DISCLAIMER

Care has been taken to confirm the accuracy of the information present and to describe generally accepted practices. However, the authors, editors, and publisher are not responsible for errors or omissions or for any consequences from application of the information in this book and make no warranty, expressed or implied, with respect to the currency, completeness, or accuracy of the contents of the publication. Application of this information in a particular situation remains the professional responsibility of the practitioner; the clinical treatments described and recommended may not be considered absolute and universal recommendations.

The authors, editors, and publisher have exerted every effort to ensure that drug selection and dosage set forth in this text are in accordance with the current recommendations and practice at the time of publication. However, in view of ongoing research, changes in government regulations, and the constant flow of information relating to drug therapy and drug reactions, the reader is urged to check the package insert for each drug for any change in indications and dosage and for added warnings and precautions. This is particularly important when the recommended agent is a new or infrequently employed drug.

Some drugs and medical devices presented in this publication have Food and Drug Administration (FDA) clearance for limited use in restricted research settings. It is the responsibility of the health care provider to ascertain the FDA status of each drug or device planned for use in their clinical practice.

To purchase additional copies of this book, call our customer service department at (800) 638-3030 or fax orders to (301) 223-2320. International customers should call (301) 223-2300.

Visit Lippincott Williams & Wilkins on the Internet: <http://www.lww.com>. Lippincott Williams & Wilkins customer service representatives are available from 8:30 am to 6:00 pm, EST.

This book is dedicated to our families—Catherine Barakat and children Joanna, Richard Jr., and Christian Barakat; Brabham Morgan Randall and children Ken, Morgan, and Marycobb Randall; and Tomes Markman and children Margaret, Jonathan, Timothy, and Elisabeth Markman. By virtue of their patience, good humor, encouragement, and tolerance of our long hours at work, they have each made significant contributions to this book.

FOREWORD

Stuart Freeman, in charge of production of oncology textbooks at Lippincott Publishers (now Lippincott Williams & Wilkins) approached the three of us—Carlos Perez, Robert Young, and me—in the early 1990s to collaborate in editing a textbook on gynecologic cancer. We met to plan the text in 1992, and 2 years later, in 1994, the first edition was published. With the able guidance of Stuart, we developed several basic principles: (a) The textbook would be multidisciplinary, with the disease chapters authored by a surgeon, a medical oncologist, a radiation oncologist, and a pathologist; (b) the editors would strive to make the textbook a definitive reference that would be written at the level of an expert in surgery, medical oncology, and radiation oncology; (c) the text would be divided into three sections: basic science, modalities of therapy, and the disease chapters, which cover current principles of treatment; (d) we would edit the book in two sessions, each lasting 2 to 3 days, with all the editors sitting at one table reading the same chapter; (e) we would strive to publish an updated edition every 3 years.

Over the next 12 years, we published four editions of the text, the first three under the guidance of Stuart Freeman and the last edition under the guidance of Jonathan Pine. We appreciate the assistance and support that we received from Lippincott Williams & Wilkins throughout. We were, and remain, grateful for the opportunity to develop a close friendship and, most important, we were satisfied that our book was a definitive and valuable text for those physicians who treat gynecologic cancer.

In the planning for the fourth edition, the three editors agreed that it would be our last edition and that we should select new editors to continue the publication of the text. As a group, we chose Richard Barakat, MD, Maurie Markman, MD, and Marcus Randall, MD, and they worked with us on the preparation of the fourth edition. In this fifth edition of *Principles and*

Practice of Gynecologic Oncology, our only involvement is to write the Foreword. This edition and the ones to come are the work of Rich, Maurie, and Marc. We are grateful that the current editors have agreed to carry on the text, and we anticipate that this text will be outstanding and uphold the tradition of presenting the state of the art in gynecologic oncology.

