Between July 1965 and June 2006, 28 patients with stage II disease were treated at the NETDC and all achieved remission. Single-agent chemotherapy induced complete remission in 16 of 20 (80%) low-risk patients. In contrast, only two of eight high-risk patients achieved remission with single-agent treatment.

Single-agent chemotherapy is well recognized to be effective as primary treatment in low-risk metastatic GTN (185,186). Summarizing the experience from four centers, single-agent chemotherapy induced complete remission in 128 (87.1%) of 147 patients with low-risk metastatic GTN (186–190). All patients who were resistant to single-agent chemotherapy later achieved remission with combination chemotherapy except two patients reported by Ayhan et al. (188).

Vaginal metastases may bleed profusely because they are highly vascular and friable. Bleeding may be controlled by packing the hemorrhagic lesion or performing wide local excision. Infrequently, angiographic embolization of the hypogastric arteries may be required to control hemorrhage from vaginal metastases. Yingna et al. (191) reported that 18 (35.3%) of 51 patients with vaginal metastases presented with vaginal hemorrhage. Bleeding was controlled by vaginal packing in 16 patients and angiographic embolization in 2 patients. Tse et al. (192) in a 20-year retrospective study confirmed that angiographic embolization appeared to be an attractive and promising alternative to hysterectomy and arterial ligation.

Between July 1965 and June 2006, 161 patients with stage III tumors were managed at the NETDC and 160 (99.3%) attained complete remission. Single-agent chemotherapy induced complete remission in 82% of patients with low-risk disease and in 27% with high-risk disease. All but one patient who was resistant to single-agent treatment later achieved remission with combination chemotherapy.

Thoracotomy has a limited role in the management of stage III GTN. Thoracotomy should be performed if the diagnosis is seriously in doubt. Furthermore, if a patient has a persistent viable pulmonary nodule despite intensive chemotherapy, pulmonary resection may be performed (193). However, an extensive metastatic survey should be obtained to exclude other sites of persistent tumor. It is important to emphasize that fibrotic nodules may persist indefinitely on the

chest radiograph after complete hCG remission is achieved (194). If a metastasis is persistent on radiography, but is of questionable viability, either a scan with a radioisotope-labeled antibody to hCG or a PET scan may be useful (180). A radioisotope hCG or PET scan may also be helpful in identifying occult sites of viable tumor (195). Tomoda et al. (196) reviewed their experience with pulmonary resection in 19 patients with chemotherapy-resistant GTN. They proposed the following guidelines for successful resection: (a) good surgical candidate, (b) primary malignancy is controlled, (c) no evidence of other metastatic sites, (d) pulmonary metastasis is limited to one lung, and (e) hCG level is <1,000 mIU/mL. Complete remission was achieved in 14 of 15 patients who met all five criteria, but in none of the 4 patients who had one or more unfavorable clinical features. Similarly, Jones

et al. (197) reported that six (66.7%) of nine carefully selected patients with drug-resistant pulmonary GTN attained complete remission following lung resection. Several investigators have reported that undetectable hCG levels within 1 to 2 weeks of resection of a solitary pulmonary nodule are highly predictive of a favorable outcome (198–202). Survival following salvage surgery is influenced by the number of preoperative chemotherapy regimens, number of disease sites, and the WHO score.

Hysterectomy may be required in patients with metastatic GTN to control uterine hemorrhage or sepsis. Furthermore, in patients with bulky uterine tumor, hysterectomy may reduce the tumor burden and thereby limit the need for chemotherapy. Hammond et al. (203) reported that patients who underwent hysterectomy had a shorter duration of hospitalization and chemotherapy. Angiographic embolization can also be effective in the management of profuse uterine bleeding in lieu of hysterectomy, especially in those patients who are hemodynamically stable and wish to retain their fertility potential (192).

Stage IV

Tables 28.9 and 28.10 outline the NETDC protocol for the management of stage IV disease and the results of treatment. These patients are at high risk for developing rapidly progressive disease despite intensive therapy.

All patients with stage IV disease should be treated with intensive combination chemotherapy and the selective use of radiation therapy and surgery (2,37). Before 1975, only 6 (30%) of 20 patients with stage IV disease attained complete remission. However, after 1975, 16 (80%) of 20 patients with stage IV tumors achieved remission. This dramatic improvement in survival resulted from the introduction of intensive multimodal therapy early in the course of treatment.

The management of hepatic metastases is particularly difficult and challenging. Hepatic resection may be required to control bleeding or to excise resistant tumor. Grumbine et al. (204) reported the use of selective occlusion of the hepatic arteries and concurrent combination chemotherapy in a patient with bleeding liver metastases who ultimately attained remission. Importantly, Wong et al. (205) noted that nine of ten patients with hepatic involvement achieved complete remission with primary intensive combination chemotherapy without any hepatic irradiation. Bakri et al. (151) similarly reported that five of eight (62.5%) patients with liver metastases who were treated with combination chemotherapy alone attained complete remission.

If cerebral metastases are detected, irradiation is promptly instituted at the NETDC. The presence of multiple lesions requires treatment to the whole head, while a solitary lesion can be treated locally. Solitary lesions can also be resected (206). The risk of spontaneous cerebral hemorrhage is reduced by the concurrent use of chemotherapy and brain

TABLE 28.10**STAGE IV. DISTANT METASTASES (NEW ENGLAND TROPHOBLASTIC DISEASE CENTER, JULY 1965 TO JUNE 2006)**

irradiation (207). Brain irradiation may also be tumoricidal. Yordan et al. (208) reported that deaths due to central nervous system involvement occurred in 11 (44%) of 25 patients treated with chemotherapy alone, but in none of 18 patients treated with brain irradiation and chemotherapy.

However, Newlands et al. (145) have reported excellent remission rates in patients with cerebral metastases who were treated with chemotherapy alone. Thirty of 35 (86%) patients with cerebral lesions achieved sustained remission with intensive combination chemotherapy including high-dose intravenous and intrathecal methotrexate (MTX). None of their patients received external beam brain irradiation.

In addition to its efficacy in removing solitary peripheral metastases, craniotomy is most useful for the management of life-threatening complications, which then allows the opportunity for chemotherapy to induce a complete remission. Infrequently, cerebral metastases that prove resistant to chemotherapy may be amenable to resection. Evans et al. (206) reported complete remission in three of four patients who underwent craniotomy to relieve intracranial pressure, and in two of three patients undergoing craniotomy for resection of chemotherapy-resistant tumor. Athanassiou et al. (149) similarly reported that four of five patients undergoing craniotomy for acute intracranial complications were ultimately cured. They also observed that most patients with cerebral metastases who achieve remission generally have no residual neurologic deficits.

Follow-Up

All patients with stage I, II, and III GTN should be followed with weekly hCG tests until normal for 3 consecutive weeks, and then monthly for 12 months. Patients are encouraged to use contraception during the entire interval of follow-up. Patients with stage IV disease are followed with weekly hCG values until normal for 3 weeks and then monthly for 24 months. These patients require prolonged follow-up because they have an increased risk of late recurrence.

False-Positive hCG Tests

It is important for clinicians to recognize that hCG molecules in GTN are more degraded or heterogeneous in serum than they are in normal pregnancy (209). Trophoblastic disease samples contain high proportions of free β -hCG, nicked hCG, and β -core fragment (210). When monitoring patients with GTN, it is therefore desirable to use an assay that detects not only intact hCG, but also all of its metabolites and fragments (211–214).

Many hCG assays have a degree of cross reactivity with luteinizing hormone. Following multiple courses of combination chemotherapy, ovarian steroidal function may be damaged, particularly in patients in their late 30s and 40s. When ovarian function is damaged, luteinizing hormone levels may rise, and owing to cross reactivity, the patient may be falsely thought to have persistent low levels of hCG. Patients who receive combination chemotherapy should therefore be placed on oral contraceptives to suppress luteinizing hormone levels and prevent problems with cross reactivity.

It is important to emphasize that some patients may have a false-positive elevation in serum hCG measurement owing to the presence of circulating heterophilic antibody called “phantom hCG” (211). These patients with phantom hCG or phantom CCA often have no clear antecedent pregnancy and no progressive rise in their hCG levels. The possibility of false-positive hCG measurement should be assessed by sending both serum and urine samples to a reference hCG laboratory. Patients with phantom hCG generally have no measurable hCG in a parallel urine sample.

Quiescent GTN

Low-level “real” hCG has recently been recognized as a new clinical entity called quiescent GTN that presents a clinical challenge to physicians who treat patients with GTN. These patients have had a molar pregnancy or other type of GTN and the hCG level initially regresses, but persists at very low levels (mostly in the nonhyperglycosylated form) for many weeks or months. In these women, extensive workup reveals no lesion in the uterus or elsewhere, and administering chemotherapy is not effective. In these patients careful follow-up is recommended, since approximately 6% to 10% will ultimately relapse with rising hCG levels. At that point in time, chemotherapy will prove effective. In all such patients who develop active disease, hyperglycosylated hCG is the major component of the hCG present (214–217).

Recurrent GTN

Mutch et al. (218) reported recurrences after initial remission in 2% of patients with nonmetastatic GTN, 4% of patients with good-prognosis metastatic GTN, and 13% of patients with poor-prognosis disease. Relapses developed within 3 and 18 months in 50% and 85% of patients, respectively. Similarly, we observed relapse after initial remission in 2.9% of stage I, 8.3% of stage II, 4.2% of stage III, and 9.1% of stage IV patients (219). The mean time to recurrence from the last nondetectable hCG level was 6 months, and this did not differ among the four FIGO stages. All patients with stage I, II, and III GTN who developed recurrence were subsequently cured, whereas both stage IV patients with recurrences died. Recently, Ngan et al. (220), reporting on a 20-year experience treating GTN in Hong Kong, observed that the median interval from remission to relapse was 6.5 months. They concluded that the most important risk factors for recurrence were attributable to patients who defaulted treatment or follow-up, and those who presented with massive disease. Yang et al. (221) in studying 901 patients with GTN who received treatment in Beijing reported a mean interval from remission to relapse of 15.3 months. The four recurrence-associated risk factors in this study identified by multivariate analysis were (a) clinical stage, (b) an interval of >12 months between the antecedent pregnancy and the start of chemotherapy, (c) a negative blood β -hCG titer after seven courses of chemotherapy, and (d) less than two courses of consolidation chemotherapy.

Chemotherapy

Single-Agent Chemotherapy

In 1956, Li et al. (222) reported the dramatic cure of metastatic CCA in three women by using MTX. In 1961, Hertz et al. (223) reviewed the initial 5-year experience with chemotherapy in treating metastatic GTN. Importantly, MTX alone induced complete remission in 28 (44%) of 63 patients with metastatic disease. After achieving impressive results in patients with metastatic disease, Hertz et al. (224) used MTX as the primary treatment of nonmetastatic GTN. Complete remission was attained in all 16 women with nonmetastatic disease by administering MTX alone. Chemotherapy, therefore, obviated the need for hysterectomy and enabled patients to attain cure while retaining their fertility. Although MTX induced cure in many patients, it was still necessary to identify other active chemotherapeutic agents. Ross et al. (225) first used actinomycin D (ACT D) in 13 patients with MTX-resistant GTN and 6 (46%) patients attained complete remission.

Since the early 1960s, MTX and ACT D have remained the two central drugs in the treatment of patients with GTN.

Single-agent chemotherapy with either ACT D or MTX has induced comparable and excellent remission rates in both nonmetastatic and metastatic GTN (226). An optimal regimen should maximize the cure rate while minimizing toxicity. Many protocols have been evaluated for administering ACT D and MTX as single agents in nonmetastatic and low-risk metastatic GTN (190,226–236). Several regimens of ACT D and MTX have induced complete remission in 70% to 100% of patients with nonmetastatic GTN and in 50% to 70% of patients with low-risk metastatic disease. Fortunately, if a patient develops resistance to the initial single-agent chemotherapeutic treatment, it is still likely that the patient may achieve remission with an alternative single agent.

In 1964, Bagshawe and Wilde (237) first reported administering MTX with folic acid (MTX/FA) to reduce chemotherapeutic toxicity. MTX/FA has remained the primary treatment of nonmetastatic and low-risk metastatic GTN at the Charing Cross Hospital. Although MTX/FA is highly effective, resistance develops in 20%, and ACT D is then used sequentially.

MTX/FA has been the preferred single-agent regimen in the treatment of GTN at the NETDC since 1974 (238–240). Between September 1974 and September 1984, 185 patients with GTN were treated with primary MTX/FA at the NETDC. Complete remission was induced with MTX/FA in 162 (87.6%) patients, and 132 (81.5%) of these patients required only one course of MTX/FA to achieve remission. MTX/FA induced remission in 147 (90.2%) of 163 patients with stage I and in 15 (68.2%) of 22 patients with low-risk stages II and III. Among the 23 patients who were resistant to MTX/FA, 14 (61%) achieved remission with ACT D and remission was accomplished with combination chemotherapy in the remaining 9. Toxicity to MTX/FA including thrombocytopenia, granulocytopenia, and hepatotoxicity occurred in only 11 (5.9%), 3 (1.6%), and 26 (14.1%) patients, respectively. No patient required platelet transfusions or developed sepsis due to myelosuppression, and no patient developed alopecia. MTX/FA not only induces an excellent remission rate with minimal toxicity, but also effectively limits chemotherapy exposure (241). The MTX/FA regimen is administered over 8 days (MTX 1 mg/kg intramuscularly on days 1, 3, 5, and 7 and folic acid 0.1 mg/kg intramuscularly or orally on days 2, 4, 6, and 8), and its effectiveness may be partly attributable to the prolonged exposure to MTX. When we infused MTX at a higher dosage (300 mg/m²) over 12 hours and 30 minutes, the remission rate declined to 69% in patients with nonmetastatic disease (242).

Whereas MTX and ACT D are the two most commonly used single agents in the treatment of GTN in the United States and in most of the world, 5-fluorouracil (5FU) has been the preferred single-agent chemotherapy in China. Sung et al. (243) reported that 5FU induced complete remission in 93% of patients with stage I and in 86% of patients with stage II GTN. Etoposide has also been utilized as a single agent in the management of both nonmetastatic and metastatic disease with considerable success (244).

Combination Chemotherapy

Modified triple therapy with MTX/FA, ACT D, and cyclophosphamide had been the preferred combination drug regimen at the NETDC (245). However, triple therapy is inadequate as an initial treatment in patients with high-risk metastatic disease (prognostic score 7 or >7). Summarizing the experience from six centers, triple therapy induced complete remission in 47 (51%) of 92 patients with metastatic GTN and a high-risk WHO score (154–158,160, 188,189,245–247).

Etoposide (VP16) has been demonstrated to be a highly active antitumor agent in GTN. Primary oral etoposide induced

complete sustained remission in 56 (93.3%) of 60 patients with nonmetastatic or low-risk metastatic disease (244). Bagshawe (248) reported an 83% remission rate in patients with metastatic disease and a high-risk score using a combination regimen that included etoposide. This regimen (EMACO) includes etoposide, MTX, ACT D, cyclophosphamide, and vincristine (Oncovin) and is currently the preferred treatment for patients with high-risk metastatic GTN. Bolis et al. (249), Lurain et al. (250), and Soper et al. (251) have similarly reported that EMACO induced complete remission in 13 (76%) of 17, in 20 (67%) of 30, and in 4 (67%) of 6 patients, respectively, with metastatic GTN and a high-risk score. Furthermore, Bower et al. (252) and Kim et al. (253) reported that primary EMACO induced remission in 130 (86.1%) of 151 patients and in 87 (90.6%) of 96 patients, respectively, with high-risk metastatic GTN. Therefore, EMACO is highly effective as primary therapy, inducing complete remission in 70% to 90% of patients with high-risk metastatic GTN.

If patients experience resistance to EMACO, they may then successfully be treated with a modification of this regimen by substituting etoposide and cisplatin on day 8 (EMAEP) (250–255). Bower et al. (252) reported that EMAEP induced remission, alone or in conjunction with surgery, in 16 (76%) of 21 patients who were resistant to EMACO. Lurain et al. (250) also noted the efficacy of using platinum. He observed that eight of ten patients (80%) resistant to EMACO were placed in remission with platinum-based chemotherapy. When patients develop resistance to EMACO, surgical intervention may also be necessary to remove sites of resistant tumor (255,256).

Unfortunately, the use of etoposide has been reported to increase the risk of later secondary tumors including myeloid leukemia, melanoma, colon cancer, and breast cancer (257). The relative risk for leukemia, melanoma, colon cancer, and breast cancer was increased by 16.6%, 3.4%, 4.6%, and 5.8%, respectively, in patients who received >2 gms/M². The increased risk for breast cancer did not become apparent until after 25 years. Among all patients who were treated with etoposide, 1.5% subsequently developed leukemia. Etoposide should therefore be used only with high-risk metastatic disease. When patients with nonmetastatic and low-risk metastatic GTN experience resistance to MTX and ACT D, it is reasonable to consider administering triple therapy before treatment with regimens containing etoposide (258).

Second-line therapy with cisplatin, vinblastine, and bleomycin (PUB) may also be effective in patients with drug-resistant GTN. Gordon et al. (259), DuBeshter et al. (260), and Azab et al. (261) reported that PUB induced complete remission in 2 of 11 patients, 4 of 7 patients, and 5 of 8 patients, respectively, with drug-resistant GTN.

The potential role of autologous bone marrow transplantation or stem-cell rescue in GTN has yet to be defined. However, individual cases have been reported where high-dose chemotherapy with autologous bone marrow or stem-cell support has induced complete remission in patients with refractory GTN (262,263).

Despite the efficacy of the well-recognized regimens used in treating GTN, efforts continue to identify new agents that are effective in treating patients with resistance. Although ifosfamide and paclitaxel (Taxol) are both active in treating GTN, further studies must be performed to determine their potential role in either primary treatment or second-line therapy (264,265). Osborne et al. (266) have reported that a novel three-drug doublet regimen, consisting of paclitaxel, etoposide, and cisplatin (TE/TO), induced complete remission in two patients with relapsed high-risk GTN. Wan et al. (267) analyzed the efficacy of floxuridine (FUDR)-containing regimens in the treatment of patients with invasive mole and CCA, some of whom had shown resistance to other regimens. Twenty-one

^aJanuary 1979 to November 2001.

patients with drug-resistant GTN received FUDR-containing regimens and all patients achieved remission. Matsui et al. (268) found that 5FU in combination with ACT D could also be used as salvage therapy and induced complete remission in 9 of 11 (82%) patients with drug-resistant GTN.

Patients who require combination chemotherapy should be treated intensively to attain remission. Treatment delay or dose reduction due to chemotherapy-induced neutropenia may contribute to tumor resistance and treatment failure. Since the goal of therapy is cure of the disease, unnecessary treatment delays and dose reduction must be avoided, particularly in high-risk patients. Recombinant hematopoietic growth factors and platelet transfusion should be used. We administer combination chemotherapy as frequently as toxicity permits until the patient attains three consecutive normal hCG values. After the patient achieves normal hCG levels, three additional courses of chemotherapy are administered to reduce the risk of relapse.

Subsequent Pregnancies

Pregnancies After Hydatidiform Mole

Patients with CHM can anticipate normal reproduction in the future (103). Patients with complete moles who were treated at the NETDC had 1,278 later pregnancies between June 1965 and November 2001. These pregnancies resulted in 877 (68.6%) full-term live births, 95 (7.4%) premature deliveries, 11 (0.9%) ectopic pregnancies, and seven (0.5%) stillbirths (Table 28.11). First-trimester spontaneous abortion occurred in 221 (17.3%) pregnancies, and major and minor congenital malformations were detected in only 40 (4.1%) infants. Primary cesarean section was performed in only 70 (18.8%) of 373 subsequent full-term and premature births between January 1979 and November 2001.

Limited information is available regarding the later pregnancy experience in patients with partial moles (Table 28.12).

^aJanuary 1979 to November 2001.

Between June 1965 and November 2001, patients with partial moles at the NETDC had 251 subsequent gestations that resulted in 189 (75.3%) full-term live births, one (0.4%) stillbirth, one (0.4%) ectopic pregnancy, and four (1.6%) premature deliveries. First-trimester spontaneous abortion occurred in 38 (15.1%) pregnancies, and major or minor congenital anomalies were detected in only three (1.5%) infants. The preliminary data concerning subsequent conceptions after partial moles are therefore reassuring.

When a patient has had a molar pregnancy, she is at increased risk of developing molar disease in later conceptions (269,270). Thirty-four (1:150) of our patients have had at least two molar gestations between June 1965 and November 2001 (101). Patients may have an initial complete or partial mole and then in a later pregnancy develop the other type of molar disease. Following two episodes of molar pregnancy, our 34 patients had 35 later conceptions, resulting in 20 (57.1%) full-term deliveries, seven (20%) molar pregnancies (six complete, one partial), three (8.6%) spontaneous abortions, one (2.9%) ectopic pregnancy, one intrauterine fetal death, and three (8.6%) therapeutic abortions. Bagshawe et al. (271) also reported that the risk of molar disease following two episodes of molar pregnancy was 15%. In six of our cases, the medical records clearly indicated that the patient had a different partner at the time of conception of different molar pregnancies (272). Patients with molar gestation appear to be at increased risk for later molar disease even with a different partner.

It therefore seems prudent to obtain an ultrasound in the first trimester of any subsequent pregnancy to confirm normal gestational development. An hCG measurement should also be obtained 6 weeks after the completion of any future pregnancy to exclude occult trophoblastic disease.

Pregnancies After GTN

Patients with successfully treated GTN can also generally expect normal reproduction in the future (103). Patients with GTN who were treated with chemotherapy at the NETDC had 581 pregnancies between June 1965 and November 2001. These later pregnancies resulted in 393 (67.6%) full-term live births, 35 (6.0%) premature deliveries, seven (1.2%) ectopic pregnancies, and nine (1.5%) stillbirths (Table 28.13). First-trimester spontaneous abortion occurred in 92 (15.8%) pregnancies and major and minor congenital anomalies were

detected in only ten (2.3%) infants. It is particularly reassuring that the frequency of congenital malformations is not increased because chemotherapy may be teratogenic and mutagenic. Primary cesarean section was performed in only 68 (20.3%) of 335 subsequent full-term and premature deliveries between January 1979 and November 2001. Later pregnancies have no increased risk for obstetric complications either prenatally or intrapartum.

Summarizing the experience from the NETDC with eight other centers, following chemotherapy for GTN, data have been reported concerning the outcome of 2,657 later pregnancies (273–280). These subsequent pregnancies resulted in 2,038 (76.7%) live births, 71 (5.3%) premature deliveries, 34 (1.3%) stillbirths, and 378 (14.2%) spontaneous abortions. Although the frequency of stillbirth appears to be somewhat increased, congenital malformations were noted in only 37 infants (1.8%), which is consistent with the general population. Woolas et al. (280) noted that there was no difference in either the conception rate or pregnancy outcome between women treated with single-agent MTX and those receiving combination chemotherapy. Furthermore, only 7% of women who wished to become pregnant following chemotherapy for GTN failed to conceive.

In general, patients who achieve primary remission with various kinds of chemotherapy may anticipate a normal future reproductive outcome. Patients occasionally become pregnant before the recommended 12-month follow-up period has elapsed. When a patient's hCG level re-elevates after completing chemotherapy, the use of ultrasound enables the clinician to distinguish between an intercurrent pregnancy and disease recurrence. Matsui et al. (281) have reported that pregnancies that occur within 6 months following remission are at increased risk of abnormalities, including spontaneous miscarriage, stillbirths, and repeat moles.

Psychosocial Consequences of GTN

Women who develop GTN may experience significant mood disturbance, marital and sexual problems, and concerns over future fertility (282–285). Because GTN is a consequence of pregnancy, patients and their partners must confront the loss of a pregnancy at the same time they face concerns regarding

TABLE 28.13

SUBSEQUENT PREGNANCIES IN PATIENTS WITH GESTATIONAL TROPHOBLASTIC TUMORS (NEW ENGLAND TROPHOBLASTIC DISEASE CENTER, JUNE 1, 1965, TO NOVEMBER 30, 2001)

malignancy. Patients may experience clinically significant levels of anxiety, fatigue, anger, confusion, sexual problems, and concern for future pregnancy that may last for protracted periods of time. Particularly, patients with metastatic disease and active disease are at risk for severe psychologic reactions. Psychosocial assessments and interventions should be provided to patients with GTN and their partners, and should be targeted particularly to patients in the metastatic and active disease groups. The psychologic and social stresses related to persistent GTN may last for many years beyond achieving complete remission. Even 5 to 10 years after attaining complete remission, 51% of patients indicate that they would be somewhat likely to very likely to participate in a counseling program today to discuss psychosocial issues raised by having had GTN.

INTRODUCTION

Breast cancer is a worldwide problem and affects more than 1.2 million women every year, making it the most common cancer diagnosis in women. Treatment paradigms require an understanding of the natural history of the disease including the various patterns of metastases and recurrence, and both the prognostic and predictive factors that may influence both response to treatment and overall survival. In addition, the complexities that govern medical and surgical decisions make the management of breast cancer far more complicated than that of other disease sites. This chapter provides the essential information regarding breast cancer with an emphasis on recent developments. It stresses an interdisciplinary view of disease management by providing the foundational aspects of breast disease and treatment.

EPIDEMIOLOGY

Each year about 180,510 women and 2,030 men are diagnosed with breast cancer in the United States (1). It is estimated that one in eight women will be diagnosed with breast cancer in their lifetime. Beginning in the late 1990s a shift in the incidence of breast cancer in the United States was noted. The steady increase in breast cancer diagnosis seen in the 1950s started to decline in 1999 and continued into 2003. The decline in the annual incidence between 2002 and 2003 was limited to women over the age of 50. Whether the declining use of hormone replacement therapy following publication of the Women's Health Initiative (WHI) results, utilization of mammographic screening and earlier diagnosis of disease, or a combination of these factors explains this trend continues to be an area of investigation. Mortality from breast cancer has been steadily declining since 1990, at a rate of 3.3% in women under 50 and 2.0% per year in older women (1). Still, over 40,000 women will succumb to breast cancer, making it second only to lung cancer.

RISK FACTORS

Risk factors for breast cancer have been well characterized. Breast cancer is 100 times more frequent in *women* than in men. Factors associated with an increased exposure to *estrogen* have also been elucidated including early menarche, late menopause, later age at first pregnancy, or nulliparity. The use of hormone replacement therapy has been confirmed as a risk factor, although mostly limited to the combined use of estrogen

and progesterone, as demonstrated in the WHI (2). Analysis showed that the risk of breast cancer among women using estrogen and progesterone was increased by 24% compared to placebo. A separate arm of the WHI randomized women with a prior hysterectomy to conjugated equine estrogen (CEE) versus placebo, and in that study, the use of CEE was not associated with an increased risk of breast cancer (3). Unlike hormone replacement therapy, there is no evidence that oral contraceptive (OCP) use increases risk. A large population-based case-control study examining the risk of breast cancer among women who previously used or were currently using OCPs included over 9,000 women aged 35 to 64 (half of whom had breast cancer) (4). The reported relative risk was 1.0 (95% CI, 0.8 to 1.3) among women currently using OCPs and 0.9 (95% CI, 0.8 to 1.0) among prior users. In addition, neither race nor family history was associated with a greater risk of breast cancer among OCP users.

Apart from endocrine risk factors, sociodemographic risks have also been established. Breast cancer is an *age*-related phenomenon, with peak incidence after 40. Family history is also a strong epidemiologic risk factor, although it accounts for less than 10% of cases of breast cancer. Clinical models can now be employed to predict the risk of breast cancer. Among those in common use are the Gail and Claus models (Table 29.1) (5,6). Although they have been widely used in the African American and other minority populations, they have not been validated sufficiently.

Beyond classification of risk based on family history, the identification of genetic mutations that are passed in an autosomal-dominant fashion has been an important scientific breakthrough. Among the most significant was the identification of mutations at *BRCA1*, localized to chromosome 17q21, and *BRCA2* on chromosome 13q12-13, both of which confer a risk for breast cancer as high as 80% among carriers (7,8). A specific *BRCA1* mutation, 185delAG, has been identified in over 20% of Jewish women younger than 40 years of age. Other mutations known to carry an increased risk are those involving p53 in the Li-Fraumeni syndrome (associated with other cancers including sarcoma, leukemia, melanoma, gastrointestinal carcinomas, and brain tumors), CHEK-2, and *PTEN* mutations associated with Cowden syndrome (mental retardation associated with increased incidence of hamartomas, endometrial cancer, and noncancerous brain tumors).

Work evaluating the long-term effects of environmental factors has established prior radiation exposure as an additional risk factor. The therapeutic use of mantle-field radiation in women with Hodgkin's disease and the sequelae of the atomic bombing of Japan in World War II identified the heightened risks of breast cancer, particularly in young women (9,10).

TABLE 29.1

MODELS FOR ESTIMATING RISK FOR BREAST CANCER

	Gail ^a	Claus ^b
Source	Breast Cancer Detection Demonstration Project (n = 284,780)	Cancer and Steroid Hormone Study (n = 9,418)
Personal risk factors	Age Age at menarche Prior breast biopsies Age at first live birth	Age
Family history	Number of <i>maternal</i> first-degree relatives with breast cancer	Number of relatives with breast cancer (beyond first-degree relatives) and ages of onset
Calculations	Absolute risk ^c at 5 years Lifetime risk up to 90 years old	Lifetime risk up to 80 years old
Limitations	Excludes paternal history Excludes ovarian cancer history Does not use pathologic findings from breast biopsy Does not account for age of onset of breast cancer among family Not validated in other ethnic groups	Excludes other risk factors May underestimate risk in families with three or more family members with breast cancer

^cRisk defined for invasive breast cancer only.

Among modifiable risk factors, obesity, weight gain in later life, and the consumption of alcohol have been identified in prospective observational studies (11). The association of environmentally found trace elements and breast cancer risk has also been evaluated with unconvincing results in general.

An association has been made between breast cancer risk and breast findings. Among the best described risk factors is the association between breast cancer and a history of biopsies for benign breast disease. In a study by Hartmann et al. the relative risk for breast cancer ranged from 1.27 for nonproliferative lesions to 1.88 for proliferative lesions without atypia to 4.24 in lesions with atypia, and this risk persisted for as long as 25 years after biopsy (12). A recent report from Worsham et al. evaluated the same risks in an inner-city clinic and reported that African American women with benign breast lesions faced similar risks in developing breast cancer (13). More recently, Boyd et al. reported on the association between risk and breast density (measured in percentage of the total breast) (14). Using 1,112 matched case-control pairs they determined the association between risk and reported that women with density of 75% or greater had a significantly increased risk of breast cancer (odds ratio, 4.7; 95% CI, 3.0 to 7.4), with younger women notably at greatest risk.

ANATOMY

The breast is a modified sweat gland composed of two components: the large ducts and the terminal duct-lobular unit (TDLU), surrounded by adipose and fibrous tissue, lymphatics, nerves, and blood vessels. The surface of the breast is attached to the underlying fibrous tissue by way of Cooper's ligaments, and the mammary gland lies over the pectoralis major muscle, extending vertically along the second to sixth ribs and horizontally from the

sternum to the anterior midaxillary line. The axillary tail comprises mammary tissue as well and extends laterally from the chest wall into the axilla. The large duct system of subsegmental, segmental, and lactiferous ducts converge and empty onto the nipple. The TDLU is the most distal part of this branching ductal system, and is felt to be the site of origin of most pathologic entities of the breast, including fibrocystic changes, ductal hyperplasias, and the majority of carcinomas (15,16). It is connected to the subsegmental ducts and represents the secretory unit of the gland (Fig. 29.1).

FIGURE 29.1. Normal breast lobules. Three terminal duct-lobular units are surrounded by adipose and fibrous tissue.

Mobility of the breast tissue over the chest wall is through the retromammary bursa, which lies between the superficial and deep fascia. The lymphatic system of the breast is vast, comprising a network over the entire surface of the chest, neck, and abdomen, with increased density under the axilla. There are three main lymphatic pathways of the breast: (a) the axillary pathway, which drains the upper and lower halves of the breast into the lateral axillary nodal chain; (b) the transpectoral pathway, which drains into the supraclavicular nodes; and (c) the internal mammary pathway, draining the inner halves of the breast, into the nodes of the internal mammary chain.

NATURAL HISTORY OF BREAST CANCER

Breast cancers can occur with predictable features. For example, it is more likely to be diagnosed in the central or outer quadrants of the breast than in the inner regions (17). It has also been reported to be more commonly involving the left breast; a study of 2,139 cases of breast cancer in Iceland showed that 13% more breast cancers occurred in the left breast versus the right (18).

Within the breast, cancer travels along ducts (intraductal carcinoma), and the process of invasion begins when the tumor erodes through the basement membrane. Continued growth results as the tumor spreads along adjacent lobules, breast lymphatics, perineural tumors, and vascular spaces. When it involves the dermal lymphatics, the overlying dermis becomes edematous and red with the classic appearance of *peau d'orange*. Continued growth of the primary tumor can result in the involvement of the pectoralis and intercostal muscles, ribs, and the clavicle.

While less frequently encountered, locally advanced or metastatic disease at diagnosis still occurs in clinical practice. Tumor spread can occur locally by direct extension, lymphatically, or via intravascular means. Lymphatic spread of tumor from the breast travels to the locoregional nodes of the chest—the axillary, intramammary, and supraclavicular nodal basins—and increasing tumor size is a well-known predictor of nodal involvement. A medial or central lesion of the breast is more likely to metastasize to the internal mammary nodes than outer quadrant lesions, and this has been theorized to explain their worse prognosis compared to upper outer breast tumors (17). Vascular invasion can be observed, even with small tumors.

Metastatic disease from breast cancer can occur in any organ site. Lee reported on presentations of metastatic breast cancer among over 2,000 women who had died of disease (Fig. 29.2) (19). The most commonly involved organs were the lungs, bones, nodes, and liver. The pleural space, adrenal glands, and

brain represented the next most commonly involved sites. Regarding survival, bloom compared a group of women with untreated breast cancer to a cohort of patients treated with radical or modified radical mastectomy, with or without irradiation, and reported an overall 10-year survival of 3.6% in the untreated cohort, versus 34% in the treated group (20).

Theories on the spread of breast cancer have been used as a foundation for subsequent treatment, and have evolved over time. Under Halsted, the notion that cancer arose from one location and travelled contiguously by lymphatics to reach local and distant locations was borne. Hence, treatment with the *en bloc* resection of the breast and lymphatics was felt to present the best opportunity for cure. Still, it was clear that even with aggressive surgery and removal of the lymphatics from the breast, women still died of breast cancer. In a seminal paper by Valagussa et al. the overall survival among women with node-negative disease was reported to be 60%, those with up to three nodes positive at 54%, and at 26% in those with more than three positive nodes. This showed that contiguous lymphatic spread alone could not explain survival outcomes (21).

The theory of breast cancer as a systemic disease was brought forward in 1980 by Dr. Bernard Fisher (22). Breast tumors were seen as a marker of this systemic syndrome, just as neuropathy would be a marker of advanced diabetes mellitus. Hence, nodal disease was not simply an extension of a primary breast cancer process, but rather a marker of disease already spread. This theory holds that achieving local control will not have an impact on overall survival and argues for the use of systemic treatment in order to effect the best outcome. Recently, however, a meta-analysis on the use of adjuvant radiation by the Early Breast Cancer Trialists' Collaborative has called this theory into question. In that analysis the use of adjuvant radiation not only improved local control but also reduced annual mortality by 13% after the 2nd year of follow-up (23).

It is likely that breast tumors express variable degrees of malignancy. Hellman argued that “synthesis” between Halsted and Fisher's theories was required (24). Recognizing that the size of tumor is proportional to the risk of metastases, he suggested that small and large tumors behave differently, and carried different prognoses. Whereas small tumors were a manifestation of a locoregional process and therefore were curable with treatment, larger tumors included a heterogeneous population of cell types, including those more likely to proliferate and be more malignant—features that made them more likely to metastasize. As such, the larger tumors were likely to be associated with systemic disease. Defining cure as “that proportion of the treated group that has the same survival as an age-adjusted peer population,” he estimated that over 80% of women with tumors less than 1 cm in size were curable and that this was manifest at 10 years of follow-up (24). In summary, he again stressed the importance of local control for small tumors, while emphasizing the importance of systemic control in larger breast cancers.

FIGURE 29.2. Pattern of metastatic disease from breast cancer based on an autopsy series of over 2,000 women.

CLINICAL PRESENTATION OF BREAST CANCER

Today the most common presentation is with an abnormal mammogram, although patients continue to present with a painless or slightly tender breast mass. In younger women, a delay in diagnosis may be attributed to benign causes such as recent trauma, changes with pregnancy, or due to breast-feeding. For those women presenting with a mass, the patient may ultimately present with breast tenderness, skin changes, bloody nipple discharge, or changes in the shape and size of the breast, with or without axillary adenopathy. Rarely will women present with axillary nodal disease but no evidence of a breast primary, otherwise known as occult breast carcinoma. Lastly, inflammatory breast cancer (IBC) presents as a tender, red, and swollen breast, often mistaken for mastitis. A crusting rash emanating from the nipple is *sine qua non* for Paget's disease of the breast, which is almost uniformly associated with an underlying malignancy. Fortunately, with the increase in screening following publication of the National Institutes of Health (NIH) Consensus Statement in 1978, patients rarely present with metastatic disease (25).

IMAGING STUDIES OF THE BREAST

Introduction

Breast imaging is performed as a screening tool in asymptomatic women to detect early cancer or as a diagnostic examination in women suspected of having breast cancer or previously treated for breast cancer. Mammography remains the most widely used technique for screening, and is the only modality proven to decrease mortality. Computer-aided detection (CAD), a tool designed to help the radiologist improve the detection of breast cancer, is now available and more frequently used by interpreting radiologists. In addition to mammography, ultrasound (US) and magnetic resonance imaging (MRI) now serve as adjunct tools in the diagnostic setting or for high-risk screening. Finally, breast tomosynthesis may prove to be an important tool in detection of early breast cancer.

Mammography

The purpose of screening mammography is the early detection of clinically unsuspected breast cancer in asymptomatic women. The efficacy has been widely established by multiple randomized, controlled trials, which have analyzed large-scale populations with and without screening over long time intervals. These studies show that screening mammography is associated with an 18% to 45% reduction in breast cancer mortality compared with unscreened groups (26–28). In 2003, the American Cancer Society (ACS) updated its guidelines for early detection of breast cancer based on results of an expert panel that reviewed evidence of early detection trials since the last guidelines were published in 1997 (29). A prior controversy regarding screening mammography in women 40 to 49 years of age was addressed as part of this review with the finding that contemporary studies did demonstrate the benefit of screening for this age group (28–30). Therefore, current guidelines recommend annual screening mammography beginning at age 40, with women at high risk of developing breast cancer beginning earlier than age 40.

There is no recommendation for age at which screening should stop; if an older individual is in reasonably good health, would be a candidate for treatment, and has a life expectancy of more than 3 to 5 years, continuing with screening mammography is recommended. There is consensus with the ACS, American College of Radiology (ACR), and the National Cancer Institute (NCI) for routine screening beginning at age 40. However, the NCI recommends mammography only every 1 to 2 years after age 40. The cost-effectiveness of age-related screening mammography has been assessed using the Markov model (30). The marginal cost per year–life saved varies from \$18,800 to \$16,100 for age groups including women ages 40 to 79, which is within the range of other generally acceptable diagnostic and therapeutic medical procedures.

Despite the success of screening mammography, the sensitivity of mammography ranges from 80% to 90%, largely because of insufficient contrast between normal and abnormal breast tissue (31–33). In a screening population, approximately 10% of patients will be “recalled” for additional imaging (i.e., additional mammographic views, spot compression views, or ultrasound evaluation). Of all positive screening examinations, approximately 5% to 10% will have a diagnosis of cancer, and of all recommended biopsies, 25% to 40% will be positive for cancer.

The screening mammogram is an x-ray of the breast, with two views of each breast obtained, a top-to-bottom (cranio-caudad, or CC) view and an angled side-to-side (mediolateral oblique, MLO) view. The images can be recorded on film or stored digitally on a computer. Two views of each breast are needed to optimize the amount of breast tissue included on each mammogram, minimize overcalling disease because of superimposed tissue on a single view, and decreasing the likelihood of obscuring a cancer by overlapping tissue on a single view. In some patients, particularly those with larger breasts, more than four views are obtained by the technologist to ensure that all the breast tissue is included on the images.

Patients who present with concerning signs or symptoms such as mastalgia, a palpable mass, skin thickening, nipple retraction, or nipple discharge require a mammogram as a diagnostic study. Diagnostic mammograms are also indicated in patients recalled for further mammographic evaluation, and those with a personal history of breast cancer, and may be considered in patients with breast augmentation. In the latter, this may be considered diagnostic because of the increased effort and time involved with obtaining necessary views. However, given that this is a procedural reason (as opposed to the workup of a suspicious finding), patients with breast augmentation should be audited within the group undergoing mammography as a screening test.

Mammography practice in the United States is rigidly regulated by the Food and Drug Administration (FDA) under the Mammography Quality Standards Act (MQSA) of 1992 (34). The MQSA mandates extensive follow-up and outcome monitoring of all facilities and interpreting radiologists. Recall rates, biopsy recommendations and results, and cancer detection rates must be analyzed for each interpreting radiologist. Cancer staging must be recorded to include histologic type, size, nodal status, and grade. It also requires analysis of any known false-negative mammograms and mandates that the facility send a letter to each patient informing her of the results of her mammogram and a formal report to the referring physician. It is *federally mandated* that the report include a final assessment category providing guidance and management recommendations.

The Breast Imaging Reporting and Data System (BIRADS), first published in 1993, is a lexicon developed by the ACR to standardize terminology used in reporting findings on mammograms (35). It includes terms for describing features of masses (shapes and margins) and calcifications (morphology

TABLE 29.2**BIRADS (BREAST IMAGING AND REPORTING DATA SYSTEM) ASSESSMENT CATEGORIES**

Category	Interpretation
0	Mammographic assessment is incomplete Additional imaging evaluation and/or prior mammograms required for comparison Used in screening situations
1	Negative No mammographic evidence of malignancy
2	Normal, but describes a benign finding No mammographic evidence of malignancy
3	Probably benign finding—initial short interval follow-up suggested Finding with less than 2% risk of malignancy, not expected to change over interval
4	Suspicious abnormality—biopsy should be considered Findings do not have classic appearance of malignancy, but greater probability than category 3
5	Highly suggestive of malignancy—appropriate action should be taken Finding had greater than 95% probability of being malignant
6	Known biopsy-proven malignancy—appropriate action should be taken Used for lesions identified on imaging studies with biopsy proof of malignancy prior to definitive therapy

Note: It is federally mandated that all mammography reports give a final assessment category.
Source: American College of Radiology BIRADS—Mammography. 4th ed. Reston, VA: American College of Radiology; 2003.

and distribution). It defines final assessment categories to describe the radiologist's level of suspicion about a mammographic abnormality, to comply with the federally mandated MQSA regulations. All mammograms must be assessed with a final BIRADS category of 0 to 6 (Table 29.2). The report must include the date of comparison films, the indication for the examination (screening, recall, clinical finding, or follow-up), an assessment of overall breast composition to indicate the relative possibility that a lesion may be hidden by normal tissue, limiting the sensitivity of the examination (Table 29.3), a description of any significant findings, and an overall summary impression.

A mammographic mass is defined as a space-occupying lesion seen in two projections, whereas an “asymmetry” is a potential mass seen only in a single projection (Fig. 29.3). Describing a mass must encompass its shape, margins, and density. Masses that are irregular in shape, with indistinct or spiculated margins, and of high density are the most worrisome for malignancy, whereas round or oval masses with circumscribed (well-defined) margins are more likely benign. Calcifications are described by type and distribution. Those that are larger, coarser, smoothly marginated, and more easily seen are likely benign, while those that are very fine, pleomorphic, or linear are more likely to be malignant (Fig. 29.4). The distribution may be telling as well;

TABLE 29.3**MAMMOGRAPHIC ASSESSMENT OF OVERALL BREAST COMPOSITION—THE OVERALL ASSESSMENT OF VOLUME OF ATTENUATING TISSUES IN BREAST, WHICH INDICATES THE RELATIVE POSSIBILITY THAT A LESION IS HIDDEN BY NORMAL TISSUE AND INDICATES THE SENSITIVITY OF THE EXAMINATION**

Mammographic description	Glandular proportion of total breast tissue (%)
The breast is almost entirely fat	<25
Scattered fibroglandular densities present	25–50
The breast tissue is heterogeneously dense; this may obscure detection of small masses	51–75
The breast tissue is extremely dense; this may lower the sensitivity of mammography	>75

FIGURE 29.3. Right craniocaudad mammographic view shows a spiculated mass in the outer breast. Biopsy showed poorly differentiated invasive mixed ductal and lobular carcinoma.

FIGURE 29.4. Magnification view of right breast calcifications shows linear and branching calcifications, which at biopsy were duct carcinoma *in situ*.

diffuse and scattered calcifications are more likely benign, while grouped or clustered, linear, or segmental calcifications are more worrisome. The side of any abnormality, location by quadrant or clock face, and depth should be included in the description.

Film Versus Digital Mammography

Film mammography is extremely effective and has been widely accepted as a screening modality for the past 20 to 30 years. With this technique, the mammography images are recorded as hard copy on film and developed by the technologist, then presented to the radiologist for review. Digital mammography, however, uses a digital detector to replace the screen film of conventional mammography. Radiation transmitted through the breast is absorbed by an electronic detector, with a response faithful over a wide range of intensities. The recorded information can be displayed using computer image-processing techniques to allow selective settings of image brightness and contrast without need for further exposure to patients. The lower system noise would be expected to enhance the visibility of subtle contrast differences between tumors and normal background tissue. With digital imaging, the processes of image acquisition, storage, and display are separated, allowing optimization of each (36,37). In addition, the average patient dose of radiation is slightly lower than that of film mammography, and examination time for each patient is shorter. The disadvantages of digital mammography are the cost of equipment, which is 1.5 to four times as much as film systems, and the slightly longer interpretation time by the radiologist (38).

Early clinical trials showed equivalent diagnostic accuracy between digital and screen-film mammography (39–43). The Senographe 2000D screening trial demonstrated a significant decrease in recall rate for digital (11.8%) versus screen film (14.9%), as well as a decrease in biopsy rate (43). In the Digital Mammographic Imaging Screening Trial (DMIST), 49,528 asymptomatic women presenting for screening mammography at 33 sites in the United States and Canada underwent both digital and film mammography, with the examinations interpreted independently by two radiologists (38). While the diagnostic accuracy of digital and film mammography was similar overall, the accuracy of digital mammography was significantly higher than that of film mammography in the following groups: women under the age of 50 years, women with heterogeneously dense or extremely dense breasts on mammography, and premenopausal or perimenopausal women. This finding is significant because it is widely recognized that increased density on mammography decreases the sensitivity of the technique (44–48). In addition, the major limitation of mammography is that cancer can be hidden by adjacent breast tissue. Digital mammography addresses this issue by allowing for contrast adjustment, which can bring out the visibility of a mass in this setting.

Computer-Aided Detection

CAD was first approved by the FDA in 1998. It aims to identify suspicious findings on mammogram which can assist radiologic interpretation. Initial studies demonstrated increased sensitivity of cancer detection when CAD was added to screening programs, with increased rates of cancer detection reported between 7.62% to 19.5% (49–52). Cupples et al. showed a particular improvement of small cancer detection by CAD, with a 164% increased cancer detection rate of invasive cancers less than 1 cm (49). Because of the reported improvement of breast cancer detection, Medicare and many insurers reimburse for use of CAD.

However, the increased detection rate with CAD has come at the cost of increased recalls and increased rate of biopsy (53–55). Recently a large-scale study conducted by Fenton et al. determined the association between use of CAD at mammographic facilities and performance of screening mammography during 1998 to 2002 (56). In that study, 223,135 women were screened at 43 facilities in three states, with and without the assistance of CAD. The specificity of screening decreased from 90.2% without CAD to 87.2% with CAD, and the biopsy rate increased by 19.7% with CAD. There was no statistically significant change in sensitivity with or without CAD, although there was a trend toward an increase in sensitivity. Overall, the increased rate of biopsy resulting from use of CAD was not clearly associated with improved detection of invasive cancer. Of the cancer detected by CAD, there was a trend toward more ductal carcinoma *in situ* detection than invasive cancer, which may be clinically important. Although there were a large number of women included in the study, the number of cancers was still relatively small, making it difficult to judge whether the benefits of routine use of CAD outweigh its harms (i.e., increased biopsy rate).

Ultrasound

Ultrasonography is used as a targeted examination, most often to determine the cystic versus solid nature of a mass. It has been shown to be effective in determining the likelihood of benign versus malignant breast masses (Fig. 29.5) (57). Prevalence studies in women with radiographically dense breasts have shown that three to four cancers per 1,000 women are detected by ultrasound only (57–62). However, the limitations of breast ultrasound as a screening tool are well known: it requires a skilled operator, is labor intensive, and there is currently no standardized examination technique or interpretation criteria. Moreover, it does not detect microcalcifications, which may be the hallmark of *in situ* breast cancer. Finally, it has a high false-positive rate and is less sensitive than breast MRI (59,60,62). Therefore, it is unlikely that screening breast US will become widely used in the United States.

Tomosynthesis

Tomosynthesis is a three-dimensional mammographic technique that allows improved visualization over mammography

FIGURE 29.5. Targeted breast ultrasound demonstrating a heterogeneous solid mass with irregular margins measuring 1.9 cm. Ultrasound guidance was used to place a wire for subsequent localization and wide local excision of the patient's known infiltrating ductal carcinoma.

by minimizing effects of overlapping tissue. The acquisition of images mimics conventional mammography with breast positioning and compression. The x-ray tube takes multiple low-dose exposures from many angles, resulting in a digital data set that can be reconstructed into tomographic sections through the breast. The images can be obtained in a CC, MLO, or 90-degree lateral projection. It is currently undergoing testing, but shows great promise. Tomosynthesis may reduce the rate of false-positive mammograms, and thus decrease the recall rate, by minimizing the effects of overlapping tissue. In this way it may have more impact in women with dense breasts.

Poplack et al. compared the image quality of tomosynthesis with conventional mammography (63). Ninety-eight women with 99 screening recalls were evaluated with tomosynthesis of the affected breast. Image quality by tomosynthesis was found to be equivalent in 52% and superior in 37% of patients compared to mammogram. In addition, many findings on mammogram would not be recalled with tomosynthesis, suggesting that it could reduce recall rates by 40%.

Of breast findings, masses are better seen on tomosynthesis, but calcifications are better seen on diagnostic mammography. This may be attributed to motion-related blur due to the somewhat long (19 seconds) exposure time of the tomosynthesis. In addition, images are reconstructed at 1 mm thickness slices, which may be too thin to ably demonstrate the clustered distribution of calcifications.

It remains to be seen whether tomosynthesis can be performed in one projection, which would minimize radiation dose and the length of examination, or whether two views will be needed. Rafferty et al. presented data on 34 patients scheduled for biopsy by performing tomosynthesis in both the CC and MLO projections, finding that most lesions (65%) were equally visible on both, but 9% were only seen on the CC view; all of these potentially missed lesions were malignant (64). Today, we believe that tomosynthesis will require imaging in both projections for optimal lesion visualization.

The cost of tomosynthesis has yet to be determined. It is expected that the technique will be substantially less expensive than breast MRI and will not require an injection, which may make this advantageous in screening high-risk women. Larger-scale trials will need to be performed to evaluate who will best benefit from the examination as opposed to conventional mammography.

Breast MRI

MRI of the breast has evolved over the past 2 decades from a research tool to the most sensitive imaging modality in the detection of invasive breast cancer. Contrast-enhanced breast MRI is increasingly being incorporated in the clinical evaluation of breast cancer (65). For breast lesion detection, intravenous injection of gadolinium-based contrast is needed as contrast enhancement to allow visualization of breast cancer against the background of glandular tissue. This distinction relies on the determination that tumor angiogenesis and surrounding tissue permeability allow contrast uptake within cancer (66). That is, a significant number of invasive tumors demonstrate rapid wash in of contrast and wash out with time (67). Significant overlap between enhancement pattern of benign and malignant processes exists, which must be recognized, and which lowers the specificity of breast MRI. As such, analysis of breast MR-enhancing lesions involves analyzing both lesion morphology and kinetics of enhancement to provide the most specificity in lesion characterization (68). For example, spiculated morphology and rim enhancement are features highly predictive of malignancy, while circumscribed margins with persistent kinetics (increasing enhancement with time) suggest a benign etiology (Fig. 29.6) (69,70).

FIGURE 29.6. Breast MRI in a 55-year-old woman with biopsy-proven infiltrating ductal carcinoma. It shows spiculated morphology and rim enhancement, features that are highly specific for carcinoma.

Variable protocols for MRI imaging of the breast exist. However, technical prerequisites for standard imaging have been set by the ACR for proper imaging and diagnosis. In general, MRI breast imaging should be performed with a dedicated breast coil, using at least a 1.5-tesla magnet and imaging extents to optimize high spatial and temporal resolution.

Technical advances in breast MRI have led to improved sensitivity for the detection of invasive breast cancer currently reported to be between 89% and 100% (71,72). Although previous studies in ductal carcinoma *in situ* (DCIS) (Fig. 29.7A,B) showed low and variable sensitivities, with improved techniques contemporary studies report higher sensitivity of up to 89% (73,74). In one multicenter prospective study, MRI had higher sensitivity than mammography in detecting DCIS, including both DCIS with associated invasive component and multicentric disease (75). Recent advances introduced the use of a CAD system in interpretation of breast MRI and data suggest that CAD significantly improves discrimination between benign and malignant masses (76). As the first step in regulating analysis and reporting of this new technique, the ACR developed a new BIRADS MRI lexicon incorporating new terminology and specific descriptors of breast MRI findings. Continued effort for standardization is a work in progress.

Screening Breast MRI

Breast MRI may be used as a screening modality and mammography. In a study by Morris et al., mammographically occult breast cancer was detected by screening breast MRI in 4% of high-risk women, with a positive predictive value (PPV) of 24% (77). A subsequent meta-analysis by Liberman including 1,305 women at high risk found that MRI detected cancer in 34% (range 24% to 89%) of women who had a biopsy based on MRI findings and in 4% (range 2% to 7%) of all high-risk women (78). For women with *BRCA1* gene mutations, MRI is a very sensitive screening tool when used in conjunction with mammography. In a multicenter multimodality prospective trial by Sardanelli et al. that looked at screening in women with genetic-familial risk for breast cancer, MRI had a sensitivity of 94% and a PPV of 63% (79).

Recently, the American Cancer Society published new guidelines for high-risk screening with MRI, based on scientific evidence and expert opinion (Table 29.4) (80). According to the new guidelines, high risk is defined as a lifetime risk of 20% to 25% or more, *BRCA* gene mutation carrier or first-degree relative of *BRCA* carrier, women treated at an early age with chest radiation, and hereditary syndromes that put women at high risk for breast cancer. Currently there are no data to support or refute annual breast MRI in women with a personal history of breast cancer or with high-risk lesions, and these patients are to be assessed on a case-by-case basis and may be referred by the breast specialist to a screening breast MRI if deemed necessary.

Breast MRI also serves to screen the contralateral breast in women with recently diagnosed breast cancer. A recent multicenter, prospective trial evaluating contralateral breast cancer in women with recently proven breast cancer found clinically and mammographically occult breast cancer in 3.1% of 969 women, with a sensitivity of 91% and a negative predictive value of 99% (81).

Diagnostic Breast MRI

There are several clinical scenarios in which breast MRI may serve as an adjunct to mammography. One of the most common is preoperative staging of a newly diagnosed invasive cancer or DCIS. Breast MRI can delineate clinically and mammographically occult additional disease including *in situ*

FIGURE 29.7. Breast MRI demonstrating DCIS in a 45-year-old woman with a positive biopsy for high-grade DCIS. **A:** Preoperative breast MR with post contrast subtraction image shows clumped linear non-mass enhancement in the medial breast corresponding to known DCIS. **B:** Post contrast subtraction image more inferiorly shows more extensive involvement than the mammogram with linear enhancement extending in a ductal distribution from posterior depth to the nipple.

TABLE 29.4**INDICATIONS FOR ANNUAL BREAST MRI SCREENING IN ASSOCIATION WITH MAMMOGRAPHY****EVIDENCE-BASED RECOMMENDATIONS**

Confirmed BRCA mutation carrier status
 Untested but with first-degree relative with positive BRCA mutation status
 Estimated lifetime risk of developing disease >20% (based on risk models)

EXPERT OPINION**Recommended**

Prior radiotherapy to the chest wall (between ages 10 and 30)
 Patients (and first-degree relatives) with predisposing cancer syndromes:
 Li-Fraumeni syndrome
 Cowden syndrome
 Bannayan-Riley-Ruvacalba syndrome

No recommendation (for or against)

Estimated lifetime risk 15% to <20% (based on risk models)
 Lobular proliferative disease (LCIS or ALH)
 Atypical ductal hyperplasia (ADH)
 Mammographic heterogeneity or density
 Women with personal history of breast cancer (including DCIS)

Not recommended

Estimated lifetime risk <15%

Note: ALH, atypical lobular hyperplasia; DCIS, ductal carcinoma *in situ*; LCIS, lobular carcinoma *in situ*.
Source: Saslow D, Boetes C, Burke W, et al. American Cancer Society guidelines for breast screening with MRI as an adjunct to mammography. *CA Cancer J Clin* 2007;57(2):75–89.

disease associated with invasive cancer and its extent, and it can detect noncalcified DCIS. Liberman et al. found that 48% of women who underwent preoperative MRI of the breast had additional foci of disease unsuspected by mammography (82). As such, the addition of breast MRI can aid in surgical planning, including decisions regarding the role of mastectomy or the consideration for neoadjuvant chemotherapy. In one study by Fischer et al., surgical management of patients was changed by 14.3% (83). It is advisable to biopsy additional suspicious foci detected by MRI to avoid overestimation of disease and unnecessary mastectomy.

Breast MRI can be added to the workup of an inconclusive mammographic finding. In this setting, however, the negative predictive value of MRI is imperfect and a negative MRI should be interpreted cautiously. If a mammographic or sonographic finding is suspicious, a stereotactic or sonographic biopsy should be performed, regardless of the MRI results.

MRI is not the best test for the exclusion of malignancy in the workup of mammographic calcifications, and suspicious microcalcifications should undergo core biopsy. A helpful role of MRI in such clinical scenarios would be to delineate the extent of disease and to rule out an underlying occult invasive component. For women presenting with suspicious clinical findings for breast cancer and negative conventional imaging tests, MRI of the breast has an added value. These instances include a woman with a palpable suspicious mass, women with metastatic axillary lymph nodes but no mammographically defined breast primary, and those with pathologic unilateral nipple discharge or Paget's disease and a negative mammogram and ultrasound.

MRI: Other Indications

In patients presenting with an increasing mammographic density at the lumpectomy site following breast conservation therapy, MRI is the most sensitive test for evaluating for recurrent disease with high specificity and negative predictive value. In

addition, MRI has a role in determining the response to neoadjuvant chemotherapy and it is more reliable than mammography or US in that respect. However, while MRI may not show residual enhancement following chemotherapy, it is not 100% accurate in the detection of residual disease, and a 23% risk of underestimation has been reported (84).

THE WORKUP FOR SUSPECTED BREAST CANCER

The diagnostic workup begins with the mammogram, with a marker placed at the site of the lesion (if not already done). Focal compression, magnification, and tangential images may be required to allow for better visualization of the mass, evaluate any associated calcifications, and to displace it from the surrounding breast. Ultrasound of the lesion is typically performed to further characterize the lesion as solid or cystic, and to give its dimensions. This may be particularly indicated in nonspiculated lesions, and those in which the differential includes benign lesions, such as fibroadenoma.

Patients presenting with a suspicious breast mass or other concerning imaging should undergo image-guided core needle biopsy using a large-gauge needle to establish diagnosis. This has been championed as the preferred technique over fine-needle aspiration or diagnostic excision for many reasons. First, it avoids unnecessary surgery in approximately 80% of BIRADS category 4 patients who require biopsy to establish if a lesion is benign. It also allows the surgeon to plan an oncologic procedure at the time of the index operation. Further, in cases of invasive carcinoma, it allows characterization of histology, grade, hormone-receptor status, and HER2/neu status, all of which are necessary to develop medical and surgical planning, including the role of nodal mapping. Although

fine-needle aspiration provides a quick and inexpensive means of evaluation, it is rarely sufficient to distinguish *in situ* from invasive disease and provides insufficient material for characterization of hormone and HER2/neu receptor status.

Core biopsy may be performed with stereotactic, sonographic, or MRI guidance, and all are acceptable methods. If the mammographic abnormality consists of suspicious calcifications without a mass, then stereotactic biopsy is performed. A specimen radiograph is required to document that calcifications are present in the specimen. With the increased refinement of ultrasonography and the increased portability

of ultrasound units, there has been a shift to ultrasound core biopsy performed in radiology or in the surgeon's office. MRI-guided core biopsy is performed for MRI-detected lesions that have no mammographic or sonographic correlate. In all cases, a clip should be deployed at the end of the procedure followed by a mammogram to confirm its placement. Evaluation for concordance between pathology and imaging is then required. If a lack of concordance is discovered, excisional biopsy is required. For patients presenting with a palpable mass, biopsy under image guidance is still preferred.

TABLE 29.5

AJCC CLASSIFICATION OF BREAST CANCER

TUMOR (T)		
Tx	Cannot be assessed	
T0	No primary tumor	
Tis	<i>In situ</i> disease	
T1	Tumor ≤ 2 cm	
T1mic	Microinvasive, ≤ 0.1 cm	
T1a	0.1 cm < T ≤ 0.5 cm	
T1b	0.5 cm < T ≤ 1.0 cm	
T1c	1.0 cm < T ≤ 2.0 cm	
T2	Tumor > 2 cm, but ≤ 5 cm	
T3	Tumor > 5 cm	
T4	Tumor of any size with:	
T4a	Chest wall extension	
T4b	Edema or ulceration of skin, or satellite nodules	
T4c	Both (a) and (b)	
T4d	Inflammatory carcinoma	
REGIONAL NODES (N)^a		
	Clinical (c)	Pathologic (p)
Nx	Cannot be assessed	No nodes assessed
N0	No nodes involved	Designations in N0 (+ or -): N0(I): detected by IHC N0(mol): detected by RT-PCR
N1	Movable axillary node(s)	N1mic: micrometastases, up to 2 mm N1a: 1–3 nodes N1b: microscopically involved internal mammary node, not clinically apparent N1c: both a and b
N2		
N2a	Fixed or matted node(s)	Four to nine nodes positive
N2b	Clinically apparent mammary nodes; axillary node negative	Clinically apparent internal mammary node involvement, no axillary nodes (+)
N3		
N3a	Positive infraclavicular node(s)	Ten or more positive nodes
N3b	Positive mammary + axillary node(s)	Internal mammary nodes and axillary nodes involved
N3c	Positive supraclavicular node(s)	Supraclavicular nodes involved
METASTASES (M)		
Mx	Not assessed	
M0	No distant metastases	
M1	Distant metastases	
<p><i>Note:</i> AJCC, American Joint Commission on Cancer; IHC, immunohistochemistry; RT-PCR, reverse transcription polymerase chain reaction. ^aRegional nodal involvement refers to ipsilateral disease only.</p>		

The major complications of biopsy are predominantly hemorrhage and infection, although these are rare and occur in less than 0.5% of biopsies performed (85).

An ultrasound of the axilla with fine-needle aspiration (US-FNA) may also be considered as part of the workup of a woman with a confirmed breast cancer on biopsy. Sonographic characteristics of the suspicious node includes size greater than 1 cm, loss of fatty hilum, cortical hypertrophy, and hypoechogenic parenchyma. In a study from the M. D. Anderson Cancer Center, the overall sensitivity of US-FNA was 86%, specificity was 100%, positive predictive value was 100%, and the negative predictive value was 67% (86). Identification of a positive node by fine-needle aspiration negates the need for a sentinel node biopsy and commits the patient to axillary dissection, and the identification of node-positive disease by US-FNA has been shown to reduce the number of sentinel node biopsy procedures by up to 15%. For those with a negative fine-needle aspiration, sentinel node biopsy is still required (87,88).

STAGING

The staging of breast cancer requires a full characterization of the primary tumor, including size, grade, biologic characterization of estrogen and progesterone receptor expression, and whether overamplification of overexpression of the HER2/neu oncogene is present. Lymphatic or vascular invasion of the primary tumor should be characterized as well as the nodal status of the tumor. In the asymptomatic patient, metastatic involvement can be ruled out clinically by physical exam, routine hematologic and chemistry profiles, and chest x-ray. For patients presenting with concerning symptoms, further evaluation with positron emission tomography (PET), bone scan, and/or computed tomography (CT) scan of the chest and abdomen may be required.

The staging of breast cancer follows the American Joint Commission on Cancer (AJCC) system which uses the tumor (T), node (N), and metastasis (M) classification (TNM, Tables 29.5 and 29.6) (89). The new classification moves supraclavicular nodal involvement from M1 to N3 disease. In addition, the revised 2003 version of the staging system includes new technologies for nodal evaluation using immunohistochemistry (IHC) and reverse transcription polymerase chain reaction (RT-PCR) (mol) in the node-negative category. For example, a patient can be node negative but positive by these techniques, allowing for a designation of N0(I+) if positive by IHC or N0(mol+) if positive by RT-PCR. Within node-positive patients,

TABLE 29.6

STAGING OF BREAST CANCER

AJCC	T	N	M
Stage 0	Tis	N0	M0
Stage I	T1	N0	M0
Stage IIA	T0-1	N1	M0
	T2	N0	M0
Stage IIB	T2	N1	M0
	T3	N0	M0
Stage IIIA	T0-T3	N2	M0
	T3	N1	M0
Stage IIIB	T4	N0-N2	M0
Stage IV	Any T	Any N	M1

FIGURE 29.8. Ductal hyperplasia. Slightly expanded ducts are filled with hyperplastic ductal epithelial cells and myoepithelial cells in an irregular fenestrated growth pattern.

classification also allows the designation of microscopic tumor deposits up to 0.1 cm in diameter as node positive with isolated tumor cells [N0(ITC)]. If a patient undergoes sentinel node evaluation only without formal axillary node dissection, the prefix “sn” is used [pN(sn)], and if staging occurs after primary chemotherapy the designation of “y” is used (yTNM).

BREAST PATHOLOGY

Fibrocystic Changes

The breast ducts and lobules can show a wide range of benign nonproliferative and proliferative epithelial lesions. Nonproliferative lesions include cysts (macroscopic and microscopic), duct ectasia, fibrosis, and apocrine metaplasia. Proliferative lesions were first separated into different risk categories based on the work of Dupont and Page (90). Patterns associated with a mildly increased risk (~twofold) of subsequent breast carcinoma are considered proliferative changes, and include usual ductal epithelial hyperplasia (Fig. 29.8), lobular hyperplasia, sclerosing adenosis, radial scars, and intraductal papillomas (12,90). Both sclerosing adenosis (Fig. 29.9) and radial

FIGURE 29.9. Sclerosing adenosis. A well-developed lobulocentric distribution of dilated ducts and overgrowth of spindly myoepithelial cells may be mistaken as malignancy in core biopsy or frozen section.

FIGURE 29.10. Radial scar. A stellate lesion with irregular ducts radiating from the elastotic center; the entrapped glands may mimic an invasive ductal carcinoma.

scar (Fig. 29.10) show distortion of normal breast architecture, and this irregular gland pattern may mimic an invasive carcinoma. These benign proliferations maintain a normal myoepithelial cell layer, which can be highlighted by special stains. Intraductal papillomas have fibrovascular cores lined by myoepithelial cells and one or more layers of epithelial cells. Papillomas involving large ducts near the nipple are the most frequent cause of bloody nipple discharge.

Atypical ductal hyperplasia (ADH) and atypical lobular hyperplasia (ALH) are associated with a higher increased risk of subsequent breast cancer, and in most studies it is increased fivefold (12,90,91). ADH is characterized by architectural patterns approaching those of *in situ* carcinoma (Fig. 29.11), while ALH shows expansion of the lobule by a loose, monomorphic cell population (Fig. 29.12). Reproducibility of the diagnosis of atypical ductal hyperplasia has been aided by more uniform criteria now used by most pathologists (92). However, there is still controversy as to whether size criteria should be used to separate ADH from low-grade ductal carcinoma *in situ* (two completely involved ducts or 2 mm). Excision is recommended for ADH found on core biopsy, as up to 30% of cases will have carcinoma (*in situ* or invasive) found on evaluation of the surrounding tissue (93). ADH can also involve a radial scar or intraductal papilloma (Fig. 29.13).

FIGURE 29.11. Atypical ductal hyperplasia. The proliferation has a cribriform growth pattern approaching that of a ductal carcinoma *in situ* but the microlumens are more irregular in sizes and shapes.

FIGURE 29.12. Atypical lobular hyperplasia. The lobular glands are somewhat expanded with a loose monomorphic cell population.

A newly appreciated group of lesions are columnar cell change, columnar cell hyperplasia, and flat epithelial atypia (FEA, Fig. 29.14). These lesions were originally described by Azzopardi and their significance has been reappraised due to their frequent association with mammographically detected microcalcifications (94–96). More recently, it has been noted that flat epithelial atypia has a high association with low-grade ductal carcinoma *in situ* and invasive tubular carcinoma (97–99). Molecular studies may be able to further characterize these lesions and their role in breast carcinogenesis. Currently, excision is recommended for atypical lesions (ADH, lobular carcinoma *in situ* [LCIS], FEA, and radial scar) identified on needle core biopsy.

In Situ Carcinoma

Ductal Carcinoma *In Situ*

Ductal carcinoma *in situ* (DCIS) or intraductal carcinoma is a heterogeneous group of lesions with the proliferation of malignant cells confined within the ductal system. It is the most common type of noninvasive breast cancer currently. Historically, DCIS presented as a palpable mass and accounted for 1% to 2%

FIGURE 29.13. Intraductal papilloma. A well-circumscribed papillary proliferation fills a dilated duct. The presence of fibrovascular core of the papillae indicates a benign lesion.

FIGURE 29.14. Flat epithelial hyperplasia. This is a columnar lesion characterized by mildly atypical epithelial cells which may represent a precursor of or the earliest morphologically recognizable form of low-grade ductal carcinoma *in situ*.

FIGURE 29.16. Cribriform ductal carcinoma *in situ*. Expanded duct is filled with low- to intermediate-grade neoplastic cells forming secondary rigid cribriform microlumens.

of positive biopsies. With screening it is now most commonly identified as clustered microcalcifications on a mammogram and accounts for approximately 20% of all mammographic abnormalities. DCIS is considered a precancerous lesion and it is estimated that approximately 30% of untreated DCIS cases become invasive within 10 years with almost all invasive lesions occurring in the same quadrant as the index lesion (100).

Traditionally, DCIS was classified on its architectural pattern, often dichotomized as comedo and noncomedo types, and solid, cribriform, micropapillary, clinging, and papillary types of noncomedo patterns were described (101). However, it is recognized that combinations of these patterns are not uncommon in a biopsy. Several grading schemes incorporating both architectural and nuclear features have been proposed, but the Holland version, where nuclear features predominate, was most reproducible in one study (102,103). The presence of intraluminal necrosis and calcifications is usually noted, along with the nuclear grade and pattern(s).

Comedo-type DCIS (comedocarcinoma) shows a solid proliferation of large, pleomorphic nuclear grade 3 epithelial cells with numerous mitoses and central necrosis containing

cellular debris, so-called “comedo-necrosis” (Fig. 29.15). The necrotic material often becomes calcified and these coarse calcifications have a distinctive mammographic appearance outlining the ductal system (“casting calcifications”). Periductal fibrosis and inflammation is common in comedo-type DCIS and can be a diagnostic problem, as microinvasion is a feature more likely associated with comedo-type DCIS than other patterns (104,105). Extension of the large pleomorphic cells into the distal lobular unit is a pattern known as “cancerization of lobules.”

The solid, cribriform, papillary, and micropapillary patterns of noncomedo DCIS are usually composed of uniform low-grade or intermediate-grade nuclei. Cribriform patterns show smooth, rounded, “punched-out” spaces (Fig. 29.16). The micropapillary subtype (Fig. 29.17) does not contain fibrovascular cores, whereas papillary DCIS does. The “clinging” or “flat” type of DCIS may have either low- or high-grade nuclei. Microcalcifications may be associated with these noncomedo patterns and may be detected by mammography. Their pattern of distribution is less specific than that of comedo DCIS and may be similar to that seen in benign conditions.

FIGURE 29.15. Comedo-type ductal carcinoma *in situ*. Markedly expanded ducts are filled with high-grade neoplastic ductal cells with central necrosis and calcifications.

FIGURE 29.17. Micropapillary ductal carcinoma *in situ*. Low-grade neoplastic ductal cells form papillary fronds in an expanded duct. The papillary fronds lack fibrovascular core.

FIGURE 29.18. Paget's disease. Large, round, pale neoplastic cells occur singly within the epidermis, mimicking malignant melanoma, which could be easily distinguished using positive immunohistochemical staining for carcinoembryonic antigen and negative for Melan-A and HMB-45.

Paget's Disease of the Nipple

Paget's disease of the nipple reflects direct extension of ductal carcinoma *in situ*, usually high grade, into the lactiferous ducts and adjacent skin (Fig. 29.18). The DCIS may or may not be accompanied by invasive carcinoma. Histologically, the Paget cells are large, round cells with prominent nucleoli and pale cytoplasm. They occur singly within the layers of the epidermis, or may form groups at the dermal-epidermal junction. Treatment is dictated by whether the underlying tumor is *in situ* or invasive.

Lobular Carcinoma *In Situ*

LCIS was first described by Foote and Stewart in 1941 and has been an enigma ever since (106). It is a multicentric lesion, with no identifying features on gross or radiographic evaluation, and is often found as an incidental finding in biopsies performed for another reason. In classic LCIS, the lobule is distended by a monomorphic population of small uniform cells with round nuclei and scant cytoplasm (Fig. 29.19). The cells may extend into the adjacent duct, growing beneath the normal ductal epithelium, a pattern known as "pagetoid

FIGURE 29.19. Lobular carcinoma *in situ*. An expanded lobule is markedly distended by a monomorphic population of small uniform cells. The underlying lobular architecture is still recognizable.

spread." There is continuing controversy as to whether LCIS is an obligate precursor of invasive lobular carcinoma, or just a marker of overall increased cancer risk in either breast (107,108).

LCIS increases the risk equally for ipsilateral and contralateral breast cancer, unlike DCIS, which increases the risk of ipsilateral breast cancer, and approximately 20% to 30% of LCIS patients will go on to develop invasive breast cancer within a median of 15 to 20 years (107,109). Patients with biopsy-diagnosed ALH or LCIS should be referred for surgical treatment given this risk. Of those who undergo definitive excision, carcinoma will be discovered at final pathologic analysis in 14% to 38% of patients (93,110,111). Plemorphic LCIS is a recently described subtype of LCIS that may confer a more aggressive phenotype. While similar in architecture to typical LCIS, the neoplastic cells show a larger degree of pleomorphism with distinctly larger nuclei (112).

Invasive Carcinoma

Invasive carcinoma of the breast is defined by the presence of stromal invasion, usually manifest by a fibrotic, desmoplastic stromal reaction around the invading cells. Tumor may be microinvasive (<1 mm) within an area of DCIS, or may form an obvious tumor mass, clinically or radiographically. Tumors are classified by the pattern of growth into ductal and lobular forms. Breast carcinoma is surgically staged using the AJCC staging system based on the size of the invasive component, and synoptic checklist reporting using templates devised by the College of American Pathologists aids in ensuring that all important pathologic features are documented. DCIS may be focally present next to the invasive component or intermixed with invasive tumor. The term "EIC" denotes a tumor with an extensive *in situ* component, defined as at least 25% of the tumor mass.