The landscape in the management of patients with gynecologic cancer has rapidly evolved in recent years. A vaccine for human papillomavirus (HPV) is being administered worldwide, with the expectation that it will substantially decrease the incidence and mortality of carcinoma of the uterine cervix. All aspects of the diagnosis and treatment of gynecologic cancer have become more complex. Surgical procedures are more radical, and there are many new chemotherapeutic and targeted agents (both cytotoxic and biologic) and new equipment and techniques in radiation oncology. Survival rates for ovarian and cervical cancer have improved, and survival for corpus cancer is stable. In 2007, the 5-year survival for all stages and all races was 45% for ovary, 72% for cervix, and 83% for corpus cancers.

This text continues to be the most comprehensive and up-to-date book for the physicians who treat women with gynecologic cancer, and with its multidisciplinary approach still addresses the most important aspects of basic biology, pathology, modalities of therapy, and therapeutic options by disease site.

As the original editors of this text, we are very pleased with this fifth edition of *Principles and Practice of Gynecologic Oncology* and congratulate the new editors, Drs. Richard Barakat, Maurie Markman, and Marcus Randall, for their achievement. We are confident they will continue to produce timely and up-to-date editions in the future.

William J Hoskins, MD
Carlos A Perez, MD
Robert C Young, MD

SECTION I: EPIDEMIOLOGY OF GYNECOLOGIC CANCER

1. Epidemiology of Gynecologic Cancers	1
<i>Louise A. Brinton and Mark Schiffman</i>	
2. Clinical Genetics of Gynecologic Cancer	31
<i>Steven A. Narod</i>	
3. The Biology of Gynecologic Cancer	37
<i>Kristin K. Zorn, Ginger J. Gardner, John H. Farley, and Michael J. Birrer</i>	
4. Tumor Invasion, Angiogenesis, and Metastasis: Biology and Clinical Application	71
<i>Christina M. Annunziata, Nilofer S. Azad, Ebony R. Hoskins, and Elise C. Kohn</i>	
5. Oncogenes and Tumor Suppressor Genes	85
<i>Jeff Boyd, John I. Risinger, and Andrew Berchuck</i>	
6. Immunotherapy of Gynecologic Malignancies	113
<i>Paul J. Sabbatini, David Z. Chang, Chaitanya R. Divgi, Philip O. Livingston, and Alan N. Houghton</i>	
7. Development and Identification of Tumor Markers	145
<i>Aleksandra Gentry-Maharaj, Ian Jacobs, and Usha Menon</i>	
8. Cancer Prevention Strategies	165
<i>Mary B. Daly</i>	
9. Clinical Trials Methodology and Biostatistics	177
<i>Mark F. Brady, Alan D. Hutson, and Daniel P. Gaile</i>	
10. Diagnostic Imaging Techniques in Gynecologic Oncology	197
<i>Darcy J. Wolfman, Susan M. Ascher, Hedvig Hricak, Cirrelda Cooper, and Leslie Scutt</i>	

SECTION II: THERAPEUTIC MODALITIES AND RELATED SUBJECTS

11. Perioperative and Critical Care	231
<i>James J. Burke II, Janet L. Osborne, and Christopher K. Senkowski</i>	
12. Surgical Principles in Gynecologic Oncology	269
<i>Dennis S. Chi, Robert E. Bristow, and Donald G. Gallup</i>	
13. Laparoscopic Surgery in Gynecologic Cancer	289
<i>Denis Querleu, Marie Plante, Yukio Sonoda, and Eric Leblanc</i>	
14. Biologic and Physical Aspects of Radiation Oncology	325
<i>Beth A. Erickson-Wittmann, Jason Rownd, and Kevin Khater</i>	
15. Principles of Chemotherapy in Gynecologic Cancer	381
<i>Michael A. Bookman</i>	

16. Pharmacology and Therapeutics in Gynecologic Cancer	409
<i>David S. Alberts, Lisa M. Hess, Daniel D. Von Hoff, and Robert T. Dorr</i>	
17. Hormones and Human Malignancies.	463
<i>G. Larry Maxwell, Amir A. Jazaeri, and Laurel W. Rice</i>	
18. Innovative 21st Century Therapies.	485
<i>Eric K. Rowinsky, Arno J. Mundt, and Nadeem R. Abu-Rustum</i>	
19. Pathogenesis and Diagnosis of Preinvasive Lesions of the Lower Genital Tract	523
<i>Thomas C. Wright Jr</i>	

SECTION III: DISEASE SITES

20. Vulva	553
<i>David H. Moore, Wui-Jin Koh, William P. McGuire, and Edward J. Wilkinson</i>	
21. Vagina	591
<i>Higinia R. Cárdenes, Jeanne M. Schilder, and Lawrence M. Roth</i>	
22. Uterine Cervix	623
<i>Marcus E. Randall, Helen Michael, Harry Long III, and Sean Tedjarati</i>	
23. Corpus: Epithelial Tumors	683
<i>D. Scott McMeekin, Kaled M. Alektiar, Paul J. Sabbatini, and Richard J. Zaino</i>	
24. Corpus: Mesenchymal Tumors.	733
<i>Gregory Sutton, John Kavanagh, Aaron Wolfson, and Carmen Tornos</i>	
25. Epithelial Ovarian Cancer	763
<i>Gini F. Fleming, Brigitte M. Ronnett, Jeffrey Seidman, Richard J. Zaino, and Stephen C. Rubin</i>	
26. Ovarian Germ Cell Tumors	837
<i>Daniela E. Matei, Helen Michael, Anthony H. Russell, and David M. Gershenson</i>	
27. Ovarian Sex Cord–Stromal Tumors	855
<i>David M. Gershenson, Lynn C. Hartmann, and Robert H. Young</i>	
28. Molar Pregnancy and Gestational Trophoblastic Neoplasms	875
<i>Ross S. Berkowitz and Donald P. Goldstein</i>	
29. Breast Cancer.	897
<i>Don S. Dizon, Trevor Tejada-Berges, Margaret M. Steinhoff, C. James Sung, Susan L. Koelliker, Hanan I. Khalil, Brigid O'Connor, Stephanie MacAusland, Charu Taneja, Robert D. Legare, and Jennifer S. Gass</i>	

SECTION IV: SPECIAL MANAGEMENT TOPICS

30. Management of Infections in Patients with Gynecologic Malignancy.	947
<i>Amar Safdar and Issam I. Raad</i>	
31. Management of Complications of Gynecologic Cancer Treatment.	965
<i>David G. Mutch, Catheryn Yashar, Maurie Markman, and Stephen C. Rubin</i>	
32. Management of Pain	983
<i>Russell K. Portenoy, Damean Freas, and Pauline Lesage</i>	
33. Nutrition Support of Patients with Gynecologic Cancer.	1005
<i>Mark Schattner and Moshe Shike</i>	
34. Quality of Life Issues in Gynecologic Oncology.	1019
<i>Lari Wenzel, Richard Penson, Jeanne Carter, Dana Chase, and David Cella</i>	
35. End of Life Care.	1029
<i>Joanna M. Cain and Susan Tolle</i>	
<i>Index</i>	1041

The publication of the fifth edition of *Principles and Practice of Gynecologic Oncology* marks the completion of the transition to three new editors, Richard Barakat, Maurie Markman, and Marcus Randall. As editors and cancer specialists, we are excited about the fifth edition and are honored to follow in the tradition of excellence established by our three predecessors, William J. Hoskins, MD, Carlos A. Perez, MD, and Robert C. Young, MD, who had worked together on this textbook for over 15 years. Without their guidance and friendship, this seamless transition wouldn't have been possible. We look forward to building on their important contribution to the medical literature.

We remain committed to the multidisciplinary theme of the textbook, with chapters authored by teams consisting of a surgeon, a medical oncologist, a radiation oncologist, and a pathologist. The increasing complexity of all aspects of gynecologic cancer treatment requires this type of approach. As in previous editions, we have rotated approximately 30% of the authors, and all chapters have been either completely rewritten or extensively updated, including the chapters on the three

major disease sites—ovarian, uterine, and cervical cancer—as well as breast cancer. We are certain that this edition contains the most up-to-date information available about the treatment of gynecologic cancers. This textbook was designed for specialists who care for women afflicted with gynecologic cancer, including surgeons, medical oncologists, radiation oncologists, pathologists, and nurses. It also serves as a valuable resource for residents and fellows in training for a career in cancer care.