Invasive Ductal Carcinoma

The majority of invasive tumors of the breast are ductal and have varying morphologic patterns that have led to several subclassifications. Most of the special types listed below are distinguished because they have an extremely good prognosis. The majority of tumors (~75%) have no specific features and are designated carcinoma, not otherwise specified (NOS) or carcinoma of no special type (NST). These tumors may be composed of small glands, tubules, solid cords, or

FIGURE 29.20. Invasive ductal carcinoma. Small solid cords of neoplastic cells with moderate to severe cytologic atypia are surrounded by a fibrous stroma.

nests of cells with varying degrees of cytologic atypia surrounded by a reactive (desmoplastic) fibrous stroma (Fig. 29.20). The recommended grading system is the Nottingham modification of the Bloom-Richardson system, which is based on adding scores for architectural pattern, nuclear pleomorphism, and mitotic count (Table 29.7) (113). Grade 1 tumors (well differentiated) have 3 to 5 points, grade 2 tumors (moderately differentiated) have 6 to 7 points, and grade 3 tumors (poorly differentiated) have 8 to 9 points. Although initially applied only to invasive ductal carcinoma, this system can also be applied to invasive lobular carcinomas and has been validated in numerous studies (114).

Mucinous Carcinoma. Mucinous (or colloid) carcinoma usually occurs in postmenopausal women. The tumor is well circumscribed and may have a gelatinous gross appearance. Microscopically, nests of uniform small cells are surrounded by pools of mucin (Fig. 29.21). The *in situ* component is minimal, but may also show intraductal mucin production. Pure mucinous tumors are low grade and have an excellent prognosis with a low rate of lymph node metastasis (115). This is not true, however, of mixed carcinomas with a prominent nonmucinous, usual invasive ductal carcinoma component.

FIGURE 29.21. Mucinous carcinoma. Nests of low-grade neoplastic cells in a cribriform pattern are surrounded by a large pool of mucin.

FIGURE 29.22. Tubular carcinoma. Well-formed angular, oval, and tubular glands with a single layer of neoplastic ductal cells diffusely infiltrate a desmoplastic fibrous stroma.

Tubular Carcinoma. Tubular carcinoma is a well-differentiated invasive carcinoma composed of small glands or tubules that can be difficult to distinguish from some benign lesions, especially radial scars. The tubules are arranged haphazardly, often with a surrounding cellular stroma (Fig. 29.22). They are somewhat angular with open lumens and are lined by a single layer of monomorphic epithelial cells. Myoepithelial cells are absent, and immunohistochemistry for myoepithelial markers is helpful in confirming the diagnosis on needle biopsy. If the tumor is composed of at least 75% tubules and has grade 1 nuclei, the prognosis is considered to be excellent (116). Invasive tubular carcinoma is often associated with a low-grade micropapillary or cribriform ductal carcinoma *in situ* or adjacent atypical columnar cell lesions (98). Tubular carcinomas are small, usually less than 1 cm, and are frequently detected by screening mammography. Tumors with a component of usual invasive ductal carcinoma should not be included in this category. Invasive cribriform carcinoma, which also has a good prognosis, may be mixed with tubular carcinoma.

Medullary Carcinoma. Medullary carcinomas occur more commonly in women under 50 and have a higher frequency in *BRCA1* mutation carriers. Clinically, the tumor is well circumscribed and may mimic a fibroadenoma. Microscopically, the tumor is composed of solid syncytial sheets of large anaplastic cells with pleomorphic nuclei, prominent nucleoli, and abundant mitotic figures (Fig. 29.23). Gland formation is absent. The tumor has a pushing border and is surrounded by a dense lymphoplasmacytic infiltrate. Despite being anaplastic, however, tumors with this strict morphology and no component of typical invasive ductal carcinoma have a good prognosis.

Micropapillary Carcinoma. Micropapillary carcinoma is a recently described entity with a characteristic morphology, high incidence of positive nodes at presentation despite small tumor size, and poor overall survival (117,118). The tumor is composed of small clusters of malignant cells floating within small clear spaces resembling lymphatic channels (Fig. 29.24). Most tumors have high nuclear grade and true lymphatic space invasion. A component of usual invasive ductal carcinoma may be present.

Papillary Carcinoma. Papillary carcinoma is a rare subtype, and the majority of cases are felt to represent an *in situ* tumor, frequently termed “intracystic papillary carcinoma.”

FIGURE 29.23. Medullary carcinoma. Highly pleomorphic neoplastic cells in a syncytial pattern are surrounded by a diffuse lymphocytic infiltrate.

The lesion forms a well-circumscribed mass, and may have ductal carcinoma *in situ* present in adjacent ducts or foci of typical invasive carcinoma around the periphery of the main mass (Fig. 29.25). A recent study suggests that these are indeed invasive carcinomas without the myoepithelial layer that defines an *in situ* lesion (119). They have traditionally been treated as *in situ* lesions and have an overall excellent prognosis (120).

Inflammatory Carcinoma. The term “inflammatory carcinoma” originated as a clinical term to describe a patient presenting with a reddened edematous breast suggesting mastitis. Skin biopsies from such patients often show tumor thrombi in dermal lymphatic channels (Fig. 29.26), but this is not true in every case.

Invasive Lobular Carcinoma

Invasive lobular carcinoma comprises about 10% of all breast cancers. The classic form of invasive lobular carcinoma is composed of small monotonous tumor cells with scant cytoplasm growing in linear columns (“Indian file”) or in concentric

FIGURE 29.24. Invasive micropapillary carcinoma. Small clusters of intermediate-grade neoplastic cells lie within small, clear spaces of a fibrocollagenous stroma mimicking tumor cells in lymphatic spaces.

FIGURE 29.25. Solid or intracystic papillary carcinoma. Whole-mount section shows a well-circumscribed tumor with branching network of fibrovascular stroma. A cystic formation is not necessary for the diagnosis.

(“targetoid”) patterns around normal ducts and lobules (Fig. 29.27). A mild stromal desmoplastic reaction may be present around the tumor cells, but many invasive lobular carcinomas do not form a discrete tumor mass. This diffuse growth pattern can be a problem when attempting conservative surgical excision, and tumors are frequently upstaged after surgery (121).

Variant forms of lobular carcinoma include alveolar, solid, and trabecular patterns composed of the same monomorphic small cells. Signet ring-cell carcinoma, in which the cells contain prominent intracytoplasmic vacuoles, is considered a variant of invasive lobular carcinoma due to its similar growth patterns. Another variant is pleomorphic lobular carcinoma, where the columns of cells show marked nuclear atypia.

Tubulolobular Carcinoma. This tumor shows a mixture of invasive lobular and tubular carcinoma growth patterns with low-grade nuclei. The mixed architectural pattern parallels the expression of markers of ductal and lobular differentiation, and these tumors appear to have a good prognosis (122).

FIGURE 29.26. Inflammatory carcinoma. Carcinomatous emboli are present in dilated dermal lymphatics.

FIGURE 29.27. Invasive lobular carcinoma. Small monotonous tumor cells invade in linear “Indian file” pattern.

Other Tumors

Metaplastic Carcinoma

The term “metaplastic carcinoma” is used to describe tumors with prominent morphologic patterns different from usual ductal and lobular patterns (Fig. 29.28). The term encompasses epithelial tumors (carcinomas) showing squamous cell differentiation, monophasic spindle cell carcinoma, and biphasic tumors with both epithelial and mesenchymal elements. Spindle cell (sarcomatoid) carcinomas express epithelial markers (cytokeratins) despite their spindle cell morphology, and are aggressive tumors with a high rate of extranodal metastases (123). Biphasic tumors (biphasic sarcomatoid carcinoma or carcinosarcoma) may contain heterologous elements, such as malignant cartilage or bone. These rare but aggressive tumors tend to be estrogen receptor (ER), progesterone receptor (PR), and HER2/neu negative, but in a case series from the Swedish Cancer Institute, survival outcomes did not appear different from matched typical breast cancer cases (124).

FIGURE 29.28. Metaplastic carcinoma. This is a poorly differentiated invasive carcinoma. To the right is an area of squamous differentiation.

Phyllodes Tumors

Phyllodes tumors, formerly known as “cystosarcoma phyllodes,” are biphasic tumors similar to fibroadenomas with a spectrum of morphology and biologic behavior. The median age is 45, which is several decades higher than fibroadenoma. These tumors are grossly well circumscribed, but are infiltrative on microscopic examination. They are composed of benign glandular elements with a prominent stromal component showing varying degrees of hypercellularity, nuclear atypia, and mitotic activity. The older term “cystosarcoma phyllodes” refers to the leaf-like architectural pattern with intervening cystic spaces. Although features such as size, mitotic activity, and cellular atypia correlate with clinical behavior, attempts to reliably divide these tumors into benign and malignant forms are not always successful. The lower-grade tumors tend to recur, especially if incompletely excised, due to the subtle infiltrative margin. Obvious malignant tumors may have stromal overgrowth, which portends a worse prognosis (125,126). Overall, lymph node metastases are uncommon and surgery is the primary treatment.

Angiosarcoma

Angiosarcoma is the most common primary sarcoma of the breast, and may be associated with previous radiation therapy. The tumors are composed of anastomosing vascular channels lined by endothelial cells that range from mildly atypical to frankly malignant. The distinction between a benign angioma and a low-grade angiosarcoma can be difficult on a small biopsy. Overall 5-year survival is around 60% with multimodality therapy (127,128). Other histologic patterns of primary breast sarcoma also occur.

GENOMIC CLASSIFICATION OF BREAST CANCER

Our understanding of breast cancer has begun to evolve with the use of modern technology, and gene expression studies have heightened our understanding of breast cancers as being composed of heterogeneous tumor subtypes with distinct biologic features. In a seminal paper, Perou et al. characterized 65 breast specimens from 42 patients with breast cancer, including 20 sampled pre- and postchemotherapy and 2 with node-positive disease (129). They demonstrated that breast tumors could be subdivided based on their genomic signature into distinct molecular types: luminal/ER positive, normal breast-like, basal/epithelial cell enriched, erb/B2 amplified, and an unknown cohort. Sorlie et al. later expanded this study into a classification of 78 tumors, and were able to separate the luminal group into three subtypes: luminal A tumors had the highest expression of ER genes; luminal B had low to moderate expression of luminal-specific genes; and luminal C was characterized by low expression of the luminal-specific genes and expression of genes of unknown function, but were also seen in the erb/B2 and basal classes of breast tumors (130). Inclusion of a *BRCA1* cohort into a later study also demonstrated the propensity of these tumors to fall into the basal subgroup (131).

Bertucci et al. sought to correlate molecular subtypes with pathologic characteristics routinely evaluated in breast cancer (132). Statistically significant differences in tumor grade, ER status, PR status, HER2/neu status, and p53 staining were noted in luminal A tumors, erb/B2 amplified, and basal-like tumors. The vast majority of luminal A tumors in this study were non-high grade (73%), ER positive (100%), PR positive

(96%), HER2/neu negative (96%), and p53 negative (85%). In contrast, the basal tumors were predominantly the opposite: grade 3 (88%), ER negative (94%), PR negative (94%), HER2/neu positive (100%), and p53 positive (53%). The erbB2 amplified cohort had the biggest mix of features: grade 2 or 3 (100%), ER negative (93%), PR negative (80%), HER2/neu positive (100%), and p53 negative (53%). Even more important than the determination of these molecular subtypes, Sorlie et al. demonstrated that the classification also separated tumors prognostically, with luminal A tumors being associated with the highest probability of remaining alive and disease-free while basal tumors were associated with poor survival outcomes (130). These data have been replicated in other reports (132,133).

PROGNOSTIC AND PREDICTIVE FACTORS

In breast cancer, there are clinical and biologic factors that can inform the anticipated responses to a given therapy (*predictive* factors) and those that are independently associated with survival outcomes, whether it be recurrence or death from breast cancer (*prognostic* factors). Understanding such factors holds the key to making decisions regarding therapy for the patient with breast cancer. For patients whose prognosis is good, chemotherapy may hold little benefit and may not be recommended. Alternatively, endocrine therapy and the use of biologic agents, such as trastuzumab, may depend on the presence of factors that will predict tumor responsiveness, which may ultimately translate into a survival advantage.

Of the known prognostic factors in breast cancer, the most widely accepted are defined surgically. Axillary node involvement is a strong predictor of both relapse risk and mortality, and risks increase with the number of nodes involved by metastatic breast cancer. Tumor size is also a well-established prognostic factor, with increasing size associated with a greater number of involved nodes and a shorter time to recurrence. The presence of lymphovascular invasion and high tumor grade also portends a worse prognosis.

Histologically, tumors associated with mutations in either *BRCA1* or *BRCA2* are high-grade invasive ductal carcinomas. *BRCA1* mutation-associated breast cancers are usually triple negative and express basal markers (134). This is in contrast to *BRCA2* mutation-associated tumors, which are usually ER positive and express a luminal A phenotype (135).

The most commonly cited biologic factor associated with prognosis is the estrogen and progesterone receptor status. Estrogen interacting with nuclear ERs regulates cell growth, proliferation, and differentiation of normal breast epithelium, and those carcinomas that express ER. PR is an ER-regulated gene product with similar implications. Hormone receptors can be measured biochemically by ligand binding assays or by IHC techniques using monoclonal antibodies directed against the receptor protein, and correlation between the two techniques is high (136). With today's smaller tumors usually diagnosed by needle core biopsy, IHC is the preferred method of analysis. This method also allows distinction between invasive tumor, *in situ* tumor, and nontumor elements. Heterogeneity exists within tumors, and most laboratories now report positivity by the percentage of cells stained or use a semiquantitative scale (137). However, hormonal status is a relatively weak prognostic indicator, and measurement of ER in breast cancers is performed to predict the response of an invasive tumor to endocrine therapy, or the benefit of hormonal therapy for risk reduction in cases of *in situ* carcinoma. Patients with ER- and/or PR-positive disease are expected to benefit from hormonal

agents. Alternatively, patients with hormone-positive disease may not derive a significant benefit from chemotherapy (138).

Recently, survivin, a member of the inhibitor of apoptosis (IAP) family, has been proposed as a prognostic factor. In one study, 293 cases of invasive breast cancer were assayed for survivin, showing that 60% were positive (139). In a multivariate analysis, survivin was shown to be significantly associated with relapse-free ($p < 0.001$) and overall survival ($p = 0.01$). This was independent of age, tumor size, tumor grade, nodal status, and estrogen receptor.

Other biologic factors have been proposed as prognostic, including Ki-67, a nuclear antigen that is not expressed at G₀ but is detected in the G₁ through M phases, the fraction of cells in S phase, and DNA ploidy analysis. However, these factors have yet to be validated in statistically robust studies, and are not recommended for use in daily practice (140).

HER2/neu or c-erbB2 is an oncogene whose protein product is a membrane receptor tyrosine kinase. Amplification of HER2/neu is seen in most cases of comedo-type ductal carcinoma *in situ* and in about 20% to 30% of invasive ductal carcinoma, usually of high grade. It can be detected by immunohistochemistry for the protein product or by gene amplification techniques, such as fluorescence *in situ* hybridization (FISH) or chromogenic *in situ* hybridization (CISH). Increased copy number is closely associated with elevated protein expression. Amplification of HER2/neu, and this used to confer a poor prognosis in breast cancer (141). However, with the advent of trastuzumab, a monoclonal antibody directed against the HER2/neu receptor, women with HER2/neu amplified breast cancers have gained significantly in their survival outcomes; as such it is no longer correct to consider it a prognostic factor, but rather to use it as a predictive factor for the selection of treatment (142–144).

The American Society of Clinical Oncology and College of American Pathologists recently published a joint guideline containing an algorithm for testing, interpretation, and reporting, as well as requirements for standardization and validation of testing techniques (145). A positive HER2/neu result is 3+ IHC staining, defined as uniform intense membrane staining of >30% of invasive tumor cells (Fig. 29.29) or a FISH result of more than six HER2 gene copies per nucleus or a FISH ratio (HER2 signals to chromosome 17 signals) of more than 2.2. Implementation of these guidelines will result in more reproducible results between laboratories.

A subset of breast carcinomas is negative for the usual markers ER, PR, and HER2/neu, and are referred to as triple negative. These tumors express cytokeratins 5/6, which

FIGURE 29.29. Positive HER2/neu. Strong (3+) HER2/neu membrane immunoreactivity is seen in this invasive ductal carcinoma.

denotes a basal phenotype, in contrast to the luminal cell phenotype of most breast carcinomas (146,147). These tumors are characteristically high grade, have a central hyalinized scar or necrosis, occur in younger women, and are associated with poor survival (148,149). Many metaplastic carcinomas fall into this group of tumors. Most triple-negative tumors are positive for epidermal growth factor receptor (EGFR), which may provide a target for future therapy (146).

GENERAL MANAGEMENT OF BREAST CANCER

SURGICAL CONSIDERATIONS

Historical Perspective

Early descriptions of breast disease date back to ancient Chinese and Egyptian civilizations, and those of breast malignancy date back to Hippocrates and Celsus. The predominant theories of Hippocrates and Galen's four bodily humours were taken as dogma until the 1700s, when LeDran proposed the revolutionary concept of lymphatic spread. Evolutions in surgical treatment of breast cancer, however, awaited the introduction of anesthesia and Listerian antiseptics.

Faced with a high incidence of local recurrence and the understanding that cancer growth and spread occurred in an "orderly sequential process," the radical mastectomy was championed as an attempt to get at "the roots" of the tumor. At the same time, surgeons suggested that the axillary nodes be removed as part of the operation on breast cancer, given the propensity of nodal involvement.

The earliest description of the mastectomy was by Jean Petit, but Charles Moore and Sir Joseph Lister are credited with advocating the more radical approach by incorporating the division of the pectoral muscles when performing a mastectomy, which allowed for improved exposure of the axillary contents. The subsequent groundwork by Pancoast, Gross, and Moore of London led to the reports of Willie Meyer and William Halsted, who simultaneously published papers advocating the systematic removal of nodes in continuity with the primary cancer in 1894 (150,151). These papers presented a systemically applied approach to the radical mastectomy and offered a standardized technique of lymphadenectomy in breast cancer in an anatomically logical and exact manner. Technically, the procedure involved an *en bloc* resection of the breast, the pectoralis major and minor,

and a full axillary dissection, levels I-III. In so doing, the local recurrence rate dropped from nearly 50%–80% to 6%, and the reported 3-year cure rate was 38.3% (152). So successful was this operation that it became the yardstick against which all other interventions would be measured. Even with this breakthrough, Halsted recognized that node negativity did not ensure survival.

The extension of the operation was explored by surgeons in Europe and the United States, including operations that involved resection of the supraclavicular nodes (Halsted) or the internal mammary nodes (Handey), and extension of surgery into the neck and/or mediastinum (Urban and Wangenstein) (153,154). However, these increasingly extensive surgeries did not improve overall survival, but did increase operative mortality, and thus were largely abandoned. Simultaneously, Sir Geoffrey Keynes first described the role of radiation therapy (RT) in local control of cancer in 1930, and Robert McWhirter first demonstrated that axillary radiation was effective in locoregional control in breast cancer (155). This presaged the controversy regarding surgical resection versus radiotherapy for locoregional control and its relationship to survival.

Advances in medicine and public health between 1880 and the mid-1900s led to improvements in breast cancer detection and smaller tumors, which led surgeons to explore options beyond the radical mastectomy. It was not until the 1970s, however, that the surgical trend for breast cancer management was deliberately directed toward less aggressive approaches (156).

Modern History

Over a decade after the first randomized clinical trial evaluating the outcomes of breast conservation combined with postoperative radiation versus mastectomy revealed no difference in either overall survival or in breast recurrence between treatment groups, the National Surgical Breast and Bowel Project (NSABP) launched a series of trials where the underlying construct was that breast cancer was systemic at origin, and therefore the technique of surgery was less important than systemic therapy. Because the dogma was that it is the systemic disease that controls survival, the group accepted negative margins delineated as "no tumor at ink" and this qualification would distinguish NSABP trials from other investigations. In total, six major prospective, randomized trials were initiated between 1972 and 1983 and are summarized in Table 29.8.

The NSABP B-06 trial compared modified radical mastectomy to lumpectomy with or without breast irradiation in 1,851 patients with stage I-II breast cancer (157). At 20 years

TABLE 29.8

RANDOMIZED TRIALS COMPARING BREAST CONSERVATION THERAPY (BCT) AND MASTECTOMY (MAS)

Trial	Local recurrence (%)		Overall survival (%)		Follow-up (years)
	BCT	Mas	BCT	Mas

NCI (161)	19	6	77	75	10
EORTC (162)	20	12	65	66	10
Danish Breast Cancer Group (159)	3	4	79	82	6

Note: EORTC, European Organization for Research and Treatment of Cancer; NCI, National Cancer Institute; NSABP, National Surgical Breast and Bowel Project.

of follow-up, there was no significant difference in either disease-free or overall survival. Additionally, whole breast irradiation was found to reduce local recurrence in patients who received breast conservation. With these results, breast conservation therapy (BCT) was rightfully established as the standard of care. A similar trial was reported by Veronesi et al. for the National Tumor Institute of Milan (158). Over 700 women with tumors under 2 cm were randomized to mastectomy versus quadrantectomy with axillary dissection followed by radiotherapy. Adjuvant chemotherapy using cyclophosphamide, methotrexate, and 5-fluorouracil (CMF) was administered to all patients with node-positive disease. With 20 years of follow-up, the actuarial disease-free and overall survivals were similar in both groups. The Danish Cooperative Group conducted a similar study of 895 patients and once more showed that with 6 years of follow-up, equivalent rates of local recurrence and overall survival were achieved (159). Finally, Arriagada et al. reported the results of a randomized trial involving 179 patients treated at the Institut Gustave-Roussy and once more demonstrated an equivalent disease-free and overall survival (160). Notable studies from the NCI and European Organization for Research and Treatment of Cancer (EORTC) showed a higher risk for local recurrences with breast conservation compared to mastectomy, but these studies were flawed for either inadequate margin assessment or frank margin involvement, respectively (161,162).

In the final analysis, the weight of evidence supports equivalence of breast conservation therapy versus radical or modified radical mastectomy for early-stage breast cancer. The NSABP trials rigorously and systematically both challenged and advanced breast cancer surgical technique and systemic therapy. Ongoing debate about which patients were candidates for BCT continued for decades, ultimately landing at the determination based on the breast-to-tumor volume ratio, absence of multicentric disease, and eligibility for postlumpectomy radiation (163).

The NSABP applied similar methodology in evaluating the benefit of surgery and radiation in the management of ductal carcinoma *in situ* (DCIS). From the NSABP B-17 and B-24 trials we learned that lumpectomy with radiation achieved the lowest rate of local recurrence but did not affect overall survival, and that tamoxifen could decrease not only ipsilateral recurrence but also contralateral new disease (164). NSABP B-32 compared axillary dissection to sentinel node biopsy in the management of the clinically negative axilla and demonstrated the success of sentinel node mapping in predicting the axilla (165). Most recently, the results of the second prevention trial from the NSABP, P-2 (Study of Tamoxifen And Raloxifene trial), demonstrated the equivalent efficacy of raloxifene for risk reduction of a new primary in postmenopausal women, but with a reduction in untoward side effects such as thromboembolic events, cataracts, and endometrial carcinoma, the latter not achieving statistical significance (166).

In Situ Disease

In the past DCIS was managed, like any breast cancer, by mastectomy. This was effective from a cancer point of view and resulted in a local recurrence rate of only 1% (167). Interestingly, at a time when breast conservation surgery was being advocated for invasive breast cancer, total mastectomy was still the standard of care for DCIS. Current therapies have since evolved based on extrapolation of the trials of breast conservation therapy with total mastectomy in invasive breast cancer, although there are no phase 3 studies comparing breast conservation therapy with total mastectomy in DCIS.

Currently, DCIS is treated by wide local excision which is now the standard of care. Margin status and size of the lesion

appear to be significant factors related to risk of recurrence (168,169). Silverstein et al. created the Van Nuys Prognostic Index (VNPI) by combining pathologic classification (non-high-grade nuclei without necrosis; non-high-grade nuclei with necrosis; high-grade nuclei), tumor size, and closest margin width (170). The VNPI score ranges from 4 to 12 and has been shown to stratify the risk of local recurrence after breast-conserving surgery. However, with respect to lesion size, accuracy is often problematic at pathologic evaluation because most DCIS is not grossly evident, yet it is not practical to submit all tissue from an excisional biopsy for microscopic evaluation. Most pathologists rectify this by sectioning of the biopsy specimen guided by the type of lesion and radiographic findings. Of note, mammography can often give a more accurate size of the lesion, though only in tumors that are entirely marked by calcifications. Margin width is most easily measured microscopically in perpendicular sections, which is only possible if the margins are inked in color, which is a prerequisite for identification of each margin.

The indications for mastectomy for DCIS are (a) persistent positive margins; (b) multicentric disease, i.e., DCIS involving more than one quadrant; (c) cosmetically unacceptable breast conservation surgery due to a large DCIS process in a comparatively small breast. For these cases a total or skin-sparing mastectomy with sentinel lymph node biopsy is most clearly recommended, to ensure that the opportunity for lymphatic mapping will not have been sacrificed should occult invasive disease be identified on final pathology.

The role of sentinel node biopsy in DCIS treated with lumpectomy is less clear. Some have advocated for sentinel node biopsy in DCIS treated by lumpectomy when the diagnosis is based on a core needle biopsy since the risk of an invasive cancer at definitive excision ranges between 10% and 20%. In the largest series of sentinel node biopsy for pure DCIS, a 5% rate of nodal metastasis was described; however, 70% of these metastases were detected only by immunohistochemical (IHC) staining (171). Others have suggested stratifying the risk of invasion based on retrospective studies, acknowledging that the implications of IHC-positive nodes are unclear, especially in the context of known disease-specific survival from DCIS of 99% (172). Taking into account the published literature, consideration of lymphatic mapping is reasonable for a span of DCIS greater than 4 cm or a mass on mammography, palpable DCIS, high-grade DCIS, and in the presence or question of microinvasion (173).

Early Invasive Disease

Early invasive breast cancer is almost uniformly diagnosed by imaging modalities. Although breast MRI has emerged as a valuable adjunct in the diagnostic evaluation of breast cancer, its widespread use as a screening tool has yet to be largely realized. Therefore, the majority of patients will present with lesions that have been identified by mammography.

Once the diagnosis of invasive cancer is established in early-stage disease, surgical planning starts. A thorough history and physical examination are essential to establish both the patient's presentation and extent of clinically apparent disease, and to screen for contraindications to breast conservation therapy or to adjuvant radiation therapy, such as connective tissue disorders or prior irradiation. Particular attention to the location of the tumor, its palpability, fixation to the skin or underlying chest wall, cutaneous changes, nipple irregularities, and regional nodal assessment are paramount.

Breast conservation surgery should aim to resect the primary tumor with clear margins. This can be achieved either with the needle localization technique, or one of the other many techniques that have been described in the literature to localize the lesion, such as intraoperative ultrasound localization

or radioisotope-guided resection (174,175). The ideal margin for breast cancer in a wide local excision has been a well-published challenge; after all, an acceptable margin for one pathology may not be appropriate for another. In an exhaustive review of the technique and significance of the surgical margin for invasive breast cancer, Singletary analyzed 38 representative studies examining the impact of surgical margin on local recurrence (176). Although it is difficult to discern a distinction between the significance of 1-, 2-, 3-, or greater than 5-mm margins in patients with invasive breast cancer treated with whole breast irradiation with tumor bed boost, she demonstrated an increased local recurrence rate in patients with positive margins. Young age, large tumor size, positive lymph nodes, and the absence of systemic chemotherapy or endocrine therapy were identified as significant independent predictors of locoregional recurrence. The time-dependent nature of recurrence is further elaborated by Neuschatz et al., who showed that graded tumor bed escalation in breast irradiation may establish equivalence in local recurrence for involved margins initially, but that after 5 years of follow-up, the local failure in the close/positive margin groups becomes apparent (177).

Intraoperative margin analysis to ensure adequacy has been explored primarily using frozen section analysis, touch prep, or intraoperative imaging. A promising technique of treating potential positive margins is the use of intraoperative radiofrequency ablation, where a multipronged probe is deployed into the surrounding breast tissue at the completion of the lumpectomy before wound closure (178). Ablation is performed under ultrasound visualization for 15 minutes. Twenty-five percent of patients avoided returning for re-excision due to close margins evident on final pathologic analysis. However, longer follow-up is needed to ensure that the local recurrence remains low.

Locally Advanced Breast Cancer

Locally advanced breast cancer is variously defined as primary tumor size greater than 3 to 5 cm, involvement of the chest wall, skin ulceration or satellitosis, and/or positive axillary nodes (179,180). Approximately 6% of breast cancers in the United States present as locally advanced breast cancer (LABC). These patients are candidates for neoadjuvant chemotherapy or endocrine therapy, which results in a higher rate of breast conservation, without a reduction in either disease-free or overall survival (181). Additionally, neoadjuvant therapy has not been shown to increase the complication rate of surgery or delay the onset of further postoperative treatment. From a biologic standpoint, neoadjuvant therapy provides the opportunity to assess the chemosensitivity of breast tumors *in vivo*. The use of neoadjuvant chemotherapy does result in a 30% to 40% decrease in the incidence of axillary nodal involvement, and up to a 20% complete response in responding patients (182–184). Although neoadjuvant chemotherapy has not been shown to improve survival in locally advanced breast cancer, it has demonstrated that up to 80% of patients have significant breast tumor shrinkage and only 2% to 3% will have progression of disease (180,181).

Approximately 25% of patients who were not candidates for breast conservation before treatment were able to conserve their breast after the administration of neoadjuvant chemotherapy. Data from the NSABP B-18 trial demonstrated that patients who achieved a pathologic complete response (pCR) have better survival than those who were partial responders (182). Kuerer et al. also demonstrated that the presence of residual disease in the axillary lymph nodes was a

predicator of poor outcome and was associated with a higher incidence of locoregional (14% vs. 5% in patients achieving a pCR in the nodes) and distant metastases (41 vs. 15%) (184). In this study the eradication of nodal metastases was associated with improved survival. In addition, a pathologic complete response to neoadjuvant therapy has been more commonly noted in younger patients and in tumors that are estrogen receptor–negative cancer, high grade, and ductal. Cancers with a high proportion of intraductal cancer are also less likely to shrink significantly. Neoadjuvant endocrine therapy has been used mainly in older women with estrogen receptor–positive disease; aromatase inhibitors are more effective than tamoxifen in inducing a local response, but pCR is rare with endocrine therapy alone.

A core biopsy of the breast is used to establish diagnosis and to obtain prognostic histologic features of the primary tumor. Multiple cores allow for staining for receptors and HER2/neu. A negative biopsy in the setting of a clinically suspicious or dominant breast mass should prompt additional workup with open biopsy. If the patient could be a candidate for breast conservation with appropriate down staging of tumor size, a microclip should be placed in the breast. This facilitates later identification of the cancer site in case of complete response to neoadjuvant therapy. Additionally, axillary evaluation is also required to establish the nodal stage. For palpable disease a needle biopsy can be performed, with sentinel node biopsy being reserved for nonpalpable disease.

However, clinical examination of the axilla remains unreliable, with reported false-negative examination in 21% to 42% of cases (182,185,186). Hence, it is important to identify other methods of accurately staging the axilla before initiation of treatment. Ultrasound combined with physical examination has been shown to increase the reliability of axillary evaluation (187). Further, fine-needle aspiration cytology of suspicious nodes, defined as size greater than 1 cm, loss of fatty hilum, cortical hypertrophy, and hypoechogenic parenchyma, has a reported sensitivity and specificity of 36% to 92% and 69% to 100%, respectively (86,87,188). In a study of 103 cases of indeterminate or suspicious-appearing lymph nodes from the M. D. Anderson Cancer Center, only 11% of node-positive patients were missed by ultrasound-guided cytology (86). All cases with three or more positive nodes, and 93% of cases where the size of the metastatic deposit was greater than 5 mm, could be identified by this technique. In this study, the overall sensitivity of US-FNA was 86%, specificity was 100%, positive predictive value was 100%, and the negative predictive value was 67%. Despite this, the false-negative rate of US-FNA remains 15% to 20% in the reported literature and a major limitation of ultrasound remains the inability to detect metastases less than 5 mm in size. While the identification of node-positive disease by US-FNA can reduce the number of sentinel lymph node biopsy (SLNB) procedures by up to 15% and identify those patients who would not otherwise be candidates for neoadjuvant chemotherapy, sentinel node biopsy is still required in those patients who are node negative based on US-FNA (87,88). Re-evaluation of the axilla after neoadjuvant therapy has also been reported in small studies to be predictive of axillary downstaging (187).

The timing of sentinel node biopsy in the US-FNA node-negative patient relative to chemotherapy remains controversial. Small single-institution studies demonstrate the feasibility of lymphatic mapping subsequent to neoadjuvant chemotherapy, and described a false-negative rate of 9%, which is comparable to the NSABP B-32 trial results for sentinel node biopsy in patients undergoing primary surgery. However, given the potential downstaging of the axilla, there remain concerns about establishing the extent of nodal involvement as patients with greater than four positive nodes will have alteration in radiation therapy field distribution. Chagpar et al. have attempted to

develop a nomogram to assist in identifying those patients more likely to require extended field radiotherapy (189).

All patients with locally advanced breast cancer should undergo a baseline bone scan and CT scans of the chest, abdomen, and pelvis since 30% of these patients have metastatic disease (190). Patients are clinically assessed for response after two to three cycles, and radiologic response can also be recorded at this time. If no response is present, a decision is made to continue with surgery if possible, or to change systemic therapy. Prior to surgical decisions being made, reimaging of the breast should be performed as clinical examination alone is unreliable (191–194). Occasional patients will have residual microcalcifications or DCIS while the invasive cancer has a complete pathologic response (195). The contraindications for breast conservation after neoadjuvant chemotherapy are similar to those for primary breast conservation therapy and include residual tumor >5 cm, skin edema or involvement, chest wall fixation, diffuse calcifications on postchemotherapy mammogram, multicentric disease, and contraindications to radiation therapy. As the risk of local recurrence after breast conservation in patients undergoing neoadjuvant therapy is slightly higher, the use of postmastectomy radiation in patients with larger cancers is recommended (181,196). Neoadjuvant endocrine therapy in hormone receptor-positive patients has also been shown to be effective.

Immediate reconstruction in patients with locally advanced breast cancer undergoing mastectomy has been shown to have a slightly higher rate of complications and results in a delay in treatment, as well as problems with cosmesis when postmastectomy radiation therapy is required. Given the multiple issues that are at play in the patient desiring immediate reconstruction, early consultations with both plastic surgeon and radiation oncologist should be performed, preferably before any surgery takes place.

Management of the Axilla

Although the clinical implications of axillary lymph node involvement has taken a varied course over the years, it still remains a major prognostic indicator of survival in breast cancer (197). Additionally, an axillary dissection remains of value in improving local control in patients with clinically positive axillae, though this has not translated into improved survival.

The largest prospective, randomized trial evaluating the role of axillary lymphadenectomy was the NSABP B-04 trial (197). In this trial, 1,079 women underwent radical mastectomy including an axillary dissection, total mastectomy with axillary radiation, or total mastectomy alone. Of note, patients did not receive systemic therapy on study. The results showed an axillary recurrence rate of 5% in clinically node-negative patients treated with surgery or irradiation compared to 20% when the axilla was observed. However, there was no difference in the rate of distant metastases or in survival in clinically node-negative breast cancer patients after 25 years. Most patients with axillary recurrence were salvaged by the performance of a delayed axillary dissection, whereas one patient had inoperable regional disease. This study thus demonstrated that leaving behind axillary nodes with metastatic disease had no significant impact on the overall outcome of the disease.

Cabanes et al. reported the results of a randomized trial of breast conservation therapy with breast irradiation, with or without axillary dissection in clinically node-negative patients, and showed a survival benefit for axillary dissection (198). However, this could be explained by the greater use of adjuvant chemotherapy and radiation in patients with positive nodes discovered at axillary dissection, whereas patients who were observed did not undergo these treatments. The rate of

axillary recurrence without axillary dissection was only 7 of 332 (2%), compared to 3 of 326 (1%), even when an axillary dissection had been performed. In another study of 401 patients with T1 breast cancer (<2 cm) treated only with tangential breast radiation ports without an axillary dissection or sampling, Greco et al. reported that only 25 patients (7.5%) subsequently developed clinically suspicious axillary nodes, although at biopsy only 19 of the 25 patients had a histologic confirmed axillary relapse (199).

A Danish randomized trial compared an extended radical mastectomy with nodal resection to total mastectomy with postoperative radiation, showing similar survival and suggesting that axillary radiation might be an acceptable alternative to surgical dissection of the axilla (200). Similarly, the 30-year results of a randomized trial of 737 patients treated with a radical mastectomy versus an extended radical mastectomy with internal mammary lymphadenectomy and with no adjuvant therapy demonstrated that the involvement of the internal mammary nodes was a predictor of poor outcome, but did not demonstrate a survival benefit (201).

In contrast, a meta-analysis reported a 5% survival advantage with axillary dissection versus observation (202). This has been questioned since the trials on which this meta-analysis were based have since been updated, reflecting no survival advantage with axillary dissection, though maintaining a lower axillary recurrence rate with axillary dissection (203). Few women in the era when the trials included in this meta-analysis were performed had mammographically identified or nonpalpable tumors, and few received chemotherapy. Thus, extrapolation of these data to contemporary breast cancer management is quite difficult, given the changes in presentation of breast cancer.

A complete axillary dissection involves removal of the level I-II nodal tissue from the axilla. This is defined as the space bounded by the pectoral muscles anteriorly, the latissimus dorsi muscle posteriorly, and superiorly by the axillary vein. The nerves to the latissimus dorsi and serratus anterior are preserved. If possible, the intercostobrachial nerve is also preserved to decrease the risk of arm paresthesias. Level III nodes, which can be accessed only by dividing the pectoral tendon, are usually not removed. These are included in the radiation field, which is recommended if multiple nodes are involved.

Sentinel Node Biopsy

The concept of sentinel lymph node biopsy was designed to evaluate the stage of the disease in lieu of lymphadenectomy. It has revolutionized the surgical management of the axilla, and largely replaced axillary dissection in the node-negative axilla. In a recent meta-analysis involving 69 trials run between 1970 and 2003 and over 8,000 patients, the false-negative rate averaged 7.3% across studies (ranging from 0% to 29%) (204).

Donald Morton et al. pioneered lymphatic mapping in the surgical management of melanoma (205). The simplicity and elegance of this technique were overwhelming and led to its adoption in several malignancies, but none as robustly as breast cancer. Armando Giuliano championed the blue-dye-only technique using lymphazurin dye to identify the sentinel nodes, and the radioisotopic technique followed 1 year later, which is credited to Krag (165,206). Currently, a combination of these techniques has become most widely employed, although continued controversy persists on the different techniques of injection, whether it be peritumoral or subareolar or subdermal (207,208). Although all are likely successful in the majority of patients, the peritumoral technique may be important for posteriorly situated lesions. The subareolar technique may not drain to the internal mammary nodes (209).

Following injection of isotope, the dissection begins with a separate axillary incision. Dissection is taken down to the clavipectoral fascia, which is opened. The axilla is interrogated

with a handheld receiving device, and further exploration for the “hot” node is performed. The node is carefully dissected from the surrounding tissue, paying attention to close dissection, as the critical motor nerves have not been identified. Each node is subsequently removed and counted over 10 seconds; if more than one node comes out together they should be separated. The node with the highest count becomes the benchmark and all nodes with greater than 10% activity are considered sentinel nodes. If blue dye is used, any blue node or node with a blue-stained lymphatic adjacent is a sentinel node. The sentinel nodes may be hot, blue, or hot and blue. Each technique used independently gives a 90% identification rate, and 95% when combined. Each agent’s benefits are inherently obvious: the visualization of the blue dye, and the audibility of the isotope. Before completion of the procedure, the axilla must be digitally evaluated for any palpable nodes, as false negativity is common with nodes replaced by tumor. Furthermore, care to try to identify low-lying nodes in the axillary tail of the breast is useful. While lymphatic mapping to the internal mammary chain has been performed, its impact on outcome remains unclear.

It has now been demonstrated that sentinel lymph node evaluation is feasible, and accurately predicts the regional nodal status (205,206,210). The analysis of the few removed sentinel lymph nodes enabled pathologists to do multiple sections and a far more careful analysis of a few nodes, rather than a single section of the 10 to 20 nodes usually obtained from an axillary dissection. This detailed examination has sharply increased (by 20% to 30%) the proportion of “positive” nodes.

Intraoperative assessment of sentinel lymph nodes using touch imprints and routine IHC staining is used by some to enable an immediate therapeutic lymphadenectomy if the nodes were positive, thus sparing the patient from a second procedure. However, intraoperative assessment may have unacceptable rates of false-negative results, ranging from 36% to 71% (211). The increased yield of small macrometastases and micrometastases from regional lymph nodes by use of multiple thin sections and immunohistochemistry had been well demonstrated even in the present sentinel lymph node era, and led to the recommendation for the current careful pathologic analysis of sentinel lymph nodes (212–215). With the technique of sentinel lymph node biopsy and the pathologic analysis now relatively standardized, the more recent focus is on the clinical significance of “positive” sentinel nodes. The most recent sixth edition of the *AJCC Staging Manual* defines nodal metastases less than 0.2 mm in extent and detected by IHC only as $N_{0(IHC)}$, indicating the uncertain prognostic implication of these minor cancer cell discoveries. Not all “positive” sentinel lymph nodes require a subsequent therapeutic lymphadenectomy since studies have shown low risk of regional nodal recurrence after observation only for patients with a positive sentinel lymph node (216). This thesis formed the hypothesis of the American College of Surgeons Oncology Group (ACOSOG) Z-11 trial, which randomized women with sentinel node positive breast cancer to observation only or completion axillary dissection. Unfortunately, this study closed early due to poor accrual, but results are expected in the near future.

Yet even now we strive to ascertain which of the patients with a positive sentinel node need to return for axillary node dissection. Nomograms have been developed to assist in this decision-making process, and the rate of completion axillary dissection has fallen off as these data have matured, likely recognizing that the extent of nodal involvement will not affect chemotherapeutic recommendations (217,218). Furthermore, in an appropriately performed sentinel node biopsy, bulky disease should not be left behind.

Current data suggest that with smaller tumor size in the era of mammographic screening, only 30% of breast cancers are

node positive at presentation. In approximately 50% to 60%, the only positive node is the sentinel node. Data from the NSABP B-04 and other trials performed before the routine use of systemic chemotherapy demonstrated no survival benefit in removing the axillary lymph nodes for occult disease.

The use of axillary dissection comes at a cost to the patient. The incidence of lymphedema after axillary dissection and after axillary radiation is similar (15% to 25%) and is higher when the two are combined. Overall, 50% to 70% of patients have some complaint after axillary dissection, including restricted shoulder motion (17%), intercosto-brachial nerve numbness (78%), and pain (25%) (186). Though these problems are not life threatening, their effect on the quality of life is significant (219).

Oncoplastic Surgery

Subsequent to the revolutionary advances taking surgeons from radical mastectomy to lumpectomy and axillary dissection, there remained a cohort of patients who required mastectomy to either resect their disease adequately or had significant risk of future breast carcinoma such that breast conservation was deemed inappropriate. For these patients, continuing with the standard simple mastectomy, and nodal evaluation lagged behind advances already achieved. But over the past 15 years, immediate reconstruction after mastectomy has been documented to be both safe, from an oncological perspective, and psychologically beneficial to the patient’s well-being (220). Simmon et al. have championed a more ideal technique of complete resection of the breast while preserving unaffected structures (221). Her landmark article compared recurrence patterns in women treated by skin-sparing mastectomy (SSM) versus non-skin-sparing mastectomy and demonstrated local recurrence rates of 3.90% and 3.25%, respectively, with an equivalent distant recurrence rate of 3.9% at 5 years.

SSM involves resection of the nipple areolar complex and nodal evaluation, but preservation of the entire overlying skin. Although initially reserved for early-stage breast cancer, Foster et al. have shown that SSM can be used in locally advanced breast cancer stages IIB and III with comparable local recurrence (222). A recent analysis of recurrence patterns revealed that local recurrence is usually in the same quadrant as the disease and is more common with high-grade DCIS or grade 3 invasive tumors (223).

Further analysis led Simmons to advance the concept of areola-sparing mastectomy, advocating that the preserved areola would enhance nipple reconstruction (224). Although retrospective, it suggested that malignant involvement of the areola was uncommon (0.9%), whereas involvement of the nipple was present in 11% of patients. Ultimately, the idea of nipple preservation has been pursued. While long-term results available in the European literature suggest comparable rates of success in appropriately selected patients, i.e., small peripheral tumors, the local recurrence rates remain higher (25%) than in the U.S. experience (225,226). The Milan group has used intraoperative radiotherapy to reduce recurrence, but the risk of nipple necrosis is approximately 10% in most series (227). Intraoperative frozen section analysis of the subareolar ductal system to exclude occult disease is reported at 98.5%, but this is likely to be dependent on local expertise. The sensitivity of the preserved nipple areolar complex ranges widely in the literature.

While the reconstructed breast proved to appear more natural, the desire for improved breast conservation has remained paramount, where we can provide not only the greatest assurance of nipple/areolar function, but, to a lesser extent, minimize the sense of “violation” by the patient. Taking techniques from breast reduction, breast surgeons have now expanded

their armamentarium in achieving cosmetically desirable lumpectomy. Incorporation of mastopexy with lumpectomy has yielded successful results that translate to improved cosmesis for patients with lesions in ptotic breasts, as well as techniques of local tissue transfer that diminish skin retraction post lumpectomy (228).

CHEMOTHERAPY

Adjuvant Therapy

An important principle in the adjuvant use of chemotherapy is the concept of dose intensity. This issue governs the treatment in breast cancer following evidence suggesting that reductions in planned dosing may have an adverse impact on survival outcomes that are often quoted to our patients. In 1995, Bonadonna et al. reported the effect of dose intensity as part of an analysis on the effectiveness of adjuvant cyclophosphamide, methotrexate, and 5-fluorouracil (CMF) following radical mastectomy for women with node-positive breast cancer (229). Groups were stratified by the percentage of planned dose actually received (also known as relative dose intensity today). If patients received at least 85% of the planned dose, estimated relapse-free and overall survival at 20 years was over 50%. However, below this, 20-year survival dropped to approximately 30%. Of even more concern was the determination that patients receiving less than or equal to 65% of the planned dose experienced similar survival outcomes to those women who did not receive chemotherapy. Similar data have been reported by Lyman et al. (230).

Early Breast Cancer Trialists' Collaborative Group Meta-analyses

Ever since the effectiveness of treating metastatic disease with systemic therapy was established, the role of chemotherapy in the treatment of breast cancer has been evaluated in numerous clinical trials. To place this into a proper perspective, the Early Breast Cancer Trialists' Collaborative Group (EBCTCG) has performed meta-analyses of all randomized trials performed evaluating the adjuvant treatment of breast cancer, provided that at least 5 years of follow-up is provided. These analyses are performed every 5 years with the first performed in 1985. In the EBCTCG, all trials evaluating a similar intervention (doxorubicin-based therapy) are grouped for subsequent analysis. Baseline risks are defined by the "control" group, which may or may not be a placebo.

In 1998, the meta-analysis included 23,000 women from randomized trials looking into the role of chemotherapy (231). In 47 trials randomization was to polychemotherapy versus no chemotherapy ($n = 18,000$); in 11 trials it was longer versus short-duration treatments ($n = 6,000$); and in 11 randomization was to anthracycline-based versus cyclophosphamide (C), methotrexate (M), and 5-fluorouracil (F), collectively referred to as CMF ($n = 6,000$). The use of multiagent chemotherapy was found to reduce the annual risk of relapse by 35% in women under 50 and 20% in women aged 50 to 69. For mortality, the reduction was 27% for women under 50 and 11% for women aged 50 to 69.

In 2005, the overview on the use of chemotherapy reported the endpoints of risk reduction at 10 and 15 years (232). The analysis included 8,000 women treated on an anthracycline-containing treatment (CAF, cyclophosphamide, doxorubicin, 5-fluorouracil or FEC, 5-fluorouracil, epirubicin, cyclophosphamide) versus placebo; 14,000 women on trials of CMF versus placebo; and an additional 14,000 women on anthracycline-based versus CMF-type treatment. Again, no trial was included that used taxanes or trastuzumab. The meta-analysis showed

that women under 50 benefited from the use of an anthracycline-containing regimen, which resulted in a reduction in the annual breast cancer death rate by 38%. Women 50 to 60 years old also benefited, with a risk reduction of 20%. These results support the gains made for adjuvant chemotherapy in not only reducing 5-year recurrence rates, but also affecting 15-year survival.

Treatment of Node-Positive Breast Cancer: Taxanes

Among the most important agents for breast cancer, and not considered in the published meta-analyses, is the role of taxanes in the treatment for breast cancer. Paclitaxel was first used in metastatic breast cancer in a study conducted by the NCI (233). In that trial of 25 patients, a 56% response rate was obtained including 12% who had a complete response. Since that time it has been utilized in numerous schedules and doses, confirming its activity in node-positive breast cancers. The first reported trial in the adjuvant setting was by Hudis et al. at Memorial Sloan-Kettering Cancer Center (234). In that study, patients with breast cancer with four or more positive nodes were treated at 14-day intervals. The drugs administered were doxorubicin (A) 90 mg/m² for three cycles, paclitaxel (T) 250 mg/m² over 24 hours for three cycles, followed by cyclophosphamide (C) 3,000 mg/m² for three cycles. Forty-two patients were treated on this regimen with over 90% dose-intensity given. At 4 years, the actuarial disease-free survival was 78%, suggesting this as a feasible and active regimen.

The role of paclitaxel in the adjuvant treatment for all women with node-positive breast cancer has been studied. Hayes et al. recently reported findings from a retrospective analysis of Cancer and Leukemia Group B (CALGB) 9344/INT0148, which evaluated the benefit of four cycles of paclitaxel after four cycles of AC (235). With 10 years of follow-up, paclitaxel continued to show overall improvements in both disease-free (HR 0.81; 95% CI, 0.73 to 0.91) and overall survival (HR 0.81; 95% CI, 0.72 to 0.92). Of more interest was their analysis evaluating interactions between paclitaxel response, HER2/neu status, and ER status. Their analysis showed that HER2/neu positivity (by either IHC or FISH) predicted improvements in disease-free and overall survival from the AC followed by paclitaxel. However, no benefit of paclitaxel was suggested in women with tumors that were positive for ER but negative for HER2/neu.

The concept of dose-dense therapy was tested against standard every-3-week treatment using paclitaxel in the Cancer and Leukemia Group B Trial, CALGB 9741 (236). Over 2,000 women with node-positive invasive breast cancer were enrolled in this two-by-two randomized trial evaluating chemotherapy delivered every 2 (dose-dense) versus every 3 weeks with the second randomization to sequential single-agent therapy of A 60 mg/m², followed by C 600 mg/m², followed by T 175 mg/m², with each given for four cycles, or combination AC for four cycles followed by T for four cycles (AC → T). Women randomized to the every-2-week treatments were given growth factors to support hematopoietic recovery. At a median of 36 months follow-up, dose-dense therapy was associated with improvements in both disease-free (risk ratio [RR], 0.74) and overall survival (RR, 0.69). Four-year disease-free survival (DFS) was 82% with dose-dense therapy compared to 75% for treatment every 3 weeks. Survival outcomes were similar by drug sequence (AC → T or sequence A, C, T).

Another trial evaluating taxane versus no-taxane adjuvant treatment was conducted by the Breast Cancer International Research Group, the BCIRG 001 trial (237). In this study almost 1,500 women were randomized to docetaxel 75 mg/m², A 50 mg/m², and C 500 mg/m² (TAC) versus F 400 mg/m², A 50 mg/m², and C 500 mg/m² (FAC). Compared to FAC,

treatment with TAC resulted in improved 5-year DFS, 75% versus 68%, respectively ($p = 0.001$), and overall survival, 87% versus 81%, respectively, $p = 0.008$. The prophylactic utilization of myeloid growth factors has enabled treatment on time with both of these schedules, which are in and of themselves significantly myelosuppressive.

Given the activity of taxanes in the adjuvant therapy in node-positive disease, studies now seek to address whether anthracyclines are required. One of the first to address this question was conducted by U.S. Oncology and evaluated AC versus a nonanthracycline regimen of TC (docetaxel 75 mg/m² and cyclophosphamide 600 mg/m²) (238). This trial enrolled over 1,000 women with stage I-III breast cancer following definitive excision. At a median follow-up of 5 years, TC was associated with a significant increase in DFS over AC (86% vs. 80%, respectively, $p = 0.015$) with similar overall survival (OS) (90% vs. 87%, respectively, $p = 0.13$). TC treatment was associated with increased myalgias, arthralgias, edema, and episodes of febrile neutropenia over AC treatment.

Considering emerging data, there is no clear standard of care for women with node-positive breast cancer. In addition, recent data support the contention that treatment recommendations should be tailored to the features of the individual patient's breast cancer. This has been most evidently demonstrated when it comes to hormone receptor expression. In a recent meta-analysis involving over 6,000 women treated on adjuvant node-positive breast cancer trials conducted by CALGB, Berry et al. reported that the benefits of chemotherapy were larger in women with ER-negative disease, where the risk reduction in both recurrence and death was 55%, translating into a 16.7% absolute improvement in overall survival at 10 years. This contrasts to the estimates for women with ER-positive disease where the reduction in the relative risk of recurrence was estimated at 26% and in the risk of death was 23%. This translated into an approximate 4% absolute benefit in overall survival (138).

Adjuvant Treatment of Node-Negative Breast Cancer

Adjuvant therapy clinical trials have often sought to include patients with node-negative disease on the basis of poor prognostic factors (large tumor size, ER-negative disease, HER2/neu positivity, and high-grade features). Thus, there have been few trials defining the appropriate chemotherapy management specifically in women with node-negative breast cancer. A large rationale for this approach is that the prognosis for women with small tumors (defined as under 1 cm) without node involvement remains favorable such that the benefits of chemotherapy are likely minimal. For those with tumors above 1 cm, receptor positivity has played a role, especially given the profound effect of endocrine therapy in both reducing risk of relapse and improving overall survival. In this group, women at high risk or with receptor-negative disease are often considered for adjuvant chemotherapy and several important trials bear mentioning.

The NSABP recently reported an update on trials where women with node-negative ER-negative tumors were enrolled (239). The trials included B-13 ($n = 760$ assigned to observation vs. MF), B-19 ($n = 1,095$ assigned to MF vs. CMF), and B-23 ($n = 2,008$ assigned to CMF vs. AC). The analysis showed steady gains in overall survival with the use of MF versus observation (HR = 0.75; 95% CI, 0.58 to 0.98) and then CMF versus MF (HR = 0.71; 95% CI, 0.55 to 0.92). However, with 8 years median follow-up, the use of AC did not demonstrate continued gains in overall survival compared to CMF (HR = 0.92; 95% CI, 0.79 to 1.27), nor did it show improvements in relapse-free survival (HR = 1.0).

Linden et al. reported the results of a Southwest Oncology Group (SWOG) trial, which tested single-agent sequential A then C versus combination AC in women with high-risk node-negative or low-risk node-positive breast cancer (240). The study enrolled 3,176 patients between 1994 and 1997 and no difference in OS at 5 years was seen: 88% AC versus 89% A then C. However, sequenced therapy showed much higher grade 4 hemotoxicity.

Recommendations for the adjuvant treatment in this population often require an individualized approach based on risk of recurrence, and several tools are currently available to aid the clinician in decision making. Among them is Adjuvant! Online (241). Developed by Peter Ravdin et al., this computer-based program takes into account multiple clinical factors including age, presence of comorbidities, ER status, tumor grade, and nodal involvement in calculating a baseline 10-year risk for both recurrence and death (242). Using Surveillance, Epidemiology, and End Results (SEER) data, overview results on the use of chemotherapy and endocrine therapy, and results of contemporary clinical trials, the relative benefits of endocrine therapy, chemotherapy, or a sequential approach of the two are calculated. To make it more understandable, a graphic depiction is included which gives estimates of lives saved out of 100 women treated with each strategy.

For women with node-negative disease, the FDA has approved a genomic microarray for clinical use. Commercially marketed as the MammaPrint assay, it stratifies patients based on an expression signature into those with a good versus bad prognosis. It was validated in a study using 295 women with stage I-II breast cancers that were node negative ($n = 151$) or positive ($n = 144$) and under 53 years old (243). In this series, 180 women fell into the poor prognosis category. Their 10-year survival rate was $54.6\% \pm 4.4\%$ with a 10-year relapse-free survival rate of $50.6 \pm 4.4\%$. For the 115 with a good prognosis, the corresponding figures were $94.5\% \pm 2.6\%$ and $85.2 \pm 4.3\%$. It is currently approved for T1-2, node-negative patients regardless of ER status. However, rigorous specimen processing is required including at least a 5 mm biopsy obtained within 1 hour of surgery, which must be placed in the provided preservative overnight and up to 1 month in a -20° freezer.

An additional option for risk stratification is the Oncotype DX. Unlike the MammaPrint, it can be performed on representative archived tissue of the primary breast cancer. The assay uses a risk algorithm based on the expression of 21 genes (16 cancer genes representing groups of proliferative, invasion, HER2, and estrogen-receptor-associated genes and five reference genes). Scoring in these groups is then used to assign a recurrence score (RS) (244). In testing Oncotype DX, data from the prospective trial NSABP B-14, which enrolled 658 women with T1-2, node-negative, ER-positive tumors on tamoxifen for 5 years followed by randomization to further tamoxifen therapy versus placebo, was used. Using tumor specimens from this trial, 51% of patients were assigned to a low-risk category (RS <18) and had less than a 7% rate of distant recurrence at 10 years. Twenty-two percent were placed into an intermediate risk category and had a 14.3% rate of distant disease, and 27% were assigned the high-risk category (RS=31) and had a 30.5% rate of distant recurrence. Although such information may help guide discussion of who may *not* need chemotherapy, there are obvious limitations of the Oncotype DX assay as it cannot predict chemotherapeutic benefits, nor does the RS predict breast cancer-specific mortality.

Adjuvant Treatment: HER2/neu-Positive Breast Cancers

Among the biggest findings in the last 5 years is the use of trastuzumab in adjuvant therapy for women with HER2/neu-positive breast cancer, now considered the standard of care in

women with high-risk node-negative breast cancer (defined as tumor size >2 cm if ER positive or >1 cm if ER negative) and those with node-positive breast cancer. The trials that have helped establish this standard are summarized in Table 29.9. The NSABP B-31 trial enrolled 2,043 women to AC/T every 3 weeks or AC every 3 weeks for four cycles followed by T for 12 weeks with trastuzumab followed by trastuzumab consolidation to complete 1 year. During this same period, the NCCTG 98311 trial enrolled 3,000 women to every-3-week AC for four cycles followed by weekly T as a control arm versus the same followed by 1 year of trastuzumab or T given with trastuzumab followed by trastuzumab consolidation to a total of 1 year. The results were reported in a combined analysis and showed that adjuvant trastuzumab resulted in improvements in both 4-year disease-free survival (HR = 0.48, $p < 0.0001$) and overall survival (HR = 0.67, $p = 0.015$) (245). Several studies have also confirmed the benefits of trastuzumab in the adjuvant setting (246–248).

The duration of consolidation required continues to be an area of evaluation. Although the majority of trials have compared observation to 1 year of trastuzumab, the FinHER evaluated the benefits of 9 weeks of chemotherapy with or without trastuzumab (248). In that trial, those women who were HER2/neu positive were randomized to chemotherapy (vinorelbine or docetaxel) with or without trastuzumab, followed by FEC. Two-hundred and thirty-two women were enrolled and they reported that adding trastuzumab to chemotherapy improved disease-free survival (89.6% vs. 76.8% without trastuzumab, $p = 0.01$) and showed a trend toward improved overall survival (94.8% vs. 88%, $p = 0.07$).

In addition, although the standard of care has been set for women with high-risk node-negative disease, another issue yet to be determined is whether all women with HER2/neu-positive invasive breast cancer warrant trastuzumab, regardless of tumor size. The consideration of the benefits, particularly in those with tumors less than 1 cm in size, must be weighed against the risks of trastuzumab therapy, especially if it follows anthracycline-based treatment.

Neoadjuvant Chemotherapy: Considerations and Outcomes

Neoadjuvant, or primary, therapy has become a standard option in the management of locally advanced breast cancer. The rationale for its use is historically based on the use of primary chemotherapy in inflammatory and advanced breast cancer, where chemotherapy was shown to be an effective treatment with the potential to provide a long-lasting remission in otherwise poor-prognosis patients. Currently neoadjuvant therapy allows patients facing a mastectomy the option of breast conservation by downstaging the primary tumor while not adversely impacting survival endpoints. In addition, it provides a measure of chemotherapy effectiveness to the intact cancer, which may guide prognosis, particularly in the patient experiencing a pathologic complete remission.

NSABP B-18 was a large randomized trial evaluating neoadjuvant therapy. The primary endpoint of the study was surgical and was measured by the proportion achieving breast conservation surgery (249). In this trial, 1,523 women with operable breast cancer were randomly assigned to AC every 3 weeks for four cycles preoperatively or postoperatively. In women treated with neoadjuvant AC, 81% underwent breast conservation surgery, compared to 57% treated with adjuvant therapy. For women with tumors ≥ 5 cm, preoperative chemotherapy increased the rate of breast conservation by 175%. Neither overall survival nor disease-free survival was affected by primary or adjuvant AC therapy, suggesting that the timing of systemic chemotherapy will not affect breast cancer outcome. However, this trial also suggested that among those who are treated with primary chemotherapy, final pathologic findings predict survival, and those who achieve a pathologic complete response (pCR) have the best prognosis. Among the factors that were associated with a pCR were being ER negative, ductal histology, being HER2/neu positive, and a high histologic grade. These factors have been used to construct nomograms to predict the likelihood of achieving a pCR for women being considered for this approach (250).

TABLE 29.9

SEMINAL TRIALS OF TRASTUZUMAB IN THE ADJUVANT THERAPY OF BREAST CANCER

Trial	N	Arms	Disease-free survival (%)	<i>p</i> value	Overall survival (%)	<i>p</i> value
NSABP B-31 (245)	2,043	AC → T	67.1	<0.0001	86.6	0.015 ^a
NCCTG 98311 (245)	3,000	AC → T + Tr	85.3		91.4	
HERA (246)	5,081	Observation	74	<0.0001	89.2	<0.0051
		Tr	80.6		92.4	
		Tr × 24 mo	NR		NR	
BCIRG 006 (247)	3,222	AC → Doc	77	<0.00001	86	0.004 ^b
		AC → Doc + Tr	83		92	
		Carbo + Doc + Tr	82		91	
FinHER (248)	210	Chemo × 9 wk → FEC	76.8	0.01	88	0.07 ^c
		Chemo + Tr × 9 wk → FEC	89.6		94.8	

Notes: A, doxorubicin; BCIRG, Breast Cancer International Research Group; C, cyclophosphamide; Carbo, carboplatin; Doc, docetaxel; FEC, 5-fluorouracil, epirubicin, cyclophosphamide; FinHER, ; HERA, ; NCCTG, North Central Cancer Treatment Group; NSABP, National Surgical Breast and Bowel Project; T, paclitaxel; Tr, trastuzumab. Unless otherwise stated, trastuzumab treatment was for a total duration of 1 year.

^aJoint analysis of 3,351 women (1,679 receiving AC → T; 1,672 receiving trastuzumab) reported survival analysis at 4 years.

^bThe second interim analysis reported survival endpoints at 4 years.

^cOne thousand and ten women were randomized in the FinHER trial to vinorelbine versus docetaxel, followed by FEC. The subgroup with HER2/neu-positive disease underwent additional randomization to trastuzumab or no trastuzumab.

Although women with a pCR after neoadjuvant chemotherapy have a very good prognosis, the opposite is also true. Women who do not achieve complete pathologic response tend to be at highest risk for relapse, but there is no clear consensus on the best treatment approach following surgery. While women with ER-positive tumors are candidates for endocrine therapy and those with HER2/neu-positive tumors are candidates for extended trastuzumab therapy, the use of further chemotherapy is of unclear benefit, and no randomized trials to date have addressed this issue. Considering the paucity of data on “adjuvant treatment” after neoadjuvant therapy, referral to appropriate clinical trials is encouraged. Completed randomized trials of primary chemotherapy are summarized at the end of this chapter. At this time, primary chemotherapy should be reserved for patients where the results of neoadjuvant treatment might positively impact cosmetic results or facilitate breast and/or axillary surgery.

Metastatic Breast Cancer

Patients who recur or develop metastatic breast cancer do not comprise a homogenous group and prognosis is guided by the sites of cancer involvement. Women with bone-only metastatic disease may survive for years following their diagnosis, while those who recur in the visceral organs (liver or lungs most commonly) face a more guarded prognosis. Current national practice guidelines stratify treatment options based on biologic factors and recommend first-, second-, and even third-line endocrine therapies for women with ER-positive disease; trastuzumab-based therapies are recommended for women whose tumors are HER2/neu positive. Women with visceral disease, are otherwise symptomatic, have hormone receptor-negative cancers, and/or are HER2/neu negative are treated with chemotherapy. In addition, the palliative intent of treatment in this context reinforces the importance of considering the patient’s wishes when choosing treatments. A young mother may be willing to undergo significant toxicity if there is a chance for a second remission, while an older woman may not want aggressive therapy, opting instead to maintain her quality of life as much as possible.

Multiple agents are active in metastatic breast cancer, and both single-agent and combination therapies are reasonable choices. Perhaps one of the biggest controversies is whether to use single-agent sequential therapies or combination treatment for metastatic breast cancer. A meta-analysis by Fossati et al. evaluated the role of polychemotherapy versus single-agent therapy in this population (251). The meta-analysis incorporated 12 trials and over 1,900 women and showed that polychemotherapy afforded an 18% proportional reduction in mortality (HR 0.82; 95% CI, 0.75 to 0.90). However, it has been criticized because none of the trials included taxane therapies, nor did the meta-analysis evaluate *sequential* single-agent treatments.

In the intergroup trial sponsored by the Eastern Cooperative Oncology Group, ECOG 1193, over 670 women with metastatic breast cancer were randomized to doxorubicin and paclitaxel (AT) in combination or as single agents (252). It showed that the overall response rates were significantly improved with AT, compared to either single-agent doxorubicin or paclitaxel (47% vs. 36%, $p < 0.007$, and 34%, $p < 0.004$, respectively). In addition, median time to treatment failure was improved with the combination to 8 months, compared to 5.8 months with doxorubicin ($p < 0.003$) and 6 months with paclitaxel ($p < 0.009$). However, there was no difference in overall survival in any of these arms (22.4 months with AT, 19.1 months with doxorubicin, 22.5 months with paclitaxel). Sequential therapy was also shown to be beneficial in this trial where approximately 56% of patients randomized to doxorubicin

crossed over to paclitaxel and vice versa, and in each case 20% of patients experienced a response. The median time to treatment failure following crossover was 4 months in both single-agent arms. Given the higher response rate seen in this trial, combination therapy continues to be an acceptable choice for some patients. Recently, two combinations have received FDA approval for metastatic breast cancer: capecitabine/docetaxel and gemcitabine/paclitaxel (253,254). A newer taxane that utilizes nanotechnology to package paclitaxel into albumin, nAb-paclitaxel, has also been approved recently as single-agent therapy (255). Another drug, ixabepilone, an epothilone B analog that stabilizes microtubules and therefore works similarly to paclitaxel, received approval in the treatment of metastatic breast cancer, in combination with capecitabine or as a single agent. Most notably, however, it has been approved in women whose tumors are resistant or refractory to standard agents including anthracyclines, taxanes, and capecitabine. In the latter approval, 126 patients were treated on a single-arm trial using a dose of ixabepilone 40 mg/m² as a 3-hour infusion on day 1 of a 21-day cycle. Eighty-eight percent of patients had received more than two lines of prior therapy (256). The overall response rate was 18% with an additional 50% achieving stable disease. Median progression-free survival was 3 months and overall survival in this heavily treated cohort was almost 9 months. The major toxicity included grade 3-4 sensory neuropathy in 14% of patients, fatigue/asthenia in 13%, myalgia in 8%, and stomatitis in 6%.

Biologic therapies are another area of active investigation. The most recent FDA approval was for the combination of capecitabine and the dual tyrosine kinase inhibitor lapatinib for the treatment of HER2/neu-positive breast cancer following progression on trastuzumab-based therapy. The approval was based on an interim analysis of a multicenter randomized trial comparing capecitabine monotherapy (2,500 mg/m² per day) versus capecitabine (2,000 mg/m² per day) with lapatinib (1,250 mg/day) for 14 days of a 21-day cycle (257). Combination therapy increased time to progression (HR 0.49; 95% CI, 0.34 to 0.71) with a median time to progression reported of 8.4 months, compared to 4.4 months in those randomized to capecitabine alone. Antiangiogenesis agents such as bevacizumab continue to be evaluated in clinical trials in the neoadjuvant, adjuvant, and metastatic settings.

ENDOCRINE THERAPY

The role of endocrine therapy has grown significantly over the past several years as both our understanding of breast cancer has matured and new therapeutic options have developed. It has become increasingly clear that endocrine therapy is the backbone of treatment for hormonally responsive breast cancer, independent of stage.

Adjuvant Endocrine Therapy

Perhaps no data set has been more instructive in helping to define the benefit of adjuvant hormonal therapy than the meta-analysis generated by the Early Breast Cancer Trialists’ Collaborative Group (232). One of the principles appreciated through this overview analysis is that the proportional benefit of a given treatment is constant through risk groups (e.g., stage) and that the absolute benefit changes based on the estimated risk of systemic recurrence. For instance, if hormonal therapy decreases the risk of cancer recurrence by 30% in a given individual, the absolute benefit would be 3% if the 10-year risk of relapse were 10%, but 18% if the 10-year risk of relapse were 60%. This concept of proportional and absolute benefit from adjuvant therapy is a guiding principle

when women are counseled regarding treatment options in the adjuvant setting.

Expression of the estrogen receptor or the progesterone receptor is predictive of response to hormonal therapy. Therefore, essentially any woman with invasive breast cancer should receive adjuvant hormonal therapy if her tumor is estrogen receptor positive (ER+) and/or progesterone receptor positive (PR+). Conversely, hormonal therapy is inappropriate in the ER-/PR- setting. The choices for treatment and duration of therapy continue to be the subject of active investigation.

Tamoxifen was the first hormonal agent used in the adjuvant setting for breast cancer (258,259). As a selective estrogen receptor modulator (SERM), tamoxifen has differential effects on various tissues. While tamoxifen may achieve its beneficial effect in the treatment of breast cancer through multiple means, the principal mode of action appears to be through competitive binding to the estrogen receptor. By preventing estrogen binding, translocation and nuclear binding of the estrogen receptor are inhibited, altering transcriptional and posttranscriptional events mediated by the receptor. The antagonistic properties of tamoxifen toward breast cancer are contrasted with its agonistic effects on other tissues, such as bone and uterus. Tamoxifen, like estrogen, improves bone mineral density in postmenopausal women and is a risk factor for endometrial cancer. Tamoxifen may negatively affect bone density in premenopausal women. The risk of endometrial cancer with the use of tamoxifen is estimated at three- to fourfold over the general population risk, though the risk is likely lower in premenopausal women and perhaps close to the general population risk as demonstrated in the NSABP P-1 trial (260). It is recommended that women on tamoxifen follow general guidelines for gynecologic screening and follow-up but, importantly, report any menstrual changes, dysfunctional uterine bleeding, or other symptoms to their gynecologist (261). Women should discuss the use of tamoxifen with their gynecologist to ensure that they are being properly evaluated.

Another important risk associated with tamoxifen is that of venous thrombosis. While perhaps less so in premenopausal women, as demonstrated by the NSABP P-1 trial, tamoxifen has an approximate fourfold increase in risk for deep venous thrombosis (DVT) over the general population risk (260). This risk is sometimes described as similar to that associated with the use of oral contraceptives and may influence choice of hormonal therapy in the postmenopausal setting. Other potential side effects of tamoxifen include hot flashes, weight gain, mood changes, increased vaginal discharge, cataracts, and rarely retinal abnormalities. Several studies have suggested an increase in risk of stroke with tamoxifen. Tamoxifen can increase fertility by increasing ovarian stimulation and is a teratogen and is therefore contraindicated during pregnancy. Moreover, premenopausal women on tamoxifen need to ensure appropriate contraception as it is possible to become pregnant while on this medication.

Benefit from the use of tamoxifen in the adjuvant setting has been demonstrated in multiple clinical trials. The Scottish tamoxifen trial published in *The Lancet* in 1987 evaluated the use of tamoxifen 20 mg daily for 5 years in 1,312 premenopausal node-negative or postmenopausal women with any nodal status (258). This trial defined tamoxifen as an effective adjuvant in node-negative and node-positive patients as well as in the pre- and postmenopausal setting and is considered a landmark trial. NSABP B-14 evaluated the use of tamoxifen versus placebo for 5 years in 869 premenopausal and 1,949 postmenopausal women with node-negative breast cancer, demonstrating statistically significant improvement in disease-free and overall survival with the use of tamoxifen (259). Although multiple dosing strategies have been tried, there is no demonstrated dose-response curve between 20 and

40 mg. Thus, 20 mg per day is the recommended dose currently. Five years of tamoxifen appears to have equal efficacy to 10 years of therapy with less toxicity and is more effective than 2 years of therapy (262,263). Therefore, 5 years of treatment is recommended. We generally estimate that the proportional benefit of tamoxifen in the adjuvant setting ranges from 30% to 50% in reducing the odds of systemic cancer recurrence (138).

Another decision-making tool in women who have an option of endocrine therapy or chemotherapy is the Oncotype DX assay. Using 668 available paraffin blocks from the B-14 trial, Paik et al. evaluated 16 cancer-related genes to define an algorithm to assess risk of recurrence at 10 years (244). By creating a continuum of recurrence score based on gene expression analysis, three risk groups were broken out: low risk, intermediate risk, and high risk. Looking at this group of node-negative hormone receptor-positive women, all of whom received tamoxifen, individuals in the low-risk category did not appear to benefit from the addition of chemotherapy to tamoxifen and are likely best served by hormonal therapy alone. Women in the high-risk group likely benefit from the addition of chemotherapy to hormonal therapy. Whether hormonal therapy alone is adequate in the intermediate risk group is less clear and is currently being studied in a prospective, randomized trial. Gene- and protein-expression prognostic and predictive models will continue to be developed to aid in defining appropriate therapy across risk groups and will complement established prognostic and predictive factors such as tumor size, grade, receptor status, nodal involvement, and Her2 overexpression.

While tamoxifen remains the only established hormonal agent in premenopausal women, choices in the postmenopausal setting have increased through the study and development of aromatase inhibitors. Initially, through the study of first-generation aromatase inhibitors such as aminoglutethimide, these agents were found to be effective therapy for postmenopausal women. Aromatase inhibitors block estrogen production by preventing conversion of androgens produced by the adrenal gland, such as androstenedione, to estrogens, such as estrone, which is later converted to estradiol. This block occurs in the breast as well as in peripheral tissues such as adipose tissue. The resulting decrease in circulating estrogen has been demonstrated through multiple clinical trials to be effective treatment for receptor-positive breast cancer. Of the three commercially available aromatase inhibitors, anastrozole and letrozole are nonsteroidal while exemestane is a steroidal aromatase inhibitor. There are currently no demonstrable differences in efficacy or toxicity among these three products. Toxicities of aromatase inhibitors commonly include hot flashes and joint or muscle aches. Unlike tamoxifen, aromatase inhibitors can contribute to osteopenia and osteoporosis, and therefore bone density should be followed carefully in women receiving these medicines. Other possible side effects include hypertension, gastrointestinal disturbance, depression, urovaginal symptoms, and possibly cardiac events. Aromatase inhibitors are not associated with an increased risk of endometrial cancer and have a lower risk for DVT compared to tamoxifen.

Several studies have demonstrated the efficacy of aromatase inhibitors in the adjuvant setting. The ATAC trial is the largest prospective adjuvant trial in breast cancer, randomizing 9,300 postmenopausal women to tamoxifen, anastrozole, or the combination (264). With a median follow-up of 47 months, there was a statistically significant benefit in disease-free survival of anastrozole over tamoxifen with a hazards ratio of 0.82 in estrogen receptor-positive patients. There was no benefit with the combination. The Coombes trial randomized 4,700 postmenopausal women to tamoxifen for 2 to 3 years followed by either tamoxifen or exemestane to complete 5 years of adjuvant therapy (265). With a median follow-up of 55.7 months,

there was a statistically significant benefit in disease-free survival for the inclusion of the aromatase inhibitor with a hazard ratio of 0.76 and a modest benefit to overall survival with a hazard ratio of 0.83. Lastly, the Goss trial studied the addition of letrozole after 5 years of tamoxifen and showed a statistically significant benefit to the inclusion of an aromatase inhibitor with a median follow-up of 30 months and a hazard ratio of 0.58 (266). The Breast International Group (BIG) 1-98 study prospectively randomized 8,010 postmenopausal women with hormone receptor–positive breast cancer to either tamoxifen for 5 years, letrozole for 5 years, tamoxifen for 2 years switching to letrozole for 3 years, or letrozole for 2 years switching to tamoxifen for 3 years. After a median follow-up of 26 months, the two groups that were assigned letrozole initially had a statistically significant improvement in disease-free survival with a hazard ratio of 0.81 (267). A follow-up analysis of this trial published in 2007 focused on the groups receiving either continuous tamoxifen or letrozole for 5 years (268). At a median follow-up of 51 months, there was an 18% improvement in disease-free survival with a hazard ratio of 0.82 favoring letrozole.

Based on these four trials, it is recommended that all postmenopausal women receiving adjuvant hormonal therapy receive at least 2 to 3 years of an aromatase inhibitor (AI) unless contraindicated, and treatment with an AI beyond 5 years is the subject of current investigation. We await further data from the BIG 1-98 trial to assess the benefit of sequential versus continuous therapy.

The degree of benefit and choice of hormonal therapy may be further influenced by primary tumor characteristics. The level of expression and potentially the relative expression of estrogen- and progesterone-receptor positivity on the surface of breast cancer cells are predictive of the responsiveness of the tumor to hormonal manipulation (265). It is therefore important to incorporate the degree of ER and PR positivity into adjuvant therapy decisions. The differential expression of ER and PR may also be important in defining response to specific hormonal agents and this remains an area of active investigation. The differential benefit to tamoxifen and aromatase inhibitors in the postmenopausal ER+/Her2+ setting also requires further study.

Ovarian Ablation

Ovarian ablation (OA) has long been explored as a therapeutic option for women with breast cancer. As the ovaries are the major source for estrogen, silencing the ovaries via surgical oophorectomy, radiotherapy, or the use of gonadotropin-releasing hormone (GnRH) analogues may provide a benefit, although controversy continues as to its role in modern breast cancer management. The EBCTCG overview on ovarian ablation included 12 trials that compared OA by surgery or radiation to control and encompassed 2,012 women with early breast cancer (269). The meta-analysis concluded that OA was associated with both disease-free and overall survival advantages when compared to observation. At 15 years, 52% were alive of those who underwent OA, compared to 46% who did not ($p = 0.001$) and 45% were disease-free, compared to 39% ($p = 0.0007$). When trials using OA versus chemotherapy following breast surgery were analyzed, however, the benefits of OA were more modest and did not achieve statistical significance. Still, among women who do not receive chemotherapy, OA may play a role in management.

Since the meta-analysis, several results have been published in this area. The International Breast Cancer Study Group (IBCSG) Trial VIII randomized 1,063 women with node-negative breast cancer to chemotherapy (CMF) versus goserelin (G) versus CMF followed by G (270). Of note, 30% of women in

this study had ER-negative disease. Restricting the analysis to women with ER-positive disease, the 5-year disease-free survival (DFS) in those treated with either chemotherapy or goserelin alone was 81%; for those receiving sequential therapy there was a trend toward improved 5-year DFS at 86%. Arriagada et al. randomized 926 women with node-positive or grade 2-3 tumors who had completed surgery and chemotherapy to ovarian ablation (by surgery or with triptorelin) or observation (271). Of the cohort, 63% were ER positive. Estimated 10-year disease-free and overall survivals were similar in both groups, though subgroup analysis suggested that women under 40 who had ER-positive disease benefited significantly. Finally, the TABLE study (Takeda Adjuvant Breast cancer study with Leuprolide Acetate) published their results with 5.8 years of follow-up (272). Six-hundred ninety-nine women with ER-positive node-positive disease enrolled in this trial comparing CMF to leuprolide acetate (LA). Disease-free survival at 5 years was similar (63.9% with CMF vs. 63.4% with LA, $p = 0.83$) but overall survival favored LA over CMF (81% vs. 71.9%, $p = 0.05$).

Contemporary trials will hopefully provide more guidance as to the role of ovarian ablation in women with hormone-positive breast cancer. This is an especially important issue given the marginal benefits of chemotherapy in women with ER-positive breast cancer and the availability of antiestrogen endocrine therapy. Whether ovarian ablation adds an additional benefit to endocrine therapy remains a question not sufficiently addressed.

Endocrine Therapy in Metastatic Breast Cancer

Hormonal therapy is optimal initial therapy in the setting of stage IV hormone receptor–positive breast cancer unless aggressive recurrence mandates chemotherapy to maximize time to response (e.g., significant hepatic metastasis). Options include ovarian suppression in the premenopausal setting with or without the addition of tamoxifen or an aromatase inhibitor, or even tamoxifen alone. In the postmenopausal setting, tamoxifen or aromatase inhibitors are initial appropriate options, with data suggesting that aromatase inhibitors might be more effective as first-line therapy when compared to tamoxifen and have more favorable toxicity profiles (273). Fulvestrant is a pure antiestrogen approved for use in the postmenopausal setting and is given by monthly intramuscular injection. Data from the EFFECT trial demonstrate equivalence to exemestane as second-line therapy after use of a nonsteroidal aromatase inhibitor (274). The goal of treating recurrent disease is palliative, trying to prolong survival while maximizing quality of life and minimizing treatment-related toxicities. Response to initial hormonal therapy can be predictive of response to subsequent hormonal treatments, which can be achieved with serial endocrine agents over many years (273,275). Hormonal resistance can evolve over time, necessitating the use of chemotherapy for cancer control. The mechanisms behind the evolution of hormonal resistance and strategies to reinduce hormonal sensitivity in stage IV breast cancer are actively being investigated.

Neoadjuvant Endocrine Therapy

As in the adjuvant and metastatic setting, hormonal therapy can also be beneficial for women presenting with locally advanced breast cancer. If chemotherapy is not being employed, neoadjuvant (preoperative) hormonal therapy in the hormonally positive setting can be important in increasing the ability to surgically resect the primary tumor as well as to

increase the ability for breast-conserving surgery. Studies suggest that neoadjuvant aromatase inhibitors are superior to tamoxifen in the postmenopausal setting.

Endocrine Therapy for Prevention

The use of tamoxifen in early adjuvant trials appeared to have the benefit of decreasing the risk of second primary breast tumors. As well, tamoxifen in the NSABP B-24 trial has demonstrated a decreased risk of invasive and *in situ* disease in women with a history of ductal carcinoma *in situ* (DCIS) (164). Based on these findings, the NSABP has studied the use of tamoxifen in high-risk women. Requiring a Gail model risk for developing breast cancer over 5 years of at least 1.66%, the NSABP randomized over 13,000 high-risk women 35 years of age or older to receive tamoxifen or placebo (260). After a median follow-up of 69 months, tamoxifen decreased the risk of breast cancer by approximately 50%. Women with atypical ductal hyperplasia (ADH), which, like lobular carcinoma *in situ* (LCIS), is a risk factor for subsequent breast cancer, had the greatest benefit for breast cancer risk reduction of 86%. The incorporation of tamoxifen as a risk reduction strategy has been limited, however, based on potential toxicity and on the modest absolute benefits it likely provides. For example, if a woman has a risk for developing breast cancer of 1% per year, the absolute benefit of tamoxifen as risk reduction would be 0.5% per year.

To maintain efficacy and decrease toxicity, the NSABP P-2 trial (STAR trial) studied the use of tamoxifen or another SERM, raloxifene, as prevention for high-risk postmenopausal women (166). Published in 2006, raloxifene appeared similar to tamoxifen in decreasing the risk of invasive breast cancer but was less effective in decreasing the risk of DCIS, which appears counterintuitive and requires further study. Raloxifene was associated with a reduced incidence of endometrial cancer compared to tamoxifen, though this was not a statistically significant finding. Overall, it did provide a more favorable toxicity profile.

Still, based on these two trials, both raloxifene and tamoxifen are FDA approved for cancer prevention. While tamoxifen can be used in both pre- and postmenopausal women, raloxifene is reserved as a risk-reducing agent only in postmenopausal women who would have met risk eligibility for the NSABP P-2 trial. Further efforts to study risk reduction, such as the benefit of aromatase inhibitors compared to raloxifene, have been thwarted by the lack of NCI funding.

RADIATION THERAPY

Radiation therapy is a well-established treatment modality in breast cancer, and for women with localized, operable breast cancer, breast conservation surgery followed by radiation provides as effective treatment as mastectomy. It is noteworthy, however, that one of the first studies to compare radical mastectomy with breast conservation surgery and radiation was negative (276). The study, reported by Atkins et al., showed a high degree of unacceptable local recurrences and inferior survival rates with the use of radiation. Further examination of the trial design, however, showed that the dose of radiation was insufficient compared to modern standards; most patients received only 35 to 38 Gy. In addition, the radical mastectomy group ultimately received adjuvant nodal radiation, including to the internal mammary nodes. Fortunately, this did not deter other investigators.

The NSABP B-04 trial was one of the first to evaluate nodal irradiation and total mastectomy to radical mastectomy in lymph node–positive patients (277). It was followed by the

EORTC 10801 trial, which compared breast conservation (with radiotherapy) versus mastectomy, and this trial also showed equivalent survival (both disease-free and overall survival) endpoints (162). However, the rate of locoregional recurrence was significantly different, with a rate of 20% in those treated with breast conservation and 12% in those treated with mastectomy ($p = 0.01$). Examination of results was noteworthy in that 50% of the lumpectomy specimens had positive margins. With adoption of the “negative margin,” however, the subsequent trial, NSABP B-06, showed a decrease in local recurrence with lumpectomy and axillary lymph node dissection from 39.2% in those not receiving radiation compared with 14.3% for those treated with adjuvant radiation (197). These results were confirmed by the Milan III trial of quadrantectomy plus axillary lymph node dissection with and without radiation therapy (278).

In 1989 the NSABP initiated the B-21 trial for all age women with tumors up to 1 cm, estrogen receptor–positive, lymph node–negative invasive breast cancer (279). Women were randomized to adjuvant treatment with tamoxifen alone versus radiation plus placebo versus tamoxifen plus radiation with primary endpoints of in-breast tumor recurrence (IBTR) and incidence of contralateral breast cancer (CBC). This study enrolled over 1,000 women and showed that tamoxifen was not as effective in preventing IBTR as radiation when given as single therapies, and that both were less effective than tamoxifen plus radiation; the incidence of IBTR at 8 years was 16.5%, 9.3%, and 2.8%, respectively. However, the rates of distant recurrences were similar between the groups and, in fact, no overall survival advantage was seen with any of the modalities used; 8-year overall survival was 93% in the tamoxifen group, 94% in the radiation group, and 93% in those receiving both ($p = 0.93$).

Besides work evaluating the role of radiation in small breast tumors, research into the role of radiation therapy among older cohorts of women has been evaluated recently. A Canadian trial examined the possibility of omitting radiation for women 50 years and older with node-negative tumors less than or equal to 5 cm. Participants ($n = 769$) were randomized following lumpectomy to tamoxifen alone or with radiation, though it is notable that the majority of patients were over 60 with tumors less than 3 cm (280). At 5 years the addition of radiation led to a significant decrease in local recurrence in the breast and axilla, 7.7% without versus 0.6% with radiation. However, there was no difference noted in the rate of distant recurrence or overall survival. A subsequent trial by CALGB evaluated the additional benefit of radiotherapy in women over 70 years old treated by lumpectomy and tamoxifen and showed similar results (281). While the rate of local recurrence was higher among women who did not receive radiation (4% vs. 1% in those who received breast radiation, $p < 0.001$), there were no other differences in distant disease or 5-year overall survival.

Although individual trials failed to show an improvement in overall survival with the use of adjuvant radiotherapy, the Early Breast Cancer Trialists' Collaborative Group meta-analysis of radiation after both breast-conserving surgery and mastectomy demonstrated a small but significant overall survival benefit for radiation therapy, with a gain at 15 years of 5.3% and 4.4%, respectively (282). Radiation produced a 70% reduction in the risk of local recurrence irrespective of age, tumor grade/size/estrogen receptor status, or amount of nodal disease, which corresponded to a 17% to 19% absolute reduction in 5-year local recurrence. This was demonstrated despite an excess of mortality in the radiation arms from causes other than breast cancer—namely, lung cancer and cardiac disease. Most local recurrences (~75%) were discovered within the first 5 years and appeared nearby the primary tumor. These should be considered “true recurrences,” whereas those

occurring beyond 5 years were more likely to represent new primary breast cancers (282).

The value of including the nodal areas in the radiation field for patients with positive lymph nodes remains controversial and we await the results of currently enrolling trials including EORTC 22922, which is evaluating the role of radiotherapy to the internal mammary and supraclavicular regions in stage I-III patients. A similar trial by the National Cancer Institute of Canada is ongoing. In the absence of randomized data, radiation is considered for patients with multiple positive lymph nodes.

The standard radiation therapy field after breast conservation surgery encompasses the entire breast tissue plus or minus some or all the regional lymph nodes (axillary/supraclavicular/internal mammary) depending on the extent of the axillary-node dissection as well as the pathologic findings in those nodes dissected. In those patients requiring chemotherapy it is usual for it to precede radiation therapy, and a recent update on a study from the Joint Center for Radiation Therapy found no difference in local control, site of first failure, time to any event, distant metastasis-free survival, or overall survival when chemotherapy was given before or after radiation therapy (283). In this study, the delivery of chemotherapy before radiation was notably beneficial for patients with greater than or equal to four positive lymph nodes, and the delivery of radiation prior to chemotherapy appeared to benefit patients with close but not positive margins.

For women who undergo a mastectomy and are deemed to be at high risk for local failure, postchemotherapy irradiation to the chest wall and regional lymphatics is indicated. Criteria that are used to consider one "high risk" has been reconsidered on the basis of randomized trials published in the late 1990s. The Danish Breast Cancer Cooperative Group (DBCCG) conducted a randomized trial involving 1,708 premenopausal women with pathologic stage II or III breast cancer who were randomized to CMF with or without irradiation of the chest wall and regional nodes (284). Radiation therapy was associated with a reduction in locoregional recurrence (alone or with evidence of distant disease) over those who received chemotherapy only, 9% versus 32%, respectively ($p < 0.001$). It was also associated with a survival benefit at 10 years where 54% who received radiation were alive, compared to 45% who had received CMF only ($p < 0.001$). Ragaz et al. reported on a similar trial comparing CMF with or without radiation therapy, but in 318 postmenopausal women with node-positive disease (285). In this group of women, the addition of radiation therapy was associated with a significant reduction in the rate of recurrence (relative risk, 0.67; 99% CI, 0.50 to 0.90) and in mortality (relative risk, 0.71; 95% CI, 0.51 to 0.99). In 1999, the results of DBCCG trial 82c, which randomized stage II-III postmenopausal women to tamoxifen with or without radiation, was published (286). Over 1,300 women were enrolled, but tamoxifen in this trial was prescribed as 30 mg daily for only 1 year. With a median follow-up of over 10 years, radiation therapy was associated with a significant reduction in locoregional recurrence, 8% versus 35% with 1 year of tamoxifen ($p < 0.001$). Overall survival was 45% and 36%, respectively ($p = 0.03$).

In Situ Breast Disease

Approximately 20% of patients treated with local excision alone for DCIS have a recurrence, with about half of these recurrences being invasive cancer. Given this, radiation is often delivered as a means of risk reduction. To date, three randomized trials have compared excision alone with excision followed by whole breast radiation therapy and all demonstrated that radiation therapy reduces the risk of a subsequent breast event by 38% to 62% (287–289).

The NSABP B-17 trial enrolled over 800 women with localized DCIS to lumpectomy with or without radiation and showed a statistically significant reduction in both noninvasive in-breast tumor recurrence (IBTR, 13.4% without radiation vs. 8.2% with radiation, $p = 0.007$) and invasive IBTR (13.4% vs. 3.9%, respectively, $p < 0.0001$) (289). EORTC 10853 enrolled over 1,000 women with surgically excised DCIS up to 5 cm in widest diameter to observation or radiation (288). The reported 4-year local relapse rate was 84% and 91%, respectively ($p = 0.005$) with similar reductions seen in both invasive and noninvasive recurrences. Finally, Houghton et al. reported on a 2×2 randomized trial in this population where over 1,700 women were randomized to both radiation and tamoxifen, either as a single agent, or to no further therapy (287). Although reported follow-up was only 1 year, recurrent DCIS was already shown to be reduced with tamoxifen treatment (HR 0.68; 95% CI, 0.49 to 0.96). Radiation was shown to reduce the incidence of both ipsilateral invasive (HR 0.45; 95% CI, 0.24 to 0.85) and noninvasive disease (HR 0.36; 95% CI, 0.19 to 0.66). The issue of tamoxifen therapy and radiation therapy has been further addressed by the NSABP. Unlike the prior study, the B24 trial showed that the addition of tamoxifen further reduced the number of invasive breast cancer events by 50% and did so in both breasts, but had a nonsignificant effect on reducing the DCIS recurrences (290).

Finally, a recent meta-analysis of the role of radiation in breast conservation therapy for DCIS demonstrated an approximate 60% reduction in local recurrence (291). The greatest benefit was seen with high-grade lesions and/or positive margins, but all age groups benefited, and as expected there was no difference in distant metastases or survival rates.

Radiation Therapy in Recurrent Disease

Palliative radiation for painful or recurrent locoregional disease in the chest wall or regional lymphatics is quite effective and has also been used to treat lesions involving the bone, brain, spinal cord, liver, and lung among other areas. Many of these lesions are now being treated on stereotactic body radiotherapy (SBRT) trials whereby a limited number of large fractions are delivered to a well-localized site (292). Palliative radiation courses usually last from a one-time 8 Gy 1-day treatment to a 2- to 3-week course of 2.5 to 3 Gy per fraction for a total dose of 30 to 37.5 Gy. There is less concern about the late effects associated with these large fractions given that most of these patients may not survive long enough to experience them. This stands in contrast to the 6- to 8-week course of low-dose-per-fraction radiation usually used to treat localized disease where the focus is on both cure and minimizing long-term/late side effects of radiation therapy.

Radiation Therapy Techniques for the Intact Breast

Following breast conservation surgery, the entire residual breast tissue, along with a small portion of the underlying chest wall and lung, is included in the irradiated volume, although careful attention to these areas is given to limit their exposure. Before treatment, patients undergo a planning session or simulation to ensure the radiation field has been mapped out. It is essential that the plan be consistently applied on a day-to-day basis to ensure the uniformity of treatment. Small tattoos are placed to ensure proper localization on a daily basis. In women who require retreatment for chest wall disease, they also serve to define the original field to avoid overlapping fields (Fig. 29.30).

FIGURE 29.30. Medial breast/chest wall tangential field with axillary lymph node levels I, II, III and supraclavicular nodes outlined. *Source:* Reprinted with permission from Goodman RL, Grann A, Saracco P, et al. The relationship between radiation fields and regional lymph nodes in carcinoma of the breast. *Int J Radiat Oncol Biol Phys* 2001;50(1):101.

Photon energies of 4 to 6 MV are preferred to treat the breast. Energies greater than 6 MV may underdose superficial tissue beneath the skin surface, but may be helpful in large breasts to decrease the integral breast dose, and wedges are used to achieve uniform dose distributions. It is usually unnecessary to apply bolus (tissue equivalent material) to the skin as it is not at risk for recurrence, unlike in the postmastectomy setting where the bolus is applied to the mastectomy scar to increase dose superficially.

As the excised tumor bed may also harbor microscopic foci of disease, a radiation boost to the tumor bed is often given and consists of a series of an additional five to eight treatments directed to the tumor bed plus a 1.5- to 2-cm margin. However, the need for a boost if the surgical margins at breast excision are clear is controversial. The EORTC 22881-10882 trial involved over 5,500 women with stage I or II breast cancer who were randomly assigned to whole breast treatment with or without a “boost” dose of 16 Gy (293). At 10 years, the rate of local relapse was 10.2% in the no-boost group and was 6.2% in the boost group ($p < 0.0001$), but there was no difference in overall survival noted (82% in both arms). A subsequent trial from France was also conducted with similar reduction in local relapse with a 10 Gy boost dose (294).

Irradiation of Regional Lymphatics

Most tangential breast fields include at least level I axillary lymph nodes inadvertently. The low axilla (levels I and II) is

FIGURE 29.31. A right-sided supraclavicular field including the supraclavicular nodes as well as the axillary lymph node levels II and III as outlined. *Source:* Reprinted with permission from Goodman RL, Grann A, Saracco P, Needham MF. The relationship between radiation fields and regional lymph nodes in carcinoma of the breast. *Int J Radiat Oncol Biol Phys* 50(1):102.

treated along with the supraclavicular field when there is extranodal/capular invasion, when greater than 50% of the lymph nodes removed are involved with carcinoma, or in the absence of an adequate axillary dissection. The supraclavicular field is extended inferiorly to the second rib or angle of Louie to cover the axilla while the lateral border falls off the anterior axillary fold of skin (Fig. 29.31). A supplemental dose delivered by a posterior axillary boost (PAB) ensures complete radiation therapy has been accomplished (Fig. 29.32). An EORTC trial is ongoing whereby patients with a positive sentinel lymph node are randomized to axillary radiation without axillary lymph node dissection or to axillary lymph node dissection in an attempt to avoid extra surgery in these patients.

Irradiation of the supraclavicular area is indicated in women with three or more axillary nodes involved. For purposes of radiation planning, surgical clips in the area of axillary dissection provide a useful guide to the design of this radiation field. Ideally, the humeral head is shielded without compromising coverage of the high axillary lymph nodes (level III).

FIGURE 29.32. A left-sided posterior axillary boost (PAB) field showing the nearby levels I, II, and III axillary lymph nodes as well as the supraclavicular nodes as outlined. *Source:* Reprinted with permission from Goodman RL, Grann A, Saracco P, et al. The relationship between radiation fields and regional lymph nodes in carcinoma of the breast. *Int J Radiat Oncol Biol Phys* 50(1):103.

The total dose delivered to the supraclavicular field is 46 to 50.8 Gy. If supraclavicular node involvement is documented on biopsy, this area may be treated with a “boost” as well.

Radiotherapy to the internal mammary lymph nodes remains unresolved, although the internal mammary nodes (IMNs) are not considered to be a necessity in most patients since most patients who would be “at risk” are usually candidates for adjuvant endocrine or chemotherapy. Still, it may be an appropriate consideration in women with medial breast tumors, those with tumors larger than 2 to 3 cm, those with multiple involved axillary nodes, or those with biopsy-proven or radiographically suspected IMN involvement. If treatment is recommended, the lymph nodes should be outlined using the CT obtained at simulation by covering the first three intercostal spaces medially while limiting the heart dose as much as possible on the left side (295). Active breathing control devices have been used to spare the heart dose, whereby radiation is delivered during maximum inspiration when the heart is pushed out of the radiation field by the expanded lung (296).

Irradiation Dose to the Contralateral Breast

A dose of 0.5 to 2 Gy to the contralateral breast has been reported in women receiving a dose of 50 Gy to the intact breast with the use of tangential fields (297). As expected, radiation fields encompassing the regional lymph nodes increase the dose to the contralateral breast significantly. A detailed dosimetric study demonstrated that most of the scatter dose received by the opposite breast originates in the collimator and accessories of the accelerator and can be significantly decreased by increasing the distance between the source and the patient’s skin (298). The use of independent jaws combined with beam splitters following the contour of the chest wall of the patient can be very helpful in decreasing the dose to the contralateral breast. Most breast radiation plans include a lateral and medial wedge. The medial wedge, however, contributes most to the contralateral breast dose, and attempts at treatment without this wedge have been successful with a resultant decrease in contralateral breast dose without a significant decrease in dose homogeneity in the treated breast (299). The clinical significance of the inadvertent radiation dose to the opposite breast is uncertain, with various studies failing to show an increased risk of contralateral breast cancer (300–302).

Irradiation Techniques to the Chest Wall

For women undergoing chest wall radiation following mastectomy, the technique in large part is determined by their anatomy, and the area treated includes the chest wall and supraclavicular fossa. If a patient has undergone an immediate reconstruction, a three-field technique is used, with two tangential fields directed at the chest wall and reconstruction with a third, carefully matched field encompassing the supraclavicular nodal area and the apex of the axilla. Photon beams are in the 4 to 6 MV range, and doses of 50 Gy over 5 weeks are appropriate, with a boost dose of 10 Gy to the mastectomy scar itself. For patients undergoing mastectomy in whom adjuvant radiation is being considered, simultaneous consultations involving plastic surgery and radiation oncology are recommended before surgery to discuss the timing and appropriateness of reconstruction and radiotherapy. In most cases, the reconstruction should occur after the radiation is completed to increase the probability of implant viability and cosmesis of the reconstructed breast (303).

For women who recur in the chest wall or regional nodes, treatment should be approached with curative intent. If possible, surgical resection remains the best option for long-term disease control and adjuvant radiotherapy may increase this likelihood. The radiation fields are similar to the approach for

the postmastectomy patient in terms of field design and dose. If palpable disease remains following resection, a boost is used to increase the total dose over 50 Gy in the affected field.

FOLLOW-UP CARE

Women treated for a diagnosis of breast cancer should be examined every 3 to 4 months for the first 2 to 3 years, then every 4 to 6 months to year 5, and then annually. Ideally, visits should be split among a woman’s multiple providers, including her surgeon, medical oncologist, radiation oncologist, and her primary care providers. Cancer follow-up requires history and physical with careful attention to new or increasing symptoms. For example, new bone pain that wakes one up from sleep may be a sign of new onset bone metastases and would require a bone scan. For the asymptomatic patient, there is no role for surveillance lab work, tumor markers such as CEA, CA 15-3, and CA 27-29, or radiographic testing and they are not recommended (304). Although they may lead to an earlier diagnosis of metastatic disease, there is no evidence that they impact survival (305). Attention to screening should be emphasized annually, and this includes tracking dates of mammography, breast MRI in high-risk patients, and screening colonoscopy (if over the age of 50 or earlier in the presence of a family history of colon cancer). Addressing health risks should be a part of routine follow-up, including smoking cessation and discussion of alcohol use. Finally, screening for issues such as sexual dysfunction, depression, and anxiety is important, as they are known to be issues in cancer survivors and can profoundly affect long-term quality of life.

SEQUELAE OF TREATMENT

The multidisciplinary treatment program can be difficult for women. Each modality has its own set of side effects and the duration of treatment (up to or more than 1 year in some cases) can exert a psychological and emotional toll.

Women who have received chemotherapy report difficulties with short-term memory (“chemo-brain”) which may or may not resolve with time, and if severe, can even have an impact on a woman’s ability to work. Unfortunately, the magnitude of the problem remains poorly characterized. Both doxorubicin and trastuzumab can affect cardiac function, which may not be reversed with the passage of time. In a recent review of trials that evaluated trastuzumab into anthracycline-containing adjuvant treatment, as much as 4% of patients experienced congestive heart failure, going as high as 14% in the NSABP B-31 trial, which in some cases was not reversed (306). Fatigue is an almost universal consequence of chemotherapy, worsens with each successive cycle, and may take a year or more to resolve. Severe menopausal symptoms and accelerated bone loss are potential issues for the premenopausal woman who experiences chemotherapy-induced amenorrhea. Treatments for hot flashes are readily available and include use of antidepressants, gabapentin, and vaginal estrogen preparations. Caution is required with the use of vaginal estrogen tablets, particularly in women with hormone-positive breast cancers, as the impact of even low subclinical rises in estrogen levels on effectiveness of antiestrogen agents (especially the aromatase inhibitors) and consequently on tumor relapse is unknown. Recently the empiric use of the bisphosphonate residronate was evaluated in this population in a randomized, placebo-controlled trial and demonstrated that treatment significantly increased bone mineral density at both the hip (by 1.3%) and the spine (by 1.2%), compared to placebo where decreases of 0.9% at the spine and 0.8% at the hip were seen ($p < 0.01$) (307). The Cancer and Leukemia

Group B has recently completed a similar trial (CALGB 79809) evaluating the use of zoledronic acid compared to placebo and results are awaited. Finally, a recently described arthralgia syndrome can accompany treatment with the aromatase inhibitors, and may lead to cessation of this therapy in some patients (308). The incidence and etiology of this have yet to be elucidated.

Besides the side effects of chemotherapy, there are sequelae from radiation treatment that may occur acutely or follow the end of treatment, taking months to years after treatment to manifest. The most common acute effects of radiation therapy include fatigue, skin irritation, breast swelling, and general breast discomfort; other side effects include muscle pain (in motion), incision-site pain, and rib pain. In one series, 31% of patients complained of breast swelling and approximately 20% complained of breast pain following radiation therapy after breast-conserving surgery (309). In another, approximately 10% to 15% of patients developed moist desquamation during their treatment (310). Generally, this occurs in the inframammary fold and can be treated conservatively. Very rarely, a patient will need a break for any of the above conditions. Almost all patients experience some form of fatigue, which is generally mild and manageable and improves over time. Most patients recover to baseline within 2 months after completion of the radiation treatment.

Of the late effects of radiation treatment in a woman who has undergone breast conservation, perhaps one of the most disturbing can be impaired cosmesis secondary to fibrosis and atrophy (311). Cosmetic outcome has been directly related to adjuvant chemotherapy, the dose of radiation, fraction size, and the degree of surgery (311,312). Whole breast radiotherapy doses greater than 50 Gy as well as total dose to the tumor site greater than 65 Gy have been shown to adversely affect cosmesis (313). Abner et al. reported on the cosmesis outcomes in 1,625 patients receiving BCT and chemotherapy, showing that long-term cosmesis was remarkably worse for those receiving concurrent and sequential chemoradiation as compared to radiation alone (314). Excellent cosmesis was seen in 56% of patients receiving sequential therapy versus 32% for concurrent chemoradiation and 75% for no adjuvant chemotherapy.

Arm edema is also one of the most feared late-term complications of radiation treatment, and the incidence of this complication is related to the extent of axillary surgery and regional radiation (315–320). Arm edema is found in only a few percent of women who undergo sentinel lymph node biopsy, level I-II dissection, or radiation alone, and adding nonaxillary radiation to a more limited surgery does not substantially increase the risk of arm edema (321,322). However, women who experience axillary node dissection and axillary radiation have a significantly higher risk of arm edema (323,324). In one report that included 200 women treated for early-stage breast cancer, arm edema developed in 38% of those treated with axillary node dissection plus axillary radiation compared to 7% to 9% of those undergoing either axillary node dissection or axillary radiotherapy (323).

Symptomatic pneumonitis is an infrequent occurrence after breast conservation surgery and is noted 1 to several months after irradiation (325). Patients present with dry cough (88%), shortness of breath (35%), or fever (53%). On radiographic studies a pulmonary infiltrate is observed in the irradiated volume (326). The risk of radiation pneumonitis is directly related to the volume of irradiated lung and is approximately 5% when treating the chest wall where there is minimal lung volume in the field (326,327). The risk increases when a supraclavicular field is added or the internal mammary nodes are treated (328,329). Concurrent chemotherapy has also been shown to increase the risk of pneumonitis. One study showed that when patients treated with the three-field

technique received chemotherapy concurrently with irradiation, the incidence of radiation pneumonitis was 8.8% (8 of 92) compared with 1.3% (3 of 236) for those who received sequential chemotherapy (329). Of note, when radiation was given to the breast alone without chemotherapy the incidence was 0.5% (6 of 1,296, $p = 0.002$). There have been conflicting data involving increased risk of pneumonitis when taking tamoxifen concurrently with radiation. Two studies found an increased risk of pulmonary fibrosis, while a series from Fox Chase Cancer Center did not show an increase in clinical radiation pneumonitis (330–332).

Another concern related to breast radiation is cardiac toxicity. The most significant risk factors for this side effect include older radiation techniques, the addition of chemotherapy, and treatment of left-sided breast cancer. Fortunately, improvement in radiation technique has substantially decreased late-term cardiac complications, and most recent trials utilizing modern radiation techniques have found no increase in cardiovascular toxicity (333–336). Valagussa et al. reported on cardiac effects after adjuvant chemotherapy and breast irradiation for operable breast cancer (333). They retrospectively evaluated 825 women in prospective trials with respect to irradiation, with or without administration of doxorubicin; 360 patients had breast conservation therapy. With a median follow-up of 80 months, the overall incidence of congestive heart failure in all patients was 0.5%. Patients receiving doxorubicin chemotherapy without irradiation had a 0.8% incidence of congestive heart failure. Patients receiving both doxorubicin and left-breast irradiation had an incidence of 2.6%, and two fatalities secondary to congestive heart failure occurred in this group.

Brachial plexus dysfunction is another possible complication of regional nodal radiation therapy and must be distinguished from neuropathies caused by axillary dissection or recurrence. Pierce et al., in a review of 1,624 patients, reported brachial plexus involvement in 1.8% of patients, though other investigators have found the incidence to be less than 1% (321,332,337).

Pregnancy and Fertility in the Breast Cancer Survivor

It has been reported that approximately 5% to 15% of young breast cancer survivors will become pregnant following treatment (338). Currently, there are no prospective studies evaluating the safety of a subsequent pregnancy after a diagnosis of breast cancer, but several retrospective studies have demonstrated no worsening of survival or increased risk of recurrence (339–342). Of interest, a number of studies report that pregnancy is associated with an improved survival, though the issue of the “healthy mother effect” as a potential confounder has been reported (339). That is, only women who feel physically and emotionally healthy will attempt pregnancy while those who continue to be affected by the disease do not. Alternatively, it is possible that the high hormonal levels of pregnancy have a beneficial effect given the documented anti-tumor effects seen both *in vitro* and in animal models of high-dose estrogens and progestins (338).

Those women who become pregnant following breast cancer treatment may be able to breast-feed, though this has only been reported in case series. Higgins and Haffty reported on 11 patients who subsequently experienced 13 pregnancies (343). Lactation was possible in the treated breast in four of ten women; in three, lactation was pharmacologically suppressed. The time interval from initial treatment to delivery did not appear to affect successful lactation. Still, this issue will need to be studied in larger series.

It may seem helpful to wait before attempting pregnancy since this is the time of highest risk of recurrence, but the available data have not clearly shown a worse prognosis if pregnancy is achieved sooner. Discussing fertility options after receiving treatment for breast cancer may be too late. Several investigators have reported that women prefer to discuss these issues at the time of treatment planning and early follow-up, suggesting that options for preserving fertility should be addressed early, including a referral to a fertility specialist as needed (344,345). Recently, the American Society of Clinical Oncology (ASCO) convened an expert panel to develop guidelines for fertility preservation and made similar recommendations (346). Still, concerns that embryo banking will inappropriately delay necessary treatment for newly diagnosed patients have been raised. A recent report by Madriagno et al. compared time intervals between egg retrieval and treatment in 23 newly diagnosed women with breast cancer. He reported that there was no delay, with average time from first consult to egg retrieval of 33 days, and time from definitive surgery to start of chemotherapy at 47 days. This suggests that embryo banking could be incorporated into the workup and surgical management of new breast cancer patients, again emphasizing the importance of early referral to reproductive specialists (347).

SPECIAL CONSIDERATIONS

Breast Cancer in Pregnancy

Pregnancy-associated breast cancer is defined as cancer diagnosed during pregnancy, lactation, or up to 12 months postpartum (348). Among women of child-bearing potential, approximately 13% of breast cancers will occur in this group, and among women younger than 40 years an estimated 10% will be pregnant (349,350). As increasing numbers of women delay pregnancy, many speculate that the incidence of pregnancy-associated breast cancer will increase.

Most women diagnosed with pregnancy-associated breast cancer present with a painless breast mass. While the differential diagnosis of a palpable mass during pregnancy involves a majority of benign masses, including lactating adenomas, fibroadenomas, and galactoceles, evaluation is warranted if palpable findings persist. Clinical breast examination is limited in a pregnant patient due to hormonally induced breast engorgement. Similarly, the usefulness of mammography during pregnancy has been questioned; however, recent studies show that with proper abdominal shielding, the irradiation dose to the fetus from a standard two-view mammography is less than 50.5 μ Gy, which is within the limits considered acceptable during pregnancy and well below the threshold exposure of 10 rad (100 mGy), where the estimated risk of fetal malformation and central nervous system (CNS) problems is 1% (351).

Studies on the effectiveness of imaging in pregnant cancer patients are limited. Yang et al. performed a retrospective study of 23 women with 24 cancers diagnosed during pregnancy (352). Of those who underwent preoperative mammography, radiographic findings were "positive" in 18 out of 20 cancers (90%) despite dense breast parenchymal patterns; the addition of ultrasonography was noted to be 100% sensitive. Although MRI has been used during pregnancy, the gadolinium required for a meaningful breast study crosses the placenta and is associated with fetal abnormalities in animals (category C), and thus contrast-enhanced breast MRI cannot be recommended (348).

As happens for nonpregnant women, negative findings on breast imaging should not delay obtaining definitive diagnosis in a persistently palpable mass. Currently ultrasound-guided core biopsies can be performed safely and this is the preferred

method for diagnosis. Despite concerns to the contrary, reports of milk fistulae are rare (353).

Historically, studies reported that pregnancy-associated breast cancer had a dismal prognosis with survival rates of less than 20% at 5 years (354–356). These statistics may have reflected the later diagnosis of these lesions, as pregnancy-associated cancers are typically larger and more often node positive (56% to 89%) compared to nonpregnant women (38% to 54%) (357,358). In addition, patients diagnosed in pregnancy frequently have high-grade tumors, are hormone negative, and are HER2/neu positive (358–360). Therefore, after controlling for these factors, patient age and stage of diagnosis at presentation, the overall prognosis of patients appears similar to nonpregnant women, and the 5- and 10-year survival for node-negative and node-positive pregnancy-associated breast cancer ranges from 60% to 100% and 31% to 52%, respectively (348,351).

There is no role for termination to improve prognosis, and it is not considered a therapeutic option. The safety of surgical intervention during pregnancy is well established, and modified radical mastectomy is considered the standard of care. This approach virtually eliminates the need for irradiation and allows optimal control of disease within the axilla. However, breast conservation is increasingly seen as a reasonable alternative to pregnant women, particularly if diagnosis is made in the latter second and third trimesters, when breast irradiation can be safely delayed until the postpartum period. In addition, for the patient presenting with locally advanced disease, the increased use of neoadjuvant chemotherapy allows a delay in definitive surgical management and a concomitant delay in postoperative radiotherapy (348). While full axillary dissection remains the most common approach to lymph node evaluation in pregnant patients, increasing reports have documented the efficacy and safety of sentinel lymph node biopsy despite the numerous concerns raised regarding the risk of fetal irradiation with use of radiocolloid in pregnancy (361–363). Still, sentinel node biopsy in pregnant women has not been systematically evaluated. Currently, it is considered *reasonable* to offer to pregnant patients but only after appropriate counseling. It is important to remember that both isosulfan blue dye and methylene blue dye are classified as pregnancy category C drugs, and intra-amniotic injection of methylene blue has been associated with hemolytic anemia, hyperbilirubinemia, methemoglobinemia, duodenal atresia, deep blue staining of the newborn, and even fetal death (364–367). Whether subareolar injections of dye would result in a similar outcome is unclear; however, its use is generally not recommended.

Most experts consider postoperative therapeutic irradiation during pregnancy to be contraindicated. If breast conservation is chosen, adjuvant radiotherapy is typically delayed until the postpartum period. However, this perspective has recently been challenged by some who feel that the risks of radiation to the fetus are overestimated (368). Kal et al. argue that fetal exposure to radiotherapy can be sufficiently reduced by proper shielding, resulting in fetal exposure doses that fall below accepted threshold doses. Unfortunately, the lack of prospective data continues to make the use of radiotherapy during pregnancy contraindicated.

Given the high prevalence of node-positive disease among women diagnosed with breast cancer during pregnancy, chemotherapy plays a crucial role in both the adjuvant and neoadjuvant treatment of these women. The effects of chemotherapy on fetal development and growth vary depending on gestational age. When administered during the first trimester, chemotherapy can result in high rates of miscarriages and malformations (369). As a result, chemotherapy is generally contraindicated during this period of organogenesis. Outside of the first trimester, chemotherapy has proven to be safe, although all chemotherapy agents are still considered category D agents. The overall incidence of major fetal malformations

following administration of chemotherapy in the second and third trimesters is reported to be ~3%, which is similar to the estimated baseline population risk of major congenital malformations (2% to 3%) (370). The most commonly reported side effects are fetal growth restriction, low birth weight, preterm delivery, and transient leukopenia of the newborn.

Several prospective case series have reported on the use of anthracycline-based chemotherapy administered every 3 to 4 weeks during the second and third trimesters (371,372). Hahn et al. reported that among 57 women treated with FAC in the second and third trimesters, there were no stillbirths reported, and no miscarriages or perinatal deaths (371). The most common neonatal complication was respiratory distress and 10% required ventilatory support; one child developed a subarachnoid hemorrhage in association with thrombocytopenia and neutropenia. The potential risk of anthracycline-associated fetal cardiotoxicity later in life during childhood or adulthood remains a concern for those fetuses exposed to chemotherapy *in utero*. Despite this, Meyer-Wittkopf et al. were not able to identify any abnormalities on echocardiograms performed *in utero* and up to 2 years of age in infants exposed to doxorubicin and cyclophosphamide starting at 24 weeks gestation (373). Aviles and Neri reported on a cohort of 84 children born to mothers who received combination chemotherapy during pregnancy for hematologic malignancies (374). Physical, neurologic, and psychologic development was normal for all children and there were no malignancies diagnosed in this group of children. At present, the dosing recommendations for chemotherapy during pregnancy are weight based. Current recommendations are to avoid the administration of chemotherapy approximately 1 month before delivery to minimize the possibility of infectious complications or hemorrhage from pancytopenia to either the mother or the fetus. The use of trastuzumab is limited to case reports and currently is considered a category B drug in pregnancy. There are no long-term data available of children following exposure to endocrine agents, such as tamoxifen, *in utero*. However, tamoxifen remains contraindicated in pregnancy and the use of nonhormonal contraception is recommended during tamoxifen treatment and for 2 months after stopping, due to its extended half-life (375).

Breast Cancer in the Elderly

Age is a well-characterized risk factor for the development of breast cancer. Yet despite the high prevalence of breast cancer in older women, there is substantial evidence that they are less likely to receive standard care (376,377). Defining the optimal treatment strategies for these women is complicated by the relatively few numbers of women over 65 enrolled in multi-institutional trials. Barriers to recruitment of older women to multi-institutional trials likely include “physician bias” and/or “patient and family bias,” based on the fear that patients may not tolerate treatment or that the potential toxicity does not outweigh the potential benefits of the treatment (378).

Studies indicate that the survival from breast cancer appears to be worse among older women, though the factors underlying this finding remain unclear (379,380). Although breast cancer presentation in older women may be more advanced at diagnosis, they also tend to be more indolent with a more favorable biologic profile and overall less aggressive disease than in younger women. Multiple studies have shown that breast cancer in older women is typically well- or moderately differentiated, node negative, estrogen and progesterone receptor positive, and HER2/neu negative (115,381,382).

Older patients tolerate surgery, including breast-conserving surgery or mastectomy, as well as their younger counterparts, and the operative mortality of patients who are in reasonable

health with a reasonable functional status is negligible (383). Careful preoperative screening will identify the small group of women who would suffer significant morbidity and/or mortality from surgery.

Some have questioned the benefit of axillary evaluation in elderly women, particularly in the presence of endocrine-responsive disease, but several studies have shown not only that it is feasible, but that treatment decisions are still made on the basis of the nodal status. The International Breast Cancer Study Group compared the outcome of axillary clearance versus no clearance in women older than 60 years (median age, 74 years) with clinically negative, operable breast cancer (384). All women with endocrine-responsive breast cancer received 5 years of tamoxifen. Although axillary relapse was not the primary endpoint, the results were reassuring and showed a low local relapse rate of 2% after 5 years of follow-up. McMahon et al. reviewed the outcomes of 261 women who were 70 years of age or older who underwent a sentinel lymph node (SLN) biopsy (385). The overall SLN identification rate was 97.1% and sentinel node status was associated with significantly different rates of systemic therapy for tumors less than 2 cm, but not with larger tumors. Finally, despite earlier studies suggesting that primary medical treatment with tamoxifen was as effective as surgery for the treatment of operable breast cancer in elderly patients, more recent randomized studies have demonstrated a more favorable outcome following surgical management of these patients. In one, women treated with surgery plus tamoxifen had a 70% relapse-free survival as compared to 47% for those treated with tamoxifen alone (386). Subsequent studies have yielded similar results, and have been confirmed by a recent Cochrane group meta-analysis (387–389).

The role of radiotherapy in older women has also been subjected to trials. In a Canadian trial patients 50 years of age or older with tumors up to 5 cm who had been treated with surgery and tamoxifen were randomized to adjuvant radiotherapy or observation (280). The local recurrence rate among women who underwent radiation and those who did not was 0.6% and 7.7%, respectively. Similarly, CALGB conducted a trial in women 70 years or older and found no significant differences between those who did not and those who did undergo radiation therapy regarding subsequent mastectomy rates, distant metastases, or overall survival. However, the rate of locoregional recurrences was significantly different (1% in those who underwent radiotherapy vs. 4% in those who did not, $p < 0.001$) (281). Based on this, radiotherapy might be reasonably withheld in the older patient who takes endocrine therapy following surgery.

The confirmed benefit of adjuvant hormonal therapy and the associated risk profiles of the available agents must be considered in the older patient. Tamoxifen may cause endometrial cancer, though rarely, and is associated with an increased risk of thromboembolic disease. As such, it is generally not recommended in patients with small (<1 cm) node-negative tumors in the presence of other serious comorbid conditions, particularly if their life expectancy is less than 10 years, as the benefits of endocrine manipulation are not likely to be realized (390). Although the aromatase inhibitors have been shown to be less of a risk in causing endometrial cancer or thromboembolic disease, they did statistically increase the risk of bone fractures compared to tamoxifen (264,268). In addition to bony disease, letrozole demonstrated significant increases in cardiac events compared to tamoxifen, including grade 3-5 ischemic disease (0.6% vs. 1.1%, respectively, $p = 0.013$), and in congestive heart failure (0.1% vs. 0.5%, respectively, $p = 0.006$) (268). For the estimated 30% of older patients with tumors negative for ER/PR receptor expression, decisions about chemotherapy must take into account tumor characteristics, the ensuing risk of relapse, and one's competing comorbidities. Still, chemotherapy may be an option especially in healthy

elderly women with hormone receptor–negative tumors considered at high risk, particularly if their estimated life expectancy would otherwise exceed 5 years (391). Still, the optimal chemotherapy regimens, doses, and schedules for elderly patients remain undefined.

Disparities in Breast Cancer

There is a relative paucity of data regarding outcomes among other ethnic groups, such as Latinas, and hence much of what we have learned about disparities among ethnic minority women we have learned from work done with the African American (AA) community. The impact of racial disparities on breast cancer survival has been the subject of multiple studies. Specifically, it has been well documented that despite a consistently higher incidence of breast cancer among white women when compared to AA women, AA women still suffer the greater mortality from breast cancer (350).

Many attribute the widening racial disparity to the fact that racial and ethnic minorities in the United States often receive less than adequate health care. Health insurance coverage and socioeconomic status have been described as important factors associated with general medical outcomes, but do not entirely explain the disparities in breast cancer in ethnic minority women. Newman and Martin conducted a meta-analysis of studies reporting on survival of AA versus white patients with breast cancer (392). After adjusting for socioeconomic status, age, and stage of diagnosis, they found that AA women still experienced a higher risk of mortality, with a mortality hazard ratio of 1.27 (95% CI, 1.18 to 1.38). Similarly, Field et al. evaluated survival among AA and white breast cancer patients receiving care through the Cancer Research Network, which covers patients using managed care health plans (393). Despite similar health coverage and access to care, 5-year survival was lower for AA women (74% vs. 82%). They concluded that among women with invasive breast cancer, being insured and having access to medical care does not eliminate the survival disparity for AA women. More recently, Jatoi et al. evaluated the medical records of 23,612 women diagnosed and treated for primary breast carcinoma through the Department of Defense health care system (394). They reported that when AA women were compared to white women, the hazard ratio for survival was 1.27 in those diagnosed between 1980 and 1984, but it had increased to 1.85 between 1995 and 1999. Therefore, it appears that inequalities in access to health care, while a reality for many AA women in the United States, are not solely responsible for the racial disparities evident among women diagnosed with breast cancer.

Some argue that differences in tumor biology or other extrinsic factors account for a significant proportion of the disparity evidenced (395,396). It is documented that AA women are diagnosed at a younger age compared to white women and that, compared to white women, AA women experience a higher incidence of disease before 45 years and declining rates after 50 years of age. Reproductive history–related risk factors have been suggested as an explanation for the younger age distribution noted among AA women (397). In addition, reports suggest that a higher frequency of aggressive subtypes of infiltrating ductal carcinoma are present among AA women, such as medullary, basaloid, and inflammatory breast cancer (398,399). Finally, studies have also demonstrated a higher prevalence of high-grade, hormone receptor–negative, and triple-negative breast cancer among AA women with more advanced stages of disease at diagnosis (400,401).

Disparities in the delivery of adjuvant chemotherapy to eligible patients also may account for disparities among AA women, and studies continue to demonstrate this disturbing trend. For example, White et al. reported that among 1,263

patients with node-positive breast cancer eligible for chemotherapy, 85.3% of white women received the indicated treatment, compared to 78.7% of AA and Latina patients (402). More recently, Bickell et al. reported data from six New York City hospitals and found that AA patients were twice as likely to be under-treated with regard to chemotherapy, radiation therapy, and/or endocrine therapy compared with white patients (403). Similar data suggest that surgical therapies, such as sentinel node biopsies and breast reconstruction, are impacted as well (403–406).

Effective evaluation of the determinants of racial disparities in breast cancer treatment will require adequate participation in randomized clinical trials, which means that efforts to increase the proportion of patients offered trials and addressing eligibility so more women qualify for trials are needed. In one study, only 21% of AA patients were offered a clinical trial, compared to 42% of white patients (404). In another, evaluating barriers to enrollment of minorities into clinical trials, Adams-Campbell et al. reported that among 235 AA patients with breast cancer, only 8.5% were deemed eligible for trial participation; most were excluded due to comorbid disease (407).

Documented racial disparities exist in the incidence, treatment, and outcomes of women with breast cancer. Of great concern, the mortality among AA women diagnosed with breast cancer exceeds that of white women, despite a lower prevalence of disease overall. The determinants of these disparities are likely multifactorial, and despite numerous studies evaluating breast cancer treatment among AA women, they remain incompletely understood. Data evaluating other ethnic groups are limited, and emphasizes the need for continued studies into this area of breast cancer research.

FUTURE DIRECTIONS

The evolution in breast therapy continues to move at a very fast pace, with new technologies under development that may transform the landscape of breast surgical practice, medical care, and radiation techniques. These will be briefly summarized.

Surgery: Contemporary Strategies

The literature is replete with reports of the successful use of thermal ablation of lung, liver, bone, adrenal, kidney, and prostate in both the metastatic and primary setting. Advances in the understanding of thermal biology, and advances in both the delivery systems and tumor imaging systems have extended this therapeutic option to other tumor sites, including breast cancer. The initial reports of ablative techniques in breast cancer therapy focused on radiofrequency ablation (RFA) (408). However, this technique suffered from two serious flaws. First, thermal heating is associated with intense discomfort for the patient; second, visualization of the treatment zone is severely compromised when RFA is administered with ultrasound guidance.

Cryoablation represents an alternative to radiofrequency ablation and may be ideally suited to breast cancer therapy (409). First, the majority of invasive breast cancers are identified by mammography, and characterized and biopsied under ultrasound guidance, making the small handheld ultrasound probe an ideal modality to guide breast therapeutic interventions. In addition, cryoablation produces a ball of frozen tissue that is imminently visible under ultrasound, in direct contradistinction to thermally heated tissue. The cryoablative process involves a freeze-thaw-freeze cycle that results in tissue destruction through intracellular ice formation, causing

cellular wall disruption, subsequent osmotic injury, and delayed microvascular disruption leading to tissue ischemia. The usual treatment time for sub 4 cm lesions is 30 minutes. In a prospective, randomized trial, 310 patients undergoing lumpectomy for a diagnosis of breast cancer were randomized to cryoassisted localization (CAL) or needle-wire localization (NWL) (410). Comparisons between the CAL and NWL groups showed no differences in positive margins (for invasive tumor) (28% vs. 31%, respectively) or in re-excision rates. The volume of tissue removed was significantly less with CAL (49 mL) compared to NWL (66 mL, $p = 0.002$). Of note, there was a trend for a higher positive margin rate for *in situ* disease with CAL (30%) versus NWL (18%, $p = 0.052$). The American College of Surgeons Oncology Group is preparing a study evaluating the sensitivity of MRI to detect residual disease after a course of therapeutic cryoablation for infiltrating ductal carcinomas less than 1.5 cm. As we have abandoned axillary dissection for sentinel nodes, so we may in a select group of patients abandon wide local excision for *in situ* ablation.

Medical Therapy: Redefining Standard of Care and Incorporating New Technology

Currently there is no one standard of care in the treatment of breast cancer. Multiple options exist at every stage along the continuum of care for the breast cancer patient. However, ongoing clinical trials will help define appropriate therapies for our patients. The NSABP B-38 trial is a node-positive randomized trial directly comparing dose-dense AC/T to the TAC regimen given every 3 weeks, and compares them to a novel regimen of dose-dense AC followed by paclitaxel and gemcitabine. This trial will help to establish the standard of care in this population. For women with node-negative disease, there is the NSABP B-36 trial, which randomizes women to four cycles of AC versus six cycles of 5-FU, cyclophosphamide, and the novel anthracycline, epirubicin (FEC). Other trials continue to explore drug sequence, such as the Hellenic Oncology Research group trial of epirubicin and docetaxel, as combination or sequential therapy. The NSABP B-42 trial will address the question of extended endocrine therapy by randomizing women completing 5 years of endocrine therapy (in at least 2 of which they must have used an aromatase inhibitor) to letrozole or placebo.

Novel regimens also continue to be explored. In the BCIRG-006 trial, women with HER2/neu-positive breast cancers are being randomized to anthracycline-containing and non-anthracycline-containing regimens. In arm 1 patients receive AC followed by docetaxel; in arm 2, patients will receive AC followed by docetaxel and trastuzumab followed by 1 year of consolidation trastuzumab; and arm 3 patients receive a platinum (carboplatin or cisplatin) and docetaxel followed by trastuzumab consolidation. Along with evaluation of survival endpoints, this novel trial will also explore the comparative toxicity (including cardiotoxicity) of these regimens.

PACCT-1 is the first trial from the NCI Program for the Assessment of Clinical Cancer Tests. It is also known as the TAILOR-Rx trial. Women with node-negative hormone-positive breast cancers will undergo an Oncotype DX test for treatment stratification. Patients who have a low recurrence score will undergo endocrine therapy, while those with a high recurrence score will undergo chemotherapy. Those with an indeterminate recurrence score (RS 11-25) will be the subjects for randomization to chemotherapy or endocrine therapy. This trial will be the pivotal validation study for the Oncotype DX assay and, if positive, will likely lead to its more widespread use in tailoring cancer therapy in this population.

The role of biologics will also be further examined. Most notable in this area will be the role of bevacizumab in the treatment of breast cancer. Contemporary trials are already

under way incorporating this agent in the neoadjuvant, adjuvant, and recurrent disease setting. Already, important trials have been reported on the use of bevacizumab in metastatic breast cancer. One trial compared capecitabine with or without bevacizumab as a second-line therapy for metastatic disease (411). Four hundred sixty-two women were enrolled in this trial with a study endpoint of prolongation of progression-free survival. While the addition of bevacizumab improved response rates (20% with combination vs. 9% with capecitabine alone, $p = 0.001$), there was no difference in either progression-free or overall survival seen. However, in a first-line metastatic disease study, the combination of bevacizumab and paclitaxel was associated with an increased response rate (30% vs. 14%, $p < 0.0001$) over paclitaxel alone, and in improved progression-free survival (HR 0.48; 95% CI, 0.387 to 0.594) (412).

The incorporation of new technology will continue to be a challenge. An example is the use of a recently developed assay to detect circulating tumor cells (CTCs) in the plasma of breast cancer patients. In the seminal paper published in the *New England Journal of Medicine*, Cristofanilli et al. demonstrated that the number of CTCs at baseline and then at first follow-up were independent predictors of both progression-free (PFS) and overall survival (OS) in women with breast cancer (413). At baseline, CTCs of five or more were associated with a shorter median PFS (2 vs. 7 months, $p < 0.001$) and median OS (10 vs. >18 months, $p < 0.001$). At first follow-up, similar findings emerged. Since then, Budd et al. showed that enumerating CTCs was an earlier indication of disease status than radiologic imaging (414). In that trial, 138 patients on a new treatment regimen underwent pretreatment and repeat imaging (at a median of 10 weeks). CTC counts were also determined at 4 weeks following treatment initiation. He showed that among patients who did not demonstrate radiologic evidence of progression, a CTC of five or more was associated with a median overall survival of 15 months, which was significantly shorter than for those with a CTC of less than five who had a median OS of 27 months ($p = 0.04$). The exact role of this assay in the clinic and its use in determining future treatment plans remain an area of active investigation.

Finally, we continue to explore the role of ovarian suppression or ablation in the treatment of breast cancer. Two studies currently ongoing include the SOFT (Suppression of Ovarian Function) trial (BIG 2-02) and the TEXT (Tamoxifen and Exemestane trial). In the SOFT trial, premenopausal women who are ER and/or PR positive will undergo ovarian suppression medically (using triptorelin), surgically, or by way of ovarian radiation therapy. Subsequently, they will be randomized to tamoxifen or exemestane for 5 years. In the TEXT trial, premenopausal patients will be randomized to a combination of triptorelin and exemestane or tamoxifen alone. In both trials, patients may have undergone chemotherapy, but must continue to menstruate to meet eligibility. These results are eagerly awaited.

Evolving Techniques in Radiation Therapy

Accelerated Partial Breast Irradiation

Accelerated partial breast irradiation (APBI) generally entails 5 days of treatment twice a day, and is quickly becoming a treatment of choice for many patients and physicians. Unlike traditional whole breast radiation, this method of radiation treats only the part of the breast where the tumor was located. This localized treatment can be theoretically validated by many pathologic and clinical studies which demonstrate that the majority of local recurrences in breast cancer are located in the same quadrant as the original cancer (415,416). Patients

TABLE 29.10**SELECTION CRITERIA FOR ACCELERATED PARTIAL BREAST IRRADIATION**

Criteria	ABS	ASBS
Age	=45	=45
Histology	IDC	IDC or DCIS
Size	=3 cm	=3 cm
Margin	Negative	Negative microscopic margin
Axillary node status	Negative	Negative

Note: ABS, American Brachytherapy Society; ASBS American Society of Breast Surgeons; DCIS, ductal carcinoma *in situ*; IDC, invasive ductal carcinoma.

at a higher risk of recurrence, including recurrences away from the original tumor, should not be considered candidates for APBI. However, there is no consensus about who belongs to this group. The American Brachytherapy Society and the American Society of Breast Surgeons have established separate, but similar, criteria for administering APBI (Table 29.10) (417).

There have been no completed phase 3 trials comparing recent methods of APBI to conventional whole breast radiation. However, institutional and phase 2 multicenter trials investigating APBI have shown excellent local control rates with low morbidity (418,419). The largest study compared women who had APBI to equally matched, low-risk women who received whole breast radiation, and APBI was associated with similar local recurrence rates. However, the trial suffers from limited follow-up and inclusion of highly selected patients (420). Currently, there are four principal methods of administering APBI: (a) multicatheter interstitial brachytherapy (interstitial), (b) balloon-based brachytherapy, (c) external beam three-dimensional conformal radiotherapy (3D-CRT), and (d) intraoperative radiotherapy (IORT).

Interstitial Brachytherapy

Interstitial brachytherapy, the oldest APBI technique, involves placing catheters surrounding the lumpectomy or seroma cavity. Generally, the catheters will be placed postoperatively 1.0 to 1.5 cm apart, extending 1.5 to 2.0 cm beyond the lumpectomy cavity. A typical implant will require between 14 and 20 catheters. Most commonly, high-dose-rate (HDR) is used with a total of 34 Gy given in ten fractions over 5 days. Although this form of APBI requires the highest level of skill, it is the most adaptable and flexible technique. Any lumpectomy cavity, regardless of size, shape, or location, can be assessed. Because it is the oldest technique, it has the most mature data (316,421). RTOG 95-17 enrolled 99 patients between 1997 and 2000 (316). The selection criteria was very broad, excluding greater than three involved lymph nodes, greater than 3 cm tumors, positive margins, DCIS, and invasive lobular carcinoma. At 3.7 years of median follow-up, the ipsilateral breast tumor recurrence rate (IBTRR) was 3%. Grade 3 or 4 toxicity was seen in 4% of the patients.

Intracavitary Balloon-Based Brachytherapy

Intracavitary balloon-based brachytherapy uses a balloon with a central catheter where an HDR source dwells. The balloon comes in different sizes and shapes to accommodate various lumpectomy cavities. The insertion of the balloon into the lumpectomy cavity is most often done after surgery, when final pathology has been performed. An imaging device, usually either ultrasound or CT, is utilized in the placement of the

balloon. Generally, the physician prescribes 3.4 Gy per fraction to 1 cm away from the center of the balloon. The total dose is 34 Gy in ten fractions over 5 days. In contrast to the multicatheter method of APBI, the MammoSite is very easy to use. Neither the insertion nor the dosimetry requires as much skill or experience, hence its popularity. However, the ability to use the MammoSite is highly dependent upon the geometry and location of the lumpectomy cavity. The radiation oncologist must work closely with the surgeon to ensure that the cavity conforms to the balloon surface while maximizing the balloon-to-skin distance. Often the surgeon must close the cavity subcutaneously to improve the depth to the balloon surface. The balloon occasionally ruptures, requiring replacement of the balloon, reimaging, and replanning. Several acute side effects are common with the MammoSite including erythema, hyperpigmentation of the skin overlying the implant, seroma formation, and breast tenderness. Other, less common side effects include moist desquamation, delayed healing, and infection. Chronic toxicity includes fat necrosis, skin atrophy, telangiectasia, and fibrosis. Intracavitary balloon therapy is fairly new; therefore, long-term data are limited. The longest follow-up is 48 months, in which there have been no local failures and good/excellent cosmesis in 82.5% of the patients (422).

Three-Dimensional Conformal Radiation

3D-CRT is a newer technique in which multiple external radiation beams are used to treat the lumpectomy cavity with a margin. The lumpectomy cavity is identified by surgical clips at the time of the CT planning session. The clinical target volume is expanded 5 mm to include movement secondary to normal breathing and 10 mm for random and systematic components of setup error (423). The planning tumor volume (PTV) excludes the chest wall and 5 mm of skin. Patients are treated with 3.85 Gy per fraction for a total of 38.5 Gy in ten fractions over 5 days. This technique has become very popular primarily because it does not involve a surgical procedure or special equipment. Additionally, it has more homogeneity of dose than the brachytherapy options. The primary disadvantage is that larger volumes of normal breast tissue are irradiated, restricting the number of candidates for this treatment. It is recommended that 50% of the ipsilateral breast volume receive <50% of the prescribed dose. The heart and lung volumes must be below those for whole breast tangents. Additionally, the patient's setup must be reproducible. There are no studies with long-term follow-up using modern fractionation and techniques. However, a William Beaumont retrospective study with 10 months median follow-up reported 61% of patients with grade 1 toxicity, 10% with grade 2, and 0% with grade 3 toxicity. The cosmetic results were rated as good/excellent in all patients (420).

Intraoperative Accelerated Partial Breast Irradiation

IORT is utilized in a limited number of institutions that have an adequate knowledge base, technology, and facilities. Currently, there are three main devices available for IORT. The intrabeam uses soft x-rays at 50 kv, while the Mobitron and Novac7 use electrons at 4 to 12 MeV. The intrabeam machine delivers a dose of 20 to 22 Gy to the tumor bed and about 5 to 7 Gy 1 cm from the tumor bed. An applicator of varying sizes is placed in the tumor bed and, if necessary, the chest wall and skin can be protected by a tungsten-filled material. The advantage of the IORT is one of convenience to the patient, who completes all local treatment at one time. Early and late side effects are minimal secondary to the small volume of tissue irradiation. Unfortunately, long-term data are lacking on the safety and effectiveness of using IORT as the sole method of radiation treatment.

SUMMARY OF CONTEMPORARY CLINICAL TRIALS

Surgical

NSABP B-32

NSABP B-32 (165) examined whether sentinel node biopsy was equivalent to axillary dissection but with less toxicity among women with a clinically node-negative breast cancer. This trial enrolled 5,611 women who were randomly assigned to sentinel node biopsy followed by full axillary dissection (group 1) or sentinel node biopsy alone (group 2), provided it was negative. All women with a positive sentinel node biopsy underwent an axillary dissection in this trial. Among group 1, the overall accuracy of sentinel node biopsy was 97% with a false-negative rate of 9.8%. Allergic reactions to blue dye were seen in less than 1% of patients.

CALGB 9343/RTOG 9702

The CALGB trial (281) was opened to women over the age of 70 with early estrogen receptor-positive breast cancer (T1N0) treated by lumpectomy. It enrolled 636 women who were randomized to tamoxifen with or without adjuvant breast radiotherapy. The primary endpoints were time to local, regional, or distant recurrence, breast cancer-specific and overall survival. After 5 years of follow-up, overall survival was 87% with radiotherapy compared to 86% in those who did not undergo radiation ($p = 0.94$). The incidence of local failure was 1% versus 5%, respectively. Both groups experienced a 2% incidence of breast cancer-specific mortality. These data support the treatment of women over 70 without adjuvant radiation therapy, provided they are candidates for endocrine treatment following surgery.

Prevention

NSABP P-2 (STAR Trial): Study of Tamoxifen and Raloxifene

This was a prospective randomized double-blind trial comparing raloxifene 60 mg/day to tamoxifen 20 mg/day as primary prevention of invasive breast cancer (166). Eligible patients were 35 and over and in general good health. Postmenopausal women with a be at high risk for breast cancer based on the Gail model risk score. Patients with ALH or ADH were eligible, but those with DCIS were excluded. This trial enrolled 19,747 postmenopausal women with a mean risk of 4.03% based on the Gail model. There was no difference in diagnoses of invasive breast cancer with raloxifene or tamoxifen (relative risk [RR], 1.02; 95% CI, 0.82 to 1.28), but there was an increase in the diagnosis of noninvasive breast cancers with raloxifene compared with tamoxifen (RR 1.40; 95% CI, 0.98 to 2.00). Uterine cancer was less frequently diagnosed with raloxifene (RR 0.62; 95% CI, 0.35 to 1.08).

Early Breast Cancer

ATAC: Anastrozole Versus Tamoxifen, Alone or in Combination

This was a trial involving 6,241 postmenopausal women with early invasive breast cancer who were randomized to anastrozole 1 mg daily versus tamoxifen 20 mg daily versus anastrozole and

tamoxifen (264). Anastrozole was shown to improve disease-free survival compared to tamoxifen (HR 0.87; 95% CI, 0.78 to 0.97), as well as time to recurrence (HR 0.79; 95% CI, 0.70 to 0.90) and time to distant disease (HR 0.86; 95% CI, 0.74 to 0.99). Five-year overall survival was similar between the two arms (84.3% with anastrozole vs. 83.8% with tamoxifen, $p = 0.7$). Comparing anastrozole to tamoxifen, anastrozole was associated with an increased risk of bone fractures (11% vs. 7.7%, $p < 0.0001$) and musculoskeletal complaints (35.6% vs. 29.4%, $p < 0.0001$). However, anastrozole had a lower incidence of hot flashes (35.7% vs. 40.9%, $p < 0.0001$), vaginal bleeding (5.4% vs. 10.2%, $p < 0.0001$), thromboembolic events (2.8% vs. 4.5%, $p = 0.0006$), and ischemic cerebrovascular events (2.0% vs. 2.8%, $p = 0.0006$). The incidence of uterine cancer was 0.2% with anastrozole, compared to 0.8% with tamoxifen ($p = 0.02$).

BIG 1-98: Breast International Group 1-98 Study

This was a four-arm trial involving 8,028 postmenopausal women with hormone receptor-positive early breast cancer (268). Arms in this trial were letrozole 2.5 mg daily versus tamoxifen 20 mg daily versus letrozole followed by tamoxifen versus tamoxifen followed by letrozole, with each arm treated for 5 years. To date, data involving the 4,922 women randomized to letrozole or tamoxifen have been reported. At 51 months, letrozole is associated with improvement in disease-free survival over tamoxifen (HR 0.82; 95% CI, 0.71 to 0.95) but there is no difference in overall survival noted (HR 0.91; 95% CI, 0.75 to 1.11).

MA-17

This trial enrolled 5,187 postmenopausal women who had completed 5 years of tamoxifen and randomized them to placebo or letrozole 2.5 mg daily (424). At 4 years, disease-free survival was 94.4% in those receiving letrozole and 89.8% in those receiving placebo ($p < 0.001$). Overall survival was similar (95.4% vs. 95%, respectively).

IES: Intergroup Exemestane Study

This was a randomized trial whereby 4,742 women completing 2 to 3 years of adjuvant tamoxifen therapy were randomized to tamoxifen or exemestane 25 mg daily to complete 5 years of total treatment (265). At 2.5 years, disease-free survival favored switching to exemestane over continuing on tamoxifen (HR 0.76; 95% CI, 0.66 to 0.88). At the time of report, there was no difference in overall survival was seen.

ARNO-95

In this trial 3,200 postmenopausal women on tamoxifen for 2 years were randomized to continuation of tamoxifen or switching to anastrozole for 3 years (275). Disease-free survival was prolonged with a switch to anastrozole (HR 0.66; 95% CI, 0.44 to 1.00). Unlike other trials, however, this showed that sequencing treatment from tamoxifen to anastrozole was also associated with a significant improvement in overall survival (HR 0.53; 95% CI, 0.28 to 0.99).

BCIRG 001

This trial enrolled 1,491 women with invasive breast cancer with axillary node involvement to docetaxel 75 mg/m², doxorubicin 50 mg/m², and cyclophosphamide 500 mg/m² (TAC) or 5-fluorouracil 500 mg/m², doxorubicin 50 mg/m², and cyclophosphamide 500 mg/m² (FAC) (237). All patients received six cycles of chemotherapy at 3-week intervals. At 55 months median follow-up, 5-year disease-free survival was 75% versus

68%, respectively ($p = 0.001$); 5-year overall survival was 87% versus 81%, respectively ($p = 0.008$). TAC was associated with increased grade 3/4 neutropenia (65.5% vs. 49.3%, respectively; $p < 0.001$), febrile neutropenia (24.7% vs. 2.5%, respectively; $p < 0.001$), and grade 3/4 anemia (4.3% vs. 1.6%, respectively; $p < 0.001$).

CALGB 9741

This adjuvant chemotherapy trial evaluated the frequency and sequencing of doxorubicin 60 mg/m² (A), cyclophosphamide 600 mg/m² (C), and paclitaxel 175 mg/m² (T) over 3 hours in a 2 × 2 factorial design (236). Patients were randomized to either every-2-week (dose-dense) or every-3-week treatment and to treatment using AC followed by T or to A then C then T. Women randomized to dose-dense treatment were also given prophylactic G-CSF. Results showed that dose-dense therapy significantly improved disease-free (risk ratio [RR] 0.74, $p = 0.01$) and overall survival (RR 0.69, $p = 0.013$). At 4 years, dose-dense therapy was associated with an 82% survival, compared to 75% if treatment was administered every 3 weeks. No differences were observed in the sequence of treatment used.

NSABP B-31/NCCTG 98311

These two trials explored the role of adjuvant trastuzumab in combination with chemotherapy in women with high-risk node-negative (defined as tumor >1 cm if ER negative or tumor >2 cm if ER positive) or node-positive HER2/neu-positive breast cancer (245). The NSABP B-31 tested doxorubicin and cyclophosphamide followed by paclitaxel (AC/T) every 3 weeks versus the same followed by 52 weeks of trastuzumab initiated with the first dose of paclitaxel. The NCCTG trial compared three arms consisting of AC followed by 12 weeks of paclitaxel versus AC/weekly paclitaxel and 52 weeks of trastuzumab (to start with paclitaxel) versus AC/weekly paclitaxel followed by 52 weeks of trastuzumab. In the combined analysis, adjuvant trastuzumab improved disease-free (HR 0.48, $p < 0.0001$) and overall survival (HR 0.67, $p = 0.015$).

Locally Advanced Breast Cancer

NSABP B-18

NSABP B-18 was a neoadjuvant trial that enrolled 1,523 women with T1-3, N0M0 invasive breast cancers (249). Patients were randomized to preoperative AC versus postoperative AC. The rate of breast conservation was 67% versus 60%, respectively. The pathologic complete response (pCR) rate to preoperative AC was 13%. At 9 years of follow-up, survival is 69% and 70%, respectively ($p = 0.80$). Disease-free survival is 55% and 53%, respectively ($p = 0.50$). The rate of in-breast tumor recurrence was 10.7% versus 7.6% (not significant).

NSABP B-27

NSABP B-27 evaluated the role of docetaxel in patients with operable breast cancer (425). In this trial 2,411 women were randomized to preoperative AC versus preoperative AC/docetaxel versus preoperative AC followed by postoperative docetaxel. The pCR in those receiving AC was 13.7%; in those receiving preoperative docetaxel it was 26.1%, $p < 0.001$. However, the frequency of breast conservation was similar between those receiving AC (61%) and AC/docetaxel (63%) as preoperative treatment ($p = 0.70$). The addition of docetaxel did not improve overall survival.

Aberdeen Tax-301

The Tax-301 trial was designed with two phases of treatment and 145 patients completed the planned eight cycles of treatment (426). In the first phase, patients with locally advanced breast cancer received a combination of cyclophosphamide, vincristine, doxorubicin, and prednisolone (CVAP). Following four cycles patients underwent clinical re-evaluation for response. In the second stage, responding patients were randomized to four cycles of docetaxel or continued with CVAP. In those not responding, treatment was switched to docetaxel for four cycles. The pCR rate was 31% in those receiving docetaxel and 15% in those completing treatment with CVAP ($p = 0.06$). Of note, the pCR rate on docetaxel in patients who did not respond to the initial treatment of CVAP was only 2%. At surgery, the rate of breast conservation was significantly higher in those women who sequenced to docetaxel (67%) as opposed to continuing with CVAP (48%), $p < 0.01$. Additionally, at 5 years of follow-up, overall survival was 97% in patients who received docetaxel, compared to 78% of those who had completed eight cycles of CVAP.

SUMMARY

The field of breast oncology has evolved significantly, with gains made in prevention, screening, diagnosis, and management. All of this has led to a reduction in the mortality rate from breast cancer with a resultant increase in the population who are considered breast cancer survivors. Despite this, multiple questions remain: How should new radiologic technologies, such as tomosynthesis, be incorporated into routine screening practice? Should breast MRI utilization be expanded to all women with a new diagnosis of breast cancer? How can we maximize the use of neoadjuvant chemotherapy in women with invasive disease? How should we treat patients who have persistent disease following primary chemotherapy? Is partial breast radiation as safe as whole breast radiation? These are only a few of the issues that oncology will need to address as we look forward into the future.