Finally, we wish to thank the readers for their support in the past and look forward to their continued support and advice in the future. We will continually strive to improve the content and quality of this comprehensive textbook. It is our hope that this textbook will play a significant role in developing future treatments to benefit women afflicted with gynecologic cancer.

*Richard Barakat, MD
Maurie Markman, MD
Marcus Randall, MD*

ACKNOWLEDGMENTS

The editors acknowledge the contributions of numerous individuals without whom this book would not have been possible. The talented staff of the publisher, Lippincott Williams & Wilkins, especially Jonathan Pine, senior executive editor; Joyce Murphy, associate director of content; Anne Jacobs, senior managing editor; and Paula Williams, senior project editor, provided invaluable encouragement, direction, and guidance during the creative process and in technical execution. Charu Dutt, senior project manager for International Typesetting and Composition, provided outstanding production services.

From the Gynecology & Breast Services Academic Office, Department of Surgery, Memorial Sloan-Kettering Cancer Center (MSKCC), we acknowledge the invaluable contributions of K. Alexandra MacDonald, senior editor; Jennifer Grady, assistant editor; and Shan-san Wu, assistant editor. Their attention to detail, patience, and communication skills were of the utmost importance throughout the publication process. Our appreciation for all their efforts cannot be adequately expressed, but we hope they know how much we value their contributions.

EPIDEMIOLOGY
OF GYNECOLOGIC
CANCER

CHAPTER 1 ■ EPIDEMIOLOGY OF GYNECOLOGIC CANCERS

LOUISE A. BRINTON AND MARK SCHIFFMAN

Disease-oriented texts often include a chapter on epidemiology or etiology, which is considered perfunctory if the book is used by therapists whose daily practice is rarely influenced by these considerations. This is not the case for physicians who treat patients with gynecologic cancers, because these clinicians have frequent opportunities to interpret epidemiologic findings and make observations of etiologic importance. Moreover, public health measures based on epidemiologic findings influence gynecologic practice perhaps more than any other clinical discipline. In particular, epidemiologic data are critical for the prevention and treatment of cervical and uterine cancers.

From the observation 150 years ago of the rarity of cervical cancer in nuns to the most recent follow-up studies of type-specific human papillomavirus infection, determining the cause, natural history, and prevention of this disease has focused on sexual practices and suspect infectious agents. Screening interventions based on natural history studies have fundamentally altered the usual presentation of this disease, and as more information about preceding infectious processes becomes available, even more radical changes in presentation and management are likely.

The probable estrogenic cause of endometrial cancer was proposed by etiologically oriented gynecologists decades before its demonstration by epidemiologists. Unfortunately, this did not prevent the largest epidemic of iatrogenic cancer in recorded history (i.e., endometrial cancer caused by estrogen replacement therapy). The resurgent interest in hormone replacement therapy, effects of progestins added to this regimen, and associated risk-benefit questions are certain to link the epidemiologist and the gynecologist for the foreseeable future. The iatrogenic chemoprevention of endometrial and ovarian cancer through oral contraception has similarly thrust the two disciplines together around issues ranging from basic biology to risk-benefit assessments.

The rich tradition of the mingling of epidemiology and gynecologic oncology has led to better opportunities for prevention, screening, and insights into basic mechanisms of disease than for any other subspecialty concerned with cancer. This chapter is written with the aim of clarifying how epidemiology is an integral part of the effort to reduce the morbidity and mortality from gynecologic cancers in women.