Unlike the gynecologic malignancies, there is no one standard of care in the management of the patient with breast cancer. The indications for the use of chemotherapy continue to evolve as evidence mounts that women with breast cancer cannot be considered one and the same. Hormone receptor status can predict who will benefit from endocrine therapy, and appears to also predict who has little to gain from chemotherapy. Our current understanding of the treatment landscape in breast cancer has reinforced one point, that treatment must be individualized, especially since multiple options are considered reasonable. The evolution of breast cancer management will undoubtedly continue as researchers seek to define more targets for treatment and refine the appropriate therapies for the patient with breast cancer, tailored to hormone and HER2/neu status. Utilization of new technologies for treatment and follow-up will be better characterized, such as the use of accelerated partial breast irradiation or the use of circulating tumor cells. Hopefully, we will continue to improve the outcomes for our patients with breast cancer, and increase the chances more women will be cured.

SPECIAL
MANAGEMENT
TOPICS

CHAPTER 30 ■ MANAGEMENT OF INFECTIONS IN PATIENTS WITH GYNECOLOGIC MALIGNANCY

AMAR SAFDAR AND ISSAM I. RAAD

Patients with gynecologic cancer are susceptible to local and systemic infection. The risk of developing an infection can arise from a number of factors such as (a) tumor encroachment and invasion of adjacent structures; (b) tumor necrosis; (c) complications arising from antineoplastic chemotherapy; (d) early and late effects of abdominopelvic radiation therapy; (e) surgical tumor excision and removal of internal organs; (f) structural abnormalities resulting from surgical diversion procedures; and (g) other causes that disrupt protective barriers in the lower and upper female reproductive tract (1,2).

The spectrum of causative organisms most frequently arises from patients' endogenous microflora. The vagina, lower urinary tract, and intestinal tract colonization with bacteria and yeast serve as important sources for infection. The normal aerobic and anaerobic vaginal bacterial flora may be altered in patients undergoing antineoplastic therapy. Among factors that influence changes in colonization are hormonal dysfunction, frequent exposure to broad-spectrum antimicrobial agents, antineoplastic therapy, hospitalization, and instrumentation. In a recent report, however, patients receiving external-beam radiotherapy for gynecologic malignancy did not experience changes in aerobic microflora in the vagina, cervix, or rectum (3,4). Whereas a significant growth in vaginal yeasts occurred during the first 2 weeks of radiation therapy mostly due to *Candida albicans* and *Candida tropicalis*, the increase of growth in *Candida* species returned to preradiation levels after 4 weeks (5). Exposure to health care facilities, especially centers that care for immunosuppressed cancer patients, has been recognized as a major influence in promoting change in cutaneous, orointestinal, and genitourinary microflora. The changes in vaginal and lower urinary tract microflora occur less commonly, even in patients following repeat exposure to the hospital environment, and are often limited to patients who undergo instrumentation. The health care-associated organisms are often less susceptible to commonly prescribed antibiotics and may lead to severe disease. It is, however, important to appreciate that changes in a host's microflora are in most cases transient and restitution of normal intestinal and vaginal flora occurs once factors promoting the change have been removed.

The female genital tract is rich in anaerobic microflora. Bacteria belonging to *Peptococcaceae* are the most prominent organisms in the normal vaginal flora. Quantitative vaginal cultures in recent studies showed that anaerobic bacteria outnumbered aerobic bacteria by nearly 10:1; peptococci, *Lactobacillus*, *Corynebacterium*, *Eubacterium*, and *Bacteroides* species are common organisms isolated (6). *Escherichia coli*, *Klebsiella* species, and *Enterobacter* species are the aerobic

gram negatives and streptococci, enterococci, and coagulase-negative staphylococcus are gram-positive bacteria isolated from the lower female genital tract. These organisms provide an important reference to local and invasive infections seen in patients undergoing treatment for gynecologic malignancy.

In this chapter we provide an overview of infections encountered in patients receiving treatment for cancers involving the female reproductive system. A detailed review of specific diseases such as postsurgical abdominopelvic infections, febrile neutropenia, and bacteremia is presented. A focused discussion regarding the changing epidemiology of causative organisms, the increasing rate of infection due to drug-resistant organisms, and an update on new antimicrobial agents is briefly discussed.

PATIENTS WITH FEVER

The factors that increase the risk for infection are shown in Table 30.1. Knowledge of underlying predisposing factor(s) is necessary in the selection of appropriate empiric therapy. Antibiotic prophylaxis and/or recent treatment with broad-spectrum antimicrobials increase the risk of breakthrough infection due to less-drug-susceptible organisms and systemic candidiasis. Awareness of specific cancer-therapy associated risks and the host's underlying immune dysfunction may allow for proper selection of empiric antibiotic therapy in critically ill patients prior to the results of microbiologic culture and radiographic studies becoming available. It is important to note that patients with gynecologic cancer may have a high risk of polymicrobial infections due to the anatomic proximity to the lower intestinal and urinary tracts. In certain infections, such as deep-tissue abscess, cellulitis in patients with chronic fistula tract, presence of large necrotic tumor, and history of multiple instrumentation, the probability of polymicrobial infection remains high (7). Furthermore, patients with a known anaerobic bloodstream infection have a high probability of concurrent bacteremia due to aerobic organism(s) (7). Patients with advanced cancer and history of radiation therapy may develop obstruction to the pelvic venous and lymphatic flow, which increases the risk for cellulitis, abscess formation, and septic thrombophlebitis.

TUMOR RELATED

The tumor-associated infections are dependent on the site and extent of tumor involvement. In patients with an early stage of locally involved cancer such as stage I cervical cancer, most

TABLE 30.1**PREDISPOSING RISK FACTORS AND INFECTIONS IN PATIENTS WITH GYNECOLOGIC TUMOR**

<p>TUMOR RELATED Obstruction of gastrointestinal or urinary tract Erosion into bowel, urinary tract, peritoneum, or retroperitoneal Necrosis of rapidly growing cancer promotes abscess formation Lymphatic obstruction</p> <p>SURGERY Aspiration pneumonia Hospital-acquired pneumonia, including ventilator-associated pneumonia Wound infection; skin, and skin structure infection Tissue necrosis due to disruption of blood supply Infected hematoma Fistula tract communication between intestinal and urinary tracts Complicated peritonitis</p>	<p>Septic deep thrombophlebitis Fasciitis, myositis, and gas gangrene are rare complications</p> <p>CHEMOTHERAPY Febrile neutropenia Pneumonia Neutropenic enterocolitis</p> <p>RADIATION THERAPY Enteritis Urinary tract infection Poor wound healing</p> <p>CATHETER AND IMPLANTABLE DEVICES Device infection Peritonitis Bloodstream infection Urinary tract infection</p>
---	---

infections remain localized to the vagina. Whereas in patients with advanced cervical cancer infections may involve the fallopian tubes or ovaries, leading to tubo-ovarian abscess, uterine involvement may cause less frequently seen pyometra. Extension of these infections to adjacent structures such as the urinary tract presents as ascending pyelonephritis, rectal abscess, and complicated peritonitis, which are serious and difficult-to-treat infections (8,9). It is also important to note that an infection may be the primary presentation of an undiagnosed malignancy involving the female reproductive tract. In a study of postmenopausal women who presented with tubo-ovarian abscess, nearly half of these patients were subsequently diagnosed with a gynecologic malignancy (10). Therefore, a thorough investigation for possible underlying cancer should be considered in postmenopausal women or those with no risk factors for sexually transmitted diseases who present with tubo-ovarian abscess or pyometra.

In a large study conducted at the M. D. Anderson Cancer Center, septicemia, pneumonia, and peritonitis in patients with gynecologic cancer were associated with high infection-associated mortality (11). In the last 2 decades, with early diagnosis, identification of factors associated with poor prognosis, empiric antimicrobial therapy in patients at high risk of infection, advances in antineoplastic and radiation therapy, and surgical techniques have substantially improved outcomes in these patients. The advances in improved outcomes for serious systemic bacterial and yeast infections are in most part due to the availability of well-tolerated broad-spectrum antimicrobial agents. The recent emergence and spread of multidrug-resistant (MDR) organisms, however, may abrogate these advances, and even patients with solid-organ cancer with limited immune suppression may develop life-threatening septicemia, pneumonia, and peritonitis as was noted during the 1970s (11).

SURGERY RELATED

Patients undergoing surgery for cervical cancer have a higher rate of infectious complications, while patients with endometrial cancer tolerate surgery better and have fewer infections during the early and late postoperative period (12). Pelvic exenteration is performed in patients with advanced and/or treatment refractory cervical and upper reproductive tract

malignancy. Infections remain as serious morbidity following pelvic exenteration; early postsurgical wound infection and wound dehiscence are not uncommon (13,14). Urinary tract infections are also frequently seen in patients with urinary fistula and/or those who develop urethral obstruction. Studies show that greater than 40% of patients undergoing pelvic exenteration for gynecologic and rectal cancer had urinary tract infection and wound dehiscence (13). Late infections such as ascending pyelonephritis may be serious, as these infections are often recurrent and seen in patients with usually irreparable structural damage to the urinary reservoir, urethral stenosis, and anastomosis obstruction. Ureterointestinal fistula, stones in the urinary reservoir, and stenosis all contribute to increased risk of infections, and unless the anatomical abnormality is corrected, these patients remain at increased risk for recurrent urinary tract infections and complications arising from prolonged systemic antibiotic therapy and hospitalization. Empiric therapy includes adequate coverage for possible polymicrobial infection, and the choice should include drugs that provide adequate coverage for enteric coliforms, enterococci, including vancomycin-resistant *Enterococcus* species, especially in patients with known prior intestinal or genitourinary tract colonization due to these drug-resistant bacteria (15). As most infections in this setting may also have an anaerobe as a co-pathogen, even in patients with negative microbiologic evidence of anaerobic infection, antibiotic selection should entertain non-representational negative anaerobic culture results. We recommend secondary suppressive antimicrobial therapy in patients with recurrent deep pelvic infection to reduce morbidity and subsequent hospitalization and surgeries. It is critical to select high-risk patients judiciously so patients are not given prolonged courses of broad-spectrum antibiotics, which is the single most important factor in promoting drug resistance in health care-associated infections.

Infections remain the main concern in patients following radical vulvar resection and inguinal lymphadenectomy. Early postoperative cellulitis is noted in nearly one third of patients undergoing inguinal lymphadenectomy, and in over 20% early surgical wound breakdown also occurred (16). Late surgery-site cellulitis was noted in patients with chronic lymphedema, and in most patients the surgical wound was not compromised (16).

Wound Infection

Infected surgical wounds in patients following female genital tract surgery include *Staphylococcus aureus*, including multidrug-resistant strains (MRSA) obtained from health care microflora (health care associated; HA) or community acquired (CA)-MRSA, which has now become the leading source of MRSA in the United States. *Streptococcus* species (group A, B, C, and G) are also common pathogens in this population and nearly one third of infections, especially those with involvement of the lower intestinal tract and urinary tract, are less likely to be monomicrobial.

In certain subpopulations of patients who have been receiving systemic corticosteroids for extended periods, patients with morbid obesity, and those with poorly controlled diabetes mellitus have a higher risk of developing postoperative wound infections. Coagulase-negative *Staphylococcus*, *Streptococcus* species, *S. aureus*, enteric gram-negative bacteria, and *Bacteroides* species are potential pathogens.

Patients who have a complicated hospital course following surgery may develop infections due to organisms acquired from the health care microenvironment. In critically ill patients infections are treated empirically, and the spectrum of causative organism(s) may not be available at the time of medical decision making. Knowledge of regional and institutional prevalence of drug-resistant organisms is required in prescribing an appropriate treatment regimen. The empiric therapy in patients with prolonged hospitalization and anatomic abnormalities such as enterourethral, entero- or rectovaginal, or enterovesicular fistula increases the probability of recurrent infection due to resistant HA-gram-negative bacteria such as *Pseudomonas* species, extended-spectrum beta-lactamases-producing *Enterobacteriaceae*, including *E. coli*. Other non-fermentative gram-negative bacteria like *Acinetobacter* spp. and *Stenotrophomonas maltophilia* are often resistant to a wide spectrum of commonly used antibiotics, and treatment for these MDR bacteria remains a daunting task (17,18).

Intra-abdominal and Pelvic Abscess

An infected collection within the peritoneal cavity may develop as a consequence of instrumentization, and breach in the physical barriers may also occur in patients with necrotizing tumors. The secondary seeding of the intraperitoneal tumor mass in patients with bloodstream infection arising from a different primary source, such as the urinary tract, or antineoplastic therapy-induced orointestinal mucositis may also occur. The spectrum of causative organisms includes enteric bacteria such as *E. coli*, *Enterococcus*, *Staphylococcus* species, *Bacteroides*, and other anaerobes. *Candida* species infection is less frequent in non-neutropenic patients, although patients with high yeast counts in multiple body sites, exposure to prolonged broad-spectrum antibiotics, poorly controlled diabetes mellitus, systemic corticosteroid use, as well as stay in critical care units and presence of foreign devices may increase the risk for invasive candidiasis.

Hematogenous or direct seeding of the retroperitoneal space may lead to paraspinal and psoas abscess; these infections escape early detection as patients may not have high-grade fever, and increase in chronic low back pain remains subject to interpretation. In the absence of a direct extension from the intestinal or urinary tract, these retroperitoneal infections are usually monomicrobial, and diagnosis requires prompt aspiration of the infected collection. In tuberculosis endemic regions, *Mycobacterium tuberculosis* must be considered in determining the etiology of these infections, especially in patients in whom the vertebral column is involved.

Pelvic abscesses that develop after instrumentization or following surgery are often polymicrobial and treatment is directed toward normal intestinal tract and cutaneous microflora.

Peritoneal infections following bowel perforation, anastomotic leaks, or fistula tracts may present with fever, abdominal pain, and fistula drainage and/or surgical wound dehiscence. Most infections, as expected, are polymicrobial and *Enterobacteriaceae*, *S. aureus*, *Streptococcus*, and *Enterococcus* species including vancomycin-resistant strains are frequently encountered. *Bacteroides fragilis* and *Clostridium* species are common anaerobes; *Fusobacterium*, *Peptostreptococcus*, and *Eubacterium* occur less frequently. Patients with peritoneal infections following surgery involving the nonsterile bowel and lower genitourinary tract may also have an increased risk for *Pseudomonas* species infection.

CHEMOTHERAPY AND RADIATION RELATED

Patients receiving chemotherapy may have an increased risk of infection; neutropenia for less than a week increases risk for systemic bacterial infections due to *S. aureus* and *Pseudomonas* species. Patients who remain neutropenic for longer than 5 days are also at an increased risk for developing systemic *Candida* species infection (1,2). Disruption of orointestinal and genitourinary tract mucosa compromises an important barrier in the prevention of bacterial and yeast invasion. In patients with severe treatment-induced mucositis, alpha hemolytic streptococcal and anaerobic septicemia may lead to devastating consequences (19).

Radiation therapy in patients with vulvar, vaginal, and cervical cancer causes microvascular damage to the tissue and may lead to difficult-to-treat intestinal, vaginal, and urologic complications.

Increased doses of radiation for gynecologic cancer have been associated with improved cancer-free survival (20). However, with increased radiation dose, the rate of complications has also risen (21). Noninfectious complications arising from high-dose radiotherapy include tissue and bone necrosis, fistula formation, enteritis, and fibrosis that may lead to vaginal, rectal, and ureteric stenosis, and increased risk for secondary infection due to stagnation and inadequate physiologic drainage (22). In rare cases, patients with radiation-induced necrosis of pelvic bones may present with osteomyelitis; for these patients, a challenging and multifaceted treatment approach may be needed for successful outcomes (23). A patient with osteomyelitis in the setting of radiation-induced bone necrosis may need surgical debridement and an appropriate selection of antibiotics for a prolonged period. A high clinical suspicion remains critical in the timely diagnosis of radiation-related infectious and noninfectious complications.

Bacteremia

Most hematogenous bloodstream infections in adult neutropenic cancer patients are due to coagulase-negative *Staphylococcus*, viridans streptococci, *E. coli*, *Pseudomonas aeruginosa*, and *S. aureus* (24). In patients with solid-organ cancer, *E. coli* and coagulase-negative *Staphylococcus* account for nearly 40% of bacteremia, whereas *Pseudomonas*, *S. aureus*, and enterococcal bloodstream infections account for 10% or less, each (25). *Klebsiella* species, other *Enterobacteriaceae*, and *S. maltophilia* are a serious concern and may become prominent bloodstream infections in certain geographic regions.

Cancer patients with bacteremia who present with extensive tissue involvement/infection are significantly less likely to respond to antimicrobial therapy (26). Other factors associated with poor prognosis in bacteremic patients with an underlying malignancy include shock, infection due to multidrug-resistant bacteria, and *Pseudomonas* and *Clostridium* species infection (26).

Bacteroides and *Clostridium* species are the most frequent cause of anaerobic bacteremia, which is most frequently seen in patients with abdominal and pelvic malignancy (26,27). Cancer patients with nonsporulating anaerobes bacteremia, *B. fragilis*, and *Fusobacterium* may be isolated more frequently compared with *Peptostreptococcus* and *Eubacterium* species (28). Polymicrobial infections are more frequent in patients with anaerobic bacteremia compared with aerobic bacterial infections. *E. coli*, *Pseudomonas*, *Klebsiella* species, and among gram-positive cocci, *Streptococcus*, *Enterococcus*, and *Staphylococcus epidermidis* may accompany anaerobic bloodstream infection (28). Concurrent candidemia is rarely seen in patients with anaerobic bacteremia. Over 90% of patients with nonsporulating anaerobic bacteremia may also have a deep tissue abscess (28). The authors suggest that all patients with gynecologic malignancy who present with anaerobic bacteremia be thoroughly evaluated for an infected abdominopelvic pelvic collection, which may not be clinically apparent at the time of initial presentation.

Clostridial bacteremia is often seen in patients with gastrointestinal or genitourinary cancer, and acute leukemia (29). Nearly one third of patients with bacteremia with *Clostridium* species alone and nearly half with polymicrobial infection present with septic shock (29). *Clostridium perfringens* is a common species, and *Clostridium septicum* is a rare, albeit serious infection seen mostly in patients with an intra-abdominal cancer (29,30). Diffuse, rapidly spreading cellulitis involving the abdominal wall, groin, and upper thigh area, gas gangrene, and acute intravascular hemolysis indicate the possibility of clostridial infection (29). Early appropriate therapy remains critical in improved response and outcome for patients with systemic anaerobic infection.

Febrile Neutropenia

The organisms associated with infections in patients with neutropenia are shown in Table 30.2. *Pseudomonas* spp. is a well-recognized cause of serious systemic infections in febrile neutropenic patients. The other nonfermentative gram-negative bacteria such as *S. maltophilia* have emerged and present as life-threatening pneumonia, bacteremia, or deep-tissue infection; these infections are commonly resistant

to standard broad-spectrum antipseudomonal antibiotics, and despite appropriate therapy response may remain suboptimum (17). Patients with peripheral blood neutrophil counts of less than 500 have significantly higher risk of serious infection, especially if the duration of neutropenia is more than 7 days (1,2). During the first 5 days of neutropenia, bacterial infections are prominent; if neutropenia extends beyond a week, invasive candidiasis becomes a concern; and in patients with greater than 2 weeks of profound neutropenia invasive mold infections such as aspergillosis may be occasionally encountered. In most patients with gynecologic malignancy, isolation of a mold even from sterile samples does not indicate invasive fungal disease; in patients with no known established predisposing factors (31), these saprophytic molds usually represent colonization or laboratory contamination (32).

Catheter-Related Bloodstream Infection

In patients with solid-organ cancer, nearly 70% of gram-positive bacteremia is associated with an infected catheter; similarly, 60% of gram-negative bacteria is also related to an infected catheter, whereas only 19% of gram-negative bacteremia in patients with hematologic cancer is due to an infected catheter (33). Coagulase-negative *Staphylococcus* remains the most commonly isolated organism in blood cultures drawn from an indwelling central venous catheter and is frequently regarded as catheter-related infection. Similarly, *S. aureus*, including MRSA bacteremia, may result from an infected indwelling catheter and successful therapy requires selection of antimicrobial agents that penetrate the biofilm and are effective against the nonplanktonic, stationary phase of the bacteria (34). *S. aureus* bloodstream infections are associated with high rates of complications (35). Patients with solid-organ cancer with catheter-related *S. aureus* bacteremia have a fivefold higher probability of developing intravascular complications such as septic thrombosis and infective endocarditis (35).

Patients with gynecologic malignancy have a higher rate of postoperative infection, catheter malfunction, and unplanned catheter removal following external intravascular catheter compared with subcutaneous/implantable venous access devices (36,37). Nearly one third of all intravascular catheters were associated with delayed complications in this cancer population; bacteremia was significantly more common in patients with nonimplantable (Hickman catheters) versus implantable (infusaport or peripheral access system ports) indwelling intravenous devices (38).

TABLE 30.2

MICROORGANISMS COMMONLY ASSOCIATED WITH INFECTION IN NEUTROPENIC PATIENTS

GRAM-NEGATIVE ORGANISMS

Escherichia coli
Klebsiella spp.
Pseudomonas aeruginosa
Stenotrophomonas maltophilia
Enterobacter spp.

GRAM-POSITIVE ORGANISMS

Staphylococcus spp. including vancomycin-tolerant organisms
Staphylococcus aureus

Coagulase-negative *Staphylococcus* such as *S. epidermidis* and *S. saprophyticus*
 Beta-hemolytic streptococci, group A, B, G
 Alpha-hemolytic streptococci (viridans streptococcus spp.)
Enterococcus spp. including vancomycin-resistant strains

FUNGI^a

Candida spp. including *C. albicans*, *C. glabrata*, *C. tropicalis*, and *C. parapsilosis*

^aPatients receiving multiple courses of fluconazole therapy or prolonged antifungal suppression or prophylaxis are at higher risk for infections due to drug-resistant *C. glabrata* and *C. krusei*.

IMPLANTABLE DEVICE INFECTIONS

Peritoneal, hepatic, and pleural implantable devices for delivering chemotherapy or drainage of recurring malignant effusions have been successfully used in the last decade. These devices are well tolerated; major complications including bowel perforation are uncommon, and serious infections are seen in less than 5% of cases (39–44). Overall, infections are seen in less than 20% of cases. While serious infections including pocket infections are seldom noticed, when infections such as these do occur, they should be treated aggressively, requiring prompt removal of the infected reservoir and appropriate systemic antimicrobial therapy (39). Abdominal pain and chemotherapy-related discomfort remain the main problems with these chemotherapy infusion devices.

Urinary Tract Infection

Patients with gynecologic cancer have an increased risk for urinary tract infection. The factors that promote infections are listed in Table 30.3. Nearly one third of patients, while undergoing pelvic radiotherapy for gynecologic cancer, may have symptoms of urinary tract infection at the onset of therapy or develop infection during the course of radiation therapy (45). Despite appropriate therapy, infections may recur and require several courses of antibiotic therapy (45). Patients who have undergone pelvic exenteration remain at increased risk for ascending urinary tract infection (14); recurrent pyelonephritis in these patients may lead to permanent renal damage. Older patients with advanced gynecologic cancer are also being considered for pelvic exenteration surgery (46). In these and other patients with lower renal reserves, a severe episode of pyelonephritis may precipitate irreversible dysfunction and renal failure. We suggest that in selected high-risk patients, pre-emptive antimicrobial therapy or even secondary antibiotic prophylaxis be considered after an episode of urinary tract infection.

ANTIMICROBIAL AGENTS

It is important to refer to the spectrum of local and regional drug resistance among commonly encountered pathogens in selecting appropriate antimicrobials, especially when treatment is initiated empirically or in patients awaiting microbiologic results.

SURGICAL ANTIMICROBIAL PROPHYLAXIS

Operative Site

Guidelines for the administration of antibiotics to uninfected patients undergoing pelvic surgical procedures were first proposed by Ledger et al. in 1975 (47). Prophylactic antibiotics are indicated for women undergoing pelvic surgery for malignancy. There have been few studies evaluating this prophylaxis in such cases. Recently, cefazolin was shown to be inferior to cefotetan as a single-dose prophylaxis in women undergoing elective abdominal hysterectomy (48). A placebo-controlled trial showed that using a broad-spectrum cephalosporin plus beta-lactamase inhibitor significantly reduced the risk of major operation-site infection from 27% in patients not given antimicrobial prophylaxis, whereas none given antibiotic developed operative-site infection (49).

The overall postoperative infection rate has been as high as 46% and surgical-site infection is seen in nearly one fourth of patients (50). The risk of postoperative infection is adversely affected by prolonged duration of surgery for >5 hours, presence of remote infection at the time of surgery, and duration of hospitalization for longer than 3 weeks; in patients with all three risk factors the relative risk of infections increases to 7.3 compared to 3 in patients who have only one of these risk factors (50). Risk factors that have been associated with an increased incidence of infection in patients undergoing surgery for reproductive tract carcinoma include lower socioeconomic status, preoperative colonization, failure to administer perioperative heparin, obesity, older patient age, a longer operative

TABLE 30.3

FACTORS PROMOTING URINARY TRACT INFECTIONS

TUMOR OBSTRUCTION

Retrograde urine flow leading to ascending pyelonephritis
Stagnation in patients with outlet obstruction and abscess formation

INSTRUMENTIZATION

Cystoscopy-related introduction of pathogens
Dilatation of strictures

FOREIGN BODY

Urethral stent
Percutaneous nephrostomy tube placement/replacement^a
Surgical drains for extended duration

RADIOTHERAPY

Inflammation of bladder mucosa
Suppression of local innate cellular and acellular immune response

SURGERY

Urinary diversions
Organ resection
Lymph node dissection
Anastomotic leak
Chronic surgical wound breakdown

CHEMOTHERAPY

Neutropenia
Suppression of local immune surveillance and response to bacterial invasion
Mucosal damage and disruption

^aPatients undergoing routine replacement of percutaneous nephrostomy tubes may develop transient bacteremia in the event of prior colonization.

period, and a longer hospital stay before surgery (51,52). Extent of surgery plays a central role in predicting probability and severity of postoperative infections (12–14,52). However, these risk factors were not uniform among investigators' evaluations.

Clinical Investigation

The overall operative-site infection rate ranges from 6.7% to 44%. Interestingly, patients with preoperative cervical colonization did not have an increase in postoperative complications including duration of hospitalization, operative time, or febrile episodes compared with patients in whom no cervical colonization was demonstrated (53). An overall decrease in significant postoperative infections was reported in retrospective studies among patients undergoing radical hysterectomy (54,55). The benefit, however, was thought to be associated only with reduced local wound infections (56).

Prospective data have not resolved this issue. Numbers of patients in comparative arms have been small, and the data may be, therefore, inadequate for detecting a statistically significant infection rate. No significant difference in overall operative-site infection was observed after preoperative prophylaxis by the research groups Rosenshein et al. (57) and Marsden et al. (58), but significantly lower incidences of infection were reported by Sevin et al. (59) and Micha et al. (60). Sevin et al. reported that a short course (three doses) of prophylaxis was as effective as a long course (12 doses) in preventing major infection after radical hysterectomy (61). If separate operative-site data from prospective studies are combined, the overall incidence of pelvic infection and wound infection was significantly reduced by the administration of prophylactic antimicrobials.

A cost-benefit analysis of three doses of cefazolin antimicrobial prophylaxis showed a 29% reduction in infectious morbidity following vaginal hysterectomy and an 18% reduction in postoperative infections in patients following abdominal hysterectomy (62).

One patient population that has a significant surgical incision breakdown is that of women undergoing radical vulvectomy. Anecdotal experience indicates the principal pathogens to be *S. aureus* and *S. epidermidis*. The administration of broad-spectrum medications, such as piperacillin or mezlocillin, did not significantly reduce the incidence of postoperative wound infection; 8 of 12 women undergoing radical vulvectomy for vulvar carcinoma who were given single-dose piperacillin or mezlocillin developed postoperative infections (63). Drain sites fall into the same category. The foreign body undoubtedly contributes to the infections; local attention, rather than parenteral or oral antibiotics, is the appropriate preventive approach.

AGENT ADMINISTRATION

Intravenous administration of antibiotics is recommended to achieve high serum and tissue drug concentration and should be given before anesthesia. Antibiotics administered to women undergoing hysterectomy for benign indications by suppository, by spray, and orally, with significant reduction in operative-site infection (64–66). There are no similar data for women undergoing hysterectomy for gynecologic cancer, and these routes of administration are presently not advised.

Timing of Drug Administration

The first dose of an antibiotic should be given intravenously in the operating room. Combination regimens and prolonged

administration did not appear to offer superior infection prevention when compared with that provided by a single agent given once. If the interval between the first dose and opening the vagina exceeds 2.5 to 3 hours, a second intravenous dose should be given 15 to 30 minutes before the anticipated vaginal entry. This conclusion is based on data provided by Shapiro et al. (67). This has not been clinically studied, but administration at longer fixed intervals has not enhanced protection at hysterectomy for benign indications. In patients who are expected to undergo a prolonged surgical procedure (>4 hours), the dose may be repeated after 4 to 6 hours.

Recommendations

Intravenous administration of 2 g cefazolin should be given in the operating room. Cefazolin provides activity against gram-negative and gram-positive aerobic and anaerobic bacteria; it is an uncommon therapeutic agent and is comparatively inexpensive—beneficial attributes for a prophylactic antibiotic. A single dose of a prophylactic agent did not result in the selection of a resistant species, as did three doses of antibiotics at hysterectomy for benign disease (68). A 1-g dose may suffice, but 2 g was superior to 1 g for vaginal hysterectomy, and three 1-g doses over 16 hours were statistically inferior to a single 2-g dose for cesarean delivery (69). A single dose (1 g) of cefotetan was significantly ($p < 0.05$) superior to 1 g of cefazolin in preventing operative-site infection after elective abdominal hysterectomy for benign diagnoses. Although the cost per vial was higher, there was an overall reduction in hospital costs owing to fewer infections and shorter hospital stays (70). Kobamatsu et al. also found superior protection for women undergoing radical hysterectomy when using expanded-spectrum cephalosporins compared with first-generation agents (71). Other alternatives include ampicillin-sulbactam, although there is little evidence to support this practice; similarly, using metronidazole as a single agent may be less effective at preventing infection compared with broad-spectrum cephalosporin agents (72). More prospective data are necessary in patients with gynecologic malignancy undergoing surgery.

If the patient is allergic to cephalosporins, or if she has a history of a type I immediate hypersensitivity reaction to a penicillin, and if she is not allergic to a tetracycline, the recommendation is 100 mg doxycycline orally at bedtime the night before surgery and again the day of surgery about 3 hours before departure for the operating room. This regimen has been evaluated prospectively in Parkland Memorial Hospital, but in a nonrandomized study using very few patients and no control regimen. If the woman is allergic to tetracycline, the recommendation is intravenous administration of 900 mg of clindamycin given preoperatively, as for cefazolin. The new generation of fluoroquinolones such as moxifloxacin may be particularly suited for the gynecologic cancer patient scheduled for pelvic surgery because of its spectrum of activity and half-life. Further studies are needed.

BOWEL PREPARATION

Unobstructed Bowel

There are approximately 10^{11} bacteria in a gram of feces, making sepsis a major hazard if the colon is opened. It is desirable to reduce the patient's normal colonic microflora to diminish the postoperative infection rate in case it is necessary to perform colonic resection and reanastomosis. Preparation for colonoscopy is a regimen of clear liquids the day before

surgery and 3 tablespoons of Fleet Phospho-Soda in one-half cup of cool water at 4:00 PM and 6:00 PM the day before surgery. Patients should be cautioned to drink eight to ten 8-fluid ounce glasses of clear liquids the day before surgery. Additional clear fluid is acceptable. Some surgeons prefer to add a Fleet enema 2 hours before surgery. An alternative mechanical preparation is whole gut irrigation with chilled polyethylene glycol and electrolyte therapy or a similar lavage solution given orally at a rate of approximately 1 L/h until the rectal effluent is clear, but for not more than 4 hours. A recent multicenter, randomized trial has placed routine mechanical bowel preparation practice into serious question; in patients who underwent elective colorectal surgery, no difference in anastomotic leak or other septic complications such as fascia dehiscence were noted in the group who had preoperative bowel preparation (73).

In the antimicrobial approach, 1 g each of erythromycin and neomycin is given orally at 1:00 PM, 2:00 PM, and 11:00 PM the day before surgery. This regimen was initially proposed in 1971 by Nichols and Condon (74). An alternative is 1 g each of metronidazole and neomycin at 2:00 PM and at 11:00 PM the day before surgery. There should be no need to add further antimicrobial prophylaxis to 2 g of cefazolin or other agents. Because this may alter hydration status and serum electrolytes, many administer intravenous fluids to patients undergoing mechanical bowel preparation (75).

Obstructed Bowel

There can be no mechanical prophylaxis for preoperative management of the obstructed bowel. Treatment principles include fluid and electrolyte therapy with mechanical decompression of the bowel from above and timed surgical intervention. Women with mechanical intestinal obstruction immediately after surgery may be able to be treated conservatively with decompression only. If necessary, surgery should be performed within 24 hours of the mechanical obstruction; these patients have the lowest mortality rate. A dose of intravenous antibiotic should be given in the operating room before the procedure, with a second dose given in the recovery room, and a third 8 hours later if it is necessary to enter the bowel lumen. The single-agent or combination regimen should provide broad coverage of both gram-positive and gram-negative aerobic and anaerobic bacterial species with a broader spectrum of antibacterial activity than with cefazolin. Evaluation has produced no evidence for a superior regimen. A single agent usually suffices unless the patient is septic, in which case triple antibiotics are appropriate because therapy, not prophylaxis, is necessary.

CLINICAL SYNDROMES

Peritonitis and Intra-abdominal Abscess

Etiology

Infection in the patient with pelvic cancer most commonly involves the pelvis and abdomen. The potential causes of infection include complications of the primary tumor, surgery, and radiation therapy. The tumor can compromise the integrity of the vaginal wall and allow seeding of endogenous vaginal flora into the pelvic and peritoneal cavities. Previous antibiotics, radiation therapy, and the tumor itself may alter the normal genital flora. The tumor can also erode into the bowel and allow entry of fecal material into the peritoneal cavity. Rare cases of several other syndromes arising from untreated pelvic tumor, including spontaneous clostridial gas gangrene and

pneumoperitoneum, have been reported (76,77). Peritonitis, with or without abscess formation, may occur postoperatively after hysterectomy or with bowel injury. Radiation therapy to the pelvis can cause radiation enteritis, leading to a chronic diarrheal syndrome, which may develop years after radiation therapy is completed. These patients are also at higher risk for bowel adhesions and subsequent obstruction, and subclinical perforation may present as late insidious intra-abdominal or deep pelvic abscess.

Signs and Symptoms

In the patient with pelvic cancer, peritonitis may develop at any time, including at initial diagnosis (e.g., tumor infiltration of bowel), immediately postoperatively, or days or weeks after surgery (e.g., tumor infiltration or radiation therapy). The signs are generally dramatic and familiar: abdominal pain, fever, and signs of peritoneal irritation. However, among postoperative patients or patients who have received radiation or corticosteroid therapy, the physical findings may resemble those of a routine postoperative patient, making the diagnosis more difficult. To ensure proper diagnosis, frequent examinations and close observation are required.

Abscess formation can also occur in several settings. In some patients, a subclinical microperforation of the bowel is successfully walled off by the body's immune system, forming a pericolic or intraperitoneal abscess. This has been shown to occur 7 to 10 days after microperforation (78). Fever or mechanical obstruction may be the only presenting sign. Subphrenic, psoas, or liver abscesses may present as a fever of unknown origin and may require a methodical, diligent evaluation for diagnosis. A fistula, usually caused by tumor but also occurring postoperatively, may form between any two organ systems, including the bladder, vagina, bowel, or skin. Persistent suppuration despite therapy or the presence of a feculent discharge from the skin, bladder, or vagina may suggest the development of a fistula.

Diagnosis

The diagnosis of peritonitis is usually made on clinical grounds. In patients who have clinical evidence of peritonitis but are unable to undergo surgery because of bulky tumor, multiple prior surgeries, or general debility, paracentesis with appropriate cultures may be useful in guiding antibiotic therapy. Radiologic investigation is generally required to diagnose an abscess. Regular plain x-ray films of the abdomen are seldom revealing. A sonogram, computed tomographic (CT) scan, or magnetic resonance image (MRI) of the abdomen may show the collection. A gallium scan may also be helpful. In a particularly confusing case in which abnormalities of scans can represent an abscess, metastatic tumor, or postoperative changes, a labeled leukocyte scan may be required to diagnose the abscess with certainty.

The diagnosis of a fistula requires demonstration of abnormal drainage from one organ system to another. This can be shown by intravenous or intravesical injection of dye for fistulae arising from the bladder, oral or rectal instillation of dye for those arising from the gastrointestinal tract, or a fistulogram for a fistula involving the skin.

In all cases, laboratory abnormalities, including an elevated leukocyte count, an elevated erythrocyte sedimentation rate, and abnormal liver function tests, may suggest the diagnosis and direct the workup. The microbiologic diagnosis in each of these syndromes requires culture for aerobes and anaerobes. Blood cultures are only rarely positive. Some patients may have an unexplained bacteremia of enteric gram-negative rods or anaerobes. This is probably from a microperforation of the bowel. Any patient with pelvic tumor and enteric gram-negative rods or anaerobic bacteremia should be radiologically evaluated for evidence of perforation.

Therapy

Acute, generalized peritonitis where gastrointestinal perforation is suspected usually requires urgent surgery to irrigate the peritoneum and repair any perforation. Broad-spectrum antibiotic coverage with agents such as cefoxitin, ticarcillin–clavulanic acid, metronidazole, clindamycin with ampicillin, and an aminoglycoside such as gentamicin is generally effective for the polymicrobial infection. Addition of the aminoglycoside is particularly important for patients who have been recently or frequently hospitalized or who have had past courses of antibiotics. These situations predispose the patient to the development of resistant organisms.

Effective treatment of an abscess requires drainage. Percutaneous drainage is adequate in many cases, but laparotomy is occasionally required. Large or persistent abscesses may require placement of a suction drain. Patients with fistulae generally require resection of the involved tissue.

For intra-abdominal infection, intravenous antibiotics directed at the recovered bacteria should continue for at least 7 to 10 days after drainage. Some patients who have been on antibiotics may have evidence of pus but no growth on cultures. In this situation, broad-spectrum antibiotics directed at enteric gram-negative rods and anaerobes should be administered. Laboratory parameters such as leukocyte counts should be followed to determine the exact duration.

Patients who are inoperable can be treated with chronic suppressive therapy, intravenously or orally. Oral agents such as amoxicillin–clavulanic acid (875 mg bid) or clindamycin (450 mg q 6 to 8 hours) may be effective. Ciprofloxacin, moxifloxacin, or levofloxacin alone should not be used in this situation because they provide limited enterococcal coverage.

Patients with infections due to vancomycin-resistant enterococci and/or vancomycin-tolerant (79) *Streptococcus* or *Staphylococcus* infections may be treated with daptomycin (6 mg/kg daily) or linezolid (600 mg twice daily), usually in combination with drugs with gram-negative and anaerobic activity. The recently approved tigecycline has a broad spectrum of antimicrobials, including multidrug-resistant gram-negative bacteria such as extended-spectrum beta-lactamase positive *E. coli*, multidrug-resistant *Acinetobacter*, *S. maltophilia*, vancomycin-resistant enterococci, and multidrug-resistant *S. aureus*. There is limited clinical data for its use in patients with gynecologic malignancy, and due to poor activity against *Pseudomonas* species it should be used cautiously. Furthermore, emergence of drug-resistant bacteria or selection of less-susceptible organisms remains a concern for widespread use of drugs with broad-spectrum antimicrobial coverage. Similarly, antipseudomonal carbapenems such as imipenem–cilastatin and meropenem should also be reserved for seriously ill patients with polymicrobial infection, as emergence and spread of multidrug-resistant gram-negative bacteria are increasing in immunosuppressed cancer patients (80). Ertapenem, a carbapenem without antipseudomonal activity, was as effective as piperacillin–tazobactam for the treatment of acute pelvic infection (81), and can be administered as a single daily dose, albeit due to lack of enterococcal coverage it is important to select patients carefully.

Urinary Tract Infection

Etiology

Many clinical situations predispose a patient to urinary tract infection. Urinary tract infection continues to be the leading cause of infectious morbidity in this population. One study showed that half of the patients with pelvic cancer admitted to the hospital because of infection had a urinary tract infection;

E. coli was the most common organism isolated (82). Another report found that the frequency of urinary tract infections is increased as much as threefold in patients undergoing pelvic irradiation (20–22). Many patients who undergo pelvic surgery require prolonged bladder catheterization, usually with a Foley catheter. These patients may develop the well-recognized infectious complications of chronic bladder catheterization, the most common of which is recurrent infection. In addition, tumor can cause urinary obstruction and subsequent infection. The role of silver- or antibiotic-impregnated Foley catheters has not yet been defined.

Signs and Symptoms

Some patients with gynecologic malignancy and urinary tract infection have the familiar clinical picture of dysuria, fever, flank or suprapubic tenderness, elevated leukocyte count, and abnormal urinalysis. In many others, these signs and symptoms are obscured by the rest of the clinical picture. For instance, a postoperative patient may be expected to have abdominal tenderness, an elevated leukocyte count, and fever. The physician should consider the entire clinical setting before embarking on a course of therapy.

Diagnosis

Diagnosis is generally made on the basis of a urine culture, from a “clean catch” or through a catheter, but the initial urinalysis is extremely helpful. Pyuria is expected in any nongranulocytopenic patient with a urinary tract infection. Gram stain of urinary sediment can direct antibiotic therapy in advance of the culture results. A common problem confronting the physician is when patients, especially those with indwelling catheters or nephrostomy tubes, have positive urine cultures but do not appear to be ill. Differentiating colonization from invasive infection is never simple and requires clinical judgment. Any patient who is not granulocytopenic should also have pyuria along with positive urine cultures. The absence of pyuria in a patient with a positive urine culture suggests the likelihood of contamination/colonization. From a practical standpoint, in a clinically stable patient, it is reasonable to withhold antibiotics pending repeated urinalysis and urine culture. If an organism persists, therapy should be considered.

Therapy

Therapy should be based on the sensitivity pattern of the recovered organism, and intravenous antibiotics are reserved for patients with drug-resistant bacteria and those with systemic infection, ascending infection, or pyelonephritis. Optimum duration of therapy in a patient with a urethral stent or a permanent indwelling catheter is often difficult to determine. It is virtually impossible to eradicate an infection in the presence of a foreign body, and removal of the foreign object is the obvious therapy. However, removal is not always feasible. A patient with a urinary tract infection and a foreign body in the urinary collecting system should be considered for chronic suppressive therapy if she has recurrent infection. In general, among patients with gram-negative rods, chronic suppressive therapy may include ampicillin, trimethoprim–sulfamethoxazole, doxycycline, or an oral fluoroquinolone such as ciprofloxacin. Patients with a chronic enterococcal infection may benefit from chronic suppressive therapy with amoxicillin–clavulanic acid (Augmentin) or amoxicillin alone or doxycycline.

In patients with pyuria and fever in whom a urinary tract infection is suspected, empiric antibiotic therapy should be given pending urine culture results. Gram stain of urinary sediment may be helpful in directing treatment. However, for those cases in which Gram stain is not helpful, broad-spectrum coverage should be given. For a patient who has had frequent or prolonged

hospitalizations, effective coverage of potentially resistant gram-negative rods dictates that two drugs be given, preferably a beta-lactam and an aminoglycoside. Cefazolin (1 to 2 g IV, q 8 hours) and gentamicin (4 to 5 mg/kg per day IV in three divided doses) is a good empiric combination for many patients. For more debilitated patients or those with prolonged hospitalizations and frequent past courses of antibiotics, a third-generation cephalosporin, such as ceftazidime (1 to 2 g IV, q 8 hours), should be substituted for cefazolin. After culture results are known, antibiotics can be adjusted and the spectrum narrowed. For any gynecologic cancer patient with an unexplained predisposition to recurrent urinary tract infection, a full investigation should be undertaken to exclude obstruction from tumor as the cause.

Wound Infections

There are important variables that influence the development of wound infection after surgery. These include hospital flora, patient flora, operative technique and variables, patient nutrition, and immunocompetency. Women being treated for reproductive tract cancer may be at risk because of specific problems with immunocompetency, possible prior chemotherapy or radiotherapy, poor nutritional status, hypoproteinemia, or low socioeconomic status. Additional risk factors for incisional infection include obesity and diabetes. Surgical variables include operative procedures in excess of 4 hours, breaks in surgical technique, excessive inoculum at the operative site, excessive cautery, passive drains, shaving of the area in which the incision is made immediately before surgery, and placement and types of sutures. Infections may range from a mild cellulitis to a devastating fasciitis, deep infection with myonecrosis, and mixed anaerobic-aerobic synergistic abdominopelvic gangrene (83).

Cellulitis

Etiology. Cellulitis is a relatively frequent occurrence. The presence of a foreign body in a wound is an unavoidable risk factor in many cases, but this variable should be removed or reduced as much as possible. Devitalized tissue, especially fat, can also act as a foreign body. Excess cautery causes thermal injury; the charred tissue may act as a foreign body. The presence of significant amounts of devitalized tissue usually produces a wound defect. A mechanical wound retractor can cause fat necrosis, and there appears to be only minimal ability to resorb these areas during wound healing. These areas should be carefully identified and excised before closing the wound. If drains are used, they should be closed, and drains should be vacuumed. Drains should not exit through the wound but rather through an adjacent puncture site, and they should be removed as early as possible. *S. aureus* is recovered from 50% or more of wound infections. If the operative procedure involves transection of the vagina, the infections may harbor other species of normal flora of the lower reproductive tract, such as gram-positive and gram-negative anaerobes and *Enterobacteriaceae*. Cellulitis of the leg occurs with increased frequency in patients after vulvectomy (84). The affected leg is not always edematous. Group B beta-hemolytic streptococci are frequently recovered. Prophylactic therapy with oral penicillin may reduce recurrences in some patients (84).

Signs and Symptoms. Cellulitis is almost uniformly associated with pain and erythema in the incisional margins, with an increase in local skin and tissue temperature, and many times with fever. Incisions are usually tender at examination. Incisional cellulitis may not become evident until the 4th postoperative day or later.

Diagnosis. The infected surgical incision should be explored. This can frequently be performed at the bedside. Opposing

skin edges in such incisions are usually separated without difficulty and may expose underlying purulent material, seromas, hematomas, or any combination of these. The wound should be explored thoroughly, and if the wound shows unusual features, aerobic and anaerobic cultures should be obtained. Foreign bodies such as sutures or drains should be removed, and obviously necrotic areas should be removed after the patient has been given parenteral pain medication. It is important to document deep fascial integrity. If this cannot be done at the bedside, it should be performed in the operating room.

Therapy. The wound should be packed open with fine-mesh gauze approximated to the incisional margins. Gauze is used to fill the intervening spaces after each dressing change. The dressing is changed two to four times daily, with chemical and mechanical debridement of necrotic areas. Commonly used solutions are hydrogen peroxide, acetic acid, and Dakin's solution (0.25% sodium hypochlorite). In general, these debriding solutions should be removed from the wound with sterile normal saline before packing because they may impede healing. Except in unusual instances, it is unnecessary to administer parenteral antimicrobials. These incisions may be left open to heal by secondary intent, or they may be closed before discharge from the hospital after the margins are completely granulated. The optimal time for secondary closure is about the 4th day after institution of wound therapy. Studies have shown that normal wound healing occurs as long as the hematocrit exceeds 17%, but that a lower level will impede healing (85).

Necrotizing Fasciitis

Necrotizing fasciitis is a potentially life-threatening infection of the soft tissues above deep fascia that can involve the abdominal wall or vulva with extension to the proximal thighs and buttocks (85). There are several descriptive names for this infection, such as beta-hemolytic streptococcal gangrene, hospital gangrene, gram-negative anaerobic cutaneous gangrene, nonclostridial gas gangrene, gangrenous erysipelas, or synergistic necrotizing cellulitis, but the name used by most is that coined by Wilson in 1952, that is, necrotizing fasciitis (86). This significant infection has been reported in patients with endometrial cancer following irradiation and hysterectomy (87–89). It has also been found in endopelvic fascia, in a suprapubic catheter site during chemotherapy, in the vulva in diabetes, and after diagnostic laparoscopy (90–95).

Etiology. Bacteria recovered from necrotizing fasciitis infectious sites include anaerobes, particularly *Peptostreptococcus*, *Prevotella*, and *Bacteroides* species, as well as *E. faecalis*, *S. aureus*, and *Enterobacteriaceae*. These bacteria produce large quantities of proteolytic and other enzymes and toxins that allow rapid spread to contiguous tissues. Superficial vessels are occluded, depriving the affected areas of oxygen, other nutrients, and antibiotics. This deprivation interferes with bacterial eradication. Patients at particularly high risk of developing this infection include women older than 50 years of age and those with arteriosclerotic heart disease, diabetes, or other chronic diseases.

Signs and Symptoms. Early in the course of necrotizing fasciitis, the signs and symptoms are those of any wound cellulitis. Because there is no response to the usual methods of therapy, antibiotic therapy will frequently be initiated. The infection, however, seems to smolder initially, then rapidly progresses to involve the wound and to produce clinical sepsis. Mortality rates for this infection have been as high as 76%. The degree of disease evident on the skin is only a small fraction of the total amount of tissue that is involved because the skin is not the primary area of infection. Hallmarks of this infection include excessive pain, edema that is unusual for the apparently minimal degree of infection, and superficial tissue crepitation. The skin overlying the affected area becomes blue or brown as

the disease progresses, and there may be formation of bullae. Edema progresses, and there may be seepage of grayish fluid from the skin, which slips over underlying tissue and does not bleed if cut. Lack of familiarity with this infection and failure to recognize its signs may delay diagnosis. Even when recognized and treated early, there is a high mortality rate.

Diagnosis. Diagnostic criteria as first outlined by Fisher et al. include (96):

1. Extensive necrosis of the superficial fascia with widespread undermining of surrounding tissue
2. A moderate to severe systemic toxic reaction
3. Absence of muscle involvement
4. Failure to demonstrate *Clostridium* species in the wound or blood cultures
5. Absence of major vascular occlusion
6. Histologic demonstration of intense leukocytic infiltration, focal necrosis of the superficial fascia and surrounding tissues, and microvascular thrombosis

Early diagnosis followed as soon as possible by appropriate treatment produces the highest cure rate. Radiologic evaluation, particularly with MRI, may confirm the diagnosis rapidly, and should be ordered whenever the disease is suspected. The average interval between diagnosis and initiation of treatment is approximately 5 days. If the interval is 4 days or less, survival rates are high, but an interval of 7 days or more is more likely to result in patient death because even intense antimicrobial therapy is rarely successful at this late stage.

Therapy. Although the administration of broad-spectrum antimicrobials is important, wide and often disfiguring surgical debridement is the treatment required for preservation of life. The excision must extend to areas that bleed. The areas of debridement should be treated as are areas of burns. Adjunctive therapy with whirlpool baths and perhaps hyperbaric oxygen may be of use.

Clostridial Myonecrosis

Clostridial myonecrosis (gas gangrene) was described by Altmeier (97). It is an infection that occurs in muscle and adjacent tissues beneath the deep fascia and is seen most commonly after trauma. However, it can be seen after intra-abdominal surgery or surgery in an area that has been contaminated by feces. Mortality rates are about 25%, and poor-prognosis factors are leukopenia, advanced age, renal failure, and intravascular hemolysis.

Etiology. Clostridial myonecrosis is caused by *C. perfringens* (80% to 95%), *C. novyi* (10% to 40%), or *C. septicum* (5% to 20%). It is usually seen in association with gastrointestinal mucosal ulceration or perforation because *Clostridium* species are normal inhabitants of the gastrointestinal tract. *C. perfringens* may be isolated from as many as 20% of the women with upper genital tract infections not involving sexually transmitted diseases. The mere presence of *C. perfringens* in a wound does not mean that the patient will develop gas gangrene; it develops in only 1% to 2% of wounds in which that species can be isolated.

Signs and Symptoms. Early signs and symptoms of clostridial myonecrosis are tense edema in tissue that is extremely tender and pain that rapidly intensifies. If an incision is open, it is not uncommon to see a swollen, herniated muscle. There is frequently a serosanguinous, dirty discharge that has many gram-positive or gram-variable rods but few leukocytes. There may also be gas bubbles, and the secretions have a particularly sweet, offensive odor. The surrounding tissue frequently has crepitus. The skin becomes red to green-purple and then turns yellow before becoming a characteristic bronze color. The usual incubation period is about 2 to 3 days, but it can be as short as 6 hours after the bacterial inoculation. With progression of

the infection, the patient becomes obviously ill, pale, and sweaty, with increased pulse rate and decreased blood pressure. Temperature is usually elevated, but hypothermia may occur with shock.

Diagnosis. A positive wound culture may accompany the characteristic signs and symptoms of clostridial myonecrosis. X-ray films of the affected area frequently show gas deep in the tissues. Blood cultures grow clostridia in approximately 15% of the cases. It is common to find a decrease in hemoglobin and an increase in circulating leukocytes. Involved muscle is pale and edematous, with loss of elasticity, and it does not bleed or contract with stimulation. Histologic findings demonstrate coagulation necrosis of muscle fibers.

Therapy. Clostridial myonecrosis is another infection that requires prompt and extensive debridement in the operating room. Cultures must be performed, and because clostridia may develop plasmid-mediated antibiotic resistance, repeated cultures with sensitivity testing may be required if a patient is slow to respond. In addition to wide debridement, the treatment of choice is penicillin G at a dose of 1 to 2 million units every 2 to 3 hours. Gram stain also may indicate the presence of gram-negative bacteria, in which case coverage should be provided for those bacteria as well. Chloramphenicol is as effective against *Clostridium* species as it is against many gram-negative species, although seldom used. Metronidazole, imipenem, or clindamycin, all of which have good *in vitro* activity against *C. perfringens*, may be considered. Other antibiotics with good *in vitro* activity include tetracycline, erythromycin, and rifampin. Hyperbaric oxygen may be adjunctive, but its efficacy is uncertain.

Intraperitoneal Catheter Infections

Etiology

Delivery of chemotherapeutic agents through an intraperitoneal catheter has enabled physicians to deliver high concentrations of drug locally while decreasing systemic side effects (42,98). However, intraperitoneal catheters can become infected at the exit site, along the catheter tunnel, or secondary peritonitis may occur in rare cases. *S. epidermidis* is the most common organism followed by *S. aureus* and *Streptococcus* species. Gram-negative bacilli and anaerobes, presumably from the bowel, are also found, especially in patients with polymicrobial infections. Patients who have been treated for bacterial peritonitis in the past may develop peritonitis due to *Candida* species.

Signs and Symptoms

With exit-site or tunnel infections, patients report discomfort at the site. Patients with peritonitis may complain of diffuse abdominal pain, with or without a change in bowel pattern. Fever may be absent in peritonitis, making the diagnosis more difficult because many patients with pelvic tumor have abdominal pain. On examination, patients with exit-site or tunnel infections have redness and sometimes have discharge where the catheter has been inserted. Patients with peritonitis have tenderness and frequently have abdominal rebound.

Diagnosis

Diagnosis of exit-site and tunnel infections is made clinically, with support from a Gram stain and culture of any discharge. Patients with suspected peritonitis should have withdrawal of peritoneal fluid for cell count and microbiologic evaluation. A rough guideline, derived from experience among patients receiving continuous ambulatory peritoneal dialysis, is that any leukocyte count in peritoneal fluid >100 cells/mm³ suggests infection. Gram stain and culture should reveal the specific

organism. Chemical peritonitis after instillation of chemotherapy can mimic infectious peritonitis. Peritoneal fluid cultures are often helpful in distinguishing between infectious versus chemical peritonitis, although occasionally peritoneal fluid cultures may not yield an organism, especially in infections due to a fastidious organism.

Therapy

For patients with peritonitis, systemic therapy is advised according to the recovered organisms. Treatment should be continued 10 days or longer, with serial peritoneal fluid cell counts guiding therapy. The peritoneum provides a large absorptive surface, and antibiotics delivered intraperitoneally readily enter the intravascular space; however, we suggest that intraperitoneal antibiotic therapy should be reserved for patients with serious, treatment-refractory infection. Treatment of fungal peritonitis is a unique problem. Amphotericin B can cause adhesions if delivered intraperitoneally. Caspofungin appears to be the treatment of choice for patients with intra-abdominal and peritoneal candidiasis (99). Fluconazole, which can be administered orally or intravenously, was shown in one study of patients receiving continuous ambulatory peritoneal dialysis to effectively treat *C. albicans* peritonitis and should be avoided in patients with *Candida glabrata* and *Candida krusei* infection (100). Fluconazole may be used for long-term therapy in patients with *Candida* peritonitis who have responded to initial aggressive therapy with amphotericin B or caspofungin therapy.

Septic Pelvic Thrombophlebitis

Septic pelvic thrombophlebitis, also known as suppurative pelvic thrombophlebitis, is a disorder that has been diagnosed most frequently after antimicrobial therapy for pelvic infection after cesarean section or septic abortion, but it can be seen as a complication of infection after any type of pelvic surgery. The mortality rate observed in 1917 was 52% after surgical therapy (101). Fortunately, this complication of pelvic infection is now very rare. The use of antimicrobial prophylaxis and the enhanced antibacterial activity of current therapeutic regimens are presumed to be paramount in the disappearance of this potentially lethal infection.

Etiology

Septic pelvic thrombophlebitis is clot formation in the pelvic veins as a result of infection. It can be seen after hysterectomy, other pelvic operative procedures including brachytherapy, and in association with pelvic trauma or perirectal abscess. Classically, there is relative venous stasis before phlebitis that develops adjacent to pelvic infection. The intimal lining of the veins is invaded by bacteria, including *Enterobacteriaceae*, especially *E. coli*, aerobic and anaerobic streptococci, and *Bacteroides*. The veins involved may be the ovarian, hypogastric, or uterine, with essentially equal involvement in the right and left sides. If common iliac veins are involved, clot formation is more frequently seen on the left for unknown reasons. Infected clot may embolize to the lungs, kidneys, liver, brain, and spleen.

Signs and Symptoms

A clinical diagnosis may not be readily evident. Presentation is essentially that of a fever of unknown cause, and the physician must rule out infections such as pyelonephritis, pneumonia, and pelvic or abdominal abscess. The most frequent presentation currently seen is persistence of fever associated with tachycardia after clinical response to antimicrobial therapy for a pelvic infection. Physical examination is normal in most instances, but it may be possible to palpate tender cords in the

vaginal fornices. In patients with bacteremia and septic emboli, chills are observed in as many as 67% of the patients, pyrexia may be elevated to 41°C, and the variations in temperature may be quite hectic. Dyspnea, tachypnea, pleuritic pain, cough, hemoptysis, restlessness, anxiety, and perhaps angina may all be seen with septic embolization.

Diagnosis

Compatible clinical presentation and CT or MRI scan are used for diagnosis (102). Criteria for diagnosis of venous thrombosis using CT studies include enlargement of the involved vein(s), sharply defined vessel walls enhanced by contrast media, and a low-density intraluminal mass (103). Diagnosis using MRI is based on intense intraluminal signals from clot in involved veins and a lack of signal with normal blood flow in uninvolved vessels; no contrast agent is needed. Blood culture should be performed if there is suspicion of septicemia. Tests for blood gases, a chest radiograph, and a ventilation-perfusion scan should be performed if there is suspicion of embolization. A gallium scintiscan may be necessary to identify very small septic embolic foci in the lungs.

Therapy

Early treatment of venous thrombosis was surgical (101). The first to advocate the use of anticoagulants in addition to antibiotics were Schulman and Zatuchni (104). In some cases antibiotics alone may be adequate and can be used in patients in whom anticoagulation can be detrimental (105). In the largest published study of heparin therapy, the mean time to become afebrile was 2.5 days, and the average duration of heparin therapy was 8 days (106,107). It is unnecessary to initiate warfarin sodium (Coumadin) therapy in patients without evidence of emboli. Thromboembolism during or after treatment with heparin has not been reported. Antibiotic therapy must be continued. If there is significant improvement in the pulse rate and temperature pattern within 12 to 48 hours after addition of heparin, reassessment is mandatory. Treatment with low-molecular-weight heparin has not been studied or standardized for this condition (108). Heparin therapy is not without complications. Between 2% and 5% of patients may have an allergic reaction; bleeding occurs in 7% to 10% of patients; and the most devastating effect is the development of the "white clot syndrome" (109). This occurs in <1% of patients, but it may be associated with major limb amputation in 20% of those suffering from it, and death has been reported for 50%. This phenomenon is a paradoxical arterial platelet aggregation associated with thrombocytopenia, and it should be suspected in patients with decreasing platelet counts or an increasing requirement of heparin to maintain adequate anticoagulation. The only current indications for surgical intervention are embolization during heparin therapy or lack of response. The usual intervention is placement of a vena cava filter, which is a procedure usually performed by an interventional radiologist.

Neutropenia and Fever

Etiology

Patients with severe neutropenia are at particularly high risk for severe morbidity and mortality unless empiric intravenous antibiotic therapy is instituted at the first evidence of fever or clinical worsening. Most commonly, the febrile neutropenic patient does not have an obvious source of fever. Even in those with bacteremia, the source is rarely clinically evident. Bacteria often enter the bloodstream through the gastrointestinal tract because of the small chemotherapy-induced ulcerations of the intestinal mucosa and the accompanying neutropenia and

thrombocytopenia. Neutropenic patients may also develop a clinically diagnosed group of infections, including pneumonia and cellulitis. Neutropenic patients with these clinically diagnosed infections may progress very rapidly, may have exceedingly subtle clinical signs and symptoms, and always require early, aggressive therapy of their infections to achieve a response.

Signs and Symptoms

Fever is often the only complaint of patients with neutropenia and bacteremia. Patients receiving chemotherapy should be instructed to take their own temperature at home twice a day (more frequently if a subjective feeling of fever develops) and to contact their treating physician for temperatures above 38.0°C or 100.4°F.

Diagnosis

Diagnosis is made by blood culture. Of all febrile, neutropenic patients from whom blood cultures are obtained, only 10% to 20% have an organism isolated. The others probably have enough organisms to cause fever and illness, but an insufficient load of organisms to be cultivated using current techniques. Coagulase-negative *Staphylococcus*, *S. aureus*, streptococci, *E. coli*, *Klebsiella* species, and *Pseudomonas* species are frequently isolated bacteria (110). In a recent report of 2,142 patients with febrile neutropenia, 499 (23%) patients developed bacteremia due to gram-positive bacteria (57%), gram-negative bacteria (34%) and polymicrobial infection was seen in 10% (111). Mortality rates were lowest (5%) in patients with gram-positive infection followed by 18% with gram-negative bacteremia, and they were 13% in patients in whom polymicrobial bloodstream infection was diagnosed (111). Polymicrobial infections are often under-reported and neutropenic patients with intestinal and genitourinary tract mucosal damage have a higher risk of systemic infection due to multiple organisms (7).

Therapy

The Infectious Disease Society of America (IDSA) updates guidelines for management of the patient with fever and neutropenia. Full consideration of this complex topic is beyond the scope of this chapter (112). In general, a febrile neutropenic patient should receive antibiotics with activity against *P. aeruginosa* pending results of blood cultures. Numerous regimens are effective, and their use should be determined according to sensitivity patterns for *P. aeruginosa* at a given hospital. In general, good results have been achieved with a beta-lactam antibiotic (e.g., semisynthetic penicillin such as ticarcillin-clavulanic acid or a third/fourth-generation cephalosporin such as ceftazidime or cefipime) or a carbapenem (imipenem or meropenem) with or without an aminoglycoside. Monitoring peak and trough levels of aminoglycosides is recommended to limit ototoxicity and nephrotoxicity. The choice of the specific aminoglycoside (e.g., gentamicin, tobramycin, amikacin) is dictated by the sensitivity patterns in a given hospital. Once-daily dosing of aminoglycosides is not recommended for the neutropenic patient but can be given in other settings. The length of therapy for neutropenic patients is determined by many factors and must be individualized. Patients with prolonged neutropenia and fever should be followed by an infectious disease specialist.

Fungal Infections

Etiology

Patients with pelvic cancer may be at risk for the development of fungal infections, particularly those caused by *Candida*

species, including *C. albicans*, *C. tropicalis*, *C. parapsilosis*, and *C. glabrata* (113). Infection may include fungemia, pelvic abscess, or infected urinary stent in patients with extensive pelvic disease and urinary outflow obstruction. Risk factors for the development of invasive candidiasis include prolonged courses (7 to 10 days) of intravenous broad-spectrum antibiotics; an intravenous catheter, particularly a central venous catheter; major abdominal surgery; prolonged neutrocytopenia, usually related to chemotherapy; and immunosuppressive therapy, especially with corticosteroids (114).

Signs and Symptoms

Patients with the appropriate risk factors who have unexplained fevers may be fungemic. Other than fevers, which can include rigors and hypotension and closely resemble bacteremia, there may be no other symptoms. Blood cultures are positive in only 50% of the patients with autopsy-proven disseminated candidiasis. Any blood culture positive for yeast should be considered to be significant. A full evaluation for a hidden source should be completed, including a thorough re-evaluation with history and physical examination, and appropriate laboratory tests that include repeat blood cultures. An ophthalmoscopic examination to exclude endophthalmitis should be performed since this complication may occur in up to 5% to 15% of patients with fungemia.

Much has been written suggesting that any patient with *Candida* species cultured from three sites (i.e., sputum, urine, wound) should be considered to have invasive disease and treated accordingly. Although somewhat helpful, antifungal therapy in all patients meeting this criterion should not be initiated until a full evaluation is performed. In many cases, no antifungal therapy will be required.

Candida species may cause urinary tract infection in a patient with such indwelling devices as a Foley catheter, internal stents, or percutaneous nephrostomies. Rarely a “fungus ball,” consisting of a matted mass of yeast, may cause urinary obstruction.

Candida species almost never cause pneumonia except as a preterminal event in a critically ill intensive care unit patient or patients with refractory relapsed acute myelogenous leukemia and prolonged severe neutropenia. Thus, recovery of any yeast from a respiratory specimen should be considered to be most likely due to oral thrush contaminating the culture. Unlike patients with leukemia and recipients of allogeneic hematopoietic stem cell transplantation, in patients with gynecologic malignancy invasive mold disease is exceedingly rare. Identification of filamentous fungi, such as *Aspergillus*, should be approached with great caution and mold-active drug therapy reserved for highly immunosuppressed patients with clinical and radiographic evidence of invasive aspergillosis. Rarely, patients with solid-organ cancer may present with non-*Aspergillus* locally invasive disease due to drug-resistant organisms (115).

Diagnosis

The diagnosis of a fungal infection is often quite difficult. The physician must differentiate between invasive disease, which must be treated, and colonization, which does not require therapy. The recovery of fungi from a urine, sputum, or wound culture does not necessarily mean that the fungus is pathogenic, and clinical judgment must be used to determine if a patient requires therapy. In general, cultures from sterile sites (e.g., blood, cerebrospinal fluid, pleural or peritoneal fluid) should be considered to represent invasive infection until a full evaluation is done. Also, fungi recovered from the initial specimen of drainage from an obstructed biliary or urinary tract should be considered to be pathogenic.

With most specimens however, the distinction between colonization and infection is not so simple. For urine, the presence or absence of pyuria is the simplest and most reliable means of differentiation: Those without pyuria are very likely only colonized and need no therapy. In such patients, a repeat urinalysis and culture may clarify the situation.

Therapy

Treatment options for invasive candidiasis have expanded in recent years. Amphotericin B and associated amphotericin B products (AmBisome and Abelcet) have the longest record for treatment of invasive fungal infections (113). The optimal duration of therapy for candidemia is not well defined and should be determined by individual responses. However, a 7- to 14-day course of therapy is probably adequate for most episodes (113).

In addition to amphotericin B products, both intravenous fluconazole therapy (400 mg daily) alone or in combination with amphotericin B and caspofungin (70-mg load and then 50 daily IV) are highly effective for non-neutropenic patients with fungemia (99,116,117). These agents offer comparable effectiveness but have fewer side effects than the amphotericin B products.

Patients who have *Candida* species consistently cultured from urine but no evidence of systemic fungal infection may benefit from bladder irrigation with amphotericin B, which reduces or eradicates bladder yeast colonization, and may prevent invasive fungal infection. Fluconazole is increasingly being given for this indication and appears to be effective.

Pneumonia

Etiology

Postoperative pneumonia remains a common cause of fever in any surgical patient, including those with gynecologic cancer. Infection may occur from aspiration during intubation or extubation or from hypoventilation due to “splinting” in patients with severe postoperative pain. Postobstructive pneumonia may occur in patients with tumor metastatic to the lungs. In addition, pneumonia may occur in patients with chemotherapy-induced neutropenia (see above).

Signs and Symptoms

The familiar signs and symptoms of pneumonia are cough, fever, chest discomfort, and dyspnea and evidence of pulmonary consolidation on lung examination.

Diagnosis

The diagnosis is usually suggested by the clinical situation and by the findings on physical examination. These are further supported by chest radiographs and sputum examination and culture. Chest radiography may show consolidation. Gram-negative organisms predominate in the mouth flora of hospitalized patients, so an aspiration pneumonia occurring in a hospitalized patient is typically due to gram-negative rods. Although thought by many to be a substantial contributor, anaerobes seldom cause aspiration pneumonia in the hospital.

Therapy

Empiric, rather than pathogen-based, coverage of a postoperative patient with clinical pneumonia is usually necessary and varies according to the setting (118). For a patient who has been hospitalized less than 3 days and has had no other recent hospitalizations or recent courses of oral or intravenous antibiotics, single-drug therapy with levofloxacin or moxifloxacin is

adequate (118). For the patient who has been hospitalized for a longer period or who has received recent antibiotics (increasing the likelihood of infection due to resistant organisms), *P. aeruginosa* should be covered by the addition of an aminoglycoside such as gentamicin or tobramycin (3 to 5 mg/kg per day in three divided doses), and a beta-lactam should be selected to cover the usual isolates in that hospital. *S. maltophilia* is now increasingly seen in cancer patients without traditional risk factors such as severe neutropenia, prolonged stay in critical care units, or mechanical ventilation (119). Treatment includes high-dose trimethoprim-sulfamethoxazole (15 mg/kg in three to four divided doses) in combination with a second drug to which the bacteria are susceptible (17). Patients with drug-resistant *S. aureus* pulmonary infection may present with rapidly progressive, necrotizing pneumonia in a substantial number of cases during influenza season; these infections are especially serious postviral superinfections and require urgent, appropriate antibiotic therapy. Vancomycin (1 g twice daily), or linezolid (600 mg every 12 hours) may be given in patients with severe pneumonia and history of recent influenza-like illness. Therapy for patients with pneumonia should extend up to 10 to 14 days depending on clinical response. Various professional societies have codified recommendations for pneumonia management (120).

Gastroenterologic Sources of Infection

Diarrhea Associated With Antibiotics or Chemotherapy

Etiology. Diarrhea is a common finding in patients undergoing treatment of gynecologic malignancy. In a study of 351 hospitalized women with gynecologic cancer, 12% developed diarrhea during the course of their hospital stay; 10% had diarrhea due to *Clostridium difficile* (121). In cancer patients *C. difficile* diarrhea may be due to exposure to broad-spectrum antibiotics or chemotherapy alone (121,122).

Signs and Symptoms. Antibiotic-associated diarrhea can occur at any time during an antibiotic course and for at least a month after discontinuation. Patients typically develop abdominal pain, fever, and frequent watery diarrhea defined as ≥ 5 bowel movements per day lasting for more than 48 hours; however, *C. difficile* colitis may sometimes cause abdominal pain and fever without diarrhea.

Diagnosis. Any patient with antibiotic- or chemotherapy-associated diarrhea should have a full evaluation of stool, including routine cultures and a test for evidence of *C. difficile* toxin (123). In patients with a highly suspicious clinical presentation but no evidence of *C. difficile* toxin in stool, sigmoidoscopy or colonoscopy may reveal the pathognomonic mucosal pseudomembranes. One study has suggested that evaluation of stool for *C. difficile* toxin is the only cost-effective test (121). A markedly elevated white blood cell count may also be a clue to diagnosis (124).

Therapy. Oral therapy with metronidazole (250 mg to 500 mg four times daily for 2 to 4 weeks) is adequate to treat most cases of antibiotic-associated diarrhea (122–124). Because of continued reports of vancomycin-resistant bacteria (125), the use of oral vancomycin is restricted in many hospitals. Oral vancomycin should be given only to patients with proven *C. difficile* diarrhea who have not responded to metronidazole. Some patients may require repeated or prolonged courses of metronidazole, particularly if their clinical course necessitates continuation of the provocative agent (i.e., continued antibiotics or chemotherapy). Antidiarrheal compounds such as Lomotil or Imodium should not be given routinely. If, however, diarrhea persists after appropriate tests and cultures, symptomatic therapy should be considered. Nitazoxanide is a

nitrothiazolidine and effectively treats intestinal infestation of *Cryptosporidium* and *Giardia* species; at low concentrations nitazoxanide also inhibits *C. difficile*. A recent trial showed that nitazoxanide 500 mg twice daily was as effective in eradicating *C. difficile* as metronidazole given 250 mg four times daily (126). Nitazoxanide may be used for patients with metronidazole-refractory or recurrent *C. difficile* colitis.

Noninfectious Causes of Fever

Not all patients with gynecologic malignancy and fever have an infection. Pulmonary embolus, drug-related fever, and tumor-related fever represent the main noninfectious sources of fever, but others, such as factitious fever and underlying collagen vascular disorder, must also be considered. The use of procalcitonin and neopterin levels has been suggested to help distinguish between infected and noninfected patients, although further studies are needed to validate these tests (127).

Pulmonary embolus should be considered in a bed-bound or postoperative patient with any combination of fever, chest pain, dyspnea, or an abnormal chest radiograph. Patients with bulky pelvic tumors are also at risk. A high level of suspicion is important and spiral chest CT scans or ventilation-perfusion scans may establish the diagnosis; in rare instances a more definite pulmonary angiogram may be performed. Therapy remains anticoagulation with low-molecular-weight heparin. For patients who are unable to tolerate these drugs or who continue to have pulmonary emboli despite therapy, inferior vena caval filters are required.

Any antibiotic may cause fever (128). Patients typically develop fever and a diffuse maculopapular rash after several days of therapy. Eosinophilia, although a helpful sign, is usually lacking. Mild elevations in liver function tests may be present though nonspecific. Atypical presentations of drug fever, including patients without rash or those who develop fever weeks into therapy or after completion of therapy, can also occur. The diagnosis is usually made by discontinuing the antibiotic and observing the patient. It is important to remember that some drug fevers may take as long as a week to resolve. Supportive measures, such as antipyretics and antipruritics, may decrease symptoms.

The diagnosis of tumor fever can be made only after systematic exclusion of all other potential causes of fever. Most patients with tumor fever have metastatic disease involving the liver or lung. In these patients, the fever may be as high as 40°C, and chills may be absent; when not febrile, these patients often feel relatively well. In patients suspected of having tumor fever, a clinical trial of broad-spectrum antibiotics is given. If the fever does not abate and no other clear infection source is evident, the likelihood of tumor fever increases.

CHAPTER 31 ■ MANAGEMENT OF COMPLICATIONS OF GYNECOLOGIC CANCER TREATMENT

DAVID G. MUTCH, CATHERYN YASHAR, MAURIE MARKMAN,
AND STEPHEN C. RUBIN

The treatment of a serious illness such as cancer always involves the judicious search for a proper balance between efficacy and toxicity. Although we strive to maximize cure and minimize side effects, a certain acceptable level of treatment-related complications is unavoidable. This chapter reviews the management of the late complications of the major therapeutic modalities used in cancer treatment: chemotherapy, radiation therapy, and surgery. The distinction between the acute and late complications of therapy is arbitrary; we consider late toxic effects to be those that initially become clinically evident more than several months after the initiation of therapy.

CHEMOTHERAPY

Anemia, myelosuppression, and thrombocytopenia, which are among the most common acute complications of chemotherapy, may persist for months after the completion of treatment. In general, a delay in return of marrow function to normal does not imply that the patient will experience any long-term hematopoietic effects of treatment. However, if the patient requires future treatment with marrow-toxic drugs, it is likely that the marrow reserve will be limited.