UTERINE CORPUS CANCER

Demographic Patterns

Cancer of the uterine corpus (hereafter referred to as uterine cancer) is the most common invasive gynecologic cancer and the fourth most frequently diagnosed cancer among American

women today. One in 40 American women will develop uterine cancer during their lives, and it is estimated that there will be approximately 40,100 diagnoses during 2008 (1). The average annual age-adjusted (2000 U.S. standard) incidence from the Surveillance, Epidemiology, and End Results (SEER) program, a cancer reporting system involving approximately 26% of U.S. residents, was 22.7 per 100,000 women for 2000 to 2004; the corresponding age-adjusted mortality rate was 2.0 per 100,000 women, reflecting the relatively good prognosis for this cancer (2). The 5-year survival rate is approximately 84%. It is estimated that approximately 7,470 women will die from uterine cancer during 2008 (1).

Uterine cancer rates are highest in North America, intermediate in Europe and temperate South America, and low in Southern and Eastern Asia (including Japan) and in most of Africa (except southern Africa) (3). The disease is rare before the age of 45 years, but the risk rises sharply among women in their late 40s to middle 60s. The age-adjusted incidence for whites is approximately twice the incidence for nonwhites (Fig. 1.1). Reasons for the discrepancy remain largely undefined. Within the last several decades in the United States, a dramatic change in the incidence pattern for uterine cancer has occurred, characterized by a marked increase that peaked about 1975 (Fig. 1.2) (4). Considerable evidence has linked this rise and fall with the widespread use of estrogen replacement therapy in the late 1960s and early 1970s. Mortality rates, albeit considerably lower, have generally mirrored incidence rates.

Reproductive Risk Factors

Nulliparity is a recognized risk factor for uterine cancer. Most studies demonstrate a two- to threefold higher risk for nulliparous than parous women. The association of uterine cancer with nulliparity has been suggested to reflect prolonged periods of infertility. The hypothesis that infertility is a risk factor for uterine cancer is supported by studies showing higher risks for married nulliparous women than for unmarried women. Several studies have found that infertile women experience a three- to eightfold increase in risk (5–7). Mechanisms that may mediate the risk associated with infertility include anovulatory menstrual cycles (i.e., prolonged exposure to estrogens without sufficient progesterone); high serum levels of androstenedione (i.e., excess androstenedione is available for conversion to estrone); and the absence of monthly sloughing of the endometrial lining (i.e., residual tissue may become hyperplastic). In addition, nulliparity has been associated with lower levels of serum sex hormone-binding globulin (SHBG), leading to increased bioavailable estrogen (8).

FIGURE 1.1. Age-specific incidence of cancer of the corpus uteri by race. *Source:* Data from the Surveillance, Epidemiology, and End Results Program, 2000–2004.

It has been established for many years that the risk of uterine cancer decreases with increasing parity, especially among premenopausal women (6,9,10). More recent attention has focused on characteristics of ages at which these births occurred. Several investigators have found decreased risks with either older ages at or shorter intervals since a last birth, and have suggested that this might reflect a protective effect of mechanical clearance of initiated cells (11,12). However, a recent analysis, which accounted for the correlation of multiple reproductive parameters, concluded that protection appeared to derive more from a late age at a first birth, suggesting an adverse effect of infertility among women who are unable to conceive at older ages (10). Additional studies are needed to confirm these latest findings and to shed further light on endogenous hormonal alterations that might underlie reproductive associations with uterine cancer risk.

An understanding of the effects of infertility on cancer risk must also consider relationships according to different methods of birth control, including oral contraceptives (discussed later in this chapter). However, it is also of interest that a number of investigations have noted reductions in risk among users of intrauterine devices (13–16). The mechanisms involved with this apparent protective effect have not been elaborated, although it is possible that the devices may affect risk by causing structural or biochemical changes that alter the sensitivity of the endometrium to circulating hormones.

An additional area of interest is the effect of exposure to fertility drugs, given a recent study showing that users of clomiphene citrate are at an increased risk of developing uterine cancers (17). Although this finding requires replication, it is of interest given the structural similarity of clomiphene and tamoxifen, which has been extensively linked with the occurrence of uterine cancers (discussed in more detail below).