Myelodysplastic Syndrome and Acute Nonlymphocytic Leukemia

Perhaps the most feared long-term complication of the administration of chemotherapeutic agents is the potential for the development of myelodysplasia and acute leukemia. Although first recognized more than a decade ago in patients with ovarian cancer treated with alkylating agents, it is now clearly documented that the *chronic* administration of this class of antineoplastic agents is associated with roughly a tenfold increased risk for the development of acute nonlymphocytic leukemia (1,2). Granulocytic leukemia is not a common disease; only approximately 12,000 cases are diagnosed in the United States each year. The peak incidence of secondary leukemia occurs 4 to 5 years after chemotherapy administration; an increased risk is noted for at least 8 years after the cessation of cytotoxic drug treatment.

Survival after the diagnosis of treatment-related acute nonlymphocytic leukemia is generally measured in months. Specific antileukemia therapy, although occasionally of clinical

benefit, is usually unsuccessful in producing complete or long-lasting remission. In many patients with this clinical syndrome, it is most appropriate that the management plan involves supportive and comfort measures only (i.e., transfusions, antibiotic therapy, pain medications).

Current chemotherapy for gynecologic or other malignancies is quite different from the prolonged alkylating agent therapy reported to result in an unacceptably high incidence of acute leukemia. In ovarian cancer, studies have demonstrated that five or six treatment cycles or more prolonged treatment regimens produce equivalent therapeutic results (response rates and survival) (3,4). With fewer courses, both short-term (marrow suppression, emesis) and chronic side effects, including the risk of acute leukemia, should be reduced.

Because the majority of reports that estimated the risk of secondary leukemia after cytotoxic drug therapy in ovarian cancer were from the pre-cisplatin chemotherapy era, an association between cisplatin and leukemia remains unsettled (5–10). One report has suggested that the use of cisplatin in ovarian cancer may increase the risk for the development of acute leukemia by approximately fourfold (11). However, it is important to note that essentially all patients who received cisplatin in the pre-paclitaxel era also received an alkylating agent (generally cyclophosphamide), a class of drugs known to be leukemogenic (2,12). Based on all available data, it is appropriate to state that even this small increase in the risk of developing acute leukemia is an acceptable price to pay for the substantial improvement in overall survival associated with the use of platinum agents in ovarian cancer.

In view of the documented risk of acute leukemia associated with the long-term use of alkylating agents in ovarian cancer and the known low response rate of the disease to this class of drugs (delivered at standard dose levels) in individuals who fail an initial cisplatin-based regimen (13), the administration of chronic oral alkylating agent therapy (chlorambucil, melphalan) as a second- or third-line treatment is strongly discouraged. Several studies have confirmed that the use of etoposide is strongly associated with the development of acute leukemia (14–17). This risk appears to be highly correlated with the total cumulative dose of the drug administered over time. Therefore, for diseases in which etoposide is an appropriate or required component of treatment (e.g., germ cell tumors), management of the malignancy should include the use of optimal doses/schedules of the agent delivered for the minimal acceptable number of cycles.

Cardiac Toxicity

Doxorubicin, which has demonstrated activity in several gynecologic malignancies, is an important component of a number of commonly used treatment regimens (18). Its most serious potential side effect is cardiac toxicity (19). Whereas acute cardiac dysfunction (e.g., arrhythmias, pericarditis) may occasionally be observed, chronic heart failure is much more common. The incidence of subclinical and clinical congestive heart failure is directly related to the cumulative dose of doxorubicin administered (20). Cardiac abnormalities are rarely observed with a total doxorubicin dose <350 mg. With a cumulative dose of >550 mg/m², the incidence of cardiac dysfunction is 1% to 10%.

Risk factors for cardiac toxicity necessitating a lowering of the doxorubicin dose that can be safely administered include a history of significant hypertension or pre-existing cardiac disease, prior cardiac or mediastinal irradiation, and age >70 years (19). Patients who have received cardiac irradiation are at a particularly high risk for developing cardiac complications even when the "safe" dose level of doxorubicin is reduced by 50% (250 mg/m²) compared with those without such a history.

Doxorubicin-induced heart injury is unique, and specific histologic features are observed in tissue obtained through a cardiac biopsy during a right-heart catheterization (21). When morphologic abnormalities are graded, an objective scoring system appears to correlate well with the severity of the underlying pathologic process. However, although the results of a cardiac biopsy are predictive of future clinical symptoms, it is not a practical procedure to use in routine clinical practice.

Evaluation of serial echocardiogram (ECG)-gated blood-pool scans allows for a reasonably accurate assessment of the effect of doxorubicin on cardiac function (22,23). In most patients, a major drop in the cardiac ejection fraction is observed *before* the onset of clinical symptoms, allowing for discontinuation of the antineoplastic agent before more serious damage results.

Treatment of doxorubicin-induced heart failure focuses on improving myocardial contractility with afterload reduction and diuresis. Many patients improve symptomatically. Continued improvement in cardiac function has been noted more than a year after initial symptoms are observed.

Several methods have been used in standard clinical practice and experimentally to reduce the risk of the development of chronic cardiac dysfunction associated with doxorubicin, including administration by continuous infusion for several days (rather than by bolus instillation) (24) and the use of dexrazoxane, the first drug demonstrated to reduce anthracycline-induced cardiac injury (25). Neither technique appears to decrease the antineoplastic activity of doxorubicin compared with standard bolus administration.

The combination of doxorubicin and paclitaxel can result in an increased risk for cardiac toxicity compared with the use of doxorubicin alone (12). The appropriate sequencing of the drugs appears to reduce the risk of cardiac effects.

The combination of doxorubicin and herceptin (anti-HER2/neu monoclonal antibody) also appears to potentiate the cardiac toxicity of doxorubicin and to a lesser extent that of paclitaxel (26). There is currently inadequate information available to recommend specific management strategies to reduce the risk of toxicity when either chemotherapeutic agent is combined with this novel monoclonal antibody.

Although paclitaxel itself has been considered to be an agent with potential cardiac toxicity, particularly in individuals with pre-existing cardiac abnormalities, available data have suggested that most individuals can safely receive the drug without concern for the development of either acute (arrhythmias) or chronic (congestive heart failure) cardiac toxicities (27).

Pulmonary Toxicity

Bleomycin, an antitumor antibiotic, is a common component of the treatment regimen for patients with carcinoma of the cervix and malignant germ cell tumors (18). The most serious toxic effect of bleomycin is subacute or chronic interstitial pneumonitis (28). This inflammatory process may progress to a fibrotic stage, with subsequent significant impairment of pulmonary function.

The most common early symptoms of bleomycin-induced pulmonary toxicity are cough and dyspnea. Bibasilar pulmonary infiltrates have been reported in as many as 5% of patients who receive total cumulative doses of bleomycin <450 mg. The incidence rises to 10% with higher cumulative doses. However, it should be noted that severe pulmonary toxicity has been observed at total bleomycin doses <100 mg.

In addition to the cumulative dose received, other risk factors for bleomycin-induced pulmonary dysfunction include pre-existing emphysema, age >70 years, single doses >25 mg/m², and prior chest irradiation.

An interesting, potentially serious complication of bleomycin is the development of postoperative respiratory failure in patients previously treated with this agent (29). It has been postulated that bleomycin makes the lung more susceptible to oxygen toxicity. Lowering the inspired oxygen concentration during surgery to an FIO₂ of 0.24 and avoiding fluid overload during surgery appear to substantially reduce the risk of postoperative respiratory insufficiency.

The pathogenesis of bleomycin-induced pulmonary dysfunction is not completely understood. The agent produces an inflammatory intra-alveolar infiltrate with edema, followed by a proliferation of alveolar macrophages and subsequent interstitial fibrosis. In experimental systems, high concentrations achieved after bolus administration of bleomycin produced more pulmonary damage than either continuous infusion or delivery of low doses on a frequent dosing schedule. These data provide strong support for the clinical use of the agent either as a continuous intravenous infusion or on a low-dose weekly bolus schedule.

No specific treatment exists for bleomycin pulmonary toxicity except discontinuing the agent if pulmonary function tests, particularly the carbon monoxide-diffusing capacity, demonstrate a significant deterioration compared with baseline. Mild worsening in pulmonary function (10% to 15%) is common in patients treated with >240 mg of bleomycin. A more substantial worsening observed in pulmonary function tests should lead to the discontinuation of the antineoplastic drug. Steroid therapy may help reduce inflammation and improve symptoms, but it has little or no impact on established fibrotic lesions. Fortunately, most patients with subclinical disease or mild symptoms demonstrate improvement in symptoms, radiographic findings, and pulmonary function tests.

Mitomycin C, an antineoplastic agent used in patients with several gynecologic malignancies, can produce a syndrome similar to bleomycin-induced pulmonary insufficiency (17). Higher cumulative doses of the agent (20 mg/m²) appear to increase the risk of mitomycin C-induced pulmonary dysfunction (30). Symptoms include cough and progressive dyspnea. Corticosteroids may be helpful, but patients can develop progressive pulmonary insufficiency. As many as 5% to 7% of patients treated with mitomycin C have been reported to have clinical or subclinical evidence of pulmonary toxicity (30).

Neurotoxicity

The dose-limiting side effect of cisplatin, one of the most important drugs in the management of gynecologic malignancies, is neurotoxicity (31–33). The neurologic effects of cisplatin

include peripheral sensory neuropathy, ototoxicity, retinal toxicity, seizures, and autonomic dysfunction.

It is difficult to know the precise incidence of cisplatin-induced neurotoxicity because most early reports only occasionally noted this form of toxicity. In the past, the dose-limiting toxicity of cisplatin was acute renal dysfunction, and in most patients, it was not possible to administer high enough cumulative doses of cisplatin to observe nervous system toxicity (34). With the development of intensive hydration regimens, it has become possible to significantly increase the amount of cisplatin administered to individual patients.

Although cisplatin-induced neurotoxicity may occur after a single dose, most reports suggest that the incidence of this class of side effects increases with higher cumulative doses (31). A summary of the oncologic literature reveals that the incidence of cisplatin neurotoxicity is approximately 15% with a total cumulative dose <300 mg/m², but it rises to 85% with doses of >300 mg/m² (31).

The most common cisplatin-induced neurologic side effects result from toxicity to the peripheral sensory nerves. Patients complain of numbness, tingling, and paresthesia that involve the feet, legs, hands, and arms. Symptoms generally begin in the feet or hands and proceed proximally. Reflexes (ankle, knee) are lost, and vibratory sensation is greatly diminished. With continued treatment, patients may lose the ability to sense touch or pinprick. Ultimately, patients have difficulty walking and using their hands for fine motion (e.g., writing, picking up a fork).

Fortunately, recovery after cisplatin-induced peripheral neuropathy is common, although frequently not complete. Improvement in symptoms has been noted more than 2 years after the discontinuation of therapy, although most patients begin to note improvement within several months of stopping the antineoplastic drug.

Another important feature of cisplatin-induced neuropathy is that the initial symptoms may develop months after the last dose, and symptoms commonly worsen when the drug is stopped, only to improve several months later. This factor makes it difficult for the clinician to know whether a patient who experiences a mild neuropathy should continue to receive the agent because the ultimate severity of the current symptoms may not be known until after the next dose is scheduled to be given.

Cisplatin administration may also cause tinnitus and hearing loss in the high-frequency range (35). High-dose cisplatin regimens (100 mg/m² per dose) that achieve very high peak plasma levels appear to result in a greater incidence of ototoxicity than lower-dose regimens (35,36). Paclitaxel (Taxol) can also produce a peripheral neuropathy, which is a dose-limiting toxicity of the agent (37). The neuropathy has been noted to worsen with higher cumulative dosing in some patients and to persist for considerable periods of time (>6 months) (37).

The combination of paclitaxel and cisplatin has been shown to have the potential to produce a higher incidence of peripheral neuropathy than either agent used alone. Of particular concern is the combination of cisplatin (75 mg/m²) and 3-hour infusion of paclitaxel (175 mg/m²), where several studies have demonstrated a 20% to 25% incidence of severe (grade 3) peripheral neuropathy (38,39).

Although less neurotoxic than cisplatin plus paclitaxel, combination chemotherapy with carboplatin and paclitaxel, a commonly employed regimen in several gynecologic malignancies, also has the potential to produce distressing symptoms associated with the development of a peripheral neuropathy (40).

Renal Insufficiency

Cisplatin is the chemotherapeutic agent most commonly associated with renal compromise (34). Although the damage to the kidney is reversible in most patients, persistent abnormalities

in renal function are common in patients who experience acute toxicity. In addition, severe irreversible renal toxicity secondary to cisplatin has been reported; fortunately, however, it is rare.

Cisplatin produces its nephrotoxic effects by damaging the renal tubules. Vigorous saline diuresis has been shown to prevent the development of major renal impairment in most patients who receive this agent, although significant decreases in creatinine clearance are common after standard cisplatin treatment programs for ovarian cancer (400 to 600 mg/m² cumulative dose).

In addition to abnormalities in renal function tests, hypomagnesemia secondary to renal magnesium wasting is common after cisplatin administration. Although this defect generally does not result in clinical symptoms of hypomagnesemia, renal magnesium wasting can be demonstrated in many patients more than a year after discontinuation of cisplatin.

Mitomycin may also be associated with renal damage and kidney failure of such severity that chronic dialysis is required (41).

Infertility and Mutagenic Potential

One of the greatest concerns of younger female patients who receive chemotherapy is its effect on fertility. The data that directly address the influence of antineoplastic agents on fertility are limited because accurate figures on the incidence of subsequent pregnancies are not available.

The development of amenorrhea during chemotherapy is influenced by patient age, as well as the specific drug used. Younger patients appear to be able to receive higher cumulative doses of cytotoxic drugs than older women before amenorrhea occurs (42). Existing data reveal that the majority of young women treated with standard chemotherapy for gynecologic malignancies, including the intensive regimens employed in ovarian germ cell tumors, have an excellent chance to maintain fertility (43–45).

One summary of the literature on the influence of chemotherapy on ovarian function concludes that, if a woman continues to menstruate after administration of cytotoxic antineoplastic therapy, no therapy-related impairment in her ability to become pregnant should exist (42). However, it remains uncertain whether such women will experience premature menopause; therefore, a woman must consider this factor in any decisions about family planning.

An additional important question about fertility is the risk of an increase in congenital abnormalities in the children of women treated with cytotoxic drug therapy. Again, although the available data in the medical literature that address this point are limited and conflicting, the consensus is that no significant increase of spontaneous abortions or fetal abnormalities in pregnancies occurs in this setting, and fetal development (including intellectual function) appears to be normal (46,47).

It is noteworthy that the administration of specific chemotherapeutic agents, most notably the antimetabolites (e.g., methotrexate), during early pregnancy is associated with the development of fetal abnormalities (46). In addition, follow-up of children exposed to antineoplastic agents *in utero* is of limited duration, and the ultimate impact of such therapy will be known only when long-term follow-up is available (47).

RADIATION THERAPY

Radiation therapy is used in the primary treatment of cervical, vulvar, uterine, and vaginal carcinomas as well as in the adjuvant setting and is often used as a palliative measure. Recent advances such as chemoradiation have improved outcomes

TABLE 31.1**RADIATION THERAPY ONCOLOGY GROUP MORBIDITY GRADING SYSTEM**

Grade	Morbidity
1	Minor symptoms requiring no treatment
2	Symptoms responding to simple outpatient management; lifestyle (performance status) not affected
3	Distressing symptoms altering patient's lifestyle (performance status); hospitalization for diagnosis or minor surgical intervention (e.g., urethral dilatation) may be required
4	Major surgical intervention (e.g., laparotomy, colostomy, cystectomy) or prolonged hospitalization is required
5	Fatal complications

but toxicity and overall control for locoregionally advanced tumors remain a concern (48-53). To combat toxicity, new treatment modalities such as intensity-modulated radiation therapy (IMRT), image-guided radiation therapy (IGRT), and 3D-based brachytherapy are under investigation as are radio-protectors such as amifostine (Ethyol).

Despite advances, radiation inevitably leads to effects on normal tissues that can be divided into two categories: acute effects and late effects. Acute effects begin during a radiation course at approximately 2,000 cGy with symptoms gradually increasing during treatment and typically resolving completely in 4 to 6 weeks. Late effects initially are manifest as early as

1 month following the completion of therapy and can last a lifetime. These effects can be seen in the skin, urinary tract, gastrointestinal tract, and reproductive tract. A significant correlation between the severity of acute effects and the development of late effects has been controversial with some studies finding a relationship (54-58).

Multiple grading systems have been used in the past to quantify normal tissue reactions and complications. In 1983, the Radiation Therapy Oncology Group (RTOG) published a meaningful grading system for radiation complications (Table 31.1). By 2007, most cooperative groups adopted a unified system to make communication easier and more complete. The reporting systems used by both the Gynecologic Oncology Group and the Radiation Therapy Oncology Group are the National Cancer Institute Common Terminology Criteria for Adverse Events and the Common Toxicity Criteria (found at the NCI website address <http://ctep.cancer.gov/reporting/ctc.html>).

Normal tissue effects are influenced by dose fractionation, field arrangement, total dose, volume irradiated, and inherent tissue sensitivity. Some reports in the literature have demonstrated a correlation between increased total external beam doses and higher complication rates (Table 31.2). Radiobiologists estimate that in the case of injury to the normal tissues, only 5% to 20% of the damage is repaired. The radiation-induced late tissue effects are usually attributed to progressive obliterative endarteritis that leads to decreased blood flow and subsequent hypoxia and scarring (59). Further injury from surgery, biopsy, or recurrent tumor will leave the tissues at even greater risk for poor healing, ulceration, fistulization, and necrosis. Table 31.3 lists tolerance of normal tissue to therapeutic irradiation.

Bone Injury

The bony pelvis is weakened by radiotherapy due to progressive microvascular obliteration leading to decreased osteoblast/osteoclast function. The subsequent changes can lead to increased fragility with subsequent stress fracture or outright necrosis

TABLE 31.2**INCIDENCE OF GRADE 2 AND 3 GASTROINTESTINAL COMPLICATIONS (RTOG SCALE) IN RELATION TO EXTERNAL PELVIC IRRADIATION DOSE**

affecting the pelvis and femoral bones (60,61). In addition, the radiation profoundly affects the bone marrow both acutely and permanently.

The incidence of asymptomatic insufficiency fractures following pelvic radiation for uterine cancer was found to range from 34% to 89% but symptomatic fracture is lower at 13%. (62–64). Diagnosis can be made with magnetic resonance imaging (MRI) or bone scan. Presenting symptoms include pelvic pain on average 1 year following completion of radiotherapy. Expectant management or treatment with non-steroidal anti-inflammatories can provide relief until recovery, but multiple fractures are not infrequent.

The quoted tolerance dose for the femoral head for a 5% incidence of fracture at 5 years is 45 Gy and every effort should be made to minimize the irradiation of the femoral head (65). However, a review from Washington University found a 15% incidence of femoral neck fracture at 15 years when doses exceeded 42 Gy, especially in those women with pre-existing osteoporosis or tobacco use (66). Postmenopausal women with low estrogen are at particular risk and women should be screened and treated for osteoporosis before and after radiotherapy and treated with estrogens, calcium, and bisphosphonates as appropriate.

Finally, since approximately 40% of the bone marrow volume lies within the pelvis, large volume irradiation may lead to subsequent changes in hematopoietic tissues with symptoms and signs manifested from 2 weeks to 2 months after the completion of radiotherapy. Permanent bone marrow changes can affect subsequent chemotherapeutic tolerance, necessitating the use of hematopoietic growth factors such as filgrastim and erythropoietin (67). Use of IMRT has been shown to decrease this effect (68–71).

Gastrointestinal Tract

The gastrointestinal tract is more susceptible to radiation injury than other pelvic organs. This includes both acute and late effects. In addition to pre-existing conditions such as diverticulitis, pelvic inflammatory disease, age, body mass index, tobacco use, and prior surgery may increase the likelihood of radiation bowel damage (72,73). The tolerance quoted for large bowel or rectum is 70 to 75 Gy and includes patients who are treated with a combination of external radiation and brachytherapy. The small bowel tolerance is quoted as 45 Gy, but small bowel is relatively spared secondary to episodic motion in and out of the radiation field. If the loops of small bowel are immobilized secondary to adhesions from tumor or prior surgery they are more susceptible to injury. Anal tolerance is somewhat lower at 60 to 65 Gy with higher doses potentially causing damage to the myenteric plexus and subsequent dysfunction (74,75). Inclusion of the para-aortic nodal chain also increases the likelihood of bowel injury as more volume is included in the radiation field. One of the most common areas of injured bowel is the terminal ileum, especially when fixed in the right lower quadrant.

Radiation for intact cervical carcinoma usually includes both external beam and brachytherapy. Historically a rectal point was chosen to represent dose, but studies have demonstrated this point to inadequately represent the full dose spectrum to the rectum and sigmoid (76). In addition, intestinal injury has not always correlated with dose to this point. With the advent of computed tomography and magnetic resonance imaging in planning of radiation, dose-volume histograms have been used to better assess dose to intestinal structures (51,52,77,78).

The increased sensitivity of the gastrointestinal tract to radiation is secondary to physiologic superficial cell turnover and high cell division rates, with a cycle time of 12 to 15 hours (79). As these cells die, rapid loss leads to initial thinning of the mucosa followed by denuded epithelium, loss of fluids, malabsorption, and diarrhea (80–82). These injuries usually resolve at the completion of radiotherapy with the robust regenerative capacity of these cells, but vascular endothelial damage may lead to small vessel obliteration, fibrosis, tissue hypoxia, and late damage (82–84).

Symptoms of acute radiation enteritis range from loose, frequent stools and tenesmus to abdominal pain with severe bloody diarrhea at times necessitating a treatment break and fluid resuscitation. Symptoms usually start at about 20 Gy of conventionally fractionated radiation. Early symptoms can be managed with a low residue diet and oral loperamide or diphenoxylate. Oral intake stimulates the bowels so it is best to take the antidiarrheal prior to meals and bedtime. One to two tablets before meals and bedtime with a maximum of eight tablets a day, titrated to bowel activity, will manage most patients. If the patient has had a recent course of antibiotics or complains of bloody diarrhea, *Clostridium difficile* colitis should be eliminated as an aggravating factor. If the diarrhea is persistent despite loperamide or diphenoxylate, Kaopectate, paregoric, or in extreme cases somatostatin and bowel rest may be used. One should pay particular attention to hydration status and electrolytes with frequent, watery diarrhea and correct abnormalities as needed. Proctitis and tenesmus can usually be managed with Proctofoam HC or Cortifoam HC per rectum twice a day for 14 days or with anti-inflammatory suppositories such as Anusol. Oral and rectal sucralfate has been used, but data demonstrating its efficacy is lacking (85–87).

Long-term complications include tenesmus, urgency, hematochezia, chronic intermittent diarrhea, bowel stricture, obstruction, incontinence, and fistulas. Late toxicity to the gastrointestinal tract is estimated to be 1% per year for the first 2 years and then decreasing to 0.06% per year thereafter. Prior surgery increases the risk of subsequent injury. Radiographically a smooth, narrowed bowel with proximal dilatation suggests injury, and direct visualization demonstrates pale mucosa with superficial telangiectasias. Management includes intake of a low residue diet, daily Metamucil, and loperamide or diphenoxylate as needed. Telangiectasias can be locally but gingerly treated with laser, and extreme cases of hematochezia may necessitate sucralfate enema, intraluminal formalin, or surgical diversion (88–90).

Genetic and Fetal Effects

Irradiation causes random damage to the DNA so generalizations are difficult. Differences in cell stage and type, dose rate, sex, oxygenation, and species all affect the mutation rate and repair. Data in models are difficult to extrapolate to humans and direct evidence is scarce. There are certainly examples of radiation-induced tumors such as an excess of skin cancers with x-rays, lung cancer in pitchblende miners, bone tumors in radium dial painters, and liver tumors in those given Thorotrast. The Japanese survivors of the atomic bombs have been the largest human group studied and results indicate an increase in death from cancer (91). There are also reports of radiation-induced increases in other diseases (92). Other studied populations including the Oak Ridge National Laboratory have also contributed to the body of knowledge regarding increased death rates and relationship to radiation exposure (93).

Radiation is thought to increase the spontaneous mutation rate, not create unique mutations. The doubling dose (doubling dose is the dose of radiation that will double the rate of spontaneous mutations) was initially based on animal data but the

atomic bomb data suggests that the doubling rate may be higher than originally predicted from 1 to 2 Gy for acute exposure and 4 Gy for chronic exposure (94). There is no known threshold dose for the genetic effects of radiation. In females permanent sterility is affected by age of exposure. The published threshold is thought to be 2.5 to 6 Gy for acute exposure in females.

Effects on the fetus are varied and depend on dose, dose rate, and gestational age at exposure. After radiation one can see embryonic, fetal, or neonatal death; growth retardation; and/or malformations. The recommendation is to limit dose for the entire gestational period to ≤ 0.5 rem (~ 0.5 cGy), with monthly exposures limited to 0.05 rem. A therapeutic abortion should be discussed with any woman exposed to ≥ 10 cGy between 1 and 26 weeks gestation. Radiation for cervical carcinoma will result in fetal demise and spontaneous abortion usually follows this. The peak in congenital malformations occurs during major organogenesis (10 to 40 days). Later exposure can lead to microcephaly and mental retardation, especially from 8 to 15 weeks of gestation. In general it is believed that high doses in the first 2 weeks primarily lead to resorption. Irradiation from 4 to 16 weeks may precipitate severe abnormalities such as deformity, stunted growth, microcephaly, and mental retardation. With irradiation from 16 to 20 weeks mild microcephaly is seen but mental retardation and growth abnormalities are most common. Irradiation after 30 weeks is unlikely to cause gross malformations (59).

Genitourinary Tract

The quoted tolerance of the whole bladder is 65 Gy with an increase in tolerance to 75 to 80 Gy when the high dose volume is limited (65). In gynecologic carcinoma external radiation is often combined with brachytherapy that concentrates dose in a specified area close to the tissue at risk. Historically, low-dose-rate (LDR) radiation (dose rate 50 to 100 cGy/h) has been used for brachytherapy, but high-dose-rate (HDR, dose rate 100 to 300 Gy/min) is becoming more common. The recommendation for HDR is to keep the bladder dose below 70% of the dose to point A, as toxicity correlates with total dose to the bladder (95,96). With the adoption of dose-volume histograms and experience with image-guided radiotherapy, a more complete characterization of the tolerance of the bladder may be achieved (97–99).

Acute radiation effects in the genitourinary tract may cause symptoms such as frequency, urgency, dysuria, hematuria, and/or bladder spasms. Histologically, the bladder wall demonstrates submucosal edema with an inflammatory infiltrate. As most patients are relatively or overtly immunocompromised from cancer, radiotherapy, and chemotherapy, it is prudent to check a urinalysis and culture in symptomatic patients. Pyridium may be successfully used for dysuria while an antispasmodic such as oxybutynin chloride will help with urinary spasms. Antibiotics should be prescribed to treat any noted infection.

Long-term bladder complications include ulceration, fistula formation, ureteral stenosis, contracted bladder, and hematuria. For curative early-stage cervical cancer the actuarial rate of major urinary complications is estimated at 0.7% per year for the initial 3 years and decreases to 0.25% per year thereafter (100). Cystoscopy demonstrates areas of pallor or intense erythema and petechiae with occasional ulceration. With progressive small-vessel fibrosis from radiation, ulcers may form. Biopsies should be avoided if the appearance is typical as further stress can precipitate fistulization (101). Fistulas are most commonly seen in patients who have bladder invasion by tumor, but can certainly be seen in its absence and likelihood is increased with prior surgery or brachytherapy.

Fistulas are often surgically corrected, many times with urinary diversion as radiated tissue exhibits a decreased healing capacity. Ureteral stricture is an uncommon but well described late radiation complication. The possibility of stricture is increased when radical surgery is combined with radiation as both modalities compromise blood supply (102,103). The incidence of stricture has been estimated retrospectively to be 2.5% at 20 years and unilateral injury is more common than bilateral. Recurrent disease should always be entertained in the differential diagnosis of late ureteral stricture (104). For hematuria, treatment can range from cystoscopic cauterization of bleeding to cautious intravesical instillation of formalin (105,106). Hyperbaric oxygen treatment has also been used successfully for hemorrhagic cystitis following pelvic radiation (107,108).

Lymphatics

Surgery or radiation alone in the pelvis or groin can lead to lymphedema, but when combined the incidence of lymphedema increases (109,110). The prevalence of lymphedema is quoted from 11% to 18% and is greater in those treated for vulvar carcinoma with inguino-femoral lymphadenectomy and adjuvant radiation (109,110). Symptoms may be unilateral or bilateral and range from mild, soft, pitting edema to severe, indurated, brawny edema placing the woman at risk for cellulitis. Treatment includes compression stockings, massage, elevation, and good skin and nail care to avoid infection.

Nerve Injury

Although rare, reports of sacral neuropathy with doses commonly used in cervical carcinoma have been reported (111). Symptoms vary along a spectrum ranging from sensory changes to muscle weakness and paralysis. An electromyogram (EMG) will show injury similar to that seen in diabetes, and recurrent tumor as a cause must be eliminated.

Reproductive Tract

Radiation has demonstrable effects on all the reproductive organs but with varying sensitivities. The cervix and uterus can tolerate an unusually high radiotherapy dose that translates into a high locoregional control rate compared to other similarly sized solid tumors. In fact, frank necrosis is uncommon despite doses to point A exceeding 90 Gy (112). In addition, the vaginal mucosa is relatively radioresistant, tolerating a mucosal dose of 140 Gy prior to severe complications or necrosis. In fact, more recent reports suggest this may be an underestimate, and the tolerance may be closer to 175 Gy (113). The distal vagina is more radiosensitive than the proximal vagina and surface doses should be limited to 98 Gy (114). As an end organ, the vulva is more radiosensitive than other gynecologic tissues and doses should be limited to 50 to 70 Gy (70 Gy only with gross disease and shrinking, limited fields). Ovarian function after radiation is highly dependent on patient age and radiation dose, but therapeutic radiation that includes the ovaries will invariably lead to premature menopause. The supporting cells of the meiotic oocytes are more radiosensitive than the oocytes themselves, but without these cells estrogen production ceases, and the follicles fail to develop. A dose of 24 Gy leads to granulosa cell death, sterilization, and menopause, but the precipitating dose may be much lower in women over 40 years of age. Permanent sterility and menopause have been

reported with doses as low as 4 Gy (115,116). Those women who desire fertility or preservation of ovarian function should have options such as cryopreservation or ovarian transposition discussed (117–120).

Acutely the patient may have symptoms of vaginitis or vulvitis with pruritus, discharge, or denuded mucosa. Most patients will experience at least patchy wet desquamation of the vulva with therapeutic doses. Vulvar reactions are exacerbated by friction and the moisture typically present in this area of the body. Acute vulvar symptoms may be managed by two to three daily sitz baths with complete perineal drying by either patting or using cool air as with a fan or hair dryer set on cool. Undergarments should be cotton to allow “breathing” and ointments should be avoided. Vaginal mucositis may respond to gentle douching twice a day with a 1:10 mixture of hydrogen peroxide in water.

After radiotherapy, the vagina may become dry, contracted, and shortened with thinning of the mucosa, especially if the patient is naturally or iatrogenically postmenopausal (121,122). The effects on the vagina are long lasting and commonly interfere with normal sexual functioning (123). If the patient is not sexually active vaginal dilators should be prescribed to maintain a patent vagina. Other vaginal symptoms such as dryness or pruritus may be alleviated by lubrication, and local and/or systemic estrogen therapy (124,125). Examination will demonstrate pale mucosa, telangiectasias, fibrosis, and/or ulceration. Biopsies of abnormalities should be undertaken cautiously as fistulas can form. Pap smears after radiotherapy may show abnormal cells attributable to the radiation and consultation with the pathologist and colposcopy should always precede biopsy. If recognized early, most superficial ulceration will heal with gentle use of douches. In cases of perinecrotic or deep ulceration, debridement and possibly hyperbaric oxygen may be required with flap coverage once granulation tissue has started. Late vulvar effects may include atrophy and fibrosis, hypo- or hyperpigmentation, permanent epilation, and telangiectasias.

Long-term effects on the uterus and cervix are usually less symptomatic, but atrophy and cervical stenosis are common. Preservation of partial uterine function has been reported despite the high doses used in curative radiotherapy and this should be taken into account if hormone therapy is prescribed (126).

Women may or may not complain of sexual dysfunction after treatment, but active investigation should remain the responsibility of the treating physician as permanent changes are inevitable. Dysfunction is often characterized by lack of lubrication, dyspareunia, and loss of libido and orgasm. This aspect of radiation has unfortunately been poorly prospectively evaluated. In completed studies to date, some degree of dysfunction after pelvic radiotherapy commonly exists and improves with intervention (127,128). Studies have demonstrated increased compliance with interventions if counseling is included as part of the recovery process (129,130). The EROS device has been shown to correct sexual dysfunction in patients post radiotherapy by increasing the blood flow to the clitoris with gentle suction (131,132). Subsequent vascular engorgement then leads to increased vaginal lubrication and a decrease in physiologic dysfunction (133).

Strategies to Minimize Normal Tissue Injury

Strategies have developed over the years to help minimize normal tissue damage including treatment of all fields each day, use of a four-field technique, 3D conformal therapy with blocking of normal structures, shrinking-field techniques, prone position, and the use of belly boards to exclude bowel

(134,135). Newer techniques such as IMRT and IGRT hold promise to decrease acute and long-term toxicity. With the introduction of high-dose-rate brachytherapy, fears were raised that the increased dose rate would lead to higher complications, but prospective studies have not demonstrated this to be the case (136–139).

Intensity-Modulated Radiation Therapy

Intensity-modulated radiation therapy is becoming rapidly adopted as the treatment of choice in many cancers. IMRT uses highly sophisticated computer software and hardware to shape the form and intensity of the radiation beam to conform more precisely to a patient's tumor and to avoid the normal tissues. It is standardly used in many centers for the treatment of head and neck and prostate cancers and interest is increasing in gynecologic cancer as well. A survey of IMRT use in 2002 and repeated in 2004 demonstrated an increase in any use from 32% to 73% of radiation oncologists and is likely far higher today (140). The first American national trial allowing the use of IMRT for gynecologic cancers for postoperative endometrial and cervical cancers was opened by the RTOG in March 2006. Interest in IMRT as a future standard for gynecologic cancers has grown as several studies have demonstrated a decrease in hematologic, gastrointestinal, and genitourinary side effects (70,141–143). While these early reports demonstrate success in an institutional setting, national adoption will require standards and trials demonstrating superiority, reproducibility, safety, and efficacy (144–146).

Image-Guided Radiation Therapy

Image-guided radiation therapy is in its infancy but holds promise for more accurately targeting IMRT. Many linear accelerators can now be equipped with on-board imaging that includes conventional x-rays and computed tomography (CT) scanners. With this technology, daily imaging of tumors or normal tissues holds promise in allowing more accurate tissue sparing and adaptation of treatment plans to organ motion or tumor shrinkage (147,148).

3D Brachytherapy

Brachytherapy as an integral part of the successful treatment of gynecologic cancers is undisputed as it allows for higher control rates as well as decreased normal tissue toxicity (149,150). Traditional low-dose-rate brachytherapy was based on clinical experience and empirical rules established with two-dimensional imaging. Doses are prescribed in two systems, mg-hrs and dose to a point, point A. Both systems have evolved over time and have clear limitations (151–153). As imaging modalities improve with the advent of CT scanners and MRI, brachytherapy equipment is adapted to include systems designed to eliminate artifact and allow more accurate evaluation. The three-dimensional view afforded by new imaging has led clinicians and researchers in gynecologic radiotherapy to investigate the actual doses received by target and normal tissues. A standard nomenclature is being adopted worldwide and data is being collected in a unified drive toward volume-directed therapy. Hopefully, this new examination of the relationship of brachytherapy implants to external radiotherapy, normal tissues, and tumor may also allow increased control and decreased normal tissue toxicity (89,99,100).

Radioprotectors

Over the years many therapies have been studied as radioprotectors and sensitizers. One of the most promising is amifostine

(WR-2721; Ethiol). Amifostine is a compound extensively studied by the Walter Reed Army Institute of Research for radioprotection and has noted protective effects on the salivary glands, bone marrow, oral mucosa, esophagus, intestinal mucosa, and bladder mucosa (154,155).

The compound is an organic thiophosphate dephosphorylated to the active metabolite (WR-1065) in the tissue. The differential protection of normal versus tumor tissue is due to a differential concentration of tissue alkaline phosphatase and pH differences that allow variable metabolite uptake (156). The compound is rapidly absorbed into normal tissues with a prolonged retention time and a differential concentration of normal tissue:tumor of 100:1. After cellular uptake WR-1065 scavenges oxygen free radicals and by this mechanism affords normal tissue radioprotection.

Several published studies have demonstrated the efficacy of amifostine for normal tissue protection without sacrificing tumoricidal effects. A phase 3 trial in head and neck cancers demonstrated a statistically superior decrease in permanent salivary gland damage (157). Two randomized trials in pelvic radiation demonstrated a significant decrease in bladder and gastrointestinal toxicity without compromising median survival or therapeutic response (158,159). The rectal cancer trial of Liu et al. demonstrated a 50% reduction in toxicity in the genitourinary and the gastrointestinal tract. Grade 3 and 4 toxicity was seen in 14% of those treated without daily amifostine compared to 0% treated with amifostine. The RTOG has recently completed a phase 1/2 trial using amifostine as a radioprotector for chemoradiotherapy for cervical carcinoma when treating the pelvis and para-aortics. The results of this trial are still forthcoming. Toxicities of amifostine include hypotension and nausea. Subcutaneous administration has decreased the incidence of hypotension, but nausea must be actively managed, especially when combined with cisplatin (160). Skin toxicity has also been seen with subcutaneous administration.

SURGERY

The complications of surgery per se occur almost exclusively in the perioperative period; therefore, a discussion of the role of surgery as it pertains to the late effects of therapy of gynecologic cancer is principally a discussion of the surgical management of irradiation injury to the intestinal and lower urinary tracts. The management of intraoperative and early postoperative complications, such as bleeding and surgical damage to the urinary and intestinal tracts, is covered only briefly in this chapter. Readers interested in detailed discussions of these topics are referred to excellent texts on the subject (161,162).

Intraoperative Urinary Tract Injuries

Intraoperative injury to the urinary tract is a relatively uncommon occurrence during surgery for gynecologic cancer. Recognized intraoperative injury to the ureter occurs in approximately 1% of nonirradiated patients undergoing radical hysterectomy for cervical cancer (163). This represents a significant improvement in the injury rate from series reported before 1980. Injuries can occur by a variety of mechanisms, but usually involve crushing or laceration of the ureter. Crushing injuries typically involve clamping and/or ligation of the ureter. When identified intraoperatively, the clamp or ligature should be removed immediately and the ureter mobilized sufficiently

from surrounding tissue so that it can be carefully inspected. Observation over a period of time may be necessary to assess the blood supply and extent of damage. Intravenous indigo carmine can be administered if there is concern about urinary leakage. If the ureter appears viable and there is no extravasation, the site of injury can be stented with a self-retaining stent (single or double pigtail) passed through either a ureterotomy or a cystotomy over a wire. The retroperitoneum near the site of injury should also be drained with a closed suction drain. Lesser degrees of injury such as those resulting from mass ligation of the ureter may not require stenting; simply removing the suture may suffice. Severe crushing injuries may require resection of the damaged segment of ureter and, depending on the site of the injury and the anatomy, either primary anastomosis or reimplantation into the bladder. Stenting should also be performed in these cases.

Ureteral lacerations that do not compromise the blood supply of the ureter can be closed primarily with absorbable suture over a stent. Larger injuries or complete transections will require primary repair or ureteroneocystostomy. Injuries below the pelvic brim can generally be managed by ureteroneocystostomy, with bladder mobilization and psoas muscle hitch if required. Those above the pelvic brim are often best managed by anastomosis, or intestinal interposition. Generally, a ureteroneocystostomy should be performed when possible, as the complication rate of this procedure is significantly lower than with other types of anastomosis. Permanent suture should never be used when suturing the uroendothelium.

Injuries above the pelvic brim can be managed with a variety of techniques, including ureteroureteral anastomosis, transureteroureteral anastomosis, Boari flap, Demel technique, or intestinal interposition. Intestinal interposition uses a portion of the ilium as a ureteral extender and interposes a segment between distal ureter and bladder. The two flaps described must be raised carefully from medial to lateral, taking care to keep the superior vesicle artery intact. This will help keep the flap well vascularized. Transureteroureterostomy is potentially dangerous, because the function of both kidneys can be compromised if there is a technical problem with the anastomosis and, in the authors' opinion, should be avoided.

Intraoperative bladder injuries occur in approximately 1% to 2% of radical hysterectomy patients or other cases of radical surgery. They are generally easily repaired with a two-layer closure using absorbable suture, followed by bladder drainage for 5 to 14 days. Irradiated bladders generally should be drained longer than nonirradiated bladders.

Postoperative Urinary Tract Complications

With modern surgical techniques, the incidence of ureterovaginal fistula following radical hysterectomy has fallen to 1% to 2% from a rate of 10% to 20% several decades ago. Most become apparent from the 5th to the 14th day postoperatively. Placement of a vaginal tampon and instillation of intravesical methylene blue can allow discrimination of a bladder fistula from a ureteral fistula. Intravenous indigo carmine intravenous pyelography, cystoscopy, and retrograde pyelography may be useful to define the site of the problem. Initial therapy of ureterovaginal fistula is directed toward elimination of infection and maintenance of renal function. Retrograde stenting should be attempted and, if successful, the stent should be left in place for several months. This will often allow spontaneous healing of the fistula. If a retrograde stent cannot be passed, percutaneous nephrostomy and antegrade stenting should be performed. If antegrade stenting cannot be accomplished, nephrostomy drainage should be established, and a decision made about the timing of surgical repair. If an active intraperitoneal urine leak is present, immediate repair is indicated. In

the absence of this, many authorities prefer to wait 6 to 8 weeks before surgical repair, although there are also proponents of routine immediate repair.

Postoperative vesicovaginal fistulas are less common following radical hysterectomy and often heal spontaneously after prolonged bladder drainage. If surgical repair is necessary, many of these can be approached by the vaginal route. One of the most troubling complications after radical hysterectomy for cervical cancer is bladder dysfunction, a result of the necessary disruption of the nerve supply to the bladder that occurs during the radical pelvic dissection (164). Minor degrees of sensory and motor dysfunction, detectable by cystometrograms, are seen in essentially all patients, and approximately 2% to 3% of patients will have long-term clinically significant difficulties with bladder function that may require chronic intermittent self-catheterization. Almost all patients have some element of bladder dysfunction after radical hysterectomy, and their bladder function should be monitored carefully.

Fistulas that occur after the patient has received a combination of radiation therapy and surgery are less likely to heal spontaneously and often require surgical intervention. Vesicovaginal fistulas resulting from radiation injury almost always require surgical correction. The repair can be achieved vaginally or abdominally. Vaginal repair often uses a portion of the bulbocavernosus muscle (Martius flap) (165,166). This allows new blood supply to be brought into the radiated field. Alternatively, abdominal repair may require using a flap of nonirradiated tissue such as the omentum between the bladder and vagina to improve the success of repair by including additional blood supply.

Urinary diversion is often required to divert the urinary stream in patients in whom it is felt a primary repair of the area cannot be achieved. The type of diversion can be continent or incontinent, depending on the clinical situation at the time that the repair is needed. Also, it will depend on the patient's willingness to care for an extraneous device. If the patient already has a colostomy, she may be more willing to care for such a device. Early complications of urinary diversion include urine leak and vascular complications. Urine leak that is clinically important is seen approximately 5% of the time (167,168). This may present as urine leaking from the perineum, incision, or stoma or through a cutaneous drain. Evidence of leakage may also manifest itself by fever with abscess formation, ileus, or decreased urine output with a contemporaneous rise in BUN or creatinine. Initial management should always be conservative. Percutaneous drains or nephrostomies can be placed by interventional radiology for drainage of the urine or abscess. The tracts will often close under appropriate conservative management. Surgical intervention should be avoided, as the operative mortality is exceedingly high. In the case of urinary diversion, one can occasionally consider an "undiversion." In this situation, the urinary conduit is attached to the dome of the bladder, reconnecting the urinary stream.

Penalever et al. (169) reported on the complications of continent urinary diversions. They observed a complication rate of over 53% and a postoperative mortality of 9%. Early complications included stricture or obstruction, anastomotic leak, pyelonephritis, sepsis, and reservoir cutaneous fistula. Late complications included stricture or obstruction, incontinence, difficulty with catheterization, and urinary stones. All complications should be treated initially with drainage and nonoperative intervention until the complication is stabilized, then appropriate surgical management can be considered.

Intraoperative Intestinal Injuries

Intraoperative injury to the intestinal tract may occur from time to time in patients undergoing surgery for gynecologic cancers. Predisposing factors include prior extensive surgery,

irradiation, inflammatory disease, and perhaps intraperitoneal chemotherapy. Intraoperative intestinal injuries generally lead to no serious sequelae, provided that the bowel has been adequately prepared and the injuries are recognized and repaired appropriately. The extent of the bowel preparation should be tailored to the surgical procedure being performed and the likelihood of intestinal injury. For high-risk patients or for those in whom intestinal resection is contemplated, a complete antibiotic and mechanical bowel preparation is indicated (see Bowel Preparation section in Chapter 11). All bowel preparations can cause dehydration, and special attention should be given to the elderly patient to prevent dehydration with associated postoperative acute tubular necrosis; this may mean administering intravenous fluids during the bowel preparation.

Small injuries to the intestinal serosa usually do not require repair. Larger injuries or those occurring in irradiated bowel should be oversewn. Injuries that transgress both the serosa and the muscular layers of the bowel wall can be recognized by a bulging of the mucosa when gentle pressure is applied. These should be repaired, generally with a single layer of interrupted sutures. Injuries that enter the intestinal lumen must be dealt with according to their site and severity, as well as the condition of the intestine. Uncomplicated injuries to the small intestine and to the well-prepared large intestine can usually be closed primarily. A common technique uses a first layer of continuous or interrupted absorbable suture, followed by an interrupted layer of permanent suture, such as 3-0 silk or Vicryl. In the presence of more extensive injury, vascular compromise, tumor, or obstruction, a more extensive procedure, such as resection and anastomosis, may be required. In the case of injury to the unprepared large bowel, diverting colostomy should be considered.

Postoperative Intestinal Complications

The spectrum of postoperative intestinal complications includes obstruction and leakage of intestinal contents. Postoperative mechanical obstruction generally results from adhesions forming in the early postoperative period. Initial management should be conservative, including gastric decompression and, possibly, intravenous nutritional support, as many postoperative obstructions will resolve spontaneously. Those that do not resolve with conservative management may require surgical correction (170).

Leakage of intestinal contents can be a devastating complication. It may occur at the site of intestinal injury or anastomosis or may develop spontaneously in unmanipulated bowel. Predisposing factors include the presence of tumor and distal obstruction. Prior radiation therapy not only increases the risk of intestinal complications, but also makes their management more difficult (discussed later in this chapter). Management must be individualized, but basic principles include cessation of oral intake, establishing a route of drainage for the leaking intestinal contents, and treatment of infection. Emergency operation and intestinal diversion may be required in the case of gross intraperitoneal leakage of intestinal contents. In less acute cases, such as enterocutaneous fistulas following surgery, supportive management with gastric suction, total parenteral nutrition, and the use of somatostatin may allow spontaneous healing.

The use of automatic-stapling devices to perform low-rectal anastomoses has greatly facilitated the avoidance of permanent colostomy in gynecologic cancer patients. The technical feasibility of the anastomosis, however, must be weighed against the risk of immediate and long-term complications. In patients at risk for poor healing of the anastomosis, a diverting colostomy should be considered. If a leak does

occur postoperatively, simple diversion of the fecal stream usually prevents serious complications. The protective colostomy or ileostomy should be well out of the irradiated field if possible. A small proportion of patients undergoing low-rectal anastomosis with circular stapling devices will experience problems with long-term stenosis of the stapled anastomosis. It is important to use the largest staple cartridge that can be accommodated by the patient's intestinal lumen. Dilatation of the anastomosis under anesthesia may be effective in relieving symptomatic stenosis. Digital inspection of the anastomosis at regular office visits can help prevent progressive or recurrent stenosis. Very low anastomoses may also produce some degree of fecal urgency and incontinence, probably related to loss of the reservoir function of the rectal ampulla and denervation of the sphincter itself during the procedure. Radical pelvic resections as described above may also result in loss of bladder function and lead to atonic bladder; therefore, postvoid residuals should be checked during the postoperative period.

The reported frequency of anastomotic leaks varies significantly, depending on the type of anastomosis and site. The rate of clinical leak varies from 0% to 30%. This rate has been shown to be even higher when integrity of the anastomosis is investigated prospectively with water-soluble contrast material. Rectal anastomoses have a higher complication rate than all other anastomoses. The complication rate may also be related to the distance from the anal verge. Authors from the Mayo Clinic reported a 1% clinical leak rate in 402 patients undergoing hand-sewn colon anastomosis. Almost 6% (5 of 107) of the patients' colorectal anastomoses developed a leak (171,172). Pelvic abscess following an anastomosis may occur and is often heralded by high spiking fevers. The diagnosis is usually confirmed by CT scan and is usually best treated by percutaneous drainage under radiographic guidance (173).

A major long-term complication of colorectal anastomoses is stricture. This may occur in as many as 3% of very low anastomoses, particularly if the EEA stapler is used. The EEA stapler allows lower anastomoses than hand-sewn, but at a cost of increased risk of stricture, particularly if the area has been irradiated (172,174). It is unusual in anastomoses of the proximal rectum. The lower anastomoses, particularly those below the peritoneal reflection, can be dilated. Other more proximal strictures, including those of the small bowel, may require surgical correction (175).

Another common complication in gynecologic cancer patients is small bowel obstruction. Unfortunately, there is little information on management of this problem in our patients. Most of the management techniques are extrapolated from the general surgery literature. Small bowel obstruction presents with dilated loops of small bowel, air fluid levels, and associated nausea and vomiting. If there is air in the rectum on abdominal x-ray, the diagnosis of obstruction secondary to ileus is made. This usually resolves with conservative management and nasogastric suction over 1 to 7 days. Any surgical procedure, whether peritoneal or extraperitoneal, may result in an ileus. Treatment for adynamic ileus is bowel rest with nasogastric (NG) suction. Some have advocated agents to increase bowel motility, but this has not been shown to be effective in any peer-reviewed publications.

Mechanical small bowel obstruction occurs in a significant portion of patients with gynecologic malignancies. The differential diagnosis is ileus, fecal impaction ischemia, and, of course, gastroenteritis. Treatment is immediate NG suction. This problem requires immediate medical attention, but may no longer require immediate surgical attention. It is now generally accepted that a trial of conservative management is warranted in cases of small bowel obstruction, provided that there is no evidence of ischemic bowel or evidence of strangulation. The majority of cases of partial small bowel obstruction resolve with NG suction and electrolyte replacement, whereas fewer

than 50% of cases of complete obstruction resolve with this treatment and ultimately require surgical intervention (176–179). The use of contrasted bowel studies is often helpful in distinguishing high-grade from low-grade obstruction and may be helpful in determining the site of obstruction. The type of contrast used is controversial. Barium often yields a better study, but can complicate subsequent operative procedures, as barium is quite caustic if spilled in the peritoneal cavity. Soluble contrast is safer, but often is diluted to such a degree that the study is not helpful (179). If one believes that there could be a large bowel obstruction, an enema with contrast should be performed before an upper GI study. If the obstruction is in the distal small bowel, evaluation by enema can also be helpful if the patient has an incompetent ileocecal valve.

The timing and advisability of surgery on a patient who has end-stage ovarian cancer are controversial and require experience and associated judgment. If the physician feels that the patient's life expectancy is greater than 3 to 4 months and that the surgery is technically feasible, it is reasonable to proceed. Patients with disseminated carcinomatosis often have large segments of dysfunctional bowel, making resection necessary if the obstruction is to be relieved, and the risk of fistula is high. A gastrostomy tube and prolonged bowel rest should be used in this setting.

Large bowel obstructions often present with progressive symptoms of constipation and difficulty defecating. Once the obstruction is complete, surgical intervention is mandatory to avoid perforation at the cecum. The risk of cecal perforation increases when the cecum acutely dilates to more than 10 cm. Management is almost always a colostomy in the form of a loop or end, depending on the clinical situation (180). A more proximal obstruction may necessitate ileostomy with mucous fistula formation.

Late medical complications of intestinal surgery include those that follow extensive resection of the ileum and right colon, which may produce chronic diarrhea from impaired absorption of water, fat, and bile salts, and problems related to poor absorption of nutrients, including the fat-soluble vitamins and vitamin B₁₂.

Postoperative Incisional Complications

Incisional complications after surgery include varying degrees of wound separation in the early postoperative period, as well as incisional hernias that become apparent in the later postoperative period. Superficial wound separations, involving only the skin and subcutaneous tissues, are generally minor problems. They may be managed by reclosure, if the tissues are in good condition, or allowed to heal by secondary intention. Wound separations involving the deep fascia are more serious. Fortunately, the use of single-layer bulk closure of the abdominal wall, a kind of "internal retention" suture, has made fascial dehiscence quite uncommon, even in high-risk patients. Fascial dehiscence must, of course, be repaired emergently.

Wound infection occurs in approximately 4% of patients undergoing a surgical procedure. The infection rate varies with the type of patient, her medical characteristics, and the type of wound. It is important to follow appropriate preoperative measures to minimize the wound infection rate (161,162).

Incisional hernia is a long-term complication that is also quite uncommon after single-layer bulk closure of the abdominal wall. However, the reported rate of hernias in the gynecologic oncology population is approximately 5% (181,182). Incisional hernia occurs more often in patients who have factors that adversely affect healing, such as advanced malignancy, poor nutrition, and the use of radiation therapy and chemotherapy. It is also more common in patients who have had multiple prior operations and in those who have postoperative incisional

complications, such as infection. The need for elective repair should be determined on an individual basis. Extensive hernias may require the use of a prosthetic material to bridge the fascial gap.

Surgical Management of Radiation Injury

The Patterns of Care Outcome Study of cervical cancer published in 1983 analyzed data on 706 patients treated with radiation therapy at 163 institutions across the United States (183). Major complications (those that required hospitalization) occurred in 86 patients (12%). Fewer than half of these complications required surgery for management.

Perez et al. (184), reporting on 811 patients with cervical cancer treated at the Mallinckrodt Institute of Radiology (St. Louis, Missouri, USA), found that complications requiring surgery occurred in approximately 5% of patients. The most common intestinal complications included rectovaginal fistula, sigmoid stricture, small bowel obstruction, and sigmoid perforation. The most common urinary tract complications were bladder ulcer, vesicovaginal fistula, and ureteral stricture. In this report, irradiation dose and technique were the primary clinical features related to risk of complications. No relationship was demonstrated between complications and age or a history of previous pelvic disease. As mentioned previously, additional risk factors cited by other investigators include conditions that predispose to atherosclerosis, such as diabetes and hypertension (185). It is reasonable to estimate that approximately 5% to 7% of patients who undergo radiation therapy for cervical cancer will experience major treatment complications including fistulas that require surgery. The incidence of complications is significantly lower in women who receive irradiation for endometrial cancer, because of the lower central doses used. On the other hand, patients who undergo whole-abdominal irradiation as salvage treatment of ovarian cancer after chemotherapy failure have a risk of major complications reported in the range of 40% to 50% (186,187). Because of the high morbidity and low efficacy, this treatment has gained only limited acceptance.

Intestinal Tract

Radiation injury to the intestinal tract severe enough to require surgery generally becomes manifest in the first 2 years after treatment. In a series of 71 patients from the M. D. Anderson Cancer Center who required surgery for radiation injury to the small intestine, Smith et al. (188) reported that 48% of the injuries developed within 1 year after completion of treatment and 74% developed within 2 years. Occasionally, however, complications may develop much later, perhaps as a result of the natural development of atherosclerosis that accompanies aging.

The most common sites of intestinal injury in patients who undergo pelvic irradiation are areas of the intestinal tract that typically lie in the pelvic field. The ileum is the most frequent site of injury, because of the greater radiosensitivity of the small intestine compared with the colon. In a series from the Mayo Clinic, Schmitt and Symmonds (189) reported that, among 93 patients who underwent surgery for radiation injury to the intestine, 78 (84%) had involvement of the ileum. The rectosigmoid colon and the cecum are also frequent sites of involvement.

The decision to operate on patients with radiation injury must never be made lightly. Surgery may be required in the management of radiation injury to the intestinal tract for palliation of severe symptoms that fail to respond to the previously outlined conservative management, as well as for relief of

life-threatening complications, such as obstruction or perforation. In a review of all intestinal surgeries performed during a 3-year interval on the Gynecology Service at Memorial Sloan-Kettering Cancer Center, Rubin et al. (190) reported that 79 (46%) of the 171 operations that involved intestinal surgery were performed in previously irradiated patients. The most common indications for these operations were intestinal obstruction (44%) and intestinal fistula or perforation (32%) that occurred in patients treated for cervical or corpus cancer.

Smith and DeCosse (15), in a review on radiation damage to the small intestine, emphasized three phases that can be applied to the management of radiation injury in all areas of the intestinal tract: stabilization, evaluation, and surgery. The patient's fluid, electrolyte, and nutritional status should be assessed and optimized before surgery; total parenteral nutrition is often required. Some investigators have suggested that the use of somatostatin to decrease gastrointestinal secretions may promote the healing of enteric fistulas (191). As mentioned previously, in contrast to fistulas in the nonirradiated intestine, those involving irradiated bowel only rarely heal with a program of intestinal rest and parenteral alimentation. In cases of bowel obstruction, intestinal intubation and decompression should be performed preoperatively. If infection is present, preoperative antibiotic therapy should be given.

Except in emergency situations, a careful evaluation of the entire intestinal tract should be made before any contemplated surgery. One should always bear in mind that recurrent cancer may, in part, be responsible for the intestinal problems; if cancer is present, the appropriate management may be altered. Radiographic studies of the large and small intestine should be performed. Cutaneous fistulas can be studied by injection of contrast medium, and stomas can be explored endoscopically. Evaluation of the ureters and bladder by intravenous pyelogram and cystoscopy may also provide useful information. As Marks and Mohiuddin (192) pointed out, the extent of radiation injury may be greater than anticipated, and the patient must understand the possible need for intestinal or urinary diversion.

At operation, it is generally advisable to explore the entire abdominal cavity. Intestinal adhesions are frequently encountered, making exploration a difficult undertaking. Irradiated intestine must be handled with great care, and meticulous dissection must be used to lyse adhesions. Injuries to the intestinal wall that may be trivial in the nonirradiated patient may lead to fistulization of irradiated intestine. Frequently, in patients with gynecologic cancer, the surgeon encounters a matted mass of distal ileum densely fixed in the pelvis that is the site of obstruction or fistula. It is often not possible to release such a mass without damage to the involved intestine and risk of injury to adjacent structures, such as the urinary bladder and ureters, rectosigmoid colon, and major pelvic blood vessels. The decision whether to resect or bypass such an agglutinated mass of bowel may tax the judgment of even the most experienced surgeon. In general, such masses are best resected, particularly in the presence of intestinal necrosis, perforation, abscess formation, and fistulization, if resection can be accomplished without undue risk of gross contamination of the peritoneal cavity or damage to adjacent structures. Bypass procedures may be more likely to lead to the development of the blind-loop syndrome or to result in subsequent spontaneous perforation or fistulization of diseased defunctionalized intestine left *in situ*. In a series of 77 patients who underwent surgery for radiation injury to the small intestine, no difference in short-term complications was noted whether patients underwent resection or bypass, although it is likely that the two groups were not comparable in clinical features (188). The authors did believe that the long-term complications of fistula formation and continued small bowel necrosis could be avoided by primary resection. In patients with peritonitis caused by perforation, Swan et al. (193) emphasized

the option of ileostomy to avoid the risk of a failed intestinal anastomosis under these circumstances. In most cases, however, anastomosis can be performed. As pointed out by Hoskins et al. (194), anastomosis in the irradiated terminal ileum should be avoided by wide resection of the terminal ileum and ascending colon with ileocolonic anastomosis.

Decisions about bypass or resection of irradiated small intestine must also take into account the presence of enteric fistulas that are draining via the vagina, bladder, or skin. Smith et al. (195), reporting on 68 enteric fistulas managed on the Gynecology Service at Memorial Sloan-Kettering Cancer Center, emphasized that if fistulized loops cannot be resected, they should be totally excluded from the intestinal stream to minimize continued fistulous drainage. For example, in the common case of a terminal ileal fistula, this exclusion may be accomplished by dividing the ileum proximal to the fistula, performing an ileocolonic anastomosis, bringing out the ileal stump as a mucous fistula, and placing a staple line across the ascending colon to prevent reflux of intestinal contents through an incompetent ileocecal valve. The ultimate decisions as to the operative management of patients with irradiation injury to the small intestine must be in the hands of the operating surgeon. Under appropriate circumstances, satisfactory results may be obtained with either the resection or bypass procedure.

The surgical management of radiation injury to the large intestine presents a different set of considerations. Usually, the injury is to the rectosigmoid, where it may be manifested as proctitis, ulceration, stricture, perforation with abscess formation, or rectovaginal fistula (196). Lesser degrees of bleeding may be controllable by dietary modifications, hydrocortisone-containing enemas (Cortifoam, Proctofoam), or the use of the endoscopic YAG laser (197). Surgery is required for bleeding that fails to respond to conservative measures or is massive, recurrent, or associated with perforation. Colostomy alone, without resection of the involved intestinal segment, may be sufficient in some cases to control the bleeding, presumably by decreasing mechanical irritation and infection of the diseased area of the colon. In more severe cases, excision of the rectosigmoid is required, although this procedure may be technically difficult as a result of radiation fibrosis of the pelvic soft tissues. Under favorable circumstances, restoration of intestinal continuity by coloanal anastomosis may be feasible (198). The refinement of surgical stapling instruments over the last decade has extended the ability of the surgeon to perform such low anastomoses successfully.

Patients with rectal perforation and abscess formation may require urgent surgery after correction of fluid and electrolyte imbalance. The extent of the surgical procedure depends on the degree of radiation injury, the severity of the infection, and the general condition of the patient. Often, a diverting colostomy and drainage of the abscess control infection without the increased morbidity that may result from attempts at resection of the involved rectum. In chronic situations without active severe infection, resection and low anastomosis with a protective colostomy that can be closed several months after satisfactory healing has been demonstrated to be efficacious and may be considered.

Fistulization of the large intestine after pelvic radiation therapy usually occurs between the rectum and the vagina. Occasionally, the sigmoid colon or cecum may fistulize to the vagina, cervix, uterine fundus, or urinary bladder. Because these fistulas result from radiation necrosis of the intestinal wall, simple closure is doomed to failure. After a radiographic evaluation of the intestinal tract, generous biopsy specimens of the fistulous tract should be taken. If recurrent cancer is documented, a diverting colostomy is generally indicated for relief of symptoms, and attention should be given to further treatment of the cancer. If no evidence of recurrence is found,

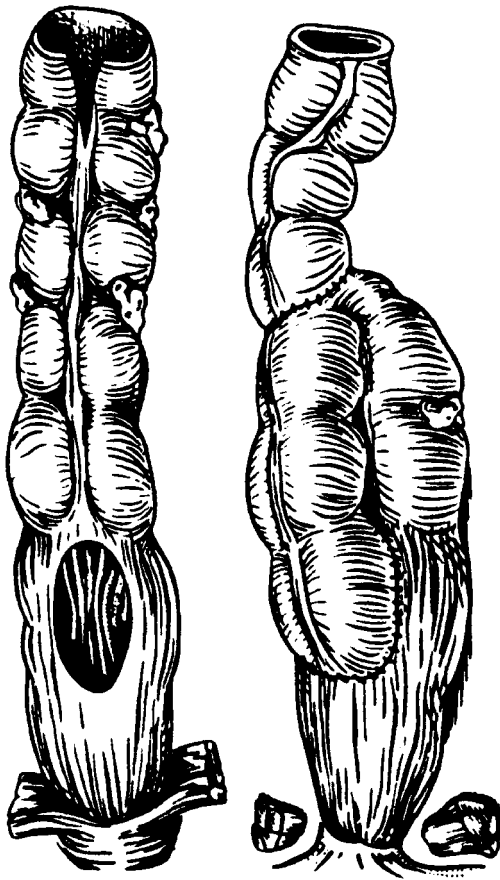

FIGURE 31.1. Bricker's technique for repair of postirradiation rectovaginal fistula. The proximal end of the colon is anastomosed end-on to the fistula, or it can be increased by an antimetenteric slit to fit a larger fistulous defect. *Source:* Reprinted with permission from Bricker EM, Johnston WD. Repair of postirradiation rectovaginal fistula and stricture. *Surg Gynecol Obstet* 1979;148:499–506.

closure of the fistula can be attempted after fecal diversion. Successful fistula repair requires the delivery of a new vascular supply to the damaged area. Perhaps the simplest means of accomplishing this task is to develop the bulbocavernosus fat pad from the labium major for use as a vascular pedicle graft between the rectum and vagina, as described by Martius (199). Although short-term results appear satisfactory with this technique (200), late breakdown can occur (201). Graham (202) has described the use of the gracilis and rectus muscles in the closure of large rectovaginal fistulas after irradiation with good success. More recently, Bricker and Johnston (203) have described an innovative technique that uses a folded piece of normal colon as a patch over the fistula, with restoration of intestinal continuity above the level of the fistula (Fig. 31.1).

Urinary Tract

Serious urinary tract complications after irradiation are somewhat less common than intestinal complications, presumably because of the greater resistance of the urinary tract to the damaging effects of ionizing radiation. Ureteral and bladder injuries that result from irradiation most often become manifest 1 to 3 years after therapy. In the series of Cushing et al. (204), 12.3 months was the mean interval for major radiation-related urinary tract complications to develop in patients treated for carcinoma of the cervix. Ureteral injury occurred

at a median time of 18 months in the report by Muram et al. (205), whereas the peak time of development of bladder injuries was 2 to 3 years in Kottmeier's (206) series. Occasionally, complications occur much later. Ureteral fistula as a complication of radiation therapy alone in the absence of surgery or recurrent cancer is extremely rare.

The incidence of ureteral stricture after pelvic radiation therapy has markedly diminished with the refinement of irradiation techniques in recent years. Everett (207), writing in 1939, noted a 15% incidence of severe ureteral obstruction in a small group of patients treated for carcinoma of the cervix. Kaplan (208) noted a 1% incidence of postirradiation ureteral obstruction in his patient population, but pointed out that this figure was probably an underestimate because patients were not routinely investigated. In the series of Underwood et al. (209), symptomatic ureteral stricture occurred in only 0.33% of 2,393 patients who underwent radiation therapy for carcinoma of the cervix; however, pyelographic evidence of stricture was noted in 4% of 100 asymptomatic patients studied 5 or more years after treatment. Villasanta (210) has pointed out that ureteral stenosis generally occurs after cervicovaginal necrosis and parametritis and must be considered at least in part a complication of infection in irradiated patients. The most common site of ureteral stricture after pelvic irradiation appears to be 4 to 6 cm above the ureterovesical junction at the point at which the ureter passes through the parametrium (208), although obstruction may also occur at the ureterovesical junction (20) or may involve a long segment of ureter from the pelvic brim downward (211).

Because most patients who develop ureteral obstruction after irradiation for cancer of the cervix have recurrent cancer as the cause of obstruction, a thorough evaluation for recurrence must be undertaken before appropriate management can be determined. In addition to a complete physical examination and routine laboratory tests, patients should generally undergo an intravenous pyelogram. Creatinine clearance and isotope renography can be performed to determine precisely the degree of impairment of renal function. Computed tomography or magnetic resonance imaging of the abdomen and pelvis should be done to look for evidence of recurrent cancer, with needle biopsies of suspicious areas performed under radiologic guidance. All patients should undergo pelvic examination under anesthesia, with cystoscopy. Biopsies of the cervix, parametrium, and bladder may help detect recurrence. Antegrade or retrograde pyelography may be needed to determine the site of obstruction or the anatomy of the involved urinary tract. In some cases, exploratory laparotomy may be needed to document recurrent cancer; however, as Boronow (212) pointed out, given the lack of effective therapy for recurrent cervical cancer after radiation therapy, unless pelvic exenteration is contemplated, laparotomy for diagnosis of recurrence is seldom indicated. However, one must be wary of making a clinical diagnosis of recurrent cancer in the absence of histologic confirmation. In an autopsy series of 68 patients with fatal hydronephrosis and uremia, Kirchoff (213) found radiation fibrosis only as the cause of urinary obstruction in 18 patients.

Once recurrent cancer has been excluded, the site and length of the ureteral stricture have been determined, and differential renal function has been assessed, a plan of management may be developed. If infection is present in an obstructed renal unit, antibiotic treatment and decompression, usually by percutaneous nephrostomy, should be undertaken. In general, the goal of intervention is to eliminate infection and preserve renal function. A patient with a mild degree of hydronephrosis may be followed with serial evaluations. If significant impairment of renal function is present or develops under observation, intervention is indicated. Temporary relief of obstruction may be achieved by stenting of the ureter, either retrograde or antegrade, with an internal self-retaining stent. Although

TABLE 31.4
LATERALITY OF IRRADIATION-RELATED URETERAL OBSTRUCTION

Reference	No. of obstructions		
	Unilateral	Bilateral	Total
Muram et al. (205)	9	3	12

Kirkinen et al. (219)	9	10	19 (7 simultaneous)
Underwood et al. (209)	3	5	8 (2 simultaneous)
Total	31 (62%)	19 (38%)	50

mechanical dilatation of radiation-related ureteral strictures has been attempted, it usually does not produce lasting relief of obstruction, probably owing to the intense degree of peri-ureteral fibrosis present in these patients. Despite the common assumption that ureteral stricture resulting from irradiation should be a bilateral process, a summary of reports providing information on laterality of involvement shows that, in approximately 60% of patients, involvement was unilateral (Table 31.4). Temporization does have the advantage of allowing one to observe the patient for the development of stricture on the opposite side, because bilateral involvement may not always develop simultaneously.

If surgery is required, the specific operative intervention depends on the site and extent of the damage and the remaining renal function on the affected side. As reported by a number of authors, simple lysis of the ureter from its fibrotic bed in the retroperitoneum is rarely successful in eliminating the obstruction (190,214). In general, it is necessary to resect the strictured segment of ureter and reconstruct the urinary tract using healthy tissue. Patients who have been heavily irradiated may have extensive fibrosis of the bladder, which makes direct reimplantation of the ureter difficult, particularly if a procedure such as bladder flap formation or psoas hitch is required to bridge the gap between the bladder and the ureter. In selected cases with minimal bladder fibrosis, satisfactory results may be obtained by ureteroneocystostomy, implanting the ureter into the lateral dome of the bladder, which usually has received a lesser dose of radiation. Often, the most prudent procedure is to interpose an isolated segment of intestine between the healthy ureter and the bladder (215,216). This bowel segment can also be used to increase bladder capacity if it has been significantly diminished as a result of irradiation. When considering how to reestablish intestinal continuity, one must remember that the ileum generally is heavily irradiated. Occasionally, a transureteroureterostomy above the irradiated field is appropriate, although one is naturally hesitant about the possibility of a complication that involves the opposite, relatively normal ureter. In extreme cases with bilateral ureteral injury or a bladder that can no longer function, urinary diversion may be required. This procedure is discussed fully in the section on pelvic exenteration, but may include continent urinary diversion, transverse or sigmoid colon conduit, or a Bricker-type conduit.

The bladder is subject to a spectrum of injuries from irradiation, which may produce sequelae including cystitis, hematuria, contracture, and occasionally severe necrosis and fistula formation. Bladder fistulas after irradiation for cancer of the cervix usually occur between the anterior vaginal wall and the posterior bladder wall because this area of the bladder receives the highest dose of radiation. In a series of 2,729 patients who underwent radiation therapy for cervical cancer at the M. D. Anderson Cancer Center, 34 patients (1.2%)

experienced vesicovaginal fistula as a complication of irradiation in the absence of recurrent cancer (217). The incidence of fistula was related to the stage of the patient's cancer, with patients who had advanced-stage disease having a greater risk of this complication.

Conventional techniques of vesicovaginal fistula repair that involve wide mobilization of the fistulous tract and a layered direct suture closure are usually not successful in the irradiated patient because of the fibrosis, poor tissue mobility, and compromised blood supply that follow irradiation (212). In the M. D. Anderson series, 20 patients underwent partial or complete colpocleisis for repair of radiation-induced vesicovaginal fistula (217). The authors were not enthusiastic about this technique, because several procedures were frequently required to achieve continence, coital function was often lost, and renal function was not improved and in many cases deteriorated. More often, once recurrent tumor has been ruled out and enough time has elapsed to allow for maturation of the fistula margins, closure may be attempted by a variety of techniques that involve the mobilization of well-vascularized tissue into the area. Boronow (212), who has contributed much to the subject, advises waiting 12 months between fistula formation and attempted closure. Gracilis muscle, omentum, and bulbocavernosus muscle have been used successfully (203,205,218,219).

Often, permanent urinary diversion is necessary. If one can subsequently repair the bladder, it is possible to attach the urinary conduit to the bladder dome in a procedure described by Boronow as the "undiversion."

In cases of bladder contracture that produces intolerable symptoms unresponsive to conservative measures, such as anticholinergic medications and bladder dilatation, augmentation cystoplasty may be indicated. Although some authors have suggested that bladder excision and replacement is preferable in radiation bladder disease (220), in the experience of others augmentation generally suffices if the bladder mucosa is not grossly abnormal (221). Techniques of augmentation cystoplasty have been described using ileum, cecum, or colon (222). In general, a nonirradiated segment of intestine should be selected and detubularized to allow it to hold a larger volume and ensure better healing (223).

CHAPTER 32 ■ MANAGEMENT OF PAIN

RUSSELL K. PORTENOY, DAMEAN FREAS, AND PAULINE LESAGE

The heterogeneous patient population managed by gynecologic oncologists presents a broad range of problems in pain management. The incidence of cancer pain varies, depending on the type of neoplasm, stage, and extent of spread. Acute pains are highly prevalent, including the rather straightforward incisional pain that follows surgical procedures. Chronic pain occurs in the context of numerous other physical and psychosocial symptoms, often in the population with advanced disease. Effective relief of pain may improve mood, coping, function, and other aspects of quality of life. Gynecologic oncologists have the opportunity and obligation to effectively treat pain.

SCOPE OF THE PROBLEM

Pain is highly prevalent in the cancer population. Overall, 30% to 50% of patients undergoing active antineoplastic therapy and 75% to 90% of those with advanced disease experience chronic pain severe enough to warrant therapy (1–3). Although data specific to gynecologic tumors are meager, those extant suggest that the overall prevalence rates mirror these averages (1,4–6).

A survey of patients with ovarian cancer illustrates the prevalence and characteristics of chronic pain in this population (6). The sample included 111 inpatients and 40 outpatients. The median age was 55 years (range 23 to 86 years), and most patients (82%) had stage III or IV disease at presentation and active disease (69%) at the time of the survey. Forty-two percent ($n = 63$) reported “persistent or frequent pain” during the preceding 2 weeks. This pain had a median duration of 2 weeks (range <1 to 756 weeks) and was usually abdominal/pelvic (80%), frequent or almost constant (66%), and moderate to severe. Most patients reported that pain caused moderate or greater interference with various aspects of function, particularly activity (68%), mood (62%), work (62%), and overall enjoyment of life (61%). In a study of 97 outpatients with breast cancer (54% metastatic disease), 47% of patients experienced cancer-related pain substantially interfering with their mood, quality of life, and functional status. The most prevalent underlying pathology was postmastectomy syndrome (56%), followed by pain from bone metastasis (26%).

Tissue injury related to the neoplasm itself is the most common cause of chronic cancer pain. Pain prevalence increases with the extent of disease and can be as high as 80% among populations with advanced illness (7). Chronic pain also may be related to an antineoplastic treatment, such as surgery (8–10), and in a small minority of patients, pain is unrelated to either the malignancy or its treatment.

Observational studies suggest that satisfactory relief of chronic pain is possible in 70% to 90% of patients with cancer (11–14). Undertreatment remains a serious problem, however (15–19), despite the availability of well-accepted guidelines for pain management (20).

Although the prevalence of severe acute pain in patients with gynecologic cancers has not been determined, and is likely changing with the increasing use of minimally invasive procedures, it is nonetheless presumed to be common and potentially controllable in a very large majority of cases. As more cancer surgeries are performed in the ambulatory setting, the ability to provide adequate treatment in unmonitored settings has become a greater challenge.

Patients with cancer, and particularly those with advanced disease, also experience numerous symptoms other than pain. The most common of these symptoms are fatigue and anxiety or depression. Acute treatment-related symptoms, such as chemotherapy-induced nausea and vomiting, also are prevalent. In the aforementioned survey of patients with ovarian cancer, the median number of symptoms per patient was nine (range 0 to 25) (Table 32.1) (6). In addition to pain, the most prevalent symptoms were fatigue (“lack of energy”), psychologic distress (“worrying,” “feeling sad,” and “feeling nervous”), and insomnia (“difficulty sleeping”). All of these symptoms had a prevalence of >50%. Compared to norms, approximately one third of the patients in this survey recorded heightened psychologic distress. The most important predictor of heightened distress was progressive impairment in physical functioning.

Fatigue is one of the most common complications of cancer and its treatment, and exemplifies the problem of concurrent symptoms in the patient with significant pain. In a recent analysis, patients perceived fatigue to be the most distressing symptom adversely affecting quality of life (21). A definition proposed for the International Classification of Diseases 10th Revision–Clinical Modification (ICD-10-CM) stresses the multidimensional nature of the phenomenon (22) and the National Comprehensive Cancer Network 2007 guidelines identified seven factors that should be assessed as potential causes of prolonged fatigue, one of which is pain (others include emotional distress, sleep disturbance, anemia, nutrition, activity level, and other comorbidities) (23). Patients with pain should be evaluated for meaningful concomitant symptoms, and the assessment of other symptoms should prompt an assessment of pain.

ASSESSMENT OF CANCER PAIN

The assessment of chronic pain in patients with gynecologic cancer requires an understanding of its phenomenology, pathophysiology, and syndromes. Optimally, this assessment must also consider the broad range of physical, psychologic, and social disturbances concurrently experienced by these patients. Patients with acute pain, particularly acute postoperative pain, pose less complex management problems, but could still potentially benefit from an ongoing comprehensive assessment.

TABLE 32.1**PREVALENCE AND CHARACTERISTICS OF SYMPTOMS ASSOCIATED WITH OVARIAN CANCER (N = 151)**

Symptom	Overall prevalence (%)	Intensity ^a (%)	Frequency ^b (%)	Distress ^c (%)
Worrying	71.7	55.4	33.5	25.0
Lack of energy	68.6	52.6	37.3	28.0
Feeling sad	63.8	46.4	22.8	22.2
Pain	61.8	50.4	32.9	24.1
Feeling nervous	61.5	39.9	25.0	19.6
Difficulty sleeping	57.3	44.0	30.7	20.7
Dry mouth	45.6	30.2	18.8	8.7
Feeling drowsy	45.3	32.7	15.9	9.3
Feeling irritable	45.9	33.8	12.2	10.8
Numbness/tingling in hands/feet	42.7	24.0	26.0	9.3
“I don’t look like myself”	35.8	25.0	—	12.8
Nausea	35.6	18.8	9.4	8.1
Difficulty concentrating	34.7	16.0	7.3	11.3
Feeling bloated	34.7	26.0	17.3	8.7
Constipation	28.6	20.4	—	11.6
Lack of appetite	28.4	20.4	14.2	8.2
Change in the way food tastes	25.7	16.2	—	8.1
Hair loss	26.4	15.0	—	9.5
Cough	25.3	11.3	6.0	4.0
Itching	22.3	11.5	8.1	3.4
Diarrhea	20.8	10.1	6.0	4.0
Swelling of arms or legs	18.9	12.2	—	8.8
Shortness of breath	18.7	10.0	7.3	6.0
Weight loss	18.5	4.8	—	3.4
Problems with sexual interest or activity	17.6	14.9	10.9	6.8
Dizziness	16.2	5.4	2.7	2.7
Vomiting	13.3	8.7	3.3	6.0
Mouth sores	8.1	4.7	1.4	2.0
Nightmares	8.0	5.3	2.0	2.0
Problems with urination	7.3	5.3	4.0	3.3
Urinary accidents	7.4	4.1	0.7	1.4
Difficulty swallowing	5.4	3.4	2.7	2.0

^aPercentage of sample describing the symptom as “moderate,” “severe,” or “very severe.”

^bPercentage of sample describing the frequency of the symptom as “frequently” or “almost constantly.”

^cPercentage of sample describing the distress associated with the symptom as “quite a bit” or “very much.”

National medical organizations have developed guidelines in an effort to more effectively detect and monitor pain. The Joint Commission on Accreditation of Healthcare Organizations developed a standard requiring that pain be assessed initially and periodically in all hospitalized patients. The National Comprehensive Cancer Network 2007 Adult Cancer Pain Guidelines require a formal pain assessment, measurement of pain intensity, reassessment of pain intensity at specific intervals, psychosocial support, and specific educational material (23).

Definition of Pain

According to the International Association for the Study of Pain, pain is “an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage” (24). Reported pain may be perceived by the clinician to be greater than or less than the observable degree of tissue injury. In the cancer population, a

physical process capable of explaining the pain can usually be identified, but this does not obviate the need for a careful assessment of other factors, including psychologic disturbances, that could be influencing the intensity of the pain or contributing to pain-related distress.

The definition of pain can be further clarified by the distinctions among nociception, pain, and suffering (Fig. 32.1) (25). Nociception is the activity produced in the afferent nervous system by potentially tissue-damaging stimuli. Clinically, nociception is inferred to exist whenever tissue damage is identified. Pain is the perception of nociception and, like other perceptions, can be determined by more than the activity in the sensorineural apparatus alone. Although tissue damage related to the tumor or its treatment is common in those with cancer pain, a careful assessment is needed to infer the degree to which the pain report is consistent with the nociception presumed by the clinician on the basis of the physical findings. In all cases, factors other than nociception, including neuro-pathic processes that can sustain pain in the absence of ongoing

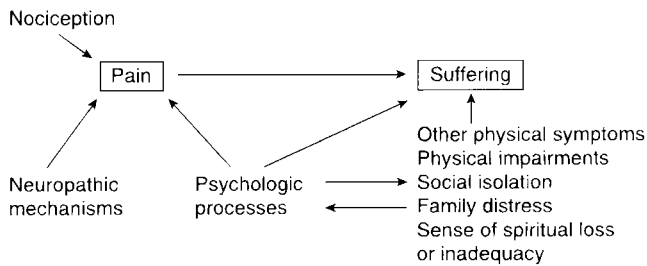

FIGURE 32.1. Distinctions and interactions between nociception, pain, and suffering. *Source:* Reproduced with permission from Portenoy RK. Cancer pain: pathophysiology and syndromes. *Lancet* 1992;339:1026–1031.

tissue injury (see below) and psychologic disturbances, must be evaluated as other potential determinants of the pain. The failure to address these other factors while targeting therapy at the sources of nociception can lead to a poor outcome in which the focus of tissue damage is ameliorated but the pain continues.

Suffering, or “total pain,” can be defined as a more global aversive experience determined by numerous perceptions, one of which may be pain (see below). Among the many other factors that may contribute to suffering are the perception of physical deterioration, the experience of symptoms other than pain, psychologic disturbances (e.g., depression or anxiety), disruption in the family, social isolation, and fear of death. Just as an inordinate focus on nociception, rather than pain, can lead to interventions that reduce tissue damage without alleviating symptoms, an emphasis on pain management alone in patients with profound suffering determined by other factors can fail to influence favorably the overall quality of life even if physical comfort is enhanced (26,27).

Evaluation of the Pain Complaint

The comprehensive assessment of pain should include information about temporal characteristics (onset and duration), course (stable or changing since onset, relatively constant or widely fluctuating), severity (both average and worst), location, quality, and provocative and palliative factors. This evaluation is complemented by information about the patient’s extent of disease, related medical and psychosocial conditions, present and past pain management strategies and their outcomes, the impact of the pain on the patient’s daily life and functioning, as well as the patient’s and family’s knowledge of, expectations about, and goals for pain management. Risk factors for the undertreatment of the patient’s cancer pain and risk factors for serious physical or psychiatric comorbidities (such as drug abuse) should also be examined.

Characteristics of Pain

Intensity. The measurement and recording of pain intensity is an essential element in the comprehensive assessment of pain. Although more information than intensity alone is needed to understand and manage cancer pain, a systematic method for assessing intensity is foundational. The most common approaches are a verbal rating scale (none, mild, moderate, severe, excruciating) and/or an 11-point numeric scale

(where 0 is no pain and 10 is the worst pain imaginable). A visual analog scale (VAS) that uses a 10-cm line anchored at one end by the words “no pain” or “least possible pain” and at the other end by “worst possible pain” is another simple and valid approach to pain measurement. The choice of scale is less important than consistency in its use over time. Brief assessment tools modeled on this approach also can be applied to the intensity measurement of nonpain symptoms, such as depression and fatigue.

Multidimensional scales are available, but usually are utilized in research settings. These scales provide a more comprehensive measure of the pain experience, often encompassing such factors as function and quality of life.

Temporal. Acute pain usually has a well-defined onset and a readily identifiable cause (e.g., surgical incision). It may be associated with anxiety, overt pain behaviors (moaning or grimacing), and signs of sympathetic hyperactivity (including tachycardia, hypertension, and diaphoresis). In contrast, chronic pain is characterized by an ill-defined onset and a prolonged, fluctuating course. Overt pain behaviors and sympathetic hyperactivity are typically absent, and vegetative signs, including lassitude, sleep disturbance, and anorexia, may be present. A clinical depression evolves in some patients. Most patients with chronic cancer pain also experience periodic flares of pain, or “breakthrough pain,” an observation with important therapeutic implications (see below).

Topographic. The distinctions among focal, multifocal, and generalized pains may influence both the assessment and treatment of the patient. Some therapies, such as nerve blocks and cordotomy, depend on the specific location and extent of the pain.

The distinction between focal and referred pain is similarly important. Focal pains are experienced superficial to the underlying nociceptive lesion, whereas referred pains are experienced at a site distant from the nociceptive lesion.

Pain may be referred from a lesion involving any of a large group of structures, including nerve, bone, muscle, or other soft tissue, and viscera (28–30). Various subtypes can be distinguished: (a) pain referred anywhere along the course of an injured peripheral nerve (such as pain in the thigh or knee from a lumbar plexus lesion); (b) pain referred along a course of the nerve supplied by a damaged nerve root (known as radicular pain); (c) pain referred to the lower part of the body, usually the feet and legs, from a lesion involving the spinal cord (called funicular pain); and (d) pain referred to a site remote from the nociceptive lesion and outside the dermatome affected by the lesion (e.g., shoulder pain from diaphragmatic irritation).

Knowledge of pain referral patterns is needed in order to target appropriate assessment procedures. For example, a patient with recurrent cervical cancer who reports progressive pain in the inguinal region may require evaluation of numerous structures to identify the underlying nociceptive lesion, including the subjacent pelvic bones and hip joint, pelvic sidewall, paraspinal gutter at an upper lumbar spinal level, and intraspinal region at the upper lumbar level.

Etiology

The etiology of acute pain is usually clear-cut. Further evaluation to determine the underlying lesion or pathophysiology of the pain is not indicated unless the course varies from the expected. In contrast, the etiology of chronic cancer-related pain may be more difficult to characterize. In most cases, pain is due to direct invasion of pain-sensitive structures by the neoplasm (24,25,31). The structures most often involved are bone and neural tissue, but pain can also occur when there is an obstruction of hollow viscus, distention of organ capsules, distortion or occlusion of blood vessels, and infiltration of soft

tissues. The etiology of pain in less than a quarter of patients relates to an antineoplastic treatment, and less than 10% have pain unrelated to the neoplasm or its treatment (31).

These data suggest that a careful evaluation of cancer patients with pain is likely to identify an underlying nociceptive lesion, which will usually be neoplastic. A survey of patients referred to a pain service in a major cancer hospital noted that previously unsuspected lesions were identified in 63% of patients (32). This outcome altered the known extent of disease in virtually all patients, changed the prognosis for some, and provided an opportunity for a primary antineoplastic therapy in approximately 15%.

Pathophysiology

Pain is labeled nociceptive if it is inferred that the sustaining mechanisms involve ongoing tissue injury. This injury can involve either somatic or visceral structures. The quality of somatic nociceptive pain is typically described as aching, stabbing, throbbing, or pressure-like. The quality of visceral nociceptive pain is largely determined by the structures involved. Obstruction of hollow viscus is usually associated with complaints of gnawing or crampy pain, whereas injury to organ capsules or mesentery is associated with an aching or stabbing discomfort.

Pain is labeled neuropathic if the evaluation suggests that it is sustained by abnormal somatosensory processing in the peripheral or the central nervous system (CNS). Neuropathic mechanisms are involved in approximately 40% of cancer pain syndromes and can be disease related (e.g., tumor invasion of nerve plexus) or treatment related (e.g., postmastectomy syndrome, chemotherapy-induced painful polyneuropathy) (31). Among those with metastatic disease, neuropathic pain usually results from neoplastic injury to peripheral nerves (peripheral neuropathic pain). Other, less common subtypes include (a) those in which the focus of activity is in the CNS (sometimes generically termed deafferentation pain); and (b) those in which the pain is believed to be maintained by efferent activity in the sympathetic nervous system (so-called sympathetically maintained pain). Identification of a neuropathic mechanism is extremely important in clinical management because several specific therapies may be useful for these conditions (see below).

Neuropathic pain is diagnosed on the basis of the patient's verbal description of the pain and typically supported by evidence of nerve injury. Patients may use any of a variety of verbal descriptors but some, such as "burning," "shock-like," or "electrical," are particularly suggestive of neuropathic pain (33,34). Areas of abnormal sensations are often found on physical examination. These may include hypesthesia (a numbness or lessening of feeling), paresthesias (abnormal nonpainful sensations such as tingling, cold, or itching), hyperalgesia (increased perception of painful stimuli), hyperpathia (exaggerated pain response), and allodynia (pain induced by nonpainful stimuli such as a light touch or cool air).

Although pain can occur as a primary outcome of psychologic processes, a somatoform disorder, this appears to be rare in the cancer population. Nonetheless, psychologic factors may augment or alter the pain complaint, and not surprisingly, pain may be associated with fluctuations in psychologic distress. In one series of 203 inpatients with cancer, for example, depression was independently associated with pain intensity after controlling for performance status, disease status, and perceived treatment effect (35).

To assess the complex relationship between pain and psychiatric disease, it is useful to have familiarity with the common disorders that are present in gynecologic malignancies. One study observed major depression in nearly one quarter of women hospitalized with cervical, endometrial, and vaginal

cancer (36), and another reported more severe depression and poorer body image among gynecologic patients than those with breast cancer undergoing mastectomy (37).

If the assessment of the pain does not provide enough information to categorize it as primarily nociceptive or neuropathic, or mixed, or yield a sufficient understanding of the psychologic factors that may be influencing the pain, it is important to acknowledge this lack of certainty and avoid labeling the patient with a term that may inappropriately direct care. The greatest concern in this regard is the labeling of pain as psychogenic when the assessment does not yield positive evidence of a psychiatric disorder but an alternative answer is lacking. In this case, it is best to label the pain idiopathic than to speculate about underlying factors that are not clearly demonstrable from the evaluation.

Pain Syndromes

Efforts to improve the assessment of cancer pain have been greatly encouraged by the description of numerous pain syndromes, each of which is defined by a cluster of symptoms and signs (Table 32.2) (24,25,31,38). Syndrome identification can help direct the diagnostic evaluation, clarify the prognosis, and target therapeutic interventions. Recognition of pain syndromes that occur commonly among patients with gynecologic

TABLE 32.2

CANCER PAIN SYNDROMES

- I. Pain associated with direct tumor involvement
 - A. Due to invasion of bone
 1. Base of skull
 2. Vertebral body
 3. Generalized bone pain
 - B. Due to invasion of nerves
 1. Peripheral nerve syndromes
 2. Painful polyneuropathy
 3. Brachial, lumbar, sacral plexopathies
 4. Leptomeningeal metastases
 5. Epidural spinal cord compression
 - C. Due to invasion of viscera
 - D. Due to invasion of blood vessels
 - E. Due to invasion of mucous membranes
- II. Pain associated with cancer therapy
 - A. Postoperative pain syndromes
 1. Post-thoracotomy syndrome
 2. Postmastectomy syndrome
 3. Postradical neck dissection
 4. Postamputation syndromes
 - B. Postchemotherapy pain syndromes
 1. Painful polyneuropathy
 2. Aseptic necrosis of bone
 3. Steroid pseudorheumatism
 4. Mucositis
 - C. Postirradiation pain syndromes
 1. Radiation fibrosis of brachial or lumbosacral plexus
 2. Radiation myelopathy
 3. Radiation-induced peripheral nerve tumors
 4. Mucositis
- III. Pain indirectly related or unrelated to cancer
 - A. Myofascial pains
 - B. Postherpetic neuralgia
 - C. Chronic headache syndromes

TABLE 32.3**PAIN SYNDROMES COMMONLY ENCOUNTERED AMONG PATIENTS WITH GYNECOLOGIC CANCER****ACUTE PAIN SYNDROMES**

At any stage of disease:

- Postoperative pain
- Mucositis

In advanced stages of disease:

- Recurrent bowel obstruction
- Ureteral obstruction
- Movement-related pain in brachial/lumbosacral plexopathy
- Movement-related pain from bony lesions

CANCER-RELATED CHRONIC PAIN SYNDROMES

- Brachial/lumbosacral plexopathy
- Chronic abdominal pain: bowel obstruction, ascites, hepatomegaly
- Tenesmoid pain
- Bone pain from metastases

TREATMENT-RELATED CHRONIC PAIN SYNDROMES

- Postmastectomy syndrome
- Radiation-induced plexopathy
- Chemotherapy-induced peripheral neuropathy (paclitaxel, cisplatin)

cancers (Table 32.3) can also facilitate the assessment of these patients.

Comprehensive Assessment

A comprehensive assessment that incorporates this pain-related information can be used to elaborate a problem list that guides the priorities and direction of therapy. In many situations, such as acute postoperative pain or chronic pain related to a well-characterized lesion (e.g., pathologic fracture), the assessment issues are simple and the problem list is brief and straightforward. In other cases, most often in populations with advanced disease, a complex group of symptoms, medical disorders, and psychosocial disturbances greatly complicate the assessment process. In these cases, a comprehensive assessment encourages efficient selection of an appropriate multimodal therapy.

The biopsychosocial model implied by this clinical reality also has provided a framework for pain research. Reflecting this, a consensus has been reached that the core outcome domains for studies of chronic pain are pain intensity, physical functioning, emotional functioning, participant ratings of improvement and satisfaction with treatment, and other symptoms and adverse events (39).

Patients whose pain had been responsive to pain medication but experience an increase in pain intensity or a change in pain characteristics should be comprehensively reassessed as the initial step in management. The goal is to determine whether specific contributing factors can be identified. Relapse or disease progression, for example, may be amenable to primary therapeutic strategies, such as chemotherapy to address disease progression associated with loss of analgesic effectiveness. Other factors such as cord compression, systemic or local infection, and psychologic distress (e.g., depression) also may be treatable.

MANAGEMENT OF ACUTE PAIN

Although the treatment of patients with acute pain, particularly postoperative pain, is typically less challenging than the long-term management of chronic pain, the outcomes achieved in routine practice settings are often inadequate. Given the potential efficacy of widely used strategies such as patient-controlled analgesia (PCA), problematic outcomes may be more related to systems issues, such as access to a pain service, prolonged pharmacy preparation times, or other factors, rather than purely clinical issues. Cancer patients may have concurrent medical problems, psychologic disturbances, and prior drug exposure that increase the heterogeneity of the population and diminish the likelihood that routine measures will provide adequate relief of pain. The need for clinicians and administrators to attend to the problem of acute pain and provide the resources and systems for expert management is therefore particularly important in this population.

“Routine” Approach to Postoperative Pain

Despite great variability in the pharmacokinetics and pharmacodynamics of single opioid doses (40), and the large proportion of patients who fail to attain adequate analgesia with routine postoperative care, many patients do respond adequately to an opioid, traditionally morphine or meperidine, administered “as needed.” In the cancer population, the starting dose must take into account the prior opioid exposure of the patient. A reasonable starting dose is the equivalent of 5% to 10% of the total opioid consumption during the previous 24 hours. If the drug or route of administration is changed, an equianalgesic dose table must be consulted to calculate the equivalent total daily dose of the new drug. Once a dose is selected, it can be initially administered every 2 to 3 hours as needed.

As-needed dosing of this type may be considered when a procedure is likely to yield no more than moderate pain for a short while. In these cases, the use of an opioid with a short half-life, such as morphine or hydromorphone, is preferred and use of the intravenous route through slow injection or brief infusion will reduce distress associated with painful injections. Meperidine, although likely to be safe during brief therapy, is generally not preferred because of the availability of safer drugs (see below).

The proportion of cancer patients with postoperative pain who will be undertreated by an as-needed dosing schedule can be diminished if several factors are recognized. The variability in analgesic requirements may require changes in the starting dose, adjustment in the dosing interval during the immediate postoperative period, or both. Some patients require several dose adjustments. Similarly, variability in pain duration after any particular operation is great and the duration of opioid treatment must be flexible and be determined solely by patient response. Some patients have concerns about opioid-induced side effects and addiction, which may augment distress and diminish patient compliance with therapy unless strong reassurance is provided by the physician and other staff.

In some populations, the routine approach to postoperative pain management can be enhanced by the use of a nonopioid analgesic, specifically a nonsteroidal anti-inflammatory drug (NSAID). In the United States, ketorolac has been approved for short-term parenteral use. In opioid-naïve patients, a standard dose of ketorolac can provide analgesia equivalent to a parenteral dose of morphine of 10 mg (41). The addition of intravenous ketoprofen (not approved in the United States) to intravenous PCA with tramadol after major gynecologic cancer

surgery also significantly reduced opioid consumption (42). At the present time in the United States, patients who are highly predisposed to opioid side effects or toxicity, such as those with severe preexisting lung disease, may benefit from a trial of ketorolac either in lieu of opioid therapy or in combination with an opioid. Ketorolac should not be used when NSAID treatment is contraindicated.

Patient-Controlled Analgesia

PCA has achieved great popularity in the management of postoperative pain and there is strong evidence that it improves analgesia, decreases the risk of pulmonary complications, and increases patient satisfaction when compared with conventional opioid analgesia (43). Theoretically, the self-administration of small doses on a frequent basis allows the patient to tailor the dose to the pain and enhance a sense of personal control while achieving a more stable plasma drug concentration. However, not all studies of this modality have been positive. For example, a randomized, controlled trial of 227 gynecologic cancer patients undergoing intra-abdominal surgery found that patients who were switched from parenteral to oral morphine on the first postoperative day experienced the same degree of pain control as those who received parenteral morphine via PCA pump (44). The latter studies suggest that careful attention to dosing rather than the availability of a pump per se is the key factor in achieving adequate pain control.

Other Approaches to Acute Pain Management

Numerous alternative approaches to postoperative pain management have been explored. Some require the expertise of pain specialists.

Preemptive Analgesia

The administration of an analgesic prior to surgical tissue injury may reduce postoperative pain and opioid requirements, and possibly have longer-term benefits (45). There are conflicting data, however, and the influence of type of analgesia, timing, and range of outcomes has not been elucidated. The role of this strategy in gynecologic surgery is unclear and it is not generally pursued.

Oral Pretreatment and Postoperative Combination Therapy

Pretreatment with sustained-release morphine reduces postoperative pain and analgesia requirements (46,47). This technique is seldom used but may be an option in patients whose postoperative pain management is expected to be problematic.

Presurgical or postsurgical addition of an NSAID in combination with an opioid can augment analgesia and reduce the use of opioids, potentially leading to reduction of opioid side effects. A recent controlled trial, for example, demonstrated that postoperative celecoxib improved outcomes and was well tolerated in patients undergoing laparoscopic surgery (48). Equally important, there is now substantial data demonstrating that the combination of gabapentin, a neuronal calcium channel modulator widely used for the treatment of chronic neuropathic pain, with an opioid improves a range of outcomes in diverse surgeries, including hysterectomy (49).

Intraspinal Analgesia

Epidural analgesia is now common practice in many hospitals. There is strong evidence that analgesia is better with this approach than with parenteral opioids (50–53). There may also be a lower risk of some postoperative complications (54,55). Some studies suggest benefits that are prolonged into the recovery phase after surgery, but the extant data are insufficient to judge these benefits adequately (51). Some side effects are more likely with this technique than with conventional systemic opioid therapy, including pruritus and hypotension, and resources, including staff with special competencies, are needed to implement the approach safely.

Given the abundant evidence of better analgesia and related outcomes, patients undergoing major gynecologic surgery should be considered for epidural analgesia if the resources exist to provide it. Although there is less clinical experience in the use of subarachnoid opioid administration for postoperative pain, the technique can also provide excellent relief (56–58).

Regional Anesthetic Techniques

There are numerous regional anesthetic techniques that may be useful for the management of acute pain. The simplest is the application of local anesthetic at the surgical site. Topical anesthetics that are longer acting are in development and may offer substantial benefits in the future.

Neural blockade capable of denervating the painful site is a potential approach in most cases. Catheters that deliver local anesthetic at a dose high enough to produce a sensory block can be placed in the epidural space or along peripheral nerves or plexus. Regional anesthesia can be used during an operation and then continued into the postoperative setting for pain control. For example, a recent study demonstrated that subarachnoid block for vaginal hysterectomy yielded significantly better immediate postoperative analgesia versus standard general anesthesia (59).

Other Approaches

Transcutaneous electrical nerve stimulation (TENS) has been suggested to be a useful modality for incisional pain after abdominal surgery (60). Despite the evident simplicity and safety of the approach, there has been little application of its potential.

Cognitive approaches, including stress reduction, relaxation, hypnosis, and distraction techniques, have also reduced postoperative pain and analgesic requirements (61,62). These techniques are labor intensive and are almost never sufficient as the sole means of analgesia. Nonetheless, studies have established that higher levels of anxiety and depression can negatively influence postoperative pain and analgesic requirements (63), and efforts to reduce anxiety through preoperative education and postoperative psychological interventions are likely to have salutary effects.

MANAGEMENT OF CHRONIC CANCER PAIN

The successful management of acute postoperative pain is an important concern of the gynecologic oncologist, and satisfactory pain relief should be considered a norm of practice. The treatment of chronic pain is a far more challenging problem, particularly among those with advanced illness.

Cancer Pain, Symptom Distress, and Palliative Care

Most cancer patients who experience chronic pain also develop other physical and psychologic symptoms. Pain, fatigue, and psychologic distress are the most prevalent symptoms across populations (64,65). A broad assessment of symptom distress, followed by concurrent therapy of the most problematic symptoms other than pain, is a fundamental aspect of pain management.

Symptom distress, in turn, is only one aspect of the multifaceted problem of suffering (26,27,66). The assessment of suffering requires an evaluation in multiple domains, including the physical, psychologic, social, and spiritual. This in turn requires open and ongoing communication between the clinician and the patient.

The assessment and management of problems that relate to the broad constructs of suffering and quality of life are part of the therapeutic model of palliative care, which focuses on patients with progressive incurable illness and their families. This therapeutic approach aims to enhance the quality of life of the patient and family throughout the course of the disease. In the United States, palliative care is rapidly evolving. Specialist care now has a well-defined purview, as codified in a consensus document published by the National Consensus Project for Quality Palliative Care (67). The American Board of Medical Specialties approved Hospice and Palliative Medicine as a formal subspecialty, and in an unprecedented event, ten separate primary boards are co-sponsoring, including the American Board of Obstetrics and Gynecology. Specialist care is now being provided by institution-based palliative care programs, which now exist in approximately 40% of U.S. hospitals, and through hospice programs.

The evolution of specialist-level palliative care highlights the paradigm of generalist-level palliative care. The effort to provide optimal palliative care should be considered to be one aspect of oncology best practice. Physicians who are caring for patients with serious illness such as cancer must understand the necessity of palliative care from the time of diagnosis onward. They must acknowledge the multidimensional nature of this endeavor, including a focus on communicating well, setting goals, coordinating care, sharing decision making, promoting advance care planning, managing symptoms, providing psychosocial and spiritual support, addressing practical needs in the home, assisting the family as needed, and dealing with the challenges of end-of-life care when this is necessary. Referral to specialist services to address complex needs, or provide hospice home care services, is central to the role of the generalist.

General Principles of Pain Management

The development of a successful strategy for pain management must consider the etiology and pathophysiology of pain, the patient's medical status, and the goals of care. Although the main approach for the management of cancer pain is opioid-based pharmacotherapy, other interventions, including disease-oriented treatments (e.g., surgery, chemotherapy, or radiation) or other analgesic techniques, may be appropriate in selected cases.

Role of Primary Therapies

Effective treatment of the pathology underlying the pain can be analgesic (68,69). Primary treatment includes antineoplastic therapies and interventions directed at specific structural pathologies (e.g., lysis of adhesions). There is evidence in a limited number of

cancers that specific chemotherapy regimens yield analgesic effects and it is a common observation that patients who attain a partial or complete response also experience improved symptoms. In a study of patients with metastatic breast cancer, for example, palliative chemotherapy with doxorubicin with or without vinorelbine resulted in an improvement of pain in 60.4% of the 111 patients who suffered from pain at baseline (70); although patients with an objective tumor response were more likely to have an improvement in pain (84.9%), fully 61% of patients with stable disease also benefited. In a small study of patients with advanced ovarian cancer, palliative chemotherapy was associated with improvement in symptom control, emotional well-being, and global quality of life (71). In a study of patients with recurrent/advanced cervical cancer, 67% of patients experienced improvement of pain after alternating treatment with PBM (platinum, bleomycin, and methotrexate) and PFU (platinum and 5-fluorouracil [5-FU]) (72).

Radiation therapy commonly is used to manage pain and there is evidence that it can provide effective and durable palliation of pain and other symptoms in chemotherapy-refractory patients with ovarian cancer (73,74) and cervical cancer (75). Radiation therapy can also provide analgesia to as many as 80% of those treated for bone metastases (76). Patients with widespread bone metastasis or bone pain refractory to local field radiotherapy may benefit from treatment with radiopharmaceuticals, such as strontium 89 or samarium-153 (77). In addition, analgesia may be an expected result when radiation is used to treat epidural disease, tumor ulceration, cerebral metastases, superior vena cava obstruction, and bronchial obstruction.

Unfortunately, many patients with chronic cancer pain have no option for primary antineoplastic therapy or did not achieve symptomatic relief from these interventions. The approach to these patients involves a diverse group of primary analgesic treatments (Table 32.4). Several concurrent interventions are often required to manage the pain. The benefits of analgesic therapies must be balanced against the side effects they produce in a way that optimizes the outcome for the patient. Repeated assessments, performed as part of a broader approach to palliative care, are essential in this process and often lead to adjustments in the therapy.

THERAPEUTIC APPROACHES: PHARMACOLOGIC MANAGEMENT

Prospective trials indicate that more than 70% of patients can achieve adequate relief of cancer pain using a pharmacologic approach (3,12–14). Effective pain management requires

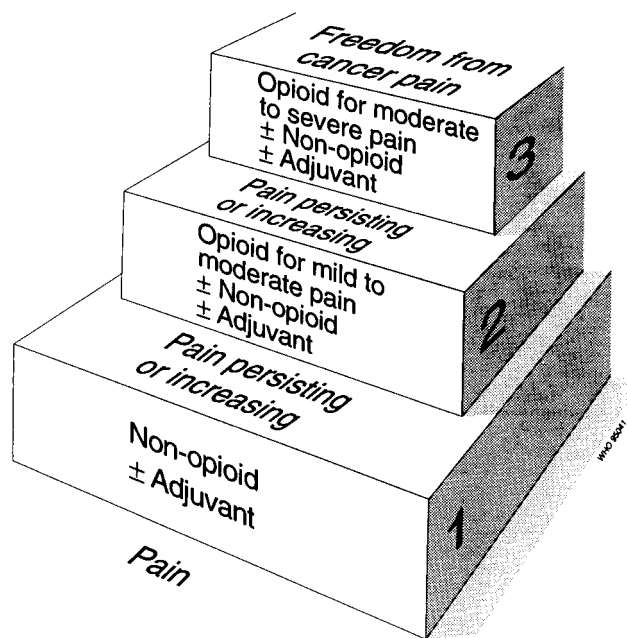

FIGURE 32.2. The three-step “analgesic ladder” proposed by an expert committee of the Cancer Unit of the World Health Organization. Source: Reproduced with permission from the World Health Organization. *Cancer Pain Relief*. 2nd ed. Geneva: World Health Organization; 1996.

expertise in the administration of three groups of analgesic medications: NSAIDs, opioid analgesics, and adjuvant analgesics. The term *adjuvant analgesic* is applied to a diverse group of drugs that have primary indications other than pain but can be effective analgesics in specific circumstances, such as in the treatment of neuropathic pain.

A model approach to the selection of these drugs, known as the “analgesic ladder,” has been developed by the World Health Organization (WHO) (Fig. 32.2) (3). According to this approach, patients with mild to moderate cancer-related pain are first treated with acetaminophen (paracetamol) or an NSAID. This drug is combined with an adjuvant drug that can be selected either to provide additional analgesia (i.e., an adjuvant analgesic) or to treat a side effect of the analgesic or a coexisting symptom. Patients who present with moderate to severe pain, or who do not achieve adequate relief after a trial of an NSAID, should be treated with an opioid conventionally used to treat pain of this intensity (previously designated a “weak” opioid), which is typically combined with an NSAID and may be administered with an adjuvant if there is an indication for one. Those who present with severe pain or who do not achieve adequate relief following appropriate administration of drugs on the second rung of the analgesic ladder should receive an opioid conventionally used for severe pain (previously called a “strong” opioid), which may be combined with an NSAID or an adjuvant drug as indicated.

The analgesic ladder is important historically and is still widely cited in the developing world in an effort to encourage policy makers to expand medical access to opioid drugs. It is a limited clinical guideline in most developed countries, where access to numerous opioid formulations and other analgesic modalities has influenced clinical practice. Nonetheless, the concept promoted by the analgesic ladder model—opioid therapy on a long-term basis should be considered the mainstay for the therapy of chronic moderate to severe cancer-related pain—remains widely accepted and a very important message of the original paradigm.

Nonsteroidal Anti-inflammatory Drugs

In the United States, the nonopioid analgesics comprise acetaminophen and the NSAIDs (Table 32.5). These drugs have a well-established role in the treatment of cancer pain (78–81). Based on clinical observations, NSAIDs appear to be especially useful in patients with bone pain or pain related to grossly inflammatory lesions, and relatively less useful in patients with neuropathic pain (82). In addition, NSAIDs have an opioid-sparing effect that may be helpful to prevent the occurrence of dose-related side effects (83,84).

NSAIDs inhibit the enzyme cyclo-oxygenase (COX) to reduce production of peripheral and central prostaglandins, and this action presumably underlies their analgesic effects. There are two forms of COX, a constitutive form (COX-1) and an inducible form (COX-2). Compounds that are relatively more selective for COX-2 than COX-1 have a lower risk of inducing gastrointestinal adverse effects (85,86), and some drugs that are relatively COX-2 selective have been labeled in this way and promoted for their enhanced gastrointestinal safety. In the United States, the only drug of the latter type now on the market is celecoxib. Rofecoxib and valdecoxib were previously available, but were taken off the market due to concerns related to cardiovascular safety.

The cardiovascular safety of the NSAIDs, including the newer COX-2 selective drugs, has been under intense review. Based on numerous studies, it is most reasonable to conclude that an increased risk of peripheral vascular disease, myocardial infarction, transient ischemic attacks, and stroke occurs during treatment with any of the NSAIDs (87,88). Mechanistically, this risk is associated with COX-2 inhibition, whether produced by the nonselective COX-1 and COX-2 inhibitors or by the COX-2 selective drugs. Although the risk varies across drugs, large comparative studies have been retrospective and results have been conflicting.

NSAIDs should be administered with caution to patients with significant risk factors for peptic ulcer disease, renal disease, cardiovascular disease, or bleeding diathesis. For patients who are predisposed to ulcer disease or would have difficulty tolerating a gastrointestinal hemorrhage, the increased safety of the COX-2 selective drugs—celecoxib in the United States—is likely to be an advantage. Coadministration of a proton pump inhibitor, such as omeprazole or misoprostol, also should be considered to reduce the risk of gastrointestinal damage induced by NSAIDs (89).

Selective COX-2 inhibitors and nonselective NSAIDs seem to be equally nephrotoxic and, therefore, should be used with the same caution. The safest nonopioid to use in patients with existing renal disease is acetaminophen, notwithstanding some data that suggest that this drug can also produce renal toxicity (90).

Other factors may also be important in the selection of an NSAID. First, there is substantial variability in the response of individual patients to different agents, and the response to an NSAID in the past should guide drug selection in the present. Second, it may be useful to consider the drug’s duration of effect when selecting an NSAID. The need to improve treatment adherence or provide a simpler dosing regimen encourages the use of a drug that can be administered once daily (e.g., nabumetone) or twice daily (e.g., celecoxib and many others), whereas the desire for as-needed dosing suggests the use of a short-duration drug (e.g., ibuprofen). Finally, drug selection may be influenced by cost, which varies greatly among both drugs and pharmacies.

The toxicities associated with the use of NSAIDs are dose-related and often occult until severe morbidity occurs. Although patients with cancer pain are commonly treated with standard doses, it is reasonable to explore the dose range and seek the minimal effective dose for long-term therapy. Dose escalation in poor responders is limited by dose-related

TABLE 32.5

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS)

Class and generic name	Trade name	Approx. half-life (h)	Dosing schedule	Recommended starting dose ^a	Comment ^b
P-AMINOPHENOL DERIVATIVES					
Acetaminophen ^c	Tylenol, Datril, Panadol	3–4	q 4–6 h	650 mg q 4 h (5 doses daily)	Overdosage produces hepatic toxicity. Not anti-inflammatory and therefore not preferred as first-line analgesic or coanalgesic in patients with bone pain. Lack of GI or platelet toxicity; however, may be important in some cancer patients. At high doses, liver function tests should be monitored.
NAPHTHYLALKANONES					
Nabumetone	Relafen	22–30	q 24 h	500–1,000 mg q 12 h	Appears to have a relatively low risk of GI toxicity; once-daily dosing can be useful.
SALICYLATES					
Acetylsalicylic acid ^c	Aspirin	3–12 ^d	q 4–6 h	650 mg q 4 h (5 doses daily)	Standard for comparison. May not be tolerated as well as some of the newer NSAIDs.
Diflunisal ^c	Dolobid, Dolobis	8–12	q 12 h	1,000 mg × 1, then 500 mg q 12 h	Less GI toxicity than aspirin
Choline magnesium trisalicylate ^c	Trilisate	8–12	q 12 h	500–1,000 mg q 12 h	Choline magnesium trisalicylate and salsalate have minimal GI toxicity and no effect on platelet aggregation despite anti-inflammatory effects. May therefore be particularly useful in some cancer patients.
Salsalate	Disalacid	8–12	q 12 h	500–1,000 mg q 12 h	
PROPRIONIC ACIDS					
Ibuprofen ^c	Motrin, Advil, Nuprin	3–4	q 4–8 h	400–600 mg q 8 h	Available over-the-counter.
Naproxen ^c	Naprosyn	13	q 12 h	250–500 mg q 12 h	Available as a suspension.
Naproxen sodium ^c	Aleve, Anaprox, Naprelan	13	q 12 h	275–550 mg q 12 h	—
Fenoprofen	Nalfon, Fenopron, Progesic	2–3	q 6 h	200 mg q 6 h	—
Ketoprofen	Orudis, Oruvail	2–3	q 6–8 h	25–50 mg q 8 h	—
Flurbiprofen ^c	Ansaid	5–6	q 8–12 h	100 mg q 12 h	—
Oxaprozin	Daypro	40	q 24 h	600 mg q 24 h	Once-daily dosing may be useful.
ACETIC ACIDS					
Indomethacin	Indocin, Indocid	4–5	q 8–12 h	25 mg q 8 h	Available in sustained-release and rectal formulations. Higher incidence of side effects, particularly GI and CNS, than propionic acids.
Tolmetin	Tolectin	1	q 6–8 h	200 mg q 8 h	
Sulindac	Clinoril	14	q 12 h	150 mg q 12 h	Less renal toxicity than other NSAIDs.
Diclofenac	Voltaren	2	q 6–8 h	25 mg q 8 h	
Ketorolac ^c	Toradol	4–7	q 4–6 h	30–60 mg load, then 15–30 mg q 6 h (parenteral); 10 mg q 6 h (oral)	Only parenteral formulation available. Approved for postoperative use. Experience too limited to evaluate higher doses.

(continued)

TABLE 32.5

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS) (CONTINUED)

Class and generic name	Trade name	Approx. half-life (h)	Dosing schedule	Recommended starting dose ^a	Comment ^b
OXICAMS Piroxicam	Feldene	45	q 24 h	20 mg q 24 h	Administration of 40 mg for over 3 weeks is associated with a high incidence of peptic ulcer, particularly in the elderly.
FENAMATES Mefenamic acid ^c	Ponstel, Ponstan	2	q 6 h	250 mg q 6 h	Not recommended for use longer than 1 week and, therefore, not indicated in cancer pain therapy.
PYRAZOLES Phenylbutazone	Antadol, Butazolidin	50–100	q 68 h	100 mg q 8 h	Not a first-line drug owing to risk of serious bone marrow toxicity. Not preferred for cancer pain therapy.
COX-2 INHIBITORS Celecoxib	Celebrex	11	q 12 h	100–200 mg q 12 h	Fewer GI side effects; no effect on platelet function.

Note: CNS, central nervous system; GI, gastrointestinal.

^aStarting dose should be one-half to two-thirds of the recommended dose for the elderly, those on multiple drugs, and those with renal insufficiency. Doses must be individualized. Low initial doses should be titrated upward if tolerated and clinical effect is inadequate. Doses can be incremented weekly. Studies of NSAIDs in the cancer population are meager; dosing guidelines are thus empiric.

^bWith all NSAIDs, stool guaiac and liver function tests, BUN, creatinine, and urinalysis should be monitored; frequency of monitoring should be increased for those on relatively high doses.

^cPain is approved indication.

^dHalf-life of aspirin increases with dose.

toxicities and a ceiling dose for analgesia above which additional dose increments fail to produce more relief. If an increase in dose maintains the therapy in the conventionally accepted safe range and provides more analgesia, it should be continued. The lack of additional pain relief following a dose increase, however, suggests that the ceiling has been reached, and the dose can then be lowered to the previously effective dose or the drug can be discontinued. All patients receiving an NSAID should be evaluated periodically for occult fecal blood, changes in blood pressure, and effects on renal or hepatic function.

Opioid Analgesics

Expertise in the administration of opioid analgesics (Table 32.6) is the foundation of cancer pain management. The clinician should have knowledge of opioid pharmacology and a clear grasp of practical guidelines for dosing (91,92).

Opioid Classes

Based on receptor interactions, the opioid analgesics can be divided broadly into pure agonists and agonist-antagonists. The pure agonist drugs used in the management of chronic cancer pain are agonists at the μ -receptor subtype. The agonist-antagonist drugs comprise a mixed agonist-antagonist subclass, which includes drugs that are weak antagonists at the μ receptor and agonists at another receptor subtype, and a partial agonist subclass, which includes drugs that are partial agonists at the μ receptor. In the United States, the mixed agonist-antagonist drugs include pentazocine, nalbuphine, dezocine, and butorphanol, and the partial agonists include buprenorphine.

All the agonist-antagonist drugs share properties that together suggest a limited role in the management of chronic cancer pain. These drugs have a ceiling dose for analgesia, and all have the potential to produce an abstinence syndrome in patients already physically dependent on an agonist drug. Some of the mixed agonist-antagonists, particularly pentazocine, are also more likely to produce psychotomimetic effects than the pure agonist drugs. In patients with chronic pain, the lack of oral formulations for all but pentazocine and buprenorphine (sublingual formulation) also limits the utility of these drugs.

Agonist drugs, the prototype of which is morphine, are preferred in the management of chronic cancer pain (Table 32.6). To optimize the administration of these drugs, widely accepted dosing guidelines must be applied systematically.

“Weak” Versus “Strong” Opioids. Unlike the division of the opioids into agonist and agonist-antagonist classes, the distinction between “weak” opioids and “strong” opioids, which was originally incorporated into the WHO analgesic ladder approach (3), is more operational than pharmacologic. The so-called weak opioids are now designated as those that are conventionally administered orally for moderate pain in patients with no or limited prior opioid exposure (second rung of the analgesic ladder), and the so-called strong opioids are those that are conventionally used to treat severe pain or moderate to severe pain in patients already using an opioid (third rung of the analgesic ladder). In the United States, the former group comprises codeine, hydrocodone, dihydrocodeine, oxycodone, propoxyphene, and occasionally meperidine. Tramadol, a unique centrally-acting analgesic with a mechanism of action that is partly opioid, also is generally included with this group. The other opioids used conventionally on the third rung of the

TABLE 32.6

OPIOID ANALGESICS

Drug	Dose (mg) equianalgesic to morphine 10 mg IM ^a PO	IM	Half-life (h)	Peak effect (h)	Duration (h)	Comment ^b
Morphine	20–30 ^c	10	2–3	0.5–1.0	36	Standard for comparison
Morphine CR	20–30	10	2–3	3–4	8–12	Various formulations are not bioequivalent
Morphine SR	20–30	10	2–3	2–3	12–24	—
Codeine	200	130	2–3	1.5–2.0	3–6	Combined with aspirin or acetaminophen. Usually for moderate pain. Also available without coanalgesic
Hydromorphone	7.5	1.5	2–3	0.5–1.0	2–4	Potency may be greater, i.e., hydromorphone:morphine = 3:1 rather than 6.7:1 during prolonged use
Oxycodone	20	—	2–3	1	3–4	Combined with aspirin or acetaminophen, for moderate pain; available orally without coanalgesic and useful for severe pain
Oxycodone CR	20	—	2–3	2–3	8–12	—
Oxymorphone	10 (rectal)	1	2–3	1.5–3.0	2–4	—
Oxymorphone CR	20 (oral)	—	2–3	1.5–3.0	2–4	—
Methadone	20	10	12–190	0.5–1.5	4–12	Although 1:1 ratio with morphine was in single-dose study, there is a change with chronic dosing and large dose reduction (75%–90%) is needed when switching to methadone. Risk of delayed toxicity
Levorphanol	4	2	12–15	0.5–1	4–6	Usage limited because only 2 mg tablets are available
Fentanyl	—	—	7–12	—	—	Can be administered as a continuous IV infusion or SC infusion; based on clinical experience, 100 µg/h is roughly equianalgesic to morphine 4 mg/h
Fentanyl TTS	—	—	16–24	—	48–72	Based on clinical experience, 100 µg is roughly equianalgesic to morphine 4 mg
Meperidine	300	75	2–3	0.5–1.0	3–4	Not preferred for cancer patients owing to potential toxicity

Note: IM, intramuscular; IV, intravenous; SC, subcutaneous.

^aDose that provides analgesia equivalent to 10 mg intramuscular morphine.

^bAll opioids may produce various common side effects, (e.g., constipation, nausea, sedation). Respiratory depression is rare in cancer patients.

^cExtensive survey data suggest that the relative potency of IM:PO morphine of 1:16 changes to 1:23 with chronic dosing.

analgesic ladder include morphine, hydromorphone, oxymorphone, levorphanol, fentanyl, and methadone.

Among those opioids conventionally used for moderate pain in the United States, codeine and propoxyphene are usually, but not always, combined with a coanalgesic (aspirin or acetaminophen); hydrocodone and dihydrocodeine are only available in combination products; tramadol is available as a single entity and combined with acetaminophen. Oxycodone, which is

available both as a single entity and as a combination tablet combined with aspirin or acetaminophen, can be considered to be a drug for the second step of the ladder when used in combination with a coanalgesic and a drug for severe pain when used alone.

The designation of the drugs conventionally used to treat moderate pain as “weak” was a misnomer because none of these drugs is characterized by a ceiling effect that would limit its use. Rather, other considerations have led to the customary

use of these opioids at doses limited to those capable of treating moderate pain in the relatively nontolerant patient. For example, the dose of any opioid combined in a single tablet with acetaminophen or aspirin can only be escalated until the dose of the nonopioid coanalgesic reaches a level associated with toxicity. As noted, hydrocodone and dihydrocodeine are available only in such combinations, and most of the other drugs in this group are typically administered in this form.

Propoxyphene and meperidine should not be used at higher doses because of the risk of enhanced toxicity due to accumulation of a metabolite. The metabolite of propoxyphene, norpropoxyphene, has not been a problem at the doses at which the parent compound is used clinically. However, this drug is associated with serious cardiac toxicity in overdose, and for this reason and its limited efficacy in the doses marketed, it is not preferred and rarely used. The metabolite of meperidine, normeperidine, has been observed to produce clinically relevant side effects in the cancer population, including tremulousness, hyperreflexia, myoclonus, and even seizures (93). This risk suggests that meperidine should not be used in the management of cancer pain.

As suggested by the analgesic ladder, the simplest approach to the management of moderate pain in the cancer patient with limited or no prior exposure to opioids begins with a combination product containing a nonopioid drug and an opioid, usually codeine, oxycodone, or hydrocodone. The dose can be increased to maximally safe levels of the coanalgesic; in products containing acetaminophen, this is usually 4 g per day.

Selection of an Opioid

The selection of an opioid for severe cancer pain is similarly empirical. Traditionally, morphine often was considered to be the preferred first-line drug based on worldwide experience, ease of dosing, and the availability of numerous formulations. The intraindividual variability in the response to the different opioids is very substantial, however, and any of the other drugs may yield a better response in the individual patient. This variability also suggests that therapeutic failure with one drug may be followed by remarkable success with another (94).

The predominant metabolic pathway for morphine is glucuronidation to morphine-3-glucuronide (M3G) and morphine-6-glucuronide (M6G), and the accumulation of morphine metabolites may be associated with side effects, such as myoclonus and chronic nausea (95). Renal insufficiency results in accumulation of M3G and M6G (96,97). For this reason, morphine should be administered cautiously to patients with renal insufficiency. The occurrence of morphine toxicity in these patients should be followed by a trial of an alternative opioid, such as hydromorphone or fentanyl. Although the supporting data are limited, morphine is often viewed unfavorably when patients have very poor renal function or are on dialysis or have renal function that is expected to change. In the latter situations, studies are inadequate to generate guidelines that are evidence based, but hydromorphone and fentanyl are often preferred (98). Given concern about the theoretical accumulation of hydromorphone metabolites, some authors recommend against this drug as well (99).

The selection of an opioid for the treatment of severe cancer pain is also influenced by pharmacokinetic factors, the most salient of which is duration of effect. In an effort to improve adherence and convenience, numerous long-acting extended-release formulations of short half-life opioids have been developed. Oral once-daily or twice-daily formulations of morphine, oxycodone, oxymorphone, and hydromorphone are available in the United States or other countries. Transdermal fentanyl provides a dosing interval of 2 to 3 days and is preferred by some patients.

Although both levorphanol and methadone have relatively long half-lives (Table 32.6), patients typically require doses at least every 6 hours to maintain stable effects. Methadone has become an increasingly popular drug for chronic pain,

presumably because of its low cost, potential for unexpectedly high potency, and relatively low abuse potential and low likelihood of diversion by individuals with a history of substance use disorder. Clinical experience suggests that rotation to methadone after inadequate treatment with another opioid can indeed produce surprisingly good results, an outcome that has been speculated to be related to the d-isomer in the formulation that is commercially available in most countries; this isomer is not an opioid, but rather blocks another receptor (the N-methyl-D-aspartate receptor, or NMDA) and in this way may potentiate analgesia or reverse some degree of opioid tolerance (100,101).

Methadone is a challenging drug to use, however, and clinicians must understand its unique pharmacology to administer it in a safe manner. Methadone's half-life ranges between 12 and 190 hours, and substantial delayed toxicity has been observed many days after methadone treatment was begun or altered (102). Its potential to have an unexpectedly high potency when substituting for another opioid increases the challenge of dose selection when starting the drug. Finally, observational studies indicate that methadone can prolong the QTc interval (103,104). Although the risk of cardiac toxicity appears very low and there is no consensus concerning electrocardiographic (ECG) monitoring, this risk suggests that a baseline ECG is reasonable in patients with heart disease or concurrent treatment with other cardioactive drugs, and in those whose methadone dose reaches relatively high levels (e.g., above 200 mg per day). Given the increased potential for serious toxicity and the need for prolonged monitoring with methadone, it is reasonable to view this drug as a second-line agent for patients predisposed to opioid side effects, including the elderly and those with major organ dysfunction.

The patient's previous favorable experience with opioid drugs should also be considered when choosing an opioid. The exception to this is meperidine, the toxic metabolite of which may accumulate with repeated dosing. A favorable experience with this drug during short-term administration should not be viewed as predictive of the response to chronic dosing.

Routes of Administration

The oral and transdermal routes are preferred in the management of chronic cancer pain. Alternative routes may be required, however, and the clinician must recognize their indications and be familiar with the accepted approaches. In a survey of patients with advanced cancer, more than half required two or more routes of administration prior to death and almost a quarter required three or more (105).

Transdermal Delivery. The transdermal route of administration is available for the highly lipophilic opioid fentanyl (106). This formulation, which offers a 48- to 72-hour dosing interval, is preferred by some patients and may be associated with relatively less constipation (107). The transdermal route may be very useful for the patient who is unable to swallow or absorb an orally administered opioid; this is particularly appropriate when the underlying pain syndrome is relatively stable. Pains that are rapidly fluctuating and require multiple supplemental doses may be more easily managed using an ambulatory infusion device with a PCA option. Transdermal fentanyl is relatively contraindicated in patients with anticipated episodes of fever; increased ambient temperature changes the delivery characteristics of the patch and fever may be associated with overdose.

Transdermal buprenorphine is efficacious and available in some countries. Although buprenorphine is a partial agonist and has a ceiling dose, and a capacity to induce abstinence if administered to a patient who is already physically dependent on another opioid, a recent observational study suggests that some patients with severe cancer can benefit and make use of this formulation until death (108).

Rectal. Rectal formulations of oxymorphone, hydromorphone, and morphine are available in the United States. There also is anecdotal experience with rectal administration of controlled-release morphine or oxycodone tablets. The rectal route usually is considered for patients who are relatively opioid nontolerant and become temporarily unable to take oral medications. The potency of opioids administered rectally is believed to approximate oral dosing (109), absorption is variable, and relative potency may be higher or lower than expected, depending on a variety of factors, including location of the suppository (low in the rectum, where the blood supply is systemic, or high in the rectum, where blood flows through the portal circulation) and contents of the rectum at the time of dosing.

Transmucosal, Buccal, and Sublingual. Absorption through the oral cavity potentially can occur with any opioid, and those that are lipophilic and relatively potent may be absorbed sufficiently to have clinical use (110). Two different types of oral transmucosal formulations of fentanyl were approved in the United States after having been shown to be safe and efficacious when used as a “rescue” dose for the treatment of breakthrough pain in cancer patients receiving a fixed-schedule opioid (111,112). These formulations appear to have an onset of action faster than orally administered drugs. They were developed for breakthrough pain on this basis. Given the perception that rapid-onset formulations address an unmet clinical need, other formulations are in development. These will deliver fentanyl, or some other opioid, intranasally, sublingually, transbuccally, and via the intrapulmonary route.

In some clinical situations, a trial of an injectable formulation placed under the tongue is reasonable. Although there is considerable experience in the use of sublingual administration of concentrated oral morphine solution during the care of patients at the end of life, this drug is relatively hydrophilic, and is poorly absorbed by this route; it is likely that most of the effects obtained occur following enteral absorption after swallowing.

Intranasal butorphanol is available, but as noted, this opioid is an agonist-antagonist and has characteristics that make it unfavorable for long-term administration to cancer patients. It is rarely used in this setting. A sublingual preparation of buprenorphine is indicated in the United States for the office-based treatment of addiction. Experience in the treatment of pain is very limited.

Continuous Infusion. Patients who are unable to swallow or absorb opioid drugs are candidates for long-term parenteral dosing. Repetitive intramuscular or subcutaneous injections are painful and should be rarely considered. Repetitive intravenous injections may be effective, but they usually require skilled nursing and may be associated with prominent “bolus” effects (toxicity at peak concentration, pain breakthrough at the trough, or both). Repetitive dosing through a “butterfly” needle placed under the skin has been used effectively in end-of-life care and experience suggests that the needle can be in place for a week without the development of local pain or other problems.

Continuous infusion. Eliminates the fluctuations in plasma concentration associated with repetitive bolus injections. Any opioid available in an injectable formulation can be used for continuous infusion. The availability of continuous subcutaneous infusion using ambulatory infusion devices has markedly enhanced the clinical utility of infusion techniques, allowing long-term administration of opioids and other drugs in the home environment (113). A diverse group of pumps that range considerably in features, complexity, and cost are now available, and the clinician often has the option of selecting a pump based on the needs and resources of the patient. PCA can be combined with continuous infusion to address episodic pains. In most cities, skilled nursing organizations can assist in the management of therapy at home.

Intraspinal Opioids. The discovery of opioid receptors in the spinal cord provided the foundation for the development of techniques to deliver opioid analgesics intraspinally. Intraspinally

administration can provide selective analgesia (i.e., without the sensory or motor blockade produced by local anesthetics) at doses lower than those required systemically. The strongest indication for a trial of intraspinal opioid administration is the occurrence of intolerable somnolence or confusion in patients who are not experiencing adequate analgesia during systemic opioid treatment of pain.

Many methods of intraspinal opioid administration are now in use (114). The most commonly used include a percutaneous epidural catheter, which is usually tunneled to the anterior abdominal wall and there connected to an ambulatory infusion pump; a totally implanted epidural catheter connected to a subcutaneous portal, which in turn is connected to an ambulatory pump; and an intrathecal catheter connected to a totally implanted continuous infusion device. The preferred drugs for chronic intraspinal infusion are morphine and hydromorphone, but many others are used empirically, and admixtures (e.g., opioid plus local anesthetic or clonidine, or both) are now commonplace.

The use of intraspinal infusion in the management of cancer pain is likely to increase with further evidence of favorable outcomes in the oncology population (115). Implantable pump systems, which are refilled percutaneously, are often chosen for patients with life expectancies of 3 or more months. A controlled trial that compared neuraxial infusion to comprehensive medical management demonstrated that the spinal opioid treatment improved pain, side effects, quality of life, and even survival (116). The potential utility of neuraxial analgesia is also likely to change with the advent of more choices in drug selection.

Based on a systematic review of the literature (117), an expert panel created an algorithm for the progressive use of an array of drugs during intrathecal therapy (118). Therapy is initiated with a single-agent opioid (either morphine or hydromorphone). If adequate pain relief cannot be achieved, a second agent is added, either bupivacaine or clonidine. Clonidine, an α_2 -adrenergic agonist that was shown in a controlled trial to be effective in neuraxial analgesia (119), is one of several classes of nonopioid and nonanesthetic drugs now being used. Ziconotide, a unique calcium-channel blocker, is now available in the United States and has been shown to be effective for cancer pain in controlled trials (120). A 2007 update of the evidence-based algorithm for drug selection during neuraxial infusion is pending publication and incorporates these and other agents. Intraspinally therapy is now often initiated with a combination of drugs in an effort to reduce side effects, such as sensory and motor block, urinary retention, pruritus, and nausea, and potentiate analgesia (121).

Guidelines for the Administration of Opioid Drugs

As noted, all patients who develop moderate to severe persistent pain should be considered for an opioid-based regimen. The opioid-naïve patient usually is offered a short-acting combination product (conventionally used on the analgesic ladder's second rung). It is acceptable, however, to initiate therapy with a long-acting formulation, as long as the dose is appropriate (122). For example, long-acting morphine can be started at a dose of 15 mg twice daily, or 20 to 30 mg once daily, depending on the formulation. Long-acting oxycodone or oxymorphone can be started at doses of 10 mg twice daily or 5 mg twice daily, respectively. Transdermal fentanyl can be initiated at 12 $\mu\text{g}/\text{h}$ in opioid-naïve patients. Given the availability of these long-acting formulations in doses appropriate for the opioid-naïve, the decision to start a short-acting or long-acting drug in a patient with new-onset persistent pain is a clinical judgment based on patient preference, convenience, cost and availability, and experience.

If a patient is receiving a short-acting drug, but pain is not controlled, it is conventional practice to switch to a single-entity pure μ agonist (third-rung drug), typically in a long-acting formulation. Starting doses may be slightly higher if the patient has

been requiring regular administration of the short-acting drug. On a daily basis, the milligram dose of a long-acting drug is the same as the short-acting formulation of the same drug.

Following selection of a starting dose, dose adjustment is almost always required. Once a favorable balance between analgesia and side effects is obtained, this is usually maintained for a prolonged time unless there is progression in the pain-producing pathology. Although several large surveys have established that patients with stable disease usually demonstrate stable dosing patterns, most patients with cancer pain do not have stable disease. Recurrent pain or the new occurrence of side effects necessitates another period of dose titration. Inadequate adjustment of the dose is probably the most common reason for unsuccessful long-term management of cancer pain.

In all cases, the dose of an opioid should be increased until acceptable analgesia is produced or intolerable and unmanageable side effects supervene. Ceiling doses for the pure agonist opioids have not been identified clinically, and doses can, therefore, become extremely high—equivalent to grams of morphine per day—as upward dose titration proceeds. The absolute dose of the opioid is immaterial as long as the balance between analgesia and side effects remains acceptable for the patient.

In many countries, it is common to coadminister a short-acting opioid on an “as-needed” basis in combination with the fixed schedule regimen of the long-acting drug. Surveys have demonstrated that one-half to two-thirds of patients with cancer pain will experience clinically significant breakthrough pain (123,124), and this approach—known as “rescue” dosing—has become widely accepted as a means to treat it. As described previously, rapid-onset transmucosal formulations have been developed specifically in an effort to improve the management of breakthrough pain, most of which have a time course that is more rapid than the typical time-action profile of an orally administered opioid.

Treatment of common side effects is an essential element in the successful management of opioid therapy (see below). Patients who experience intolerable toxicity despite treatment should be designated as poorly responsive to the specific drug and route, and an alternative strategy for pain control should be implemented (125–127). This may include more sophisticated management of the treatment-limiting side effect, the addition of a pharmacologic or nonpharmacologic analgesic approach that could reduce the opioid requirement, or opioid rotation.

Opioid rotation, or the switching from one drug to another in an effort to improve the outcomes of an opioid regimen, is now widely used, despite guidelines that remain based on experience rather than research (128). Switching requires an appreciation of relative potency, as codified on the equianalgesic dose table (Table 32.6). To switch to another opioid drug or route, the equianalgesic dose table is used to calculate a dose of the new drug that would be theoretically equianalgesic with the old drug or route. With few exceptions, the dosing regimen based on this calculated dose should be reduced by 25% to 50% to account for incomplete cross-tolerance between drugs. A larger reduction, 75% to 90%, is prudent if the new drug is methadone (because of a unique pharmacology in this agent). In contrast, no reduction in the equianalgesic dose is needed if the switch is to transdermal fentanyl (because a reduction is already built into the recommended equianalgesic ratios).

Management of Common Opioid Side Effects

Although there is no maximum dose or ceiling dose for the μ -agonist opioids, the appearance of side effects imposes a practical limit on dose escalation. Given the importance of side effects in determining the response to an opioid, the successful management of common adverse side effects is a fundamental aspect of therapy (129). The most common side effects are related to gastrointestinal and neuropsychologic function (Table 32.7).

TABLE 32.7

COMMONLY USED PHARMACOLOGIC APPROACHES IN THE MANAGEMENT OF OPIOID SIDE EFFECTS

Opioid side effect	Treatment
Constipation	<p>Approaches for all patients:</p> <ul style="list-style-type: none"> Increase fluid intake and dietary fiber Ensure comfort and convenience, etc. <p>Discuss approaches with patient and select one or more:</p> <ul style="list-style-type: none"> Daily contact laxative plus stool softener (e.g., senna plus docusate) Daily osmotic laxative or lavage agent Intermittent use of laxative <p>Consider alternative approaches in refractory cases:</p> <ul style="list-style-type: none"> Enema Prokinetic agent (metoclopramide) Oral naloxone
Nausea	<p>Several approaches:</p> <ul style="list-style-type: none"> If associated with vertigo or if markedly exacerbated by movement, antivertiginous drug (e.g., scopolamine, meclizine, dimenhydrinate) If associated with early satiety, prokinetic agent (metoclopramide) In other cases, dopamine antagonist drugs (e.g., prochlorperazine, chlorpromazine, haloperidol, metoclopramide)
Somnolence, mental clouding	<ul style="list-style-type: none"> If analgesia is satisfactory, reduce opioid dose by 25% to 50% If analgesia is satisfactory and the toxicity involves confusion, consider a trial of a neuroleptic (e.g., haloperidol) If analgesia is satisfactory and the toxicity is somnolence, consider a trial of a psychostimulant (e.g., methylphenidate) Consider pharmacologic approaches to reduce the opioid requirement (addition of a coanalgesic or adjuvant) Consider trial of an alternative opioid If appropriate, consider nonpharmacologic analgesic approaches

Constipation is a highly prevalent side effect of opioid therapy. It may contribute to abdominal pain, distension, nausea, and worsening anorexia, and occasionally may progress to obstipation and bowel obstruction. The management of drug-induced constipation should begin with the elimination of nonessential constipatory drugs and, if possible, an increase in both fluid and fiber intake. Fiber should not be increased in those with likely partial bowel obstruction or marked debility because of the potential for worsening obstruction.

Laxative therapy should be considered whenever constipation cannot be controlled through nutritional measures. Routine laxative therapy should not be administered, however, if there is reason to believe that obstruction or impaction is present. These problems should be addressed before laxative therapy is initiated. Patients who are starting opioid therapy and have other predisposing factors for constipation should be considered for prophylactic laxative therapy.

There are numerous types of laxatives, including bulk-forming agents, osmotic agents, lubricants, surfactants, contact cathartics, prokinetic drugs, agents for colonic lavage, and oral opioid antagonists (129,130). The conventional first-line approach is a combination of a stool softener, usually docusate, and a cathartic agent, such as senna. Most patients respond to this therapy. The oral lavage agent, propylene glycol, in a powdered formulation offers another well-tolerated and usually effective approach. Osmotic agents, such as lactulose, are often tried in more refractory cases. Lubiprostone, a chloride channel opener, is available in the United States and also may be considered. A variety of other strategies are used seldomly, for challenging cases. These include trials of metoclopramide, misoprostol, colchicine, or donepezil.

Oral opioid antagonist therapy also can be tried for refractory constipation and is likely to become more common with the availability of new drugs. Opioid antagonists that can reverse opioid-induced constipation through local action on opioid receptors in the gut without causing systemic opioid withdrawal may be useful laxatives. At the present time, this treatment is implemented using oral naloxone, which is typically administered at a dose of 0.8 mg twice daily; the dose is doubled every 2 to 3 days until favorable effects occur or side effects are experienced (131,132). The daily dose needed to reverse constipation usually is 12 to 18 mg per day. Quarternary opioid antagonists, such as methylnaltrexone and alvimopan, are undergoing development as peripherally acting antagonists and may expand the utility of this approach in the future (132–134).

Nausea or vomiting constitutes a problem for some 10% to 30% of cancer patients receiving opioid therapy (135). Potential contributing etiologies should be evaluated and the treatment adjusted accordingly. If the assessment suggests that factors other than opioids are contributing to the nausea, antiemetic therapy may be combined with specific interventions to reverse or minimize these factors. The usual first-line drugs are the dopamine antagonists, including prochlorperazine, metoclopramide, and haloperidol. Patients with refractory nausea may need other pharmacologic approaches. Although the antiemetic efficacy of corticosteroids is unexplained, these drugs are clearly beneficial for some patients. Others respond to a commercially available cannabinoid. Although a 5HT antagonist, such as ondansetron, can be beneficial for patients with refractory symptoms, they are very costly and should be considered only after other therapies have failed. In difficult cases, combinations of drugs from unrelated classes often are tried.

Sedation or mental clouding is very common when an opioid regimen is begun or the dose increased. Most patients develop tolerance to this effect relatively quickly, but some do not, and some have other factors that cause cognitive impairment and compound the effect of the opioid. If these side effects are mild, reassurance and education are usually sufficient interventions. When toxicity is severe or persistent enough to compromise the

benefits of therapy, other interventions are needed. Treatment of potential etiologies other than the opioid (e.g., elimination of another nonessential drug or treatment of a metabolic disturbance), when feasible and indicated, is the first step in the management of neuropsychologic symptoms. If pain is well controlled, it is reasonable to try an opioid dose reduction of 25% to 50%.

Symptomatic therapies for opioid-induced sedation or mental clouding also should be considered (Table 32.7), but few have been well studied in clinical trials. Methylphenidate has been shown to decrease opioid-induced sedation in cancer patients (136–138). The starting dose is 5 mg at breakfast and at lunchtime. Other psychostimulants that have been used empirically for this indication include dextroamphetamine, amphetamine, and modafinil. A role for modafinil in cancer has been suggested by a positive controlled study that demonstrated improvement across cognitive, mood, and fatigue outcome measures, with the maximum benefit at 8 weeks after initiation of treatment (139). A new stimulant drug, atomoxetine, has a pharmacology that may indicate its utility for fatigue but experience is lacking and it has not yet been studied.

Tolerance, Physical Dependence, and Addiction

The clinical implications of tolerance, physical dependence, and addiction are commonly misunderstood by patients and clinicians. These misapprehensions may lead to concern about adverse events and, possibly, undertreatment of pain.

Tolerance is a pharmacologic property of opioid drugs defined by the need for escalating doses in order to maintain effects (140,141). Patients may have other reasons for declining analgesic effects, however, among which are progressive nociception and increasing psychologic distress. Abundant survey data suggest that the most common reason for dose increase is worsening pain due to progression of a nociceptive lesion. Most patients with stable disease continue to require the same opioid dose for extremely long periods of time (141,142). Fear of analgesic tolerance should never delay the implementation of opioid therapy, and tolerance should not be invoked to explain the need for higher opioid doses unless a comprehensive reassessment has failed to identify an alternative explanation.

Physical dependence also is a pharmacologic property of opioid drugs, which is defined by the occurrence of an abstinence syndrome following abrupt dose reduction or administration of an antagonist (140). Neither the dose nor the duration of dosing required to produce physical dependence is known, and it is prudent to assume that all patients who have received an opioid drug for more than a few days have the potential for withdrawal. This implies that dosing should not be discontinued suddenly and that antagonist drugs, including the agonist-antagonist opioids, should be avoided.

Patients who become physically dependent on opioids appear to develop increased sensitivity to the effects of antagonist drugs. Very small doses of naloxone may produce a severe abstinence syndrome. For this reason, the use of naloxone should be limited to patients with symptomatic respiratory depression. When naloxone must be used in patients receiving chronic opioid therapy, only a dilute solution (e.g., 0.4 mg in 10 mL saline) should be administered and incremental doses should be given only until respiration improves. The goal of this intervention is improved respiration and not a return of consciousness, which may be associated with recurrent pain and withdrawal phenomena.

Both tolerance and physical dependence are distinct from addiction. Because the labels applied to patients can determine the attitudes and behaviors of caregivers, it is extremely important that appropriate terms are used to describe these phenomena. Patients who are perceived to have the capacity for withdrawal should be labeled physically dependent and not “addicted.”

Addiction is a genetic, psychological, and behavioral syndrome characterized by craving, loss of control over drug use, compulsive use, and continued use despite harm to the patient or others (140). Although abusable drugs, including opioids, can be shown to have reinforcing effects in animals, the capacity to produce addiction should not be considered an inherent property of the drug. Addiction presumably results from an interaction between the drug and a variety of factors that predispose the individual to compulsive use. These factors probably encompass genetic vulnerability, situational factors, and psychological disturbances, as well as access to the drug.

Cancer patients who engage in aberrant drug-taking behaviors, such as hoarding or selling, unsanctioned dose escalation, or manipulation of the medical system to obtain additional drugs, may or may not meet criteria for the diagnosis of addiction. If such aberrant behaviors are identified, measures should be taken to eliminate them while a detailed assessment is performed to clarify their meaning. In some cases, aberrant drug-related behaviors appear to be driven by uncontrolled pain. This has been termed pseudoaddiction and is managed by improved efforts to provide pain relief. Occasionally, aberrant behaviors are related to a psychiatric disorder other than addiction or to the development of a mild encephalopathy, which leads to confusion about drug taking. These explanations for problematic drug use are not mutually exclusive and the complexity of the clinical situation requires careful assessment, and often referral of the patient to a pain specialist or an addiction medicine specialist. The clinician must avoid the stigmatizing label of addiction for patients who have reasonable alternative explanations for aberrant behaviors, but be willing to render the diagnosis of addiction in those who actually have this disease.

The risk of true iatrogenic addiction is clearly relevant in judging the overall utility of opioid therapy for chronic cancer pain. There is substantial evidence that this risk is extremely low among those with no prior history of abuse or addiction (143). It is now widely accepted that all patients who are being considered for a trial of an opioid should be evaluated for risk factors that may predict aberrant drug-related behavior, such as a history of substance abuse, a family history of substance abuse, and major psychiatric disorder, but that fear of addiction should not be considered a contraindication to opioid therapy of severe cancer pain. Rather, patients should be stratified by risk before therapy begins, and monitored for aberrant drug-related behavior during the course of therapy. Should concerns arise, the clinician may structure therapy in a way to reduce risk, or refer appropriately.

Adjuvant Drugs

Most patients with cancer pain require multiple drugs for symptom management. Some of these adjuvant drugs are used to treat symptoms other than pain, particularly those that occur as side effects of the opioid (Table 32.7). Other drugs are used in an effort to provide additive analgesia. The latter drugs comprise the NSAIDs and the so-called adjuvant analgesics. Adjuvant analgesics may be defined as drugs that are commercially available for indications other than pain but may be analgesic in selected circumstances (144). In recent years, the number of these drugs has increased substantially, and several have become approved for primary pain indications due to the abundance of evidence for analgesic efficacy.

The adjuvant analgesics are particularly helpful in the treatment of pain syndromes that are often relatively less responsive to opioids, such as neuropathic pains (Table 32.8). Although neuropathic pains, such as postmastectomy syndrome, painful polyneuropathy, and painful plexopathy, can respond well to an opioid regimen, they are relatively more likely to be poorly

TABLE 32.8

ADJUVANT ANALGESICS

Indication	Drugs	
Neuropathic pain	Antidepressants	
	Tricyclic antidepressants	
	Amitriptyline	
	Desipramine	
	“Newer” antidepressants	
	Duloxetine	
	Anticonvulsants	
	Gabapentin	
	Pregabalin	
	Carbamazepine	
	Phenytoin	
	Valproate	
	Clonazepam	
	Lamotrigine	
	Sodium channel blockers	
	Mexiletine	
	Tocainide	
	Alpha ₂ -adrenergic agonists	
	Clonidine	
	Tizanidine	
	NMDA receptor antagonists	
	Ketamine	
	Dextromethorphan	
	Cannabinoids	
	Tetrahydrocannabinol (THC)	
	Topical anesthetics	
	Capsaicin	
	Lidocaine	
	Miscellaneous	
	Baclofen	
	Calcitonin	
	Bone pain	Bisphosphonates (e.g., pamidronate)
		Calcitonin
Radiopharmaceuticals (e.g., strontium 89 and samarium 153)		
Bowel obstruction	Scopolamine	
	Glycopyrrolate	
	Octreotide	
Multipurpose	Corticosteroids	
	Dexamethasone	
	Prednisone	

responsive and represent the most common target of the adjuvant analgesics.

Corticosteroids are among the adjuvant analgesics commonly used to treat neuropathic pain. These drugs also may improve anorexia, nausea, and fatigue, and are often used in open-ended therapy when cancer is relatively advanced. Anticonvulsants and antidepressants are the most commonly used adjuvant analgesics for neuropathic pain. Evidence for analgesic efficacy is best for specific anticonvulsants, such as gabapentin and pregabalin (145–149); for the tricyclic antidepressants, such as amitriptyline and desipramine (150,151); and for the serotonin and norepinephrine reuptake inhibitors, specifically duloxetine (152). Gabapentin or pregabalin usually is tried first, given their lack of drug-drug interactions, but sequential trials of various drugs often are required before a well-tolerated and effective adjuvant analgesic is identified.

If the drugs with relatively good evidence of analgesic efficacy in neuropathic pain are not tolerated or are ineffective,

trial of other anticonvulsants or antidepressants may be undertaken empirically. Other second-line agents for neuropathic pain also are considered in refractory cases. Sodium channel blockers may be given orally (e.g., mexiletine) or tried via brief infusion of lidocaine (153,154). NMDA antagonists have limited evidence of efficacy, with the exception of ketamine, and this drug is sometimes tried at subanesthetic doses (155,156). Cannabinoids are analgesic (157–159), and a marijuana derivative is available in some countries, with approval for pain due to multiple sclerosis and to cancer. This drug is under development in the United States, where tetrahydrocannabinol and nabilone are the commercially available cannabinoids. Experience with the latter drugs as analgesics is very limited. In contrast, there is a larger experience with the gamma-aminobutyric acid (GABA) agonist baclofen and with the α_2 -adrenergic drugs tizanidine and clonidine; these drugs also are tried in selected patients with refractory neuropathic pain.

The use of topical agents represents another adjuvant analgesic strategy. A lidocaine patch (Lidoderm)[®] (160,161) is now available and has been shown to be effective in postherpetic neuralgia. This formulation is commonly tried for all types of neuropathic and musculoskeletal pains. Topical creams also are used empirically in patients with cancer pain, including compounds containing other local anesthetics, capsaicin, an NSAID, a tricyclic antidepressant, or an opioid.

Opioid-refractory malignant bone pain is another syndrome for which adjuvant analgesics often are considered. The preferred drugs include bisphosphonates, radiopharmaceuticals, and calcitonin. Although the bisphosphonates carry the risks of renal insufficiency and osteonecrosis of the jaw, there is evidence that they can improve overall morbidity associated with bone metastases, and a trial of one of these agents is typically considered in the setting of significant bone pain (162).

Adjuvant analgesics also are commonly employed in the setting of bowel obstruction that is not surgically correctable. Aggressive pharmacotherapy, particularly in those with advanced disease, may control symptoms and obviate the need for drainage procedures. Treatment usually involves the combination of anticholinergic drugs (e.g., scopolamine or glycopyrrrolate), octreotide, corticosteroids, and opioids (163).

THE THERAPEUTIC APPROACHES: OTHER APPROACHES IN CHRONIC PAIN MANAGEMENT

Although most patients with cancer pain can achieve adequate relief with pharmacologic approaches alone, a multimodality strategy always should be considered in an effort to optimize the balance between analgesia and side effects, promote better function, or concurrently manage other problems. Multiple therapies commonly are needed to address the broader palliative care concerns of the patient and family, which derive from the complex interaction between pain and suffering (Fig. 32.1).

When the focus is pain control, there are a large number of noninvasive and invasive approaches that may be considered adjunctive to opioid-based pharmacotherapy. Only a small minority of patients will require an invasive analgesic modality if the other therapies are optimally administered.

Interventional Approaches

The interventional strategies include injections, neural blockade, and implant therapies. Trigger point injections may be considered within the purview of all practitioners. Myofascial pains are extremely common in patients with chronic cancer pain, and the use of local anesthetic injections into painful trigger points may be a useful adjunctive approach in these patients.

The advances in neuraxial infusion of opioids and other drugs, as described previously, have largely supplanted the neurodestructive approaches that were employed in the past for pain syndromes refractory to systemic opioid therapy. Nonetheless, some types of neural blockade continue to be widely used (114). Sympathetic nerve blocks with local anesthetic are used to manage those cancer-related neuropathic pains that are presumed to be perpetuated at least in part by sympathetic efferent function. Other temporary somatic nerve blocks may be diagnostic, prognostic, or therapeutic. Diagnostic blocks elucidate the afferent pathways involved in the experience of pain. Prognostic blocks are implemented prior to a neurolytic procedure, and although extensive clinical experience indicates that a favorable response does not predict permanent relief following neurolysis, the failure to achieve pain relief with local anesthetic is commonly viewed as a contraindication to a destructive procedure. Repeated therapeutic blocks with local anesthetic are occasionally used in cancer patients who obtain substantial and fairly prolonged relief after such a temporary block. Recently, local anesthetics have been used to provide more prolonged neural blockade through techniques of perineural or epidural infusion.

Neural blockade with neurolytic solutions, usually alcohol or phenol, have been developed to denervate virtually any area of the body (114). Their use is very limited, however, because of the short-term risks associated with the injection of these substances, such as damage to soft tissues and local hemorrhage or infection, and the longer-term risks of neuritis and deafferentation pain. The one generally accepted exception is celiac plexus blockade for the management of epigastric pain due to neoplastic invasion of the celiac axis. The response to neurolytic celiac plexus blockade in pain due to pancreatic cancer has been observed to be so satisfactory that earlier use is warranted whenever the typical pain syndrome occurs (164).

Intermittent nitrous oxide inhalation is an anesthetic technique that has been proven to be useful in the management of severe breakthrough pain in patients with advanced cancer (165). Although the availability of masks that reduce ambient leakage of the gas has increased the potential usefulness of this approach, it continues to be applied rarely.

Neurostimulatory Approaches

It has been appreciated for some time that stimulation of afferent neural pathways may result in analgesia. The best-known application of this principle is TENS. Other approaches include counterirritation (i.e., systematic rubbing of the painful part), percutaneous electrical nerve stimulation, dorsal column stimulation, and brain stimulation. Published experience in the use of these modalities for the management of cancer pain is meager. Surveys of the techniques that have been used most extensively in nonmalignant pain (TENS and dorsal column stimulation) suggest that the majority of patients will achieve analgesia soon after the approach is implemented but only a few can obtain prolonged relief. A trial of TENS is usually considered in patients with neuropathic pain that has been proven to be difficult to manage with opioids.

Physiatric Approaches

Although evidence from clinical trials is lacking, the potential for analgesic effects from physiatric therapies, including the use of orthoses or prostheses, occupational therapy and physical therapy, and modalities such as heat, cold, vibration, and ultrasound, is well accepted. For example, refractory movement-induced pains may be partially relieved by bracing the painful part, such as in patients with back pain due to metastatic lesions of the spine and those with arm pain

related to a malignant brachial plexopathy, and a well-fitting prosthesis can reduce stump pain. In addition to the potential for salutary effects on symptoms, physical therapy and occupational therapy can potentially forestall painful complications, such as contractures, and generally increase well-being.

Neurosurgical Approaches

Procedures designed to denervate the painful area surgically have been developed for every level of the nervous system from peripheral nerves to cortex. Historically, the most useful approach has been cordotomy. Like neurolytic blocks, however, these procedures are rarely considered now, largely due to the advent of more sophisticated, nonneurodestructive interventions such as neuraxial infusion.

Psychologic Approaches

Some patients or families who present with severe psychologic distress may benefit from a multidisciplinary approach in which psychologic interventions are emphasized within a program designed to palliate symptoms and provide family support. These goals may be accomplished in some cases through referral to a hospice or palliative care program. Occasionally, patients with psychiatric disorders are identified, indicating the need for further assessment and treatment by an appropriate specialist (166).

Specific cognitive and behavioral approaches also have been applied in the management of pain and related symptoms (167,168). Cognitive approaches include relaxation training, distraction techniques, hypnosis, and biofeedback, all of which may enhance a patient's sense of personal control and reduce pain. Although many of these approaches require experienced personnel to implement, several forms of relaxation training can be taught by the nonspecialist. Behavioral therapy, which has achieved wide acceptance in the management of nonmalignant pain, is occasionally considered in patients with limited disease whose level of functional impairment is perceived to be out of proportion to the effects of the neoplasm. Cognitive and behavioral psychologic approaches can focus the patient's attention on issues related to function and quality of life and reduce rumination about the disease.

Complementary and Alternative Medicine Approaches

Therapies that are typically considered to be complementary or alternative have had a growing role in pain management (169). These approaches often are very attractive to patients because they endorse a holistic strategy that is perceived as providing hope and self-control. Some interventions that are termed "complementary" are actually used routinely by specialists in pain medicine or palliative care. These include mind-body therapies (e.g., relaxation, meditation, and others), nutritional support, acupuncture, and massage. Other interventions, such as homeopathy, naturopathy, and many others, are considered to be far outside the mainstream and are rarely suggested (170). Health care professionals have the difficult task of expressing concerns about some of the latter therapies, while respecting patients' pursuit of complementary treatments that may be beneficial or, at least, offer no significant chance of harm.

CONCLUSION

Pain is highly prevalent among patients with gynecologic tumors. The clinicians involved in the care of these patients have a challenging task in being able to provide state-of-the-art management approaches for both acute pain and chronic

pain. Fortunately, the most effective strategy for both acute and chronic pain, namely, opioid-based pharmacotherapy, is clearly within the purview of all practitioners. The knowledge and skills necessary to optimize this therapy, and integrate it with the broader principles of palliative care, are fundamental to the practice of gynecologic oncology.

CHAPTER 33 ■ NUTRITION SUPPORT OF PATIENTS WITH GYNECOLOGIC CANCER

MARK SCHATTNER AND MOSHE SHIKE

INTRODUCTION

Cachexia and weight loss are common manifestations of cancer and exert major impacts on quality of life and survival. Malnutrition is a complex, multifactorial phenomenon that leads to progressive weight loss and deficiency of specific nutrients. Both the cancer and its various therapeutic modalities contribute to cachexia. Advances in understanding nutritional requirements and intermediary metabolism, and major technological progress in the ability to provide nutritional support, have made it possible to feed almost any patient with cancer. Nevertheless, the indications for and the appropriate use of the various modalities of nutritional support are still evolving, and many questions remain unanswered.

Malnutrition in most patients with cancer is usually a manifestation of general calorie-protein deficits that result in progressive weight loss and weakness; however, it is important to recognize that in some patients specific nutrient deficiencies, such as magnesium deficiency or vitamin B₁₂ deficiency, can be present even in the absence of weight loss and can contribute significantly to morbidity and even mortality.

Gynecologic malignancies and their multimodal therapies may be associated with severe malnutrition. Although some nutritional problems occur in patients with cervical and endometrial cancer, they are most commonly seen in those with ovarian cancer, particularly in advanced stages when intra-abdominal metastasis severely impairs gastrointestinal function. Because of the high incidence of malnutrition and its impact on the patient with cancer, nutritional assessment and appropriate therapy should be integral parts of the overall treatment plan.

NUTRITIONAL ASSESSMENT

Nutritional assessment in cancer patients is an ongoing process. It should be a part of the patient's initial evaluation and should be updated periodically. It is especially important to determine the nutritional state prior to therapeutic interventions as well as during and after an acute illness, with the goal of identifying those patients who could benefit from a specific form of nutritional support. The nutritional assessment method used must be simple, accurate, and inexpensive. Anthropometric parameters, serum protein measurements, and immunologic tests had classically formed the basis of the nutritional evaluation; however, they all have significant deficiencies.

Anthropometric and Biochemical Markers

Anthropometric measurements such as weight, skin fold thickness, midarm muscle circumference and creatinine/height index can all provide useful information but have major limitations. Change in weight is the single most useful measurement of the nutritional status when the change does not reflect changes in total body water. The often-present edema, effusions, ascites, or intravenous hydration limit the use of weight as a nutritional parameter. In addition, inaccuracies in scales and different clothing in hospitals and at home can often be sources of misleading information on changes in weight. Measurements of skin folds and midarm muscle circumference (1) are useful tools in studies but have very limited use in clinical practice. A creatinine/height index derived by dividing the patient's 24-hour creatinine excretion by that of a healthy person of the same height offers a sensitive measure of early protein calorie malnutrition (2) but requires collection of a 24-hour urine specimen and is affected by alterations in renal function which may not be indicative of the nutritional state.

Low levels of serum proteins such as albumin, pre-albumin, transferrin, and retinol-binding protein were classically thought to represent malnutrition. However, in the malnourished, sick patient low levels of these proteins can be nonspecific. They are dependent on intact hepatic synthetic function as well as hydration status. At times they can be low as a manifestation of severe illness (infection, metastatic cancer, multisystem organ failure) without being a reflection of the nutritional state. In addition, they can function as acute phase reactants and therefore be in the normal or elevated range in a clinically malnourished patient. The role of serum protein measurements in the nutritional assessment of an ill patient with cancer is therefore very limited. Similar limitations apply to the role of immunologic parameters such as total lymphocyte count and delayed cutaneous hypersensitivity. In simple starvation both of these measures may be decreased and can return to normal with initiation of nutritional support. However, in the cancer patient undergoing chemotherapy, surgery, radiotherapy, or in the midst of an acute illness, these parameters have little determinative value in the assessment of the nutritional state (3,4).

The above parameters have been combined to create numerous nutritional assessment indices. The most extensively studied is the Prognostic Nutritional Index (PNI), which factors measurements of serum albumin, serum transferrin, triceps skin fold, and delayed cutaneous hypersensitivity (5). Buzby et al. prospectively studied the PNI in patients undergoing

gastrointestinal surgery and found that it could accurately stratify patients into high, intermediate, or low risk of developing postoperative complications (6). It must be understood, however, that the index is only as good as the parameters from which it is calculated, and the same limitations outlined above are present in any of these indices.

Subjective Global Assessment

The clinical assessment of the nutritional status has always been used to some extent as part of the general medical history and physical examination. The validity of a formal clinical assessment of the nutritional status was demonstrated in a landmark study by Baker et al., who developed the Subjective Global Assessment (SGA) (7). The SGA is based on a complete history and physical examination with special emphasis on six areas: change in weight, dietary intake, gastrointestinal symptoms, functional capacity, physiologic stress, and physical signs of nutritional deficiencies. These data are used to place the patient into one of three groups. Group "A" (normal nutritional status) is made up of those patients without restriction of food intake or absorption, no change in functional status, and stable or increasing weight. Group "B" (mild malnutrition) consists of patients with evidence of decreased food intake and functional status but little or no change in body weight, while those with severe reduction in food intake, functional status, and loss of weight comprise group "C" (severe malnutrition).

The SGA has consistently been shown to be reproducible and reliable in identifying patients at risk for developing complications associated with malnutrition. In the initial study of 59 patients electively admitted to a general surgical ward, interobserver reproducibility in classification of the nutritional status was 81%, and in a later study of 202 patients it was found to be 91% (7,8). Group assignment based on the SGA had prognostic significance on the ensuing clinical course. The initial study by Baker et al. showed a significant increase in incidence of infection, use of antibiotics, and length of hospitalization in group C when compared to group A (7). In the follow-up study of 202 patients undergoing gastrointestinal surgery, the rate of septic and nonseptic complications in group C was seven times greater than in group A (8). However, it must be recognized that although nutritional parameters are used to determine the SGA, the classification may still represent severity of illness rather than specific nutritionally related complications. Only a determination that the classification predicts which patients will respond favorably to nutritional support (with a decrease in complications) can validate the specificity of this technique. Nevertheless, the SGA provides a simple, reproducible, and accurate method to identify patients who are malnourished who could possibly benefit from nutritional support. Clinical assessments similar to the SGA have been shown to be superior to immunologic testing, plasma protein measurements, and bioelectrical impedance in providing a useful evaluation of nutritional status (7,9-12).

PREVALENCE OF MALNUTRITION

The prevalence of malnutrition depends on the tumor type and stage, the organs involved, and the anticancer therapy. Concurrent nonmalignant conditions such as diabetes and intestinal diseases can be important contributing factors.

The prevalence of weight loss during the 6 months preceding diagnosis of cancer was reported from a multicenter cooperative study of patients with 12 types of cancer (13). The lowest frequency (31% to 40%) and severity of weight loss were found in patients with breast cancer, hematologic cancers,

and sarcomas. Intermediate frequency of weight loss was found in patients with colon, prostate, and lung cancer (54% to 64%). Patients with cancer of the pancreas and stomach had the highest frequency (over 80%) and severity of weight loss. Approximately 35% of the patients with lung cancer lost more than 5% of their body weight. This underscores the fact that even if the tumor does not involve the gastrointestinal tract directly, there can be significant weight loss because of systemic and metabolic derangements and loss of appetite. The study did not report on patients with gynecologic malignancies, in whom weight loss can also be very frequent and severe. Other studies revealed that over 40% of patients receiving medical treatment for a variety of cancers were malnourished (14,15). Among surgical patients in a Veterans Administration hospital, 39% of those undergoing a major operation for cancer were malnourished, as judged by either a nutrition risk index or a combination of weight loss and low serum proteins (16). In a study from our institution, the majority of patients with pancreatic cancer undergoing a curative resection were malnourished, as determined by weight loss (17).

Data on the prevalence and impact of malnutrition in patients with gynecologic tumors are limited. The findings in these patients mirror the observations in patients with other cancers. A recent study of 67 consecutive patients hospitalized with gynecologic cancers at the University of Texas found that 54% of the women were malnourished as determined by the prognostic nutritional index (18). In 1983 Tunca (19) examined the nutritional state of gynecologic oncology patients at time of diagnosis using serum albumin, serum transferrin, immune response, and weight loss. Patients with advanced (stage III or IV) ovarian carcinoma had the highest incidence of severe malnutrition while those with cancer of the cervix, endometrium, or vulva reported weight loss with no indication of malnutrition from serum markers or immune response testing. Twenty of the 21 patients with advanced ovarian carcinoma were anergic to recall antigens, and the mean levels of all serum markers examined were significantly lower than those found in patients with early (stage I or II) ovarian carcinoma or cancer of the cervix, vulva, or endometrium. Orr et al. (20,21) assessed the degree of protein-calorie malnutrition and evidence of vitamin deficiency in 78 patients with untreated cervical cancer. The incidence of protein-calorie malnutrition as assessed by anthropometrics, serum markers, and immune testing was directly related to tumor stage: 4% in stage I, 20% in stage II and III, and 60% in stage IV disease (20). Two thirds of patients with untreated cervical cancer were found to have reduced blood levels of at least one vitamin. Mean serum levels of folate, beta-carotene, and vitamin C at the time of admission were all significantly below control values (21). Similar observations of significant protein-calorie malnutrition were seen in 25 patients with endometrial cancer (22).

At Memorial Sloan-Kettering Cancer Center, 49 inpatients with gynecologic malignancies were referred to the clinical nutrition service over a 2-year period (1998 to 2000). This represented a diverse group of patients with the vast majority being evaluated for support with parenteral nutrition and tended to represent the sickest population. Thirty-five of the patients had ovarian cancer, six had endometrial cancer, seven had cervical cancer, and one patient had cancer of the vulva. Twenty patients had intestinal obstruction, seven had enterocutaneous fistulas, three had intractable nausea and vomiting, eight had prolonged ileus (>5 days), and the remainder had gastric outlet obstruction, mucositis, or dysphagia. The average weight loss in this group at the time of consultation was 8 kg, which represented a loss of 9.1% of the usual body weight. The weight loss in these patients was multifactorial in origin, secondary to the effects of the tumor and therapeutic interventions on the gastrointestinal tract, decreased appetite, and possibly metabolic effects of the underlying malignancy.

These patients, representing the sickest of those with gynecologic malignancies, demonstrate the association between the frequently seen complications (fistulae, intestinal obstruction, ileus, etc.) and significant weight loss.

SIGNIFICANCE OF MALNUTRITION

The impact of malnutrition on the cancer patient was demonstrated in a report by Warren in 1932 (23). Based on data from autopsies, the conclusion was that cachexia was the leading cause of death in a group of 400 patients with various cancers. More recent studies have confirmed the significant impact of malnutrition on the quality of life and prognosis of the cancer patient. In the aforementioned multicenter cooperative study of patients receiving chemotherapy (13), those who presented with weight loss at the time of diagnosis had decreased performance status and survival as compared with those without weight loss. In a study of patients with limited, inoperable lung cancer, weight loss was a major predictive factor for survival (14). The negative impact of malnutrition was also demonstrated in surgical patients with malignant and benign diseases. Malnourished patients undergoing a major operation were at greater risk for postoperative morbidity and mortality than were well-nourished patients (16,24).

The impact of malnutrition in patients with a primary gynecologic malignancy is striking. In 1988, while examining the role of total parenteral nutrition (TPN) in their patients, Terada et al. noted that those patients who developed major complications such as a fistula, wound infection, pneumonia, renal failure, respiratory failure, or died had significantly more weight loss and lower serum transferrin levels at the time of presentation (25). They concluded that these parameters might be of value in predicting clinical outcome in patients requiring nutritional support. Undernutrition also adversely affects surgical outcome in patients with primary gynecologic malignancies. Burnett et al. (26) reported that in 92 gynecologic oncology patients requiring colonic surgery, those who were classified as malnourished on the basis of serum markers were significantly more likely to develop major perioperative complications or die. Donato et al. (27) reported that of 104 patients with ovarian carcinoma undergoing intestinal surgery those considered to be malnourished on the basis of serum protein measurements and weight loss preoperatively had significantly more infectious complications, while other variables including preoperative bowel obstruction, extent of debulking, number of intestinal procedures, or hand versus stapled anastomosis failed to correlate with the rate of infectious complications. In 1993, Massad et al. reported on 128 patients undergoing operations by the gynecologic oncology service at Barnes Hospital in St. Louis and showed that serum markers of malnutrition including decreased preoperative albumin and hemoglobin concentrations were strong indicators of increased length of hospitalization (28). Among women with gynecologic cancers who were hospitalized for any reason, malnutrition was associated with prolonged hospital stay (18).

ETIOLOGY OF MALNUTRITION

Cancer can induce a wide variety of derangements in the nutritional status, ranging from generalized malnutrition with severe weight loss and muscle wasting to a single nutrient deficiency. The etiology of malnutrition in the cancer patient is multifactorial. Nutritionally relevant derangements can be induced by the tumor locally (i.e., gastrointestinal obstruction), by malabsorption, or by humoral factors produced by the tumor itself or by reaction of the immune system to the

tumor. All modalities of cancer therapy—surgery, radiation, chemotherapy, immunotherapy, and palliative treatments—may be associated with side effects and complications that can impair the nutritional status.

The etiologic factors of malnutrition in the cancer patient whether caused by the tumor or antitumor therapies can be classified into three major categories: decreased food intake, malabsorption, and metabolic derangements that result in inefficient, wasteful metabolism.

Impaired Food Intake and Absorption

Both tumor and cancer treatment modalities can lead to decreased food intake through direct effects on the gastrointestinal tract or systemic effects leading to anorexia. Obstruction of the gastrointestinal tract can be caused by any gynecologic malignancy through external compression, or more rarely, by direct invasion. Although at times localized obstructions can be relieved surgically, the obstruction due to peritoneal carcinomatosis often seen in advanced ovarian cancer is particularly difficult to manage surgically. Often, draining gastrostomy with parenteral nutrition (when appropriate) is the only option for providing nutrition and symptomatic relief (29–31).

Tumors can induce anorexia without local involvement of the gastrointestinal tract. The pathophysiology of this phenomenon is not well understood. Norton et al. (32) utilized a model of surgically coupled tumor-bearing and normal rats with parabiotic cross-circulation to show that tumor-induced anorexia is mediated by circulating substances. Tumor-induced impairment of smell and taste has been well described (24,33–36), but the mechanism has not been defined. There is growing evidence that glycoproteins, cytokines, and neuropeptides play an important role in the pathogenesis of cancer cachexia. Bernstein et al. (37,38) demonstrated in a rat model that infusion of tumor necrosis factor (TNF) mimics tumor-induced anorexia and these effects are mediated via the area postrema and the caudal medial nucleus of the solitary tract in the central nervous system.

Therapies used for gynecologic malignancies often result in complications which impair nutrient intake and absorption. Surgical interventions can lead to fistulae, short bowel syndrome, infections, and ileus, all of which impair oral intake significantly. In a review of 12 years of colonic surgery in gynecologic oncology patients, the rate for major systemic complications (myocardial infarction, pulmonary embolism, renal failure, sepsis) was 13.7%, and the rate of major bowel complications (abscess, fistulae, hemorrhage, obstruction) was 12.1% (26). Adjuvant radiation and chemotherapy have been shown to increase the incidence of major complications after pelvic exenteration (39).

Radiotherapy can lead to various derangements in the structure and function of the gastrointestinal tract. Damage to the gastrointestinal tract following radiation to the abdomen and pelvis most commonly affects the small bowel, followed by the transverse colon, sigmoid, and rectum. Predisposing risk factors include previous abdominal surgery, pelvic inflammatory disease, thin body habitus, hypertension, and diabetes mellitus (40). In general, a dose of 5,000 rads is the threshold for significant injury. In the acute phase of radiation enteritis virtually all patients experience anorexia, nausea, and vomiting, which are thought to be mediated by effects of serotonin on the gut (41) and the central nervous system (42). This is followed 2 to 3 weeks later by diarrhea caused by direct injury to the intestinal mucosa resulting in diarrhea and mild to moderate malabsorption. Most patients will have complete resolution of these acute symptoms. However, a significant minority of patients who received radiotherapy will experience chronic dysfunction of the gastrointestinal tract (43).

There is often a latent period of 1 to 2 years and possibly as long as 20 years before the symptoms of chronic radiation enteropathy surface (44,45). In a review of 102 patients with radiation enteritis after treatment for cervical or endometrial cancer, the median time to development of severe symptoms such as obstruction or perforation was 18 months (46).

Chronic radiation enteropathy is characterized pathologically by transmural injury leading to submucosal fibrosis, edema, lymphatic ectasia, and obliterative endarteritis, which can induce colicky abdominal pain, diarrhea, steatorrhea, ulceration, perforation, stricture, and fistula formation (40). Yeoh et al. (47) retrospectively studied the effects of pelvic irradiation given for the treatment of cervical cancer in 30 randomly selected women who had undergone radiotherapy 1 to 6 years earlier. Significant dysfunction of the gastrointestinal tract was detected. Nineteen of the patients had frequency of bowel movements, bile acid absorption, and vitamin B₁₂ absorption outside of the control range. The authors concluded that abnormal gastrointestinal function is essentially an inevitable long-term complication of pelvic irradiation (47). Husebye et al. (48) prospectively studied the gastrointestinal motility patterns in 41 patients with chronic abdominal complaints after radiotherapy for gynecologic cancer. Impaired fasting motility was found in 29% of patients, and motor response after a meal was attenuated in 24%. Postprandial delay of the migrating motor complex was found to be an independent predictor of malnutrition as assessed by weight loss and serum albumin. Impaired motility of the small bowel, therefore, is a key factor in the symptoms experienced by patients with chronic radiation enteropathy (48). Chronic radiation enteritis predisposes to numerous secondary complications. Danielson et al. (49) studied 20 patients with chronic or intermittent diarrhea occurring in women 2 or more years after receiving radiotherapy for gynecologic tumors. Bile acid malabsorption was detected in 65% of patients while evidence of bacterial overgrowth on D-xylose or cholyglycine breath tests was found in 45%. Treatment with bile acid binders or antibiotics resulted in a significant decline in the number of daily bowel movements. The authors concluded that treatment of these secondary complications of radiation-induced enteropathy can offer significant symptomatic relief. In 47 patients with gynecologic malignancies who had gastrointestinal complaints lasting more than 4 months after radiotherapy, Kwitko et al. (50) found 19 partial small bowel obstructions, 11 cases of malabsorption, and five fistulae. The mortality from radiation damage to the small bowel in this report was 32%. Improved fractionation of radiotherapy and protective shielding of the intestine where possible have reduced these complication rates (51). More recent studies of patients who received radiation therapy for uterine cancer found the prevalence of significant chronic radiation enteritis to be approximately 4% (52).

Chemotherapy is often associated with decreased food intake. Odynophagia, oral ulcers, and diarrhea are commonly seen during therapy with cytotoxic agents which affect the replicating cells of the intestinal mucosa such as 5-fluorouracil, methotrexate, and bleomycin. The Vinca alkaloids can cause ileus and constipation mediated by toxic effects on gastrointestinal neural pathways, while cisplatin and nitrosoureas are highly emetic (53,54). Significant nausea, vomiting, stomatitis, and diarrhea occur in 15% of patients receiving intravenous paclitaxel (Taxol) and in 55% of those receiving the drug orally (55).

The psychological impact of a malignancy and its associated therapies can also lead to decreased nutrient intake. Depression is a frequent cause of anorexia in this population and learned food aversions are a common consequence of radiation or chemotherapy. As many as 56% of patients undergoing chemotherapy and 62% of those undergoing radiation therapy developed a learned food aversion in one study (56). This is characterized by a psychologic association

between the consumption of a particular food and a temporally related unpleasant reaction to the therapy such as nausea and vomiting. This results in future avoidance of that particular food item. A recent Swedish study of patients with ovarian cancer showed that a multidisciplinary approach involving antiemetic drugs, in conjunction with anxiolytics, training in relaxation techniques, nutritional advice, and continuity of nursing care resulted in significantly less cisplatin-induced emesis than antiemetics alone (57).

Metabolic Derangements

Even with normal nutrient intake patients with cancer are at risk for malnutrition due to inefficient nutrient utilization and wasteful metabolic pathways. Compared to simple starvation, cancer cachexia is associated with altered metabolism of carbohydrates, fat, protein, vitamins, and minerals. Therefore, in order to optimize nutritional support in the cancer patient it is imperative to consider metabolic derangements along with problems of ingestion, digestion, and absorption.

Increase in basal energy expenditure has been reported in many but not all studies of patients with malignancy (58–64). In patients with newly diagnosed small cell lung cancer Russel et al. (62) showed a mean increase of 37% in basal energy expenditure, which fell substantially in those who responded to chemotherapy. Similar findings have been reported for gastric cancer (59) and sarcoma (65). Elevated basal energy expenditure will drop after tumor resection (66). There are limited data on the metabolic rate in patients with gynecologic cancers (64). Dickerson et al. (67) used indirect calorimetry to determine the resting energy expenditure in 31 patients with ovarian cancer and 30 patients with cervical cancer. Fifty-five percent of those with ovarian cancer were found to be hypermetabolic (BEE >110% predicted by the Harris-Benedict equation) while only 13% of patients with cervical cancer were hypermetabolic. These differences could not be explained by differences in the extent of disease, nutritional status, body temperature, or nutrient intake.

Abnormalities in carbohydrate metabolism in cancer patients include glucose intolerance and peripheral insulin resistance (68–71). These most often become apparent in the patient with advanced metastatic cancer found to have hyperglycemia, which is refractory to high-dose insulin infusion (71,72). In comparison, in simple starvation, patients are most often euglycemic or hypoglycemic. The hyperglycemia in cancer patients is exacerbated by increased hepatic gluconeogenesis. Shaw et al. (73) showed that this increase in glucose production is correlated with tumor burden and decreases after tumor resection. A number of energy wasting metabolic cycles involving glucose have been identified. In the Cori cycle, glucose is converted to lactate by tumor cells and by the liver. This futile cycle results in a net loss of adenosine 5'-triphosphate (ATP) and may contribute to the loss of energy and weight experienced by the cancer patient (64,74,75).

Lipid metabolism may also be abnormal in patients with a malignancy. There is often increased lipolysis with weight loss and this leads to a decrease in fat mass, which can be out of proportion to the loss of lean body mass (70,76). In addition, patients with cancer are often hyperlipidemic and this may be mediated by TNF- α (77). In contrast to normal homeostasis cancer patients fail to suppress lipolysis with glucose infusion (73). Several causes of increased lipolysis have been proposed including decreased food intake, stress response to illness with adrenal medullary stimulation and increased circulating catecholamine levels, insulin resistance, and release of lipolytic factors produced by the tumor itself or by myeloid tissue cells (78). One such factor has been well characterized (79). Lipid-mobilizing factor (LMF), a 24 kDa glycoprotein produced by

tumors, has been shown to stimulate increased lipid mobilization from adipocytes (80). Lipid-mobilizing factor has recently been shown to be identical to the plasma protein zinc- α -2-glycoprotein (ZAG) (81). It is thought to act through binding of β -adrenergic receptors and subsequent upregulation of mitochondrial uncoupling proteins (82,83). Animal studies demonstrate that lipid-mobilizing factor causes loss of body weight (specifically a loss of body fat), which is independent of caloric food intake (84). The activity of lipid-mobilizing factor in the urine and serum of cancer patients has been shown to correlate with the degree of weight loss (85) and tumor burden (86). In addition to its effect on lipid metabolism, there is preliminary evidence that lipid-mobilizing factor may protect tumor cells from free radical toxicity and may therefore make tumors less responsive to certain chemotherapeutic agents which induce oxidative damage (87).

High total body protein turnover, with increased synthesis and catabolism, characterizes the alterations of protein metabolism seen in cancer patients (88,89). This results in depletion of muscle mass and loss of nitrogen and contrasts with the adaptive decrease in protein turnover seen in patients with uncomplicated starvation (90). Total parenteral nutrition given to patients with cancer will result in gains of weight and body fat, net gains of total body nitrogen, but no suppression of the high protein flux (89,90). The predominant mechanism of muscle protein loss in cancer patients is a ubiquitin-associated pathway (91). In this pathway, polyubiquitin chains are attached to proteins, which are then recognized and degraded by a proteasome complex. This pathway is regulated, in part, by proteolysis-inducing factor, a 24 kDa glycoprotein produced by tumors (92). Effective treatment of the underlying cancer has been shown to reverse ubiquitin-dependent proteolysis of skeletal muscle (93). Better understanding of this process holds the promise of improving therapy to attenuate the loss of protein seen in patients with cancer (94).

Cytokines play an important role in inducing the metabolic derangements seen in the cancer patient (64). They mediate increased energy expenditure, whole body protein turnover, rise in serum triglyceride levels, and high glycerol turnover (23,95). TNF can be detected in the serum of cancer patients (96), and in animal models it causes protein wasting, depletion of body fat, and anorexia (97,98). High serum levels of interleukin-1 and interleukin-6 are also present in patients with advanced cancer and cachexia. Interventions to down-regulate these cytokines result in improved appetite, body weight, and quality of life (99).

The combined effects of these wasteful and inefficient alterations in metabolism make it difficult to restore nutritional status in the patient with cancer and cachexia despite use of specialized nutritional support. This is in contrast with what is seen in patients with uncomplicated starvation who exhibit changes in metabolism that act to conserve energy and body tissues and in whom nutritional support is highly efficacious in reversing the effects of malnutrition.

NUTRITIONAL THERAPIES

There are four types of nutritional therapies: parenteral nutrition, enteral nutrition, oral dietary therapy, and drug therapy aimed at improving appetite and food intake. Depending on the patient's condition, nutritional support in the cancer patient has two distinct objectives: (a) provision of nutrition during anticancer therapies to counteract their nutritionally related side effects and improve outcome following these therapies; (b) provide support in patients with long-term or permanent severe impairment of the gastrointestinal tract. In these patients nutritional support may be required for indefinite periods of time. Results of numerous clinical trials support the use of nutritional

support only in limited situations during anticancer therapies. In the group with prolonged gastrointestinal failure, nutrition support may be a lifesaving therapy because patients could die of starvation without TPN or enteral feeding.

Total Parenteral Nutrition

TPN is an effective method for delivery of nutrients directly into the blood, and thus overcomes the major causes of cancer cachexia, including decreased food intake and dysfunction of the gastrointestinal tract. Survival for more than 20 years in patients nourished exclusively by TPN clearly demonstrates the lifesaving role of this method of nutritional support. Initially, it seemed logical that TPN would be an effective adjuvant therapy for most cancer patients undergoing radiation therapy, surgery, or chemotherapy because of the accompanying cachexia and inability to eat adequately. Randomized studies, however, have shown that TPN only benefits a select subgroup of cancer patients during anticancer therapy.

Efficacy

In patients receiving chemotherapy with or without radiation therapy TPN can lead to improvements of several nutritional parameters. Both body weight and body fat increase (90). Deficits of specific vitamins, minerals, and trace elements can be corrected and hydration status can be improved (90,100). TPN, however, does not alter many of the metabolic derangements encountered in the cancer patient. Increased glucose oxidation and turnover persist (73,101) as does muscle proteolysis (102,103) and increased lipolysis (104). Finally, TPN does not stop the overall losses of body nitrogen (105). The relevant issue for the clinician is the effect of TPN on the morbidity and mortality associated with cancer therapy and whether TPN can allow more intense therapy as was initially hoped. Numerous randomized trials have examined this issue. Studies of patients undergoing chemotherapy for carcinoma of the ovary (29), lung (106,107), colon (105), testes (108), lymphoma (109), and other tumors (110) have been conducted. However, the patients in these studies were largely unselected. Many were not malnourished and others had adequate oral intake with intact gastrointestinal function, thus making intravenous nutrition unnecessary, futile, and potentially harmful. Numerous meta-analyses concluded that nondiscriminatory use of TPN in patients undergoing chemotherapy offers no improvement in mortality, response to chemotherapy, or reduction in treatment-associated complications (111–113). This conclusion was echoed in a recent joint consensus statement from the National Institutes of Health, the American Society for Parenteral and Enteral Nutrition, and the American Society for Clinical Nutrition (114). The improvement in nutritional parameters afforded by TPN in patients receiving chemotherapy is not necessarily translated into improved clinical outcome. Thus, the routine use of TPN in these patients is not indicated. There are circumstances, however, in which nutritional support with parenteral nutrition should be considered. These include prevention of the effects of starvation in a patient unable to tolerate oral or enteral feedings for a prolonged period of time (usually more than 7 to 10 days), maximization of performance status in a malnourished patient prior to chemotherapy or surgery, and in patients undergoing bone marrow transplantation (115).

TPN may have a stimulatory effect on tumor cell cycle kinetics (116). It was hoped that this effect would induce improved tumor response to cell cycle-specific chemotherapy. Conclusive proof of such a response remains elusive.

A few randomized studies have examined the use of TPN in patients receiving radiotherapy to the abdomen and pelvis (117–120). These studies did not show any clear benefit from the routine administration of TPN.

The role of TPN in the perioperative period has been extensively studied (16,17,121–125). In an early study by Mueller et al. (125), 10 days of preoperative TPN was associated with nutritional improvement and significant reduction in major postoperative complications and mortality. These impressive results have not been confirmed in subsequent studies. At Memorial Sloan-Kettering Cancer Center, a prospective study of 117 patients undergoing curative resection for pancreatic cancer randomized to receive TPN or intravenous fluids in the postoperative period showed no benefit from routine use of postoperative TPN (17). The group receiving TPN had a significant increase in postoperative infectious complications. The largest prospective, randomized trial investigating the role of TPN in the perioperative setting was the Veterans Administration Cooperative Study (16). In this study 395 patients were randomized to receive 7 to 15 days preoperative and 3 days postoperative TPN, or oral feeding plus intravenous fluids. TPN did not improve morbidity or 90-day mortality. However, subgroup analysis showed that patients considered to be severely malnourished had fewer infectious complications if they received TPN. The authors concluded that the routine administration of preoperative TPN should be limited to patients who are severely malnourished unless there are other specific indications.

Randomized studies specifically examining the role of perioperative TPN in patients with gynecologic malignancies are lacking. In a report by Terada et al. (25), perioperative parenteral nutritional support was given to 84 of 99 patients. There were no major complications attributed to TPN, but 27% of the patients experienced minor complications: 11% due to central line placement or catheter sepsis, 2% due to fluid overload, and 13% had metabolic complications. There was no report on overall perioperative morbidity or mortality in comparison to patients who did not receive perioperative TPN.

These data and others provide the basis for the recent joint consensus statement from the National Institutes of Health, the American Society for Parenteral and Enteral Nutrition, and the American Society for Clinical Nutrition regarding the use of perioperative TPN, which states the following: (a) 7 to 10 days of preoperative TPN in a malnourished patient with gastrointestinal cancer results in a 10% reduction in postoperative complications; (b) routine use of postoperative TPN in malnourished surgical patients who did not receive preoperative TPN results in a 10% *increase* in complications; (c) if by

postoperative day 5 to 10, a patient is unable to tolerate oral or enteral feedings then TPN is indicated to prevent the adverse effects of starvation. This panel, however, cautions that in the majority of studies looking at perioperative TPN the amount and type of parenteral nutrition given was not optimal, and often patients were given excess calories. Therefore, the results may differ with the provision of relatively hypocaloric formulas (114). It is reasonable to extend these recommendations to the gynecologic oncology patient undergoing surgery (Table 33.1).

Composition of TPN Solution

Once the decision to proceed with parenteral nutritional support is made, access to a large-bore central vein should be obtained. This allows the use of calorically dense, hypertonic solutions, which are often necessary in severely ill patients who may have restriction on the amount of intravenous fluids they can receive. When possible, this line should be used exclusively for TPN infusion and should be treated with strict aseptic technique. The composition of the TPN solution should be individualized based on the patient's condition and requirements, preferably by a dedicated nutrition support team (126). The solution must provide the protein and caloric needs, fluid, minerals, trace elements, and vitamins. Although indirect calorimetry and nitrogen balance can be used to determine energy and protein requirements, they are too costly and cumbersome for routine use. There are numerous formulas, charts, and tables that can provide estimates of protein and calorie requirements. Estimates of nutrition requirements are based on weight and adjusted for the degree of physiologic stress encountered by the patient. Generally, patients require 30 Kcal/kg nonprotein calories, 1 g/kg amino acids, and about 2,000 mL of fluid. As illness severity increases and organ functions change, adjustments may be required. Thus, patients with kidney or liver failure require decreased amounts of amino acids while those with heart failure require restriction of sodium and fluids. Nonprotein calories can be provided as dextrose or lipid and the relative amounts of these should also be individualized. Lipids provide 9 Kcal/g compared to 3.4 for dextrose. (In dextrose solutions the glucose is present as glucose-monohydrate, hence a gram contains less than 4 Kcal.) Lipid calories are particularly useful in patients who have high caloric requirements but cannot

TABLE 33.1

INDICATIONS FOR TPN IN HOSPITALIZED PATIENTS WITH GYNECOLOGIC CANCERS

Perioperative	Seven to 10 days preoperatively in a malnourished patient (who cannot be fed enterally) Postoperative complications that prevent oral or enteral intake for more than 7 to 10 days Enterocutaneous fistula No indication for routine use
During radiation or chemotherapy	Maximization of performance status prior to therapy in a malnourished patient who cannot be fed enterally Severe persistent (more than 7 to 10 days) mucositis, diarrhea, ileus, or emesis No indication for routine use
General	After 7 to 10 days of inability to tolerate oral or enteral feeding due to any cause

Note: TPN, total parenteral nutrition.

tolerate a large fluid load. In addition, lipids are useful in patients with severe pulmonary or hepatic dysfunction as glucose metabolism produces more carbon dioxide, which can add to the burden of the ailing lung and can lead to fatty infiltration of the liver. Up to 60% of caloric requirements can be provided as lipid, but serum triglyceride levels must be monitored closely. Appropriate electrolyte content of TPN solutions is of critical importance. The amounts have to be tailored to the patient's requirements and organ function. Care must be taken to prevent potentially fatal hypokalemia or hypophosphatemia (particularly in the patient with severe weight loss), which can be precipitated by insulin-induced transport of the minerals to the intracellular space when inadequate amounts are given. Other electrolyte disorders such as cisplatin-induced hypomagnesemia and syndrome of inappropriate antidiuretic hormone secretion (SIADH) are common in the patient with gynecologic malignancy and must be addressed when ordering TPN. The TPN solution must also contain vitamins, minerals, and trace elements. Typically these are available as standard commercial combination products. However, certain patients require specific modifications. For example, a patient with persistent diarrhea requires zinc supplementation in excess of the amounts present in standard trace element solutions.

Complications

Complications associated with TPN can be classified as catheter related, metabolic, or infectious. Catheter complications most often occur during placement of a central venous catheter and include pneumothorax, hemothorax, arterial injury, and hematoma. These can all be minimized when the procedure is performed by an experienced physician (127). Cobb et al. (128) reported a 3% incidence of pneumothorax, arrhythmia, thrombus, or bleeding during 523 intravenous catheter placements. A more recent study of subcutaneous peripheral infusion ports in women with gynecologic malignancies demonstrated a thrombosis rate of 26% during a mean follow-up of 105 days. The authors concluded that other types of vascular access devices may be preferable in this patient population (129).

Metabolic derangements are frequently encountered during support with TPN and the prescribing physician must be well versed in the pathophysiology of these disorders. Hyperglycemia is the most common abnormality (127) and if not corrected can lead to an osmotic diuresis, dehydration, acidosis, and hyperosmolar coma. Patients receiving parenteral nutrition should have continuous monitoring for glycosuria and if the dipstick is positive, the blood sugar concentration should be determined and sliding scale insulin coverage should be provided. One metabolic complication that deserves special mention is the "refeeding syndrome." In chronically ill patients with severe malnutrition there is often a depletion of total body phosphorus and potassium. The phosphorous deficits may be masked by increased renal phosphorous absorption designed to maintain normal serum levels. When TPN is initiated the infusion of a large glucose load with subsequent surge in insulin leads to increased cellular uptake of phosphorous and potassium, which may induce severe life-threatening hypokalemia and hypophosphatemia (130,131). These disorders cause widespread tissue and organ dysfunction including muscle weakness, rhabdomyolysis, heart failure, cardiac arrhythmias, and respiratory failure and may result in death in extreme cases (131). Therefore, in patients with evidence of severe undernutrition, TPN should be initiated with small amounts of dextrose calories, supplemental phosphorous and potassium, and careful monitoring of serum phosphorous and electrolytes.

TPN has been associated with cholestatic liver disease as well as fatty infiltration of the liver and glycogen deposition. These abnormalities have been attributed to infusion of excessive glucose calories, imbalance of amino acids, and rarely fatty

acid deficiency (132). Elevation of serum transaminases may occur but it is generally mild (132,133). Severe liver dysfunction in adult TPN recipients is rare and requires a search for causes other than TPN.

Infections are particularly serious complications in patients with malignancy receiving TPN. In an evaluation of seven studies comparing TPN plus chemotherapy to chemotherapy alone, Klein and Koretz found four studies that showed an increase in infectious complications in patients receiving TPN (119). A meta-analysis by the American College of Nutrition showed a fourfold increase in infections when patients receiving chemotherapy were given TPN (111). In a prospective, randomized study of TPN following pancreatic resection, recipients of TPN had significantly more infectious complications (17). Data from a Veteran's Administration randomized cooperative study showed that patients with mild to moderate malnutrition given perioperative TPN had increased rates of infections, while those with severe malnutrition developed significantly fewer infections when supported with TPN (16). Infectious complications are related to both central venous catheters and a variety of sites (wound infection, abscess, and pneumonia). While there are now promising data to show that the use of catheters impregnated with antimicrobials may provide a significant reduction of catheter-related sepsis (134), it is not clear that the use of these catheters will eliminate the increase in infections in patients receiving TPN.

Home TPN

Long-term TPN in the home can be a lifesaving treatment in an appropriately selected group of patients. It is clear that cancer patients who have had severe gastrointestinal injury, such as massive intestinal resection or severe radiation enteritis, and in whom the cancer has been cured or is well controlled, benefit from long-term TPN at home (135). Survival rates and TPN-related complications in such patients are comparable to those seen in patients with benign diseases (Crohn's disease, intestinal necrosis) who require home TPN. Among patients with widely metastatic disease and poor prognosis, home TPN offers very limited benefit (103). Only 15% of such patients survive longer than 1 year on home TPN (48). Recently developed techniques for placing feeding tubes make it possible to hydrate and feed patients enterally, even in the presence of gastrointestinal obstruction (115), and thus obviate the need for home TPN in patients with upper gastrointestinal tract dysfunction. In terminally ill patients TPN should be avoided. The concern that such patients should not be "starved to death" is not a justification for TPN. A recent uncontrolled study of terminally ill cancer patients hospitalized at a long-term care facility suggests that these patients did not experience hunger or thirst, and that in those who experienced such symptoms, small amounts of food alleviated the symptoms (136). In such patients the utilization of TPN either in the home or at health care facilities cannot be justified.

At Memorial Sloan-Kettering Cancer Center the clinical nutrition service prescribed home TPN for 20 patients with gynecologic malignancies (3 cervical, 15 ovarian, and 2 endometrial) from 1995 through 1998. This represented 9% of all cancer patients given this therapy. The indications for home TPN included bowel obstruction (ten patients), enterocutaneous fistula (seven patients), radiation enteritis (two patients), and short bowel syndrome (one patient). These patients were given home TPN because they had a good performance status or were considered candidates for further antitumor therapies. On average, they received home TPN for 163 days. Thirteen of the patients were able to resume oral or enteral feedings in amounts sufficient to sustain themselves after additional

Severe chronic radiation enteropathy
 Short bowel syndrome
 Persistent enterocutaneous fistula
 Selected patients with obstruction due to peritoneal carcinomatosis (selection based on performance status and potential for further chemotherapy)

therapy and seven patients died while still dependent on TPN.

For patients with inoperable bowel obstruction due to metastatic ovarian cancer, predicting which patients will benefit from home TPN can be difficult (137). In a review of 9,897 days of home TPN administered to 75 patients with various cancers and intestinal obstruction it was shown that a Karnofsky performance status greater than 50 at the initiation of TPN could accurately predict which patients would have improved quality of life while on home TPN. The authors concluded that home TPN should be avoided if the performance status is below this level (138). In addition, patients with a life expectancy of less than 2 to 3 months will not benefit from home TPN (103,138). In a study from Yale-New Haven Hospital of 17 patients with inoperable bowel obstruction due to malignancy, patients with ovarian cancer had the shortest survival (39 days) compared to patients with colon cancer (90 days) and appendiceal cancer (184 days) (139). Therefore, only a highly selected minority of patients with inoperable bowel obstruction can potentially benefit from home TPN. A recent study from Brown University evaluated 55 patients with terminal ovarian cancer and found that the use of TPN conferred a median survival benefit of 4 weeks (140). Currently the best selection criteria for such patients are a fair or better performance status and the potential for further antitumor therapy (Table 33.2).

Enteral Nutrition

Enteral feeding delivers a liquid-nutrient formula into the gastrointestinal tract through tubes placed into the stomach or small intestine. As in oral feeding, an adequately functioning small intestinal mucosa is required for absorption of nutrients. Enteral feeding can overcome many difficulties encountered in patients with a wide variety of gastrointestinal tract dysfunctions. A proximal gastrointestinal obstruction can be bypassed; tubes can be placed distal to obstructions as far as the jejunum and thus circumvent obstructing lesions of the oral cavity, esophagus, stomach, duodenum, or proximal jejunum (141,142). The liquid-nutrient formula can be delivered as a slow, continuous infusion, thus maximizing absorption by a limited intestinal surface, which can be overwhelmed by the higher volume delivered during oral feeding. Such an approach may be useful in patients with radiation enteritis, short bowel syndrome (with adequate remaining short bowel, usually 3 to 4 feet), or partial obstruction of the bowel.

Route of Administration and Nutrient Formula

Short-term (<2 weeks) access to the gastrointestinal tract can be obtained through nasogastric or nasoenteric tubes. Patients requiring longer nutritional support should have a gastrostomy or jejunostomy tube placed endoscopically, radiologically, or

surgically. In comparison to nasal tubes, gastrostomy or jejunostomy tubes are wider (15 to 24 French) and therefore less likely to be obstructed by medications or nutrient solutions. In addition, they are fixed in the stomach or the upper intestine and do not migrate into the esophagus. Thus, the risk of aspiration is considerably decreased (141). These tubes are more comfortable and aesthetically pleasing (143). These benefits were demonstrated in a recent randomized study of patients after an acute dysphagic stroke, which showed that patients fed with a gastrostomy tube had more optimal provision of nutrients, achieved a better nutritional state, and had less mortality than those fed with nasogastric tubes (144). Patients with gastrostomy tubes have been shown in prospective studies to receive over 90% of prescribed feedings compared to only 55% in patients fed through nasal tubes. These differences are largely attributed to nasogastric tube dislodgment (145). In a randomized study of 33 women with gynecologic malignancies, enteral feedings through a needle catheter jejunostomy maintained postoperative nutrition as measured by serum transferrin levels and was associated with few complications (146). The authors concluded that women with gynecologic cancers should have a jejunostomy placed at the time of operation if it is anticipated that long-term nutritional support will be required.

Endoscopically placed percutaneous gastrostomy tube (PEG) has become the procedure of choice for placement of enteral feeding tubes because of its ease, safety, and the ability to perform it on an outpatient basis. Percutaneous jejunostomy (PEJ) tubes can also be placed endoscopically (142). PEJs allow for continued enteral feeding in patients with gastric resection, gastric outlet obstruction, or gastroparesis. Major complications (bleeding, peritonitis, abdominal wall abscess, colonic perforation, and aspiration) from PEG and PEJ placement are rare, occurring in 0% to 2.5% of patients, while minor complications (wound infection, tube migrations, or leak) are seen in 5% to 15% (65,142,147,148). This favorably compares to the 2.5% to 16% complication rate and 1% to 6% mortality from a laparotomy required for surgical placement of feeding tubes (149–151).

More than 100 different enteral feeding formulas are currently commercially available (152). They are designed to provide either complete nutrition, single nutrients, or only fluids and electrolytes. Formulas differ in protein concentration, calories, osmolarity, and percentage of nonprotein calories delivered as carbohydrates or fats. Enteral feeding formulas that provide 1,500 to 2,000 Kcal per day normally contain all the necessary nutrients including proteins, vitamins, minerals, and trace elements. In addition, there are disease-specific formulations for patients with diabetes or hepatic, renal, or pulmonary dysfunction. The choice of formula should be individualized and often helps to minimize problems such as diarrhea, bloating, or hyperglycemia (141).

Enteral solutions may be administered by either bolus feedings or by continuous infusion (141,149,150). Bolus feeding is possible when the tip of the feeding tube is in an intact stomach. Up to 500 mL of a feeding formula can be infused over 10 to 15 minutes by a syringe or gravity into the stomach. The pyloric sphincter regulates flow into the duodenum. All bolus feedings should be done with the patient sitting upright to minimize the risk of aspiration. When the tip of the feeding tube is distal to the pylorus, continuous feeding must be employed to avoid abdominal distention and diarrhea. Rates as high as 150 mL per hour are generally well tolerated (141).

Efficacy

Data from randomized trials examining the efficacy of enteral nutrition given as an adjuvant therapy in patients receiving chemotherapy for a variety of cancers have failed to demonstrate

a clear benefit in terms of survival or response to treatment (153–157). The validity of the conclusions of these studies, however, is limited by their small size and poor design. Similar difficulties plague the studies examining the role of standard enteral nutrition in the perioperative period (158–161). While recent data examining early (postoperative day 1) enteral feeding in patients following resection of an upper gastrointestinal tract tumor showed improved protein metabolism, there is no evidence that this translates into improved clinical outcome (162). In a prospective, randomized study of early enteral feeding in 195 patients after resection of upper gastrointestinal malignancy there was no proven benefit. Complication rates, mortality, and length of hospital stay were not affected by early postoperative enteral feedings (163). Therefore, routine use of enteral nutrition support in patients receiving chemotherapy or undergoing operations for cancer cannot be justified. Accepted indications for enteral nutrition in cancer patients include (a) obstruction of the upper digestive tract in those who are not candidates for an operation, (b) the presence of chronic malnutrition due to inadequate oral intake, (c) perioperative support of the malnourished patient (164).

Complications

Enteral nutrition is generally safe if careful attention is paid to the following: (a) choice of an appropriate formula, (b) infusion into an appropriate portion of the gastrointestinal tract, (c) use of the correct infusion method, and (d) an ongoing clinical and metabolic monitoring of the patient. The most serious complication of enteral feeding is aspiration, which occurs in 1% to 32% of patients (153,165,166). The risk is minimized by keeping patients upright during bolus feedings and using jejunal feedings if there is predisposition for aspiration, gastroparesis, or an impaired gag reflex. Diarrhea is reported in 5% to 30% of patients receiving enteral nutrition (167). While the diarrhea may be related to underlying disorders of the gastrointestinal tract such as radiation enteritis or short bowel syndrome, a commonly overlooked cause is medications. Patients on enteral feeding often receive magnesium-containing antacids or antibiotics, both of which may induce diarrhea. Metabolic complications include dehydration, azotemia, hyperglycemia, and hyperkalemia. These are usually due to the patients' underlying disease and can be avoided with the choice of the proper formula and careful monitoring.

Home Enteral Nutrition

Home enteral nutrition (HEN) is increasingly being used to provide nutrients and fluids outside the hospital. Cancer is the most common indication for its use and accounts for 42% of all patients receiving HEN (135,141). It is a safe therapy in patients with cancer with only a 0.4% annual rate of complications requiring hospitalization (168). The overall 1-year survival for cancer patients on HEN is 30%. However, in patients with cancer of the head and neck who have been successfully treated, HEN has provided good nutrition for periods exceeding 7 years (65,141). Regular medical follow-up is essential to ensure appropriate functioning of the feeding tube and optimization of the nutrition regimen. This form of therapy is useful in patients with gynecologic malignancies with upper gastrointestinal tract obstructions that cannot be treated surgically.

Oral Dietary Therapy

Patients who are able to eat but have impairment of the gastrointestinal tract or have special metabolic requirements may benefit from a specialized oral dietary therapy (159). Often

this may obviate the need for more costly and complex interventions such as parenteral nutrition. In oral dietary therapy the regular diet is modified based on the pathophysiologic changes induced by the underlying disorder with the goal of providing the most optimal nutrition possible (159). When the main problem is inadequate food consumption, various commercial oral supplements can be used but usually for only short periods because of taste fatigue. Some preparations provide complete nutrition while others are intended to supplement deficits of specific nutrients. Problems common in patients with gynecologic malignancies such as partial small bowel obstruction, chronic radiation enteritis, and short bowel syndrome may all be amenable to dietary therapies. In partial small bowel obstruction or motility dysfunction a diet comprised of frequent, small, calorically dense meals with minimal amounts of fiber is indicated. Patients with radiation enteritis should receive a low-fat, low-fiber, and lactose-free diet. Dietary management of short bowel syndrome patients includes frequent small meals; limitation of fiber, lactose, and simple sugars; taking liquids separately from meals; and supplementation of calcium and zinc orally and magnesium and vitamin B₁₂ parenterally.

Bye et al. (169) conducted a prospective, randomized trial of a low-fat, low-lactose diet in 143 women with gynecologic malignancies undergoing radiation therapy. The intervention group had significantly less diarrhea. Diarrhea in the control group correlated with increased fatigue and decreased physical function. The authors concluded that diet intervention during radiotherapy reduced the severity of diarrhea, influenced patients' ability to cope with diarrhea, and gave them more control over their situation.

The successful implementation of prescribed diets depends to a large extent on a dietitian converting the prescribed diet to a meal plan and working with the patient to implement it. In a prospective, randomized study of 57 patients undergoing chemotherapy for ovarian, breast, or lung cancer, those who received intensive dietary counseling had improved long-term food intake (170). Similar data have been demonstrated in cancer patients undergoing radiotherapy (171) and in patients with acute leukemia undergoing induction chemotherapy (172).

Pharmacologic Agents

Agents that will reverse the wasting seen in advanced cancers have long been sought to complement or replace the provision of nutrients via the oral, enteral, or parenteral route. Hormones, appetite stimulants, and most recently, cytokine antagonists have been examined. Studies of growth hormone (173,174), insulin-like growth factor (IGF)-I alone (174), or IGF-I with insulin (175) in cancer-bearing rodent models showed significant attenuation of tumor-induced weight loss. In human clinical trials, these agents provided modest gain in weight but no improvement in quality of life and no other benefits (176).

Appetite Stimulants

Anabolic steroids have no proven efficacy in treating cancer cachexia. In a murine model, administration of norandrolone propionate resulted in weight gain but this was largely due to fluid retention (177). In human trials steroids produced transient improvement of nutritional parameters and appetite, but continued use is associated with negative nitrogen balance, net calcium loss, glucose intolerance, and immunosuppression (176).

Megestrol acetate is a progestational agent that has been shown to improve appetite and ameliorate weight loss in numerous but not all studies of patients with cancer and cachexia (176). Doses in these studies ranged from 160 mg per day to 1,200 mg per day, and maximal weight gain was

generally seen within 8 weeks. However, the change in weight is largely due to increased adipose tissue and edema (178). Nevertheless, improvement in quality of life has consistently been demonstrated in several large, prospective studies in patients with cancer cachexia treated with megestrol acetate (179,180). It is generally well tolerated but can exacerbate underlying diabetes mellitus and rarely lead to adrenal suppression. Dronabinol, a marijuana derivative, has shown some promise in small studies, improving appetite and causing weight gain; however, large randomized trials are lacking (176). Food and Drug Administration (FDA) approval is currently limited to treatment of nausea and vomiting during chemotherapy and for cachexia in HIV-positive patients.

Cytokine Inhibitors

Inhibitors of cytokines involved in cancer cachexia and anorexia have the potential to be potent agents in the treatment of malnutrition in cancer. Monoclonal antibodies against TNF lead to improved food intake and diminished loss of protein and fat in murine models of cancer cachexia (168). Similar data are available for anti-interleukin-6 (anti-IL-6) (181,182) and anti-interferon- γ (anti-IFN- γ) (183). Suramin, a direct IL-6 receptor antagonist, decreased several key parameters of cachexia in tumor-bearing mice (184). A recent study from Japan of a novel inhibitor of IL-1 and TNF- α showed that direct injection of the drug into tumor did not alter tumor growth but did result in attenuation of loss of body weight and epididymal fat in tumor-bearing mice (185). Human studies utilizing the anticytokine approach are limited. Pentoxifylline and thalidomide have been shown to inhibit TNF- α , but only

thalidomide improved weight loss associated with AIDS and tuberculosis (186). Interestingly, recent data show that the clinical anticachexia effect of megestrol acetate is due, at least in part, to inhibition of cytokines (Table 33.3) (99).

Drugs to Relieve Symptoms

The use of medications to relieve cancer or treatment-related symptoms that impair oral intake is an important adjuvant to nutritional support in these patients. For example, optimal antiemetic therapy can now adequately control acute and delayed emesis in 70% to 90% of patients (187). Despite this the incidence of chemotherapy-induced nausea and emesis is underestimated by oncologists and nurses (188). This highlights the importance of a careful history and review of systems when completing a nutritional evaluation of a cancer patient. Many cancer patients assume that nausea and vomiting are normal during treatment and will not report it as a problem unless specifically asked.

Antidepressant medications should be considered when evaluating a patient with cancer and malnutrition. Depression occurs in 25% to 45% of cancer patients and can lead to loss of appetite and weight loss (189). Pharmacotherapy for depression utilizing selective serotonin reuptake inhibitors or tricyclic antidepressants is effective in cancer patients (189). Methylphenidate, a stimulant, has also been shown to be effective for the treatment of cancer-related depression (190). Although the relief of depression may improve appetite, it should be noted that in patients without cancer, selective serotonin reuptake inhibitors and tricyclic antidepressants are associated with weight gain that is independent of the response of the

TABLE 33.3

PHARMACOLOGIC AGENTS USED FOR THE TREATMENT OF CANCER CACHEXIA AND ANOREXIA

Class of agent	Example	Efficacy	Adverse effects
Hormones	Insulin, IGF, GH	Attenuation of tumor-induced weight loss; <i>no</i> improvement in survival or quality of life demonstrated	Hypoglycemia, hypokalemia
Anabolic steroids	Oxandrolone, nandrolone	Transient improvement in appetite	Fluid retention; net loss of calcium and nitrogen; hyperglycemia, immunosuppression
Progestational agents	Megestrol acetate	Improved appetite, weight, and quality of life	Weight gain is mostly due to fluid retention and adipose tissue; may exacerbate diabetes mellitus; rare cases of adrenal insufficiency
Cannabinoids	Dronabinol	Improved appetite and weight gain in small studies	CNS effects (slurred speech, nausea, dizziness, sedation)
Cytokine inhibitors	Pentoxifylline, thalidomide, suramin, monoclonal antibodies to IL-1, IL-6, and TNF- α	Improved food intake and attenuation of protein loss in animal models	Clinical studies pending

Note: CNS, central nervous system; GH, growth hormone; IGF, insulin-like growth factor; IL, interleukin; TNF, tumor necrosis factor.

underlying depression (191). Pilot studies suggest that these drugs may also produce weight gain in patients with cancer (192). As for methylphenidate, it is associated with anorexia in patients without cancer; however, in patients with cancer-related depression and anorexia its use is associated with relief of anorexia (193). Therefore, methylphenidate can be used to treat depression in cancer patients with depression and malnutrition.

ETHICAL CONSIDERATIONS

Prior to the advent of enteral and parenteral feedings the inability to receive nutrients through oral intake inevitably led to wasting and death. Therefore, in the majority of patients the natural history of cancer led to death because of dehydration and starvation (194). In patients with potentially curable or stable disease, nutritional support, when indicated, is an important and often critical part of the overall treatment plan. On the other hand, the role of nutritional support in the terminally ill is a subject filled with ethical and legal dilemmas. These problems come to light when the wishes of the patient or the patient's representative are not in agreement with the recommendations of the physicians. For example, a patient may wish to forego nutritional support despite recommendations that such a therapy should be given. Alternatively, patients or their representatives may want to initiate or continue TPN even after all anticancer therapies have failed and the patient is in a terminal state. Two general principles apply: in the first case, autonomy, and in the second, medical futility.

Autonomy is the right of competent patients to make decisions about their care and implies that the physician must solicit these decisions. It was not until the mid-1960s, a time of vast societal changes and challenges to authority, that autonomy began to supersede the Hippocratic tradition with its emphasis on the authoritarian role of the physician. This principle is clearly outlined in a report from the President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research, which states, "The voluntary choice of a competent and informed patient should determine whether or not life sustaining therapy will be undertaken, while healthcare institutions and professionals should try to enhance patients' abilities to make decisions on their own and to promote understanding of the available options" (195). With regard to most treatments (operations, chemotherapy, radiation therapy), the patient's knowledge and experience may be very limited and thus the physician's recommendations may form the sole basis for the patient's decisions. This is not the case with nutrition. People understand the role of nutrition in sustaining life and it is often hard for a layperson to understand why parenteral nutrition may not be indicated or even harmful when the patient has no other source of nourishment. In such situations it is the responsibility of the physician to thoroughly explain the reasons for withholding TPN.

The principle of medical futility often surfaces in discussions of nutritional support of the cancer patient, especially if the disease is advanced and unresponsive to therapy. There are four aspects to medical futility (196): (a) lack of physiologic rationale for the proposed therapy; (b) failure of the same therapy in a previous attempt; (c) all possible treatments for the underlying disease have failed; (d) the therapy will not improve quality of life or achieve a goal of care (such as living to see a particular life event). In the case of parenteral (and rarely enteral) nutritional support of the cancer patient, aspects (c) and (d) may be specifically applicable.

It should be noted that these principles, autonomy and medical futility, should govern decisions for both initiation and withdrawal of an ongoing therapy. As stated in the report from the President's Commission, "A justification that is adequate for not commencing a treatment is also sufficient

for ceasing it. Moreover, establishing a higher requirement for cessation might unjustifiably discourage vigorous initial attempts to treat seriously ill patients that sometimes succeed" (195).

Religious beliefs will often strongly influence decisions regarding nutritional support. Publicly stated opinions on the subject include (a) a statement from the Archbishop of Canterbury that removal from life support was permitted if it was better to allow the patient to die (197); (b) a report from the National Conference of U.S. Catholic Bishops, which states that Catholics are not required to use extraordinary means when recovery is hopeless and only the burden of care remains (198); and (c) a review of Orthodox Jewish rabbinical decisions, which concluded, "the imperative to preserve life supersedes, with a few exceptions, quality of life considerations" (199).

For the gynecologic oncologist, management of the patient with an inoperable bowel obstruction due to peritoneal carcinomatosis is a difficult and recurrent problem. A recent review attempts to outline the role of parenteral nutrition in this population (137). TPN should be considered in only those patients with a good performance status, and careful attention must be paid to likely medical and symptomatic outcomes as well as ethical considerations. It is interesting to note the views of patients on various life-sustaining treatments. In a study from the University of Michigan, 90% of women undergoing treatment for a gynecologic cancer could envision a time when they would refuse ventilatory support, but only 37% could foresee a time when they would refuse artificial nutrition (200). It is important for the physician and other members of the health care team to inform the patient and the family that in the terminally ill, provision of food and water by enteral or parenteral routes will not improve comfort (136,176) and, in fact, may add to discomfort (136,201–203). At Memorial Sloan-Kettering Cancer Center TPN is used infrequently in patients with gynecologic cancer and bowel obstruction due to malignant carcinomatosis who do not receive any further anticancer therapy. TPN is used under these conditions only when it is judged that it will enhance the quality of life of a patient who is not at imminent risk of dying in spite of the widely metastatic disease. When considering the chance of improving the quality of life, the burden of TPN administration and monitoring and the risk of complications have to be considered.

CHAPTER 34 ■ QUALITY OF LIFE ISSUES IN GYNECOLOGIC ONCOLOGY

LARI WENZEL, RICHARD PENSON, JEANNE CARTER,
DANA CHASE, AND DAVID CELLA

INTRODUCTION

Health-related quality of life (QOL) is an increasingly important endpoint in clinical trials, and a fundamentally important issue for patients. Quality of life is a multifaceted and complex paradigm that reflects patient's experiences with disease, treatment, and accompanying long-term sequelae (1,2). While a specific definition of quality of life may require articulating the patient's status on physical, functional, emotional, and social well-being (3), it can also encompass the disparate aspects of patient demography (age, ethnicity, education, income), social circumstances (relationships and roles), and spiritual issues. It is no longer acceptable to pursue curative treatment with the hope of improving mortality without consideration of treatment morbidity, and without including patient-centered decision-making and quality of life implications. Therefore, this chapter provides an overview of state-of-the-science perspectives broadly incorporating medical interventions (e.g., recent clinical trials) which have influenced quality of life and other patient-reported outcomes, and gynecologic cancer survivorship issues, including several challenging symptoms (e.g., fatigue, neurotoxicity, lymphedema) and long-term concerns (e.g., sexual dysfunction, reproductive concerns, emotional well-being).

QUALITY OF LIFE

Quality of life is an abstract, multidimensional construct that covers the subjective perceptions of the positive and negative aspects of patients' experience. We all know good quality of life, but it is rarely simple. It integrates symptoms; physical, emotional, social, and cognitive functions; and reflects the impact of cancer and the side effects of treatment (4,5). Figure 34.1 lists elements of quality of life (6–8).

Considering well-being or quality of life is as old as Aristotle's concept of eudaimonia, or "good." The first attempt to quantitatively measure the impact of cancer was described in 1949, when Karnofsky and Burchenal reported a simple 11 (0 to 10) point scale for the clinical evaluation of chemotherapy. This was simplified into the ECOG (Eastern Cooperative Oncology Group) Zubrod scale (0 = asymptomatic, 1 = symptomatic, 2 = functional for >half the day, 3 = functional for <half the day, 4 = moribund), and performance status probably remains the single most significant bias that contributes to the big differences between the results of phase 2 studies (9). Early QOL studies rapidly revealed considerable discrepancy between

observers and between the doctor's and his or her patient's evaluation of the patient's QOL, and it became clear that any method for measuring QOL, quintessentially subjective, would have to rely on patients themselves and not caregivers (10). Patient-reported outcomes (PROs) are now widely considered an excellent methodology to evaluate the utility of treatment. A simple composite measure of clinical benefit (measurements of pain [analgesic consumption and pain intensity], Karnofsky performance status, and weight) was used as the primary efficacy measure in a small but randomized study that led to Food and Drug Administration (FDA) approval of gemcitabine in advanced pancreatic cancer (11). Quality-adjusted time without symptoms of disease or toxicity of treatment (Q-TWIST) was an important addition as duration of symptoms, where they occur in the trajectory of the disease, and their source (disease or treatment) all influence their perception and impact (12). Recently, large randomized, controlled trials incorporating QOL endpoints have reported that docetaxel is associated with less neurotoxicity than paclitaxel (13), and erythropoietin (rHuEpo) significantly impacts anemia and fatigue (14). As physical functioning deteriorates, relational, spiritual, and psychologic issues become relatively more important (15,16).

Quality of life has been shown to predict survival in numerous disease settings (17,18). In the Heart and Soul Study, a study of outcomes in 1,024 patients with coronary artery disease, depressive symptoms were more predictive of overall health than conventional measures of cardiac function such as ejection fraction and ischemia (19). Recent work conducted within the Gynecologic Oncology Group (GOG) suggests that baseline QOL scores predict survival and may serve as an early barometer of patients who may or may not respond to aggressive treatment (20,21).

Quantitative measure of patient outcomes is dependent on the use of validated instruments of psychometric data. Such questionnaires, or scales, list items (questions about particular constructs) in related domains (dimension or focus of behavior or experience). Retesting between subjects and over time establishes reliability (test-retest, interobserver variation, and correlation with related instruments), responsiveness, and applicability (generalizability or external validity). Good scales have to be (a) internally consistent (similar domains report agreement—Cronbach's alpha ≥ 0.7), (b) stable (reliability coefficient), (c) equivalent or superior to other scales purporting to measure the same thing (kappa statistics), and (d) accepted by patients and experts. Approximately 500 instruments have been developed (22). Commonly used tools include the Functional Assessment of Cancer Therapy (FACT—with gynecologic and

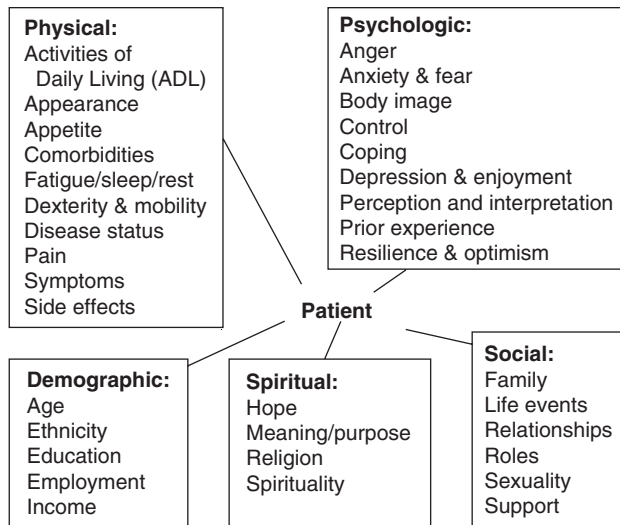

FIGURE 34.1. Elements of quality of life. *Note:* ADL, activities of daily living. *Source:* Modified from Ferrell B, Smith SL, Cullinane CA, et al. symptom subscales), the European Organization for the Research and Treatment of Cancer QLQ-C30 (EORTC QLQ-C30), Hospital and Anxiety Depression Scale (HADS), Profile of Mood States (POMS), Rotterdam Symptom Checklist (RSCL), MOS-Short Form 36 (SF-36), and Visual Analogue Scale (VAS).

The Functional Assessment of Cancer Therapy (FACT) instrument (scale) is a 27- (generic core) to 50-item compilation of specific subscales, comprising physical, social/family, emotional, functional, and disease-specific well-being/concerns (<http://www.facit.org/>) (23,24). The EORTC also developed a similar QOL instrument consisting of a core component applicable to all cancer patients and modules developed for specific cancer sites (25). EuroQol-5Dimension (EQ5D) utilizes a brief five-item questionnaire covering mobility, self-care, usual activities, pain/discomfort, and anxiety/depression, and a thermometer visual analogue scale ranging from 0 (worst imaginable health state) to 100 (best imaginable health state) (26).

For much of the last decade the research agenda has been dominated by the comparison of instruments that evaluate the harder to measure aspects of clinical care (Fig. 34.2) (27,28).

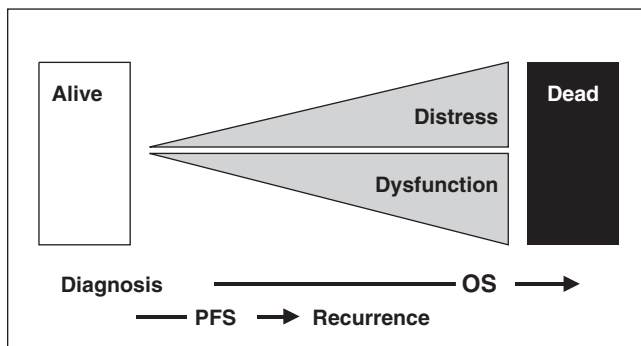

FIGURE 34.2. Health-related quality of life—measuring the grey outcomes. Black and white outcomes: PFS, progression-free survival; OS, overall survival.

These studies have helped develop tools that have allowed important randomized clinical trials to now report QOL data (13,29). Formalizing the evaluation of health-related QOL is becoming established, with ongoing debate over methodology and the distillation of a minimum set of criteria for assessing outcomes in cancer clinical trials that inform decisions in clinical practice (30). New modeling approaches that account for nonrandom omission of data are beginning to be accepted (31). Evaluating QOL helps describe populations, predict outcomes, and guide decisions (trade-offs and gambles), and can screen for dysfunction, help allocate resources, and improve awareness as patients approach end-of-life issues (32).

A novel approach to patient-reported outcomes is now funded by the National Institutes of Health (NIH). The Patient-Reported Outcomes Measurement Information System (PROMIS) network, which is part of the NIH Roadmap Initiative, aims to improve how PROs are selected and assessed in clinical research. PROMIS is establishing a publicly available resource of self-reported health domain measures, including those specifically targeted to cancer. More information can be found at <http://www.nihpromis.org/> (23). Additional useful resources for quality of life measurement include <http://www.facit.org/>, <http://www.isoqol.org/>, <http://www.euroqol.org/>, <http://www.cancer.gov>, and <http://www.q1-recorder.com/>.

QOL OUTCOMES AND CLINICAL TRIAL UPDATES FOR ENDOMETRIAL, CERVICAL, AND OVARIAN CANCER

Integrated multidisciplinary care has appropriately become the necessary standard of the complex care of patients frequently in specialist centers, with goals of care changing over the course of the disease (Fig. 34.3).

Endometrial Cancer

Recent literature has identified quality of life data that may inform therapeutic choices for women with endometrial cancer. In a recent study, advanced endometrial cancer patients were randomized to whole abdominal irradiation (WAI) versus doxorubicin-cisplatin (AP) chemotherapy. Although overall QOL did not differ between the two treatment groups, there were symptom-related differences (33). Specifically, WAI patients reported significantly higher fatigue than those who received

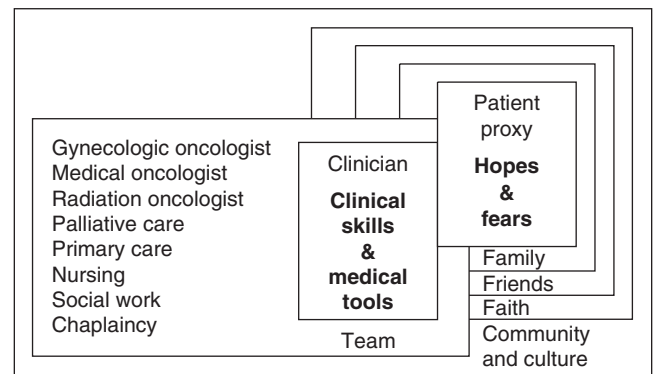

FIGURE 34.3. Holistic care.

AP chemotherapy for seven cycles plus an additional cycle of cisplatin alone. Significant differences in functional alterations due to changes in bowel function were identified at the end of treatment ($P < 0.01$), and at 3 months ($P < 0.01$), with radiation associated with poorer scores. However, the AP group showed significantly higher peripheral neuropathy scores at the end of treatment and at 3 and 6 months posttreatment compared to the WAI group ($p < 0.01$). Therefore, although doxorubicin-cisplatin showed increased survival, the authors emphasize that the patients should be counseled regarding significant peripheral neuropathy that may have a significant impact on QOL.

Notably, quality of life has also recently been evaluated in comparisons of laparoscopy versus laparotomy (34,35). In both studies, QOL was superior in the laparoscopy group. In the GOG LAP2 trial, which compared differences in quality of life between those endometrial cancer patients who underwent comprehensive surgical staging via laparoscopic technique versus traditional laparotomy, patients treated by laparoscopy had a superior quality of life through 6 weeks postsurgery compared to those treated by laparotomy, likely due to it being a less invasive procedure resulting in less pain, faster recovery, and a small but significant reduced length of hospital stay. However, except for a significantly better body image in the laparoscopy than the laparotomy group, these differences were not sustained at 6 months.

Cervical Cancer

In treatment of advanced cervical cancer, quality of life considerations are primary. Several recent studies have demonstrated important QOL results which have influenced clinical trial paradigms. For example, a randomized phase 3 trial demonstrated that although there was greater toxicity in the cisplatin/paclitaxel (CP) regimen, there was no statistically significant difference in overall QOL scores between this treatment arm and the cisplatin (C) single-agent regimen. This finding, combined with the improved response rate and progression-free survival (PFS) in the CP arm and a higher dropout rate in the C arm, suggests a worse outcome for the single-agent regimen. In this case QOL measurement contributed to the conclusion that CP is superior to C alone with respect to response rate, progression-free interval, and sustained or improved QOL for patients treated with cisplatin versus cisplatin plus paclitaxel (20,36).

Several other trials have reported quality of life as a secondary endpoint to use in addition to survival data when choosing chemotherapeutic regimens to treat advanced cervical cancer (37,38). These authors effectively argue that when determining if certain chemotherapy combinations may improve survival, it is critical to consider quality of life, as toxicity may worsen. One such study prospectively assessed the impact of treatment with cisplatin alone (C), versus C in combination with topotecan (C+T) on QOL in patients with advanced or recurrent cervical cancer, and explored the prognostic value of baseline QOL scores. Importantly, results from this study employing the FACT-Cx measure indicated there were no statistically significant differences in QOL up to 9 months postrandomization, despite more hematologic toxicity in the C+T arm. The baseline FACT-Cx was also associated with predicting survival (38). This was the first advanced cervical cancer study to note that patient-reported QOL measures may be an important prognostic tool in advanced cervix cancer. These phase 3 trials have challenged a traditional study design for chemotherapeutic agents by incorporating patient-reported outcomes into the interpretations and implications of the relative value of these regimens. Clearly, quality of life is a critical factor in palliative chemotherapy for

recurrent and/or persistent advanced cervical cancer, where life expectancy is likely to be brief (36).

Ovarian Cancer

Several recent phase 3 clinical trials have included longitudinal assessment of quality of life as a secondary study endpoint. This information continues to influence a comprehensive interpretation of results, clinical trial design, and clinical decision making. For example, in a study of suboptimally debulked advanced ovarian cancer, although the addition of interval secondary cytoreduction to postoperative chemotherapy resulted in no notable long-term difference, a clinically significant QOL improvement was seen in both arms at 6 and 12 months after starting therapy. Of interest, fewer complaints of neurotoxicity at 6 months were reported among patients who did versus did not undergo interval secondary cytoreduction, likely due to the break in chemotherapy (39). In this study it was also shown for the first time in ovarian cancer that baseline QOL scores could predict survival, attributed primarily to the lowest scoring quartile on the FACT-O. QOL has also predicted survival for patients participating in a phase 3 trial comparing gemcitabine with pegylated liposomal doxorubicin (40).

A controversial randomized phase 3 trial in optimal stage III epithelial ovarian cancer showed that intravenous paclitaxel plus intraperitoneal cisplatin and paclitaxel significantly lengthened progression-free survival and overall survival compared to intravenous paclitaxel and cisplatin (41). During active treatment, patients on the intraperitoneal arm experienced more health-related quality of life disruption, abdominal discomfort, and neurotoxicity compared to those receiving conventional intravenous therapy. However, only neurotoxicity remained significantly greater for intraperitoneal patients 12 months posttreatment, and generally for both groups QOL improved over time (42). Given the continued controversy regarding intraperitoneal therapy, QOL information will continue to provide clinically meaningful information from which to guide treatment decisions.

Several additional recent phase 3 trials have incorporated quality of life endpoints into advanced ovarian cancer clinical trials (e.g., 43–48). For example, du Bois et al. compared paclitaxel plus cisplatin (PT) with paclitaxel plus carboplatin (TC) in patients with advanced ovarian cancer, evaluating QOL utilizing the EORTC QLQ-C30 questionnaire (45). There were significant QOL differences in favor of the TC arm, therefore leading to the conclusion that paclitaxel plus carboplatin is a more reasonable and better-tolerated treatment overall. In a subsequent study, Greimel et al. (47) examined hematologic and nonhematologic toxicity of the paclitaxel/carboplatin (TC) versus paclitaxel/cisplatin (PT) regimens, and the effects of toxicity on QOL. Again, quality of life was better in the TC regimen, resulting in confirmation that where two regimens have equal progression-free and overall survival, paclitaxel/carboplatin is preferable. A similar recommendation can be made from QOL data where it was demonstrated that gemcitabine plus carboplatin significantly improved progression-free survival and response rate without worsening QOL (44). The relationship between cancer treatment efficacy, benefit, and quality of life for elderly patients is also being studied. In one phase 3 trial comparing cisplatin and paclitaxel to carboplatin and paclitaxel, although quality of life scores did not differ between elderly and younger patients, the elderly patients showed a higher rate of early treatment discontinuation. The authors speculate that this may be due to provider and/or patient unwillingness to continue treatment in the setting of toxicities which might otherwise be managed differently in a younger population (49).

CHALLENGES IN GYNECOLOGIC CANCER SURVIVORSHIP

As noted previously, treatment side effects can influence short-term quality of life for many women, and longer if sequelae persist or worsen over time. Recognition of and management for these issues can vary from simple strategies to improve quality of life (i.e., managing nausea and vomiting), to complex psychosocial issues (e.g., reproductive concerns), for which clear guidelines may not exist. This section illustrates some of the current, potentially unique, and more complicated aspects of gynecologic cancer survivorship.

Pre-treatment factors may influence a patient's quality of life both during and post-treatment. Several authors have noted that quality of life is affected by preoperative factors such as education, lifestyle, general health, and obesity (50–52), all of which in turn may affect a patient's ability to tolerate therapy. The interplay between cancer or cancer treatment symptoms and quality of life is well documented in the gynecologic cancer literature (e.g., 53,54). Several recent and/or prominent investigations deserve mention.

Although a considerable and growing body of literature exists specific to cognitive impairment and fatigue during and after chemotherapy, only recently has this been considered within the gynecologic cancer cohort. For example, Hensley et al. were the first to study cognitive functioning prospectively in an ovarian cancer trial (55). Although they did not find significant decreases in cognitive functioning in women receiving paclitaxel, gemcitabine, and carboplatin in a phase 2 trial, they did note that highly educated women might suffer greater impairments and thus future trials should include cognitive functioning measures in their quality of life assessments. Fatigue, during and subsequent to cancer treatment, is a related, prevalent, and understudied issue for gynecologic cancer patients.

Fatigue occurs in 70% to 100% of patients with cancer, and is often underdiagnosed, inadequately treated, and hard to disentangle from other symptoms of physical compromise and psychologic distress (56). Treatable causes of fatigue include anemia, malnutrition, medications, infections, pain, depression, insomnia, muscle dysfunction, and anticancer therapy (57,58). In a notably important QOL investigation, in 2,370 anemic cancer patients undergoing chemotherapy, recombinant human erythropoietin significantly improved patient-reported functional capacity and quality of life independent of tumor response (14). Many authorities also advocate either energy conservation or pushing apparent boundaries with graded exercise and cognitive-behavioral therapy (59). Psychostimulants, such as short- and long-acting methylphenidate, have been initially positive, but more rigorous studies have suggested that there is questionable benefit over placebo or daily telephone calls from a research nurse (60).

Neurotoxicity, an increasingly documented long-term problem, can cause sensory loss, pain, loss of function, loss of mobility, and for some women loss of professional and recreational activity. Platinum compounds, the mainstay of treatment for most gynecologic malignancies (61), are associated with cumulative myelosuppression (particularly thrombocytopenia), neurotoxicity, and nephrotoxicity, as well as severe nausea and vomiting (62,63). Neurotoxicity, anemia, and nausea/vomiting all have well-known adverse effects on QOL. Paclitaxel in combination with a platinum compound is now considered the standard of care as first-line chemotherapy for advanced ovarian cancer (64,65). However, paclitaxel has a number of toxicities (e.g., granulocytopenia, neurotoxicity) that synergistically overlap those of the platin, and the coadministration of paclitaxel and a platinum compound can increase the frequency and/or severity of shared toxicities, especially neurotoxicity. Docetaxel is associated with significantly less neurotoxicity (66).

Administration of glutamine or the antidepressant venlafaxine may be helpful in cases of paclitaxel-induced neuropathy, and amifostine may provide protection from cisplatin-induced neuropathy (67,68). However, at present there appears to be no drug available to reliably prevent or treat chemotherapy-induced neuropathy (67,69). Therapeutic interventions for neurotoxicity remain controversial with vitamins B₆ and E possibly reducing the efficacy of alkylator chemotherapy. Nonpharmacologic approaches to treatment of chemotherapy-induced neuropathy are based on patient education about potential neuropathic side effects, and the impact of these side effects on performance of daily activities and related safety issues (e.g., tripping in the dark, driving).

It is worth noting that a new, reliable, and valid patient-reported measure is now available to document symptoms of neurotoxicity. The FACT/GOG-NTX measure consists of 11 items assessing sensory, motor, and hearing symptoms as well as possible functional impact, and was administered to 263 advanced endometrial cancer patients prior to each of seven cycles of chemotherapy. Results of this study indicated that the patient-reported sensory symptom scores (sum of four item scores) increased significantly over the treatment duration ($p < 0.001$) in the paclitaxel/doxorubicin/cisplatin (TAP) arm compared to the doxorubicin/cisplatin (AP) arm. It was also noted that as few as four sensory symptoms in the FACT/GOG-NTX subscale can be used to reliably and sensitively assess chemotherapy-induced neurologic symptoms in clinical oncology without compromising the psychometric properties of the overall scale (70).

Lymphedema is a chronic, progressive condition in which protein-rich fluid accumulates in the superficial tissues of the body, ranging from a mild and reversible condition (stage 1) to chronic edema (stage 2), or a persistent condition with moderate to severe edema (stage 3) (71). The specific incidence of lower extremity lymphedema following treatment for gynecologic cancer as well as risk factors for development of lymphedema are not well documented in the literature, in contrast to research on upper extremity lymphedema (72). Several studies have estimated that lymphedema occurs in approximately one third of gynecologic patients treated for vulvar cancer (73,74). Recent findings from a retrospective study demonstrate that women treated with radical hysterectomy for cervical cancer were at an eightfold increased risk of developing lymphedema (75). Lymphedema in patients undergoing lymphadenectomy for endometrial cancer has been reported in the 5% to 10% range (76,77), although prospective data are sparse. Nodal sampling has also been documented as a factor in the development of symptomatic lymphedema (73,78), with an increased risk after removal of greater than ten or more regional nodes during surgical staging (79).

Studies examining the psychologic ramifications of lymphedema in other cancer cohorts (i.e., breast cancer) note that signs and symptoms may come as a shock if adequate information is not provided (80). Feelings of distress, anger, and helplessness emerge from limited and conflicting information (81,82). Many women are unaware of the risk factors, symptoms, and management of lymphedema (83). Furthermore, significant psychologic ramifications (i.e., anxiety, depression, and adjustment problems), as well as physical and sexual difficulties have been described in the literature (84). Untreated cluster symptoms (i.e., heaviness, swelling, and numbness) of lymphedema may contribute to poorer QOL (85,86). Additional issues of financial burdens (i.e., compression garments, medications, and bandages), limited clothing options, decreased activities due to restrictions from swollen legs, recurrent infection, and loss of work can also be problematic (87,88). Lymphedema may also be socially embarrassing or undermine confidence in appearance or body image (88). The chronicity of this condition also serves as a reminder of ones'

cancer history, possibly heightening fear of recurrence or advancing disease (89).

Manual decompression therapy (massage and bandaging, or compression stockings) appears to help, but is an ongoing commitment. Other therapies are unproven. Lymphedema requires long-term management, and the psych morbidity of lower extremity edema on a patient's quality of life can be significant. Future research should focus on prospective studies assessing the prevalence of lower extremity lymphedema following surgical staging and adjuvant therapy for gynecologic malignancy, which is a significant limitation in gynecologic oncology. This deficit prevents us from understanding not only the risk factors for lymphedema, but also the implications of this chronic condition on the emotional well-being and overall quality of life of cancer survivors.

Sexual dysfunction—all of the therapies associated with the treatment of gynecologic malignancies have been shown to interfere with multiple aspects of sexuality including body image, desire, frequency, satisfaction, vaginal dryness, dyspareunia, and a decrease in vaginal length. Intimacy can be disrupted and altered in the setting of a cancer diagnosis and treatment. The most common changes in sexual function for female cancer survivors include decreased libido or sexual interest and dyspareunia (90,91). Various surgical procedures can directly affect sexual functioning (92), depending on the anatomy involved. For women diagnosed with gynecologic cancer, surgery could involve the removal of the ovaries, uterus, cervix, vulva, and/or vagina. Surgical procedures may lead to damage to nerves as well as the possibility of scarring or adhesions in the pelvic area as part of the healing process. When ovaries are removed hormonal deprivation occurs, resulting in abrupt menopause for many women. Research on surgical treatment and sexual function demonstrates that hysterectomy for benign conditions does not appear to impair sexual function (93). Recent studies investigating sexual function after treatment for cervical cancer noted changes in lubrication, vaginal elasticity, pain, or arousal difficulties, much of which resolves by 1 year (94–96). However, vaginal dryness and decreased sexual satisfaction/interest have been shown to persist up to 2 years or more (95,96).

Abdominal and sexual sequelae have been reported in long-term survivors (97–99), since survivors may face the reality of surgical scarring and loss of body parts on a daily basis. Individuals receiving treatment for advanced disease or bowel obstruction may require the placement of temporary or permanent ostomy(ies) for urine or stool. Management of these appliances requires practice and support from medical specialists and often other patients (100). Radiation therapy can also have long-term adverse effects on sexual functioning. Issues of dyspareunia, vaginal stenosis, scarring, and fibrosis can emerge (101,102). Some authors note that chronic fibrotic changes to the pelvis may worsen vaginal atrophy over time, in some cases up to 5 or more years post radiation therapy (103).

Simple strategies have been shown to be helpful in rehabilitating sexual function with cancer survivors (104–106). The first step in restoring vaginal health should address using water-based vaginal lubricants, nonhormonal vaginal moisturizers, and pelvic floor exercises. For women with persistent vaginal dryness interfering with quality of life, a low-dose vaginal estrogen may be considered for a short time span, but many questions exist about hormone replacement in the setting of cancer. Low-dose vaginal estrogens may initially show a temporary increase in serum hormone levels, creating a complex and controversial issue for patients and medical professionals (107); however, these levels return to the normal postmenopausal range. This is not the case for systemic absorption of oral or transdermal administration of estrogen and testosterone (106,108). More safety data and long-term studies are needed in cancer populations.

For treatment of dyspareunia, vaginal dilators can be beneficial in treating vaginal stenosis and adhesions (104,109). Dilator therapy has been recommended as the only modality meeting reasonable standards for evidence-based medicine in the treatment of pelvic radiation-induced sexual dysfunction (110). The theory behind vaginal dilator therapy is that it mechanically stretches the vaginal tissues, allowing for the secondary remodeling of fibrotic tissue, thus improving elasticity. However, some authors question whether stimulation of the vaginal walls improves blood flow to the affected area (106). More research is warranted, but a combination of dilator therapy with pelvic floor exercises to get both potential benefits is not unreasonable. A recent study evaluated the reliability of an instrument (the Vaginal Sound) which was designed to measure vaginal length. The Vaginal Sound is a simple, inexpensive, reproducible instrument that has demonstrated acceptable reliability and appears to be able to detect hypothesized changes in vaginal length (33). This instrument can be used to document the degree of vaginal stenosis associated with radical hysterectomy and radiation therapy plus or minus chemotherapy in women treated for cervical carcinoma. The ability to measure vaginal length and correlate vaginal stenosis with sexual function will provide a rationale for much needed interventional studies to maintain vaginal length and sexual function.

Embarrassment and fear have been shown to decrease compliance with dilator therapy, but in most cases, education and support can enhance compliance (104). Unfortunately, for many hospitals and office settings, it is not feasible or practical to have a sexual health program or professional on staff. Therefore, it is important to identify a referral network of local professionals with experience in treating sexual difficulties, which may include mental health professionals as well as gynecologists with expertise in treating patients with changes in sexual function (i.e., menopause) related to medical illness. Educational resources are also available to help patients achieve greater comfort with these issues.

Reproductive concerns of female cancer survivors have been shown to negatively impact quality of life (39). Gynecologic cancer can present before childbearing has been started or completed, during pregnancy, or can even arise out of pregnancy (gestational trophoblastic disease). Reproductive concerns can vary by site of disease, and some women may have the option of conservative surgical management. For example, radical surgery was previously recommended for early-stage operable patients up to stage IIA. More recently, however, cone biopsy alone has become a therapeutic option for young patients with stage IA1 cervical cancer who wish to preserve fertility (111,112), and radical trachelectomy, initially received with skepticism because of the small but definite increase in risk of recurrence, is gradually gaining recognition and acceptance (113) (see Chapter 22).

However, many women will be medically unable to have fertility-preserving treatment, leaving the meaning and emotional ramifications of infertility to be dealt with as a cancer survivorship issue (114). Gynecologic cancer survivors have reported feelings of sadness and grief lasting more than a year posttreatment (115), with some feeling deprived of choices or misunderstood (116) in the setting of cancer-related infertility. Others have voiced feelings of stigma or being “less than a woman” due to loss of reproductive organs (109,117). A woman's reaction will be contingent on her personal desire for a biologic child, the degree of fertility impairment, and willingness to use and access to reproductive assistance or family building options. It is heartening to note that a recent study of women treated for malignant ovarian germ cell tumors found that reproductive and sexual functioning was encouraging, although emphasizing the importance of a stable relationship at the time of diagnosis (118).

A recent study investigating the emotional impact of fertility-preserving surgical treatment for early-stage cervical cancer

(radical trachelectomy) found that distress about future conception, pregnancy, childbirth, and cancer recurrence persisted postoperatively over time (119). Recent guidelines published by the American Society of Clinical Oncology highlight the lack of research on the reproductive concerns of cancer survivors as well as the need for more information (120). Despite the availability of reproductive technology, little is known about whether patients are utilizing reproductive assistance or have knowledge about resources, or the emotional impact of fertility/family building issues in survivorship.

Psychologic well-being—patients with gynecologic malignancies face an array of emotional challenges, many of which persist 5 to 10 years after diagnosis (99). Psychologic sequelae can include distress, depression, anxiety, fear, and social disruption. Distress extends along a continuum, ranging from common normal feelings of vulnerability, sadness, and fear, to problems that can become disabling, such as depression, anxiety, panic, social isolation, and spiritual crisis. Recently the National Comprehensive Cancer Network (NCCN) has advocated recording distress as the sixth vital sign using a simple thermometer (10 cm) VAS (121), given that 20% to 40% of patients have significant distress, and only 10% of them are identified and referred for psychosocial evaluation (122). Depression is the least recognized and least effectively treated psychologic problem in patients with cancer (123). In the context of life-threatening illness, diagnostic criteria for depression typically include a significant change in mood on most days for more than 2 weeks. Clinically significant levels of distress and depression, greater than what would be expected in the general population, have been documented in gynecologic cancer patients (97). Specifically, higher levels of distress have been identified in the newly diagnosed, in those undergoing intracavitary brachytherapy (124), in patients with advanced or recurrent disease (6,125), or younger patients (97,114,125), perhaps due to the loss and adjustment many experience about issues of sexuality, fertility, and premature menopause (98,115).

Psychologic shifts have also been observed in women following completion of cancer treatment. In a prospective study with ovarian cancer patients, depression levels were found to decrease 3 months after completion of chemotherapy; however, levels of anxiety were shown to increase (126), perhaps reflective of the uncertainty that many women face about possible recurrence and concerns of future prognosis. However, studies with long-term survivors (5 to 10 years) show that disease-free early-stage survivors have resilience and adjustment over time with an overall good quality of life (99). Despite the identification of many psychologic difficulties within the gynecologic cancer experience, the literature also reveals that many women are not using psychologic services (125), but specify a need for cancer-specific support (127). It has been noted that patients may not be aware of or have access to supportive resources, but would utilize them if offered (99).

Psychologic care considerations—outcomes are improved by an integrative approach, only possible through a proactive collaboration with surgical, radiation, medical, and nurse oncologists working together with psychosocial support. Psychosocial support should include services such as emotional, spiritual, nutritional, genetic, and financial counseling, and general cancer information and support, as needed. At the core of a compassionate response there has to be both acknowledging and responding to physical, psychologic, and spiritual issues. An empathic response occurs when the clinician explicitly makes the connection between the clinical situation and how the patient is feeling. A compassionate response requires action, mobilizing the whole medical team to challenge fear and isolation (128). The medical interaction should be therapeutic on every level. Building a relationship takes more than asking questions. Courteous introductions and a genuine effort to establish rapport pay huge dividends.

Consultations should have clear, explicit objectives. Avoid assumptions and be flexible, using focused but open-ended questions, frequently summarizing and screening for concerns. Find out how the illness affects the person. Information should be simple and clear and tailored to the patient's understanding, with the goal of reinforcing realistic hopefulness and supporting shared decision making.

The very process of exploring a patient's emotional symptoms can be therapeutic, but many patients may benefit from professional counseling, support groups, and/or medication. Meta-analyses indicate that preventive psychologic interventions in cancer patients may have a moderate clinical effect upon anxiety but less on depression, and that group therapy is perhaps at least as effective as individual psychotherapy (129). Treatment of anxiety can include antidepressant and anti-anxiety medication (e.g., buspirone, clonazepam), counseling, and behavioral therapies (130). A wide variety of antidepressant medications with different mechanisms of action and adverse effects are available. Selective serotonin reuptake inhibitors (e.g., fluoxetine, paroxetine, sertraline, and citalopram) are usually well tolerated and can improve depression within 2 to 4 weeks in 60% of patients. The tricyclics (amitriptyline and nortriptyline) have a slightly longer onset of action but can be useful for patients with significant sleep disturbances. "Atypical antidepressants" (bupropion, venlafaxine, and mirtazapine) have a relatively rapid onset of action and paucity of adverse effects. Stimulants (methylphenidate and pemoline) provide the most rapid onset (hours to days). With respect to novel counseling methodologies, a recent psychosocial telephone counseling intervention was shown to improve quality of life for cervical cancer survivors, compared to controls (131). This type of intervention has promise for people unlikely to access traditional services. However, counseling information and resources should be routinely provided to all patients.

CONCLUSION

Quality of life research activity in gynecologic cancer has increased substantially over the past decade. This has included key findings developed within and disseminated through national and international cooperative groups. These contributions have become more robust and influential as the study and science of QOL and other patient-reported outcomes have advanced. Consequently, future directions in gynecologic cancer quality of life research are likely to include a continued focus on measurement science and trial interpretation to aid in treatment decision making, as well as provision of interventions to enhance quality of life. For example, in endometrial cancer we may see areas of active investigation which include the role of obesity as a comorbid factor in the development of this cancer, as well as the role of obesity on potential response to treatment and survival. Cervical cancer investigations may emphasize identifying behavioral or social factors that influence uptake of the human papillomavirus (HPV) vaccine. With respect to this disease, additional QOL studies specific to outcomes and morbidity from multimodality therapy are anticipated. Areas of active investigation in ovarian cancer will continue to focus on evolving paradigms of care such as intraperitoneal therapy, treatment for an asymptomatic rising CA-125, and continual or intermittent therapy for recurrent disease versus therapy only for symptomatic progression. The quality of life implications in each of these treatment considerations are paramount and should be systematically studied within well-designed trials. Further investigation is also needed in palliative care strategies for women with gynecologic cancer. This may include careful examination of the role of chemotherapy in the elderly, as well as interventions to reduce significant issues associated with advanced or advancing

disease (e.g., bowel obstructions, neurotoxicities). In each case, evaluation of quality of life and other patient-reported outcomes will serve a significant role in advancing gynecologic cancer care and survivorship.

CHAPTER 35 ■ END OF LIFE CARE

JOANNA M. CAIN AND SUSAN TOLLE

The goal of end of life care is to provide, in the continuum of oncology care, maximal palliation of symptoms and maximal psychological support at the end of life. Ensuring that our patients get the best care as the goal of medicine shifts from curing disease to relief of suffering is one of the obligations of health professionals. To do so effectively requires engaging not only the physicians and nurses who have been part of the oncology treatment, but also the skilled assistance of palliative care and hospice professionals with the patient and their caregiving network of family and friends.

THE END OF LIFE TRANSITION

Discussions about the nature of disease, the status of treatment, and the expectation and side effects of treatment are an ongoing conversation in oncology care. With the lengthening of survival for even the most deadly gynecologic cancer, ovarian cancer, and the multiplicity of options for ongoing chemotherapy, the decision to limit chemotherapy or other interventions may come out of any of the multiple conversations over time aimed at balancing the potential side effects of new chemotherapies or other treatments against the expected benefit and impact on quality of life for the patient. In this setting of continuing conversation between the health care team and the patient with or without her significant support individuals, there is often a point at which the ongoing therapy aimed at disease control or cure has a harm to quality of life that is greater than any benefit—a point in which the transition to comfort-focused end of life care is more clear, although palliative care may well have been initiated for some symptoms prior to this point (Table 35.1).

The balance can be difficult, as Callahan points out: “The most fundamental problem with technological medicine is two-fold: that it can give us a longer life and a slower dying and that it can keep us alive when we might be better off dead” (1). Patient perspectives on what constitutes high-quality end of life care reinforces the importance of interactions most physicians would identify such as communication, accessibility, continuity, and emotional support, but surprisingly oncology patients compared to terminal patients with other diagnoses more often hold on to a desire to maintain hope (2). Keeping this door open while realistically portraying prognosis and options, and pursuing palliative care can be the hardest balance of all.

The timing and expectation of death for cancer patients continues to change. Thirty years ago survival from high-grade ovarian cancer longer than 2 years was very unlikely and now is routine. As a backdrop to this advance, the age of death in the developed world has steadily increased, as the major cause of death has changed over the past hundred years from sudden death from infection, trauma, and childbirth in the young to a slower decline from chronic illnesses usually in

advanced age. Cancers that previously caused a rapid death now follow a more chronic recurring course, which changes not only patient and family perceptions about the length of time until they need to deal with the issue of death, but offers a longer time to work through the phases of dying and the opportunity to bring to closure key goals for an individual. Even the gender and role of caregivers at the end of life are changing, and the role of men as caregivers for women with gynecologic cancers deserves special attention (3). The development of palliative care teams, usually in hospital settings, has added significant expertise to symptom management, discharge planning, and accomplishing improved end of life care (4). Given this prolonged course, the advance planning for end of life care has both more time for consideration and can evolve as the patient’s prognosis changes.

ADVANCE PLANNING FOR END OF LIFE CARE: REDUCING THE EMOTIONAL BURDEN ON SURROGATE DECISION MAKERS

Along with improved symptom management at end of life have come improved vehicles for ensuring that patients have their wishes represented in their care, in terms of legal documents, but also ensuring that surrogate decision makers adequately represent patient wishes.

Serving as a surrogate for a woman with advanced cancer who can no longer make her own treatment decisions places a profound burden on the surrogate. Nothing can completely lift this burden, but advance planning can make the burden lighter. Health care professionals often underestimate the burden of serving as a decision maker. Formal measures of stress document that months after serving as a surrogate in a decision to withdraw life-sustaining treatment the surrogate’s emotional stress levels remain remarkably high. One study found that the stress of serving as a health care decision maker was twice as high as the stress levels on households who had lost their homes to fire in the Berkeley-Oakland fire storm (5). Decision makers commonly report waking up at two in the morning and wondering if they made the right decision. They make statements such as, “It was the hardest thing I have ever done in my life.”

Some surrogates experience far more distress than others. When patients have not previously documented their wishes about life-sustaining treatment, the stress levels of their surrogate decision makers tend to be even higher. When surrogates are guided by the patient’s written advance directive, their stress levels are about 30% lower, when measured 2 months after a decision to stop life support (5).

TABLE 35.1**KEY ISSUES TO ADDRESS WHEN THE THERAPEUTIC FOCUS SHIFTS FROM CURE TO CARE**

Issue	Examples
Communication about terminal nature of cancer should occur in the course of ONGOING communication.	“We are not achieving the goals we set together with this chemotherapy.” “The cancer is continuing to grow despite our efforts with this new agent.”
Assess what the patient WANTS to know.	“I would not continue any further chemotherapy at this point, but feel we should focus on relieving your symptoms of . . . What do you think?” “Do you have questions about what we just discussed?”
Identify that, in fact, the patient’s condition is terminal, and particularly if asked directly.	“Am I going to die of this?” “Yes, but our attention now needs to be focused on making whatever time you have as pain-free and active as it possibly can be.”
Identify the goals that the patient wants to achieve.	“Are there any special events or things that are on your agenda that we need to know about as we plan your treatment?”
Identify what resources the patient is planning to access (e.g., support systems as well as insurance coverage/hospice coverage).	“Have you talked to your . . . spouse/partner/children/friends about your plans to be at home, and do they have ideas about how that will work?”
Make sure that the priority items for the patient are dealt with immediately.	“What is the number one issue for you right now?”

Surrogates who “stand by” and affirm the patient’s prior written instructions worry less about whether they made the right decision. Those who had never talked with the patient ahead of time feel the anguish of “deciding for” a woman they love. An important message to women with cancer who are reluctant to engage in advance care planning is, “Lift a burden from those you love: complete an advance directive.”

THE ROLE OF TRADITIONAL ADVANCE DIRECTIVES

Advance directives provide a woman with a means to legally document her preferences about medical treatments in the event she is no longer able to make her own decisions. The legal details and breadth of clinical context vary substantially by state within the United States, and by country of the world. In many jurisdictions, these documents allow the formal appointment of a surrogate who becomes the woman’s legally authorized medical decision maker in the event of future incapacity. Being asked to document one’s preferences for treatment in conditions like “imminent death regardless of treatment” and “persistent vegetative state” can be anxiety-provoking for anyone. The context of a new diagnosis of cancer often makes completing an advance directive seem very real, and perhaps overwhelming. It is difficult to combine conversations about advance care planning with initial discussions of curative treatment. It is tempting to put off these discussions until they have no further treatment options to offer or the patient declines further curative treatment.

Waiting until the patient is near death to have these important conversations risks that the patient may become too ill to be able to make her wishes known. If the patient has not given any instruction, the burden of decision making often weighs more heavily on surrogates. Without prior planning, the patient will not have appointed the surrogate of her choice. Sometimes, family and friends disagree on treatment decisions, which adds further to family distress. In addition, patients and their loved ones often benefit from having advance planning be more of a process than an event. Having discussions with the

patient about who should and should not be given medical information can naturally lead into who would be the most appropriate decision maker should the patient temporarily be unable to make decisions for herself. When the patient reveals strongly held value differences within her social network, or when she indicates that her most trusted surrogate is not her legal next of kin, the patient should be strongly encouraged to complete a written advance directive.

Advance directives are remarkably effective in allowing the patient to designate her choice of a surrogate decision maker. These legal instruments are also effective in silencing those whose wishes and values diverge from the patient’s. Advance directives are also helpful to focus end of life treatment decisions on what the patient would have wanted. Advance directives are effective in designating a surrogate but are less effective in turning values into action, which require medical orders. Increasingly, we have learned that advance directives alone are not enough to ensure that patients’ wishes regarding life-sustaining treatment will be followed (6).

MEETING THE NEED FOR MEDICAL ORDERS: THE POLST PARADIGM PROGRAM

In technologically developed countries, decisions about whether to use cardiopulmonary resuscitation, ventilators, antibiotics, and feeding tubes are an integral part of the care of women with advanced gynecologic cancers. Most persons with advanced stages of cancer and other chronic diseases ultimately make a decision to forego some forms of life-sustaining treatment. Interviews with over 1,000 next of kin reveal that in the months prior to death, a majority of patients or their surrogates make a decision to withhold or withdraw a medical treatment (7).

When a thoughtful decision has been made to forego attempts at resuscitation, it is most distressing to family members to have the patient receive unwanted cardiopulmonary resuscitation (CPR). Surrogates sometimes anguish over having “let Mom down.” Family members express surprise to learn

that emergency medical personnel cannot follow the patient's traditional advance directive. Emergency medical personnel need written medical orders indicating not to provide specific treatments like CPR. Without such medical orders, emergency medical services (EMS) must attempt all possible life-sustaining treatments.

Because traditional advance directives have vague language that requires further interpretation, they have proven inadequate in ensuring that a woman's wishes to limit life-sustaining treatment will be respected. As patients move from one place to another, a uniform set of medical orders is needed to be sure the patient's wishes will be followed no matter what their setting of care.

One of the best-studied systems of medical orders to document advance care planning is the Physician Orders for Life-Sustaining Treatment paradigm. The POLST program is designed primarily for patients with advanced disease who the physician would not be surprised if they died in the coming year. The POLST document is a brightly colored medical order form that converts patient treatment preferences into written medical orders based on a conversation among health care professionals, the patient, and/or surrogates about treatment goals. The form transfers with the patient across care settings, to ensure that her wishes are honored no matter whether she is cared for at home, in an ambulance, in a nursing home, or in an acute care hospital. A 1-year prospective study of nursing home residents with advanced chronic illness followed residents whose POLST forms included a Do Not Resuscitate order and an order for comfort measures only. None of these patients received unwanted intensive care, ventilator support, or cardiopulmonary resuscitation (8).

In summary, women beginning cancer treatment often benefit from the first stage of advance care planning, which is formally appointing a surrogate decision maker who shares their wishes and values. Women with advanced cancer who wish to forego one or more forms of life-sustaining treatment are more likely to have their wishes respected if the POLST or other standardized medical orders are written to provide guidance to all other health care personnel who currently are, or in the future may, provide care in life's last chapter (www.polst.org).

ROLE OF FAMILY IN DECISION MAKING

Given the sequential and repetitive conversations described above, the inclusion of family and other support persons is almost universal and clearly preferable. For many patients, they are the ones with whom they have shared their lives and their dearest and deepest emotions. They are also the ones by whom the patient wants to be surrounded during the last phase of life. However, patients have the right to exclude or include whomever they wish in conversations, and occasionally medical events are so acute that they trigger discussions with family members, without clarity, about what the patient herself would have wished or about which family member truly speaks for the patient. Expert communication with the family then becomes the most critical means of ensuring that the patient's best interests are served. Unfortunately, research suggests that communication is not as effective as it needs to be in these circumstances. Fifty-four percent of families did not understand basic information (diagnosis, prognosis, treatments) after physician-family meetings in an intensive care setting (9), a finding that could lead to potential conflict with families that could impede an appropriate transition to palliative care in any setting. Well-structured discussions that focus on the disease process, the goals of palliative therapy, and understanding the concerns of family members may help

the family formulate decisions that support the dignity and choices that the patient herself would have chosen.

To prevent problems, it is wise to respect several rules:

- Always ask the patient if she has preferences in her contacts with friends and relatives. Often, she wants special persons to be more involved than others.
- Ask the patient for one or two contact persons to organize the communication with family and friends. Communicate essential information always in the presence of them or of other relatives or friends chosen by the patient. In this way, the family and friends are well informed and they share the same information with the patient. They can also help the patient with the evaluation of the information afterward.
- Never talk about the patient "behind her back." If the physician does, and the patient finds out, the relationship of trust may be upset and will take quite some time and work to be restored. This also prevents the patient from thinking that the family knows more than she does, which can also put pressure on family relationships.
- In countries where health care is a financial burden to the family, it is the responsibility of the physician to ensure that decision making concerning continuation of treatment or starting a treatment is based on the ethical principles of autonomy, beneficence, and nonmaleficence. It is not acceptable that this decision making is driven by financial pressures alone.

At the end of life, we can expect emotional reactions by patients and their significant others, including family, to the inevitable lifestyle changes and impending death. It is the task of the physician to try to understand the thoughts and behavior of the patient regarding death and dying as well as her worries and unfinished emotional and personal business. Information on the patient's values and beliefs should be sought—even information about very personal matters like relationships and sexuality might be needed for a proper assessment of her situation. Also, it is important to respect the balance, and the patient has to know that she has the choice to what extent she wants to participate in this assessment and what information she is comfortable to share both with the physician or care team and with her family and friends. In normal life, family and friends often meet the spiritual and emotional needs of a patient, and the role of the health team is to support these relationships.

UNIQUE CIRCUMSTANCES FOR DECISION MAKING: PREGNANT PATIENTS

A rare but particularly poignant context of end of life decision making is that of the pregnant woman with terminal, metastatic cancer where survival even to the end of a normal pregnancy is unlikely. The choices for palliative therapy (e.g., pelvic radiation for control of local bleeding and pressure) may directly impact the likelihood of fetal survival. The possibility of delivery of a newborn—particularly prematurely with all the known consequences—without surviving to mother the child make the choices even more complex for the woman and for her family. The primary objective of care for the mother is alleviation of symptoms, and choices to decrease the level of palliative care in order to facilitate fetal development are considered only if strongly desired and pursued by the patient herself. Maternal autonomy in making such decisions has been supported by both ethical and legal reviews, and these confirm that the patient's wishes must guide decisions regarding fetal well-being, including accepting or not accepting caesarian section in the terminal phase of disease (10). There is no role

for withholding appropriate and maximal pain and symptom management simply because the woman has a concurrent pregnancy (11). The health care team carries a special burden in this circumstance to ensure that the patient has all relevant and unbiased information regarding harms and benefits of all potential options for her and for her pregnancy, to maximize her ability to make choices.

In the absence of the ability of the patient to speak for herself, the surrogate decision makers must weigh not only her wishes regarding a premature timing of delivery of the child and invasion with a surgical procedure such as a caesarian section, but also the likelihood of viability of the fetus and the supporting family's ability and choices about caring for a significantly premature child. End of life directives for pregnant patients that specifically address these issues may be helpful in discussion and documentation of patient wishes (12). Some states and countries have special restrictions regarding decision making about limiting life-sustaining treatment in terminally ill pregnant women. In fact, 27 states have statutes that prohibit an out of hospital Do Not Resuscitate order being written on a pregnant woman or otherwise have a "pregnancy limitation." The role of the woman in fixing the parameters for balancing fetal well-being against her own needs for alleviation of pain and suffering is central, both if she can speak for herself or in representing those wishes by surrogate decision makers, and it is her health care team's obligation to make sure that these are well defined, described, and that the patient's wishes about her health care (autonomy) are respected in the terminal phase of her disease.

MAXIMIZING PALLIATION: MANAGING SYMPTOMS AT THE END OF LIFE

Pain Control

The mainstay of pain management at any time, and even more critically at the end of life, is a careful assessment of the type of pain (nociceptive [somatic or visceral], or neuropathic), the level of pain, the location and referral of pain, and the actions that increase or decrease the pain. This assessment will need multiple repetitions as the kind of pain and level are likely to shift with disease progression. The management strategy is to focus on not only the type and level of pain but also the level of consciousness and the level of activity that a woman would like to achieve, and to vary the strategies accordingly (13).

The World Health Organization's three-tier pain ladder starts with low to increasing levels of pain and increasing strategies from acetaminophen and nonsteroidal anti-inflammatory drugs to opioid analgesics for more severe pain. Using usually a 1 to 10 (10 being the worst) pain scale with patients fixes their position on the tier and suggests management strategy, although combinations from other levels or even within a level may be required for maximal comfort. Given that many gynecologic oncology patients are in the severe category (7 to 10) at the end of life, this might even include combining two opioids, particularly during pain syndrome escalation, to control the pain (14). In the course of adequate pain or symptom management, the anticipated side effects may shorten the time to death (principle of double effect), which is a well-recognized consequence of ensuring maximal palliative care. The ethical obligation is to alleviate the pain and suffering first and foremost, and the side effects that cannot be avoided (which rarely impact time to death simply because most patients already have substantial tolerance for narcotic pain medications) are accepted in this setting.

Pharmacologic measures to address severe nociceptive pain usually require narcotic medications. The options for

administration are broad and can be tailored to the patient's circumstances. As a principle that supports patient and family control, a means such as dermal, oral (pill, sublingual, and liquid), buccal, or rectal can make administration easier. With long-term sustained-release formulations, the goal is to establish adequate base pain coverage with every 8- to 12-hour dosing and adequate breakthrough pain coverage with an immediate-release form of the agents. Having the patient or caregiver track the amount and timing of breakthrough dosing can help adjust both the base and rescue dosing and timing. Sustained-release formulations are available for morphine, oxycodone, and hydromorphone (15).

Methadone is another option that has been utilized and can be particularly helpful when morphine is not adequate or is problematic for individual patients. It has a variable conversion ratio and pharmacokinetics in individuals and is much more difficult to titrate and manage with other medications. Methadone may be particularly helpful in patients where neuropathic pain resistant to opioids is a significant part of the pain complex. The final option to avoid intravenous pain management is the transdermal fentanyl patch. This is particularly helpful, when stabilized dosing is reached, for individuals who require continuous baseline coverage but are unreliable about taking doses of pain medications. The downside is the long time to peak concentrations, which renders initial evaluation and titration of dosages difficult and requires significant use of short-term release opioids to cover (16).

The use of intravenous forms of opioids with patient-controlled analgesia pumps can be accomplished in the home setting if needed. The use of a basal intravenous infusion with patient-controlled boluses is the preferred method. Subcutaneous infusion of opioids can also be used, with near equivalent efficacy, and it can be more easily managed in some home settings (17). For all methods, titration to comfort is the goal, with management of secondary symptoms such as nausea or sleepiness as needed by the patient and within the context of her goals. The last few hours of life can be marked by both increased or decreased pain, and a strategy to address this needs to be in place as part of the pain control program.

The multiplicity of tumor-related and therapy-related pain syndromes that result in neuropathies from invasion, radiation, or other therapy often require additional therapies (18). Anticonvulsants are helpful adjuncts. The most commonly used would be gabapentin, which is routinely used for postherpetic, chemotherapy-related, and diabetic neuropathies. Clonazepam and lamotrigine also may be effective. Additionally, tricyclic antidepressants (e.g., amitriptyline, desipramine, nortriptyline) may be helpful for neuropathic pain as they also treat underlying depression, have their own direct analgesic effect, and potentiate opioid analgesia (19). Alpha 2 adrenergic agonists, usually clonidine, have also been effective adjuvant analgesics for neuropathic pain as they work through a different receptor from opioids and decrease sympathetic outflow related to neuropathic pain. Corticosteroids such as dexamethasone can provide additional relief, particularly for inflammation irritating nerve endings. For the extensive pelvic tumor invading the nerves in the pelvic floor, the use of sacral or regional nerve blocks, epidural pumps, or ablation of nerve roots may have an important role (20).

Nausea, Vomiting, and Bowel Obstruction

The etiology of nausea and vomiting at the end of life can be related to medications, but more often for gynecologic cancer patients it is related to malignant bowel obstruction. Ovarian and endometrial cancers have a higher likelihood of developing obstruction. It is critical to distinguish the obstructed bowel from constipation/obstipation for obvious reasons in terms of management. Since the majority of patients are already at risk for constipation from medications (opioids as well as serotonin antagonist antiemetics) as well as low motility of the

bowel, initiation of a bowel program or extension of one is part of palliative care. Initial efforts with fiber in the diet and fluid intake can assist in management. Both peristalsis stimulants and fecal softeners may be required for an adequate bowel program with rectal laxatives added as needed. Usually the use of propulsive agents such as the anthranoid laxatives (senna) or polyphenolic compounds rather than stool softeners will better manage the constipation related to opiate and other drug use, and may require higher doses of these to resolve constipation (21).

If obstruction is diagnosed, the consideration for surgery should be limited to those in whom their overall condition is otherwise good. Various studies have shown that advanced age, poor general health or nutritional status, diffuse peritoneal carcinomatosis, ascites, palpable masses, prior radiation, and multiple obstructed sites carry a higher mortality and morbidity (22). Careful selection of patients has been shown to not only achieve symptom relief but extend survival (23,24). Evaluation to ascertain the likelihood of benefit for individual patients should include imaging procedures (Gastrografin enemas, carefully chosen use of computed tomographic, and limited upper gastrointestinal evaluations) that target the identification of multiple sites of obstruction. Failure to identify the presence of multiple sites of obstruction can lead to failure of the procedure and add to the pain and discomfort of the patient during the dying phase.

Symptom management is usually the path taken in the treatment of bowel obstruction. Nasogastric tubes provide quick relief, but are uncomfortable, and some reports suggest that they are ineffective in longer-term management of symptoms. Gastrostomy tubes are generally more comfortable, but require surgical or radiology intervention that may not be desired by patients. For individuals with partial and complete bowel obstruction and carcinomatous ileus, gastrostomy tubes can provide significant symptom management with just dependent drainage or suction. Distal rectal obstruction can sometimes be relieved through the use of stent placement (25,26) if that is available, and is worth consideration.

Additionally, there are pharmacologic options to consider, with haloperidol being an additional choice for antiemetics in the setting of bowel obstruction (27). Additionally, hysocine hydrobromide and hysocine butyl bromide are helpful with patients experiencing colicky pain and nausea. Corticosteroids have been used to reduce inflammation, and potentially reduce the obstruction in some patients, and are worth a trial as part of conservative management. Dexamethasone in a dose of 4 to 8 mg per day for 3 to 5 days is generally used for this (28). Finally, somatostatin analogues such as octreotide can limit the secretions and motility and diminish the symptoms of bowel obstruction overall (29). Octreotide has the option of a long-acting formulation, which only requires monthly injections and has been shown to assist in the setting of advanced ovarian cancer (30).

Nutritional Management at End of Life

The value of end of life nutritional maintenance must be firmly set in the context of what the goal of the intervention is. Giving artificial nutrition in the dying phase of life has generally not been shown to prolong survival, adds risk, and may not enhance comfort (31). Families and patients can have culturally and religious-based concerns about not providing “nutrition” in the dying phase, often framed as “starving” the patient, which need to be addressed. It is very important to explain to patients and families that hunger and thirst are symptoms that are experienced differently in healthy people from those who are seriously ill. Those who are near death are often comfortable even though they are no longer eating.

At times, earlier in the trajectory of the patient’s illness, management of nutrition as a trial to achieve another palliative

or quality of life goal, for example to maximize stamina for a special event with a limited time line for treatment, may be an appropriate strategy. In this context, nutritional support might be started as a trial to evaluate whether this can achieve greater palliation of symptoms or to reach a clearly defined goal of the patient, such as attending a specific event, and defined time lines need to be discussed with patients ahead of time to assess the efficacy of this strategy in meeting these goals. In a sense, it allows patients to try to meet the energy needs for the energy expenditure they have set as a goal that they are otherwise unable to accomplish.

The options for artificial nutrition are enteral if feasible and parenteral if not. Most patients at the end of life have tried increased oral feeding, but owing to low transit times with associated nausea and lack of appetite, have ceased trying to eat. If a time-limited option to increase appetite is desired, then corticosteroids such as dexamethasone can be considered, although their efficacy is limited. Additional appetite stimulants include progesterones such as Megace. Both can have a limited impact on oral intake. Diet supplements then form the basis for increasing nutritional input, including simple formulations such as instant breakfast or intact protein formulations with low lactose.

Other enteral feeding approaches generally focus on feeding tubes either placed under fluoroscopy via a nasogastric approach or surgically placed in the jejunum or the stomach. These use protein hydrolysates with timed feedings or continuous infusions (32,33). The discomfort of nasogastric feeding tubes sometimes prevents this means of enteral feeding from being effective, but does allow for easy removal. J tubes require surgical intervention in abdomens where landmarks are possibly obscured by tumor, and placement must be evaluated in light of the potential issues with the type of tumor and the likelihood of surgical difficulty. In patients with low motility and partial obstruction, the use of enteral feeding formulations may allow the patient to meet her goals without requiring the cumbersome and more difficult to adjust total parenteral nutrition (TPN).

TPN remains the final option for attempting to improve nutritional status transiently in end of life care. Undertaking TPN ties a patient to an intravenous line as well as incurring increased expense and potential for morbidity that could add to the burden of symptoms such as dyspnea at the end of life. It is often more than a support person can manage at home, and may obligate the individual to undesired nursing home or hospital care settings. Furthermore, intravenous access with ports in the face of terminal disease and often-compromised immune surveillance can result in infections that diminish access not only for TPN, but also access for needed pain control or other intravenous medications (34). This, therefore, must be understood in a framework that defines clear stopping parameters (failure to meet goals of symptom relief or improved stamina for an event) and a clear overall time line. In general, TPN is not of benefit in the end of life for patients with cachexia from metastatic cancer (31).

Ascites Management

For women with ovarian cancer, ascites (and associated pleural effusions) create continual pressure, pain, and diminished pulmonary capacity that significantly impact activities of daily life and their quality of life in the dying process. Management relies on elements of constriction of influx and increasing efflux. The pathophysiology of malignant ascites is not only obstructed efflux through lymphatics in the diaphragm (35), but also increased production of fluid. The fact that the protein content of the fluid is 85% of plasma levels versus 25% of plasma levels for transudates suggests that the vessel walls are compromised. An emerging culprit is vascular endothelial growth factor (VEGF) (36). This suggests

that VEGF receptor inhibitors might have a role in palliative management of this problem.

The mainstay of ascites management, however, remains paracentesis, and this has been improved through ultrasound guidance. The use of pleuracentesis kits and vacuum bottles allows this to be done in outpatient settings or even at the bedside at home with ease, and many patients are managed simply with once or twice weekly removal of 1 to 4 L in an office setting, often without fluid replacement (37). Use of the closed drainage system developed for pleural drainage (Pleur-X; Denver Biomedical, Golden, Colorado, USA) has been successful with malignant ascites as well and offers a method that can be managed by the patient and family (38). Large volumes of fluid (10 L) can be removed (39), but this must be balanced with colloid infusions and risks further diminishing of the intravascular albumin and protein concentrations (40), leading to worsening anasarca and associated symptoms.

Another common strategy in the management of ascites is the use of diuretics to diminish vascular volume and loss through the vascular tree. Spironolactone is the mainstay of managing ascites associated with cirrhosis and is worth considering for malignant ascites (41). Other diuretics can be considered as well, particularly furosemide, but their primary benefit may be the peripheral edema associated with hypoproteinemia. There have been no clear head-to-head studies of diuretics versus paracentesis and quality of life outcomes in these patients to guide therapy.

In the presence of a slow-growing malignancy, but a palliative stage of disease that requires frequent paracentesis, peritoneovenous shunts as well as the tunneled catheter described above can be considered. Both Denver and Le Vein shunts have been used, with a complication rate of 25% being quoted in a review of multiple series by Helzberg and Greenberger (42). More radical means such as laparoscopically guided intraperitoneal hyperthermic chemotherapy have a role in earlier palliative care, but would rarely be applicable in the end of life setting (43).

Pulmonary Management

Among the most frightening symptoms for women and their families at the end of life are the symptoms of dyspnea and chest pain. Three etiologies stand out in metastatic gynecologic cancers: malignant pleural effusions, parenchymal metastases, and nodal/mediastinal metastases with airway compromise. Although quite different in etiology, some basic principles form the basis of symptom management. These include the use of oxygen, relief of bronchospasm, control of secretions, and measures to promote relaxation, which are helpful with all these etiologies.

Probably the most difficult issue to treat is pleural effusions, particularly as they compound the pulmonary constriction caused by ascites in ovarian cancer patients. Thoracentesis (with ultrasound guidance) gives immediate relief, but reaccumulations are common. Repeated thoracentesis may be a strategy appropriate to short-term management or if only needed every few weeks, with the 4% or greater risk of pneumothorax with each procedure as well as the concurrent discomfort (44). Alternatives are restricted to those who have recurrent symptomatic pleural fluid, where this is the primary source of symptomatology and survival is expected to be more than a few weeks. One option is a tunneled closed system pleural catheter which can provide considerable relief without requiring more major surgery and is successful in over 80% of patients (45). Another option for these patients is chemical pleuradesis, now virtually always done with talc by direct application with video-assisted thoracoscopic surgery (VATS) or through a chest tube (46,47). Success is more limited in the setting of repeated prior thoracentesis with scarring that can make the procedure less effective. Any suggestion of a trapped lung or an endobronchial

obstruction further diminishes success to the point that pleuradesis would not be a useful choice (48). Most individuals will have a fever and moderate to severe pain around the time of instillation, and complications include arrhythmias, pneumonitis, empyema, and respiratory failure. Such a procedure requires the patient to be in the hospital, occasionally in the intensive care unit for observation overnight if a VATS plus talc procedure is done, and creates costs and side effects that must be weighed carefully against the benefits. Pleuradesis should be restricted to individuals in whom this intervention has a significant chance of alleviating the primary symptoms to avoid exposing women unnecessarily to pain and side effects that further burden their dying phase of life.

Management of pulmonary metastases in the end of life setting, even if solitary, is focused on symptom relief. Many parenchymal lesions are asymptomatic, but pleural irritation can be problematic with coughing as well as hypoxemia. Lymphangitic carcinomatosis is less common in gynecologic malignancies than in others, such as breast or lung cancer, but dyspnea and hypoxemia with the thickened septa and interstitial edema are the primary symptoms to be managed. The dyspnea associated with lymphangitic spread is often symptomatically greater than the actual pulmonary disease present (49). Strategies to treat these symptoms are attention to environment, and diminishing walking or activity requires doing simple activities of daily living by changing the environment. The use of a fan for air circulation, nasal oxygen (with portable units), and trials of pursed lip breathing may all help. Certainly, consideration should be given to diuretic therapy if there is any component of fluid overload, and opiates, particularly morphine, are helpful. Morphine, often in use for pain control, also has a role in decreasing air hunger and dyspnea and should be tried in this setting if not already in use. Anxiolytics, although helpful for the anxiety component and commonly used as an adjuvant, can occasionally worsen symptoms by causing respiratory depression and more air hunger and should be used judiciously in addressing pulmonary symptoms.

Airway obstruction and cough have similar symptoms, and some of the therapy is similar. Cough may be due to multiple issues including conditions unrelated to malignancy such as asthma or sinusitis and from gastroesophageal reflux, which is more common with ascites. Therapies tailored specifically to these issues such as the use of inhaled or intranasal steroids, antihistamines, and proton pump inhibitors for reflux are appropriate. Cough due to airway obstruction responds to narcotic suppression with morphine or codeine. Occasionally, steroid inhalers add additional relief from bronchial irritation induced by metastatic disease. Even humidifiers may be helpful for some patients, particularly for coughs from irritated mucosal linings from prior mediastinal chest radiation. In some cases, radiation therapy targeted to specific areas of obstructing disease in the mediastinum, with an obviously longer survival estimate, may be of value in managing symptoms. In sum, the therapies for pulmonary symptoms rely on supplemental oxygen, local suppression of inflammation, suppression of cough and air hunger through opiates, and removal of fluid compression as needed.

Central Nervous System Involvement: Management of Seizures, Brain Metastases, and Mental Status Changes

Mental status changes are usually present at the end of life and management of this symptom is often the key toward patients achieving their personal goals at the end of life, many of which center around being awake and conversant to bring closure with family and friends. Delirium is particularly distressing to family members who also are seeking closure with the dying patient. For both, the decline in function from a prior baseline

heralds more losses to come and creates even greater anxiety. Etiologies can be metabolic abnormalities (sepsis, renal failure), innumerable drugs, and structural brain lesions with obvious differences in approach to treatment. There are clear predisposing factors, including age, multisensory impairment, medical illness, depression, dehydration, and abnormal serum electrolyte levels, pertinent to the end stage of malignancies (50–52).

Understanding the nature of the delirium is important in addressing what may be more than one contributing factor. Assessing alertness, distractibility, the patient's ability to concentrate and talk easily, and simple cognitive disturbances of memory, reasoning, or perception all contribute to the delirium, along with specific neurologic deficits or neuromuscular activity that can point to central nervous system metastases. Laboratory and physical evaluation with infection, hypercalcemia, renal failure, hypoglycemia, hypomagnesemia, and hypoxemia being key conditions to look for (53–55). Tuma and DeAngelis (56) noted that with appropriate workup, a significant number of patients can improve their symptoms (68%) even when terminal.

Addressing electrolytic abnormalities and treating infection have value when the goal of a clearer sensorium at the end of life can be achieved. If opioid-induced delirium is the diagnosis, then rotation of types of opioids used can be helpful in restoring function (57). If there are hallucinations and agitation, particularly in elderly dying patients, consideration of haloperidol or droperidol if more sedation is desired is appropriate (58,59). Given intravenously, haloperidol can be effective within 30 minutes and generally lasts for at least 4 hours. Given by mouth, the half-life of haloperidol is considerably longer, and could be used in mild delirium states. It is important to remember that these drugs have the potential of lowering the seizure threshold, as the more common electrolytic abnormalities associated with prior chemotherapy such as magnesium deficiency also may be present and compound the risk. Finally, some patients may benefit from combining drugs and including a benzodiazepine to decrease associated agitation. Some studies have noted that delirium in patients with advanced cancer more commonly requires more than one medication (60). The most commonly used are lorazepam (up to 2 mg) or midazolam, which is preferred if a subcutaneous route is to be used (61).

Another source of delirium or abnormalities in central nervous system function is brain metastasis. Initial therapy after diagnosis is the immediate use of corticosteroids to decrease local edema and also headache associated with this. This may, in fact, be all that is needed if the patient has a very short time to live as median survival with brain metastasis with steroids alone is about 2 months. However, if a patient is otherwise functional and treatment could improve her overall quality of life, then targeted radiation therapy should be considered. For this use, generally 300 Gy total dose given in 30-Gy fractions is administered (62). For care at the end of life, more aggressive resection and radiation is generally not appropriate.

Control of seizures depends on the etiology of the seizures. The more common causes in gynecologic oncology patients would be electrolyte induced, often hypomagnesemia or hyponatremia. Primary brain etiologies range from brain metastases to brain hemorrhage and stroke. Virtually all will be able to be controlled initially with lorazepam either intravenously or by mouth. Electrolyte repletion should be undertaken (63). Seizures associated with brain metastasis may be controlled with simply the decrease in inflammation with corticosteroids.

Local Comfort Measures

Many of the measures for comfort at the end of life are related to simple things that can escape notice but create comfort for the dying woman (64). The environment itself gives comfort if

familiar things are around, including sounds, smells, and pictures that hold meaning for the woman. Assuring that the issues of access and fall prevention are addressed by a care team is important to the success of home care. Skin protection through rotation if the patient is bed bound and early identification and treatment of skin breakdown prevents unnecessary sources of pain and infection. Many patients derive great comfort from gentle massage and virtually all benefit from human touch and presence. Developing a plan for passive (or active) movement during the day alleviates pain and discomfort from decreased mobility. Eye care with artificial tears or even hydrogel eye patches may be needed. Perineal care and the use of urinary catheters to eliminate skin breakdown in the perineum are commonly used when the patient is no longer mobile. Families and patients sometimes need “permission” from their health care team to make the environment home rather than a hospital at home. Yet it is the breeze from the window, the smells of home, the sights of loved ones rocking in a chair beside them that bring the most comfort—and the physician must actively support choices that make this possible at the end of life.

Management of Fistulas in the Terminal Care Setting

The fistulas encountered at the end of life from both the urinary system and the gastrointestinal (GI) system are often the most difficult for family and caregivers to deal with. The principles of management are simple but difficult to achieve. The options are diversion, containment, and closure regardless of the site of the fistula.

Enterocutaneous fistulae can occur from every part of the bowel, but those from the small bowel have high output and are irritating to the skin. Diversion is rarely an option in the setting of terminal cancer, primarily because the intra-abdominal spread of disease is frequently the etiology of the fistula itself in association with prior therapies such as radiation. Surgical diversion, if the patient is medically stable and surgery could be limited, has benefits solely to provide better control and better fit of pouches over the ostomy site than over a fistula site. As noted by Marsden et al., this does not remove the problem as there may still be a discharge from the site of tumor-related necrotic material that must be managed (65). If this is not possible, the only recourse—similar to bowel obstruction—is to attempt to diminish flow through the GI tract with octreotide and then to minimize and manage skin irritation actively. Large bowel fistula, most commonly to the vagina, can be more easily diverted and this is the first choice if the patient is medically stable. Even a simple loop colostomy can provide relief from the volume of vaginal discharge. However, some discharge usually remains. The use of metronidazole for tumor necrosis and discharge in the vaginal area relieves some of the anaerobic odors, and sitz baths and douches as needed to control odor are also helpful.

Vesicovaginal and ureterovaginal fistulae are primarily handled by diversion, if appropriate. The primary problem with diversion is the discomfort and management of new percutaneous nephrostomies, and the additional factor that for some patients there may be a component of renal failure that there is no desire to reverse. Additionally, nephrostomies alone may not be adequate for resolution, and the use of ureteral occlusion with coils and sponge pledgets may also be helpful (66). Local measures, including scrupulous management of pelvic and perineal hygiene, the use of adult diapers, and the use of creams such as 1% silver sulfasalazine or skin barriers are primary measures. There are no vaginal means to control or contain the output that have so far been effective. Various measures such as the use of diaphragms glued to catheters or local tissue glues have generally been ineffective in this setting.

Bleeding related to the pelvic/vaginal fistula or to vaginal recurrence can potentially be controlled by single fraction pelvic radiation (67) or if severe and causing significant distress with embolization. Local measures such as Monsel's solution have only limited efficacy and packing can add considerably to patient discomfort. So, try to pick an approach that fits both the overall status of the patient (if only a few days are likely, then the value of any intervention would be negligible) and the comfort and decrease in anxiety she might gain from addressing the bleeding.

Management of Bone Metastases

Bone metastases are rare in terminal gynecologic cancers, being primarily confined to unusually high-grade cell types such as glassy cell malignancies, neuroendocrine tumors, melanomas, small cell malignancies, or clear cell malignancies. When they occur, however, the pain associated with bone metastases can be the most excruciating of all the symptoms to be managed at the end of life. Corticosteroids and nonsteroidal anti-inflammatory drugs may have a significant role in managing the inflammatory pain from bone metastases and should be considered as part of initial management. If the metastases are localized, radiation therapy on a palliative basis may supply additional pain relief with a success rate of 24% to 50% total pain relief and 80% to 90% of patients noting relief of pain (68). Relief of pain may be immediate or it may require several months, and the use of anti-inflammatory pain medications during treatment may aid in symptom relief until the effects of radiation become evident.

Key aspects of treatment include ensuring that radiation fields encompass the entire area of bone involvement (69) and also the prevention of overlap with prior radiation fields. Multiple schemes have been used depending on the urgency and the overall expected survival time of the patient. There does not seem to be a difference between single-fraction versus multiple-fraction approaches, except for the need for retreatment with single fraction (70). Also, if there is a longer life expectancy, consideration should be given to prophylactic surgical fixation of weight-bearing bones with >50% cortical destruction or size >2.5 cm prior to radiation therapy (71,72).

Another option for consideration is the use of osteoblast-affinic agents such as strontium 89 or samarium 153 that deliver localized radiation to osteoblastic bony metastases. The primary problem in their use is bone marrow suppression, which often limits their use in patients with ongoing residual suppression from their prior therapies. These agents are not appropriate for use in hypercalcemic patients, and the pain relief is slower in onset with a duration of about 12 weeks. This option may require multiple doses to increase efficacy (73,74).

Psychologic Needs in Terminally Ill Cancer Patients

An important aspect of palliative care in terminally ill cancer patients is the recognition and treatment of psychologic symptoms to improve quality of life at the end of life. The understanding of suffering requires not just addressing physical needs, but also distress, existential concerns, and social relational worries which contribute to overall suffering in terminal cancer patients (75). Health care professionals often ignore the role that religion and spirituality play in coping with terminal illness. Most patients consider religion or spiritual aspects to be at least somewhat important and the majority report that their spiritual needs were supported minimally or not at all by the medical system (76). Referral to chaplaincy

services or other integrative medicine services is seen as having value to our patients and assessing their desire for this should be part of psychologic assessment and treatment (77). This is an area where little training and modeling exist in medical education, and the ability to address spirituality comfortably with patients is limited but important for health professionals to improve in discussing and addressing (78,79).

Depression and anxiety occur in a high percentage of cancer patients, particularly as disease advances and curative cancer treatment fails (80). The prevalence of depression in cancer patients has been the subject of numerous studies, and the reported rates have ranged from as high as 58.0% to as low as 4.5% with age, lower performance status, smaller social networks, and less participation in organized religious services all significant in predicting depression and anxiety (81).

Anxiety in terminally ill cancer patients has received less attention than depression. Anxiety commonly increases as patients become aware of both the relative ineffectiveness of medical treatments in halting the progress of their disease and, consequently, their limited life expectancy (82). The awareness of the inevitable death is likely to cause anxiety in terminally ill cancer patients. Breitbart et al. suggest that the incidence of both anxiety and depression in cancer patients increases with higher levels of disability, advanced illness, and pain (83). The closer the patient is to dying, the higher the score on depression and the lower the score on physical performance.

Although depression and anxiety are important to continually assess in terminally ill patients prior to death, data show that a relatively high percentage of terminally ill cancer patients suffer from psychologic distress a few weeks before death, which appears to be related to physical symptoms. Treating the physical symptoms maximally is the first task in addressing depression and anxiety. Standard treatment for depression and anxiety is effective in this population, and tricyclic antidepressants which additionally address neuropathic pain are reasonable choices. Lorazepam is often used for assisting in managing other symptoms but also provides relief for anxiety. Some integrative medicine solutions such as aromatherapy massage can be shown to assist in decreasing anxiety and depression (84). In sum, psychologic symptoms in terminally ill cancer patients need to be systematically assessed and considered by the care team in the overall decision-making and treatment plan at the end of life. Treatment of anxiety and depression clearly also improves overall management of pain as well as making the process of closure more possible for dying women. If patients can reconcile their concerns with psychologic and pharmacologic support, this will substantially remove the suffering from emotional distress for the patient and her family.

REQUESTS FOR HELP IN DYING

Sometimes, patients ask to end their life because of fear of an inability to control suffering at the end of life or inadequately managed pain or suffering. In most countries in the world, the law forbids assisted suicide. In the Netherlands, Belgium, and the United States (State of Oregon), individuals have access to laws that make assisted suicide available for those experiencing unbearable suffering and this access is highly regulated. Data from the Oregon experience (85) show that most patients do not follow through even with an expressed intent for assisted suicide.

Regardless of where health providers are in the world, this is a question that will come up directly or indirectly if actively caring for dying patients—and challenges our communication skills as few have been educated specifically for end of life discussions (86). Additionally, having such a discussion requires physicians to address for themselves their own understanding and barriers to discussing dying, futility, and assisted suicide (87).

Dying patients expect and need at least a minimal level of emotional support defined by them as compassion and treating the whole person and not just the disease (88). Set in this context, this conversation is an opportunity to embrace the compassion and acknowledgment of the whole person that is expected by the patient and to enhance understanding of the fears and the needs of the patient in the present. Patients who state that they would like “extra” prescriptions for pain medicine or anxiolytics, or who blatantly state that they are thinking of ending it all themselves or would like help in doing so are asking for an exploratory conversation about how “unbearable” dying will be.

Even in the middle of a busy clinic, time has to be made for this discussion. Confirming that the patient’s request has been heard and confirming the patient’s importance to her health professionals is part of the therapeutic relationship. A consult room with the inclusion of whomever the patient wants to include (or not) is a better setting than an examination room if available. Exploration with more open-ended questions such as, “Why do you feel you need this extra prescription right now?” “What do you think will happen that might make you think of (whatever phrasing the patient used)?” is a way to begin the dialog. Remembering that suffering is not only physical, but also psychologic and spiritual is important to be sure that all dimensions of fear and questions are answered, or if unanswerable, acknowledged as important. Follow-up questions that explore the patient’s motivation are outlined in Bascom and Tolle’s article (85). Then exploring each fear and, more importantly, assuring that with maximal effort at palliative care this can be addressed (and how), and that the patient is not viewed as a burden and is valued will open critical communication and provides an opportunity to address the underlying concern of the patient. In addition, this is an optimal time to introduce or reintroduce the importance of advance directives and to implement specific written orders regarding life-sustaining treatments (89). If this is an area of communication that is uncomfortable to the physician, then having another member of the team lead this discussion with the patient would be valuable, but with the specific assurance that respecting her wishes and continuing to care for the patient are still of importance to the physician who has been a critical member of that patient’s care.

BEREAVED FAMILY AND FRIENDS

Medicine focuses on the individual care of patients, and the needs and issues of the social network that supports patients are often ignored. End of life care, however, engages that entire social network of family and friends and requires understanding their needs and roles as the patient nears the end of life. Families define high-quality end of life care as first achieving good palliation of symptoms for the patient, but they also weigh quality on how well the dying person was able to control decisions and whether the family members felt that they had to be constant advocates for the wishes of the dying person. In addition, education and emotional support for the family and friends caring for the patient were seen as important (90). All the members of this network of care for the patient experience high levels of stress, burden, and diminished quality of life that can be helped with specific coping skills training (91). Caregivers who are able to accept and reframe the patient’s illness feel less strain and feel more capable of solving illness-related problems, all of which will directly improve the care of the dying woman (92).

While the care and comfort of the families and friends of dying patients are not a direct responsibility of the oncologic physician, advocating for the development of support for this network for patients and providing access to such support are

In addition, regardless of whether the physician and primary oncology team are directly involved in the end of life care of the patient, acknowledging the patient’s death and the team’s concern for her family with a card or phone call to the family is important in closing the circle for the family as well as the primary oncology team.

CARE FOR THE CAREGIVERS

Within palliative care in general and end of life care in particular, there is a tendency for patients and relatives to demand and benefit from a more personal care and personal approach. Because of this contact-intensive nature of end of life care, it can be expected that physicians and nurses run a serious risk of depleting their emotional resources, especially when they cross the border between their professional and personal involvement. This can result in burnout. Physicians and nurses should be aware of the risk factors in order to prevent this serious threat to their health. In oncology, and especially in end of life care, the stressors appear to be strongly related to the social and interpersonal aspects of the job, including relationships with patients and co-workers on the team (93–96).

To understand and prevent emotional exhaustion and burnout, physicians and nurses should be able to share their responses and feelings with others at work. This can be done by the organization of support groups at work where they can discuss what moved them and how they dealt with the situation (97–99). Improvement in physician communication skills around these stressful issues actually diminishes physician stress since the doctor-patient relationship plays an important role in this regard (100). The participants get the opportunity to discuss the emotional aspects of the care of the terminal patient. This can include revisiting conversations that were held about death with patients and their families. The team listens and discusses how these emotional events affected the person involved. Especially for younger and inexperienced personnel, this type of guidance by “peers” is very important. For the more experienced members, the team meetings can work as control. Much experience can result in diminished emotional involvement and distancing the relationships to a routine. Comments, advice, and help of colleagues are important factors in staying mentally fit—again, a message for all health professionals, at all parts of end of life care.

CONCLUSIONS

End of life care is a very important part of caring for women with cancer. It requires total commitment of the entire health care team. It includes medical interventions to relieve suffering, but also psychosocial care. Communication skills are very important to ensure optimal end of life care. In this communication, the autonomy of the patient has to be respected. The caregivers must respect the delicate balance between professional and personal involvement. Communication not only involves the patient, but also her relatives and friends. It is important that this communication take place in the presence of the patient as much as possible to avoid misunderstandings. Psychologic symptoms need to be routinely assessed and considered by physicians in the overall decision making concerning the end of life. Special attention must focus on anxiety and depression to be sure that all domains of suffering are addressed.

End of life care in oncology does not mean that the physician has to postpone the inevitable as long as possible. The goal is quite simply to continue the expert and compassionate care the patient has received throughout her treatment into the maximal alleviation of symptoms and suffering at the end of life.