The relationship of risk to breast-feeding remains controversial. Although some recent studies suggest that prolonged lactation may offer protection (18,19), in one of these investigations

FIGURE 1.2. Incidence and mortality trends among U.S. white females for cancer of the corpus uteri. *Source:* Data from the Surveillance, Epidemiology, and End Results Program, 1975–2004.

the reduced risk did not persist into the age range when uterine cancer becomes common (19).

Menstrual Risk Factors

Early ages at menarche have been related to an elevated risk for uterine cancer in several studies, although associations have generally been rather weak and trends inconsistent (5,6). Several studies have found stronger effects of ages at menarche among younger women, although this has not been consistently demonstrated (6). The extent to which these relationships reflect increased exposure to ovarian hormones or other correlates of early menarche (e.g., increased body weight) is unresolved.

Most studies have indicated that age at menopause is directly related to the risk of developing uterine cancer. About 70% of all women diagnosed with uterine cancer are postmenopausal. Most studies support the estimate that there is about a twofold risk associated with natural menopause after the age of 52 years as compared to before age 49 years (20). It has been hypothesized that the effect of late age at menopause on risk may reflect prolonged exposure of the uterus to estrogen stimulation in the presence of anovulatory (progesterone-deficient) cycles. The interrelationships among menstrual factors, age, and weight are complex, and the biologic mechanisms of these variables operating in the pathogenesis of uterine cancer are subject to substantial speculation.

Exogenous Hormones

Oral Contraceptives

Studies have demonstrated significantly higher risks in users of sequential oral contraceptives (i.e., containing a high dose of estrogen and a weak dose of progestin) as compared to users of estrogen-progestin combination pills. Studies have shown that women who used Oracon, a sequential preparation that employed dimethisterone (weak progestogen) with a large dose of a potent estrogen (ethinyl estradiol), had substantially elevated risks of uterine cancer (6,21). The risk associated with the use of other sequential oral contraceptives remains unclear, mainly because these drugs are no longer marketed.

In contrast, the use of combination oral contraceptives may reduce the risk of uterine cancer by 50% compared to nonuse, and long-term use may decrease risk further (21–24). Kaufman et al. (23) showed that the reduced risk persisted for at least 5 years after discontinuation, but Weiss and Sayvetz (21) found that the protective effect waned within 3 years. In several studies, the greatest reduction in risk was associated with high-progestin-dose pills, although recent findings indicate that this may be true only among obese women (25). A number of studies indicate that the protective effect of the pill appears greatest among nulliparous women (6,22). In other studies, the protection has been limited to nonobese women or those who have not been exposed to menopausal estrogens (6,21).

Menopausal Hormones

It is well established that unopposed estrogens are associated with a 2- to 12-fold elevation in uterine cancer risk (26–29). In most investigations, the increased risk does not become apparent until the drugs have been used for at least 2 to 3 years, and longer use of estrogens is generally associated with higher risk (26,30,31). The highest relative risks (RRs) have been observed after 10 years of use (up to 20-fold), although it is unclear whether risk increases after 15 years. Most but not all studies have found that cessation of use is associated with a relatively rapid decrease in risk, although a number of studies have found significantly elevated risks to persist 10 or more years after last usage (26,30–33). Although higher doses of estrogen are associated with the greatest elevations in risk, one study showed that even 0.3 mg of unopposed equine estrogen can result in a significant increase in risk (34).

This large body of evidence linking estrogen use to increases in the risk of uterine cancers has led to estrogens being prescribed in conjunction with progestins among women who have not had a hysterectomy. Progesterone has been shown to cause regression of endometrial hyperplasia, the presumed precursor of uterine cancers (35). The large Women's Health Initiative (WHI) clinical trial showed that women assigned to 0.625 mg of conjugated equine estrogen plus 2.5 mg of medroxyprogesterone acetate daily had a lower

hazard ratio (0.81, 95% confidence interval [CI] 0.48 to 1.36) than those assigned to placebo, but this risk was based on relatively small numbers of endometrial cancers and short follow-up (36). Similar observational results derive from the Million Women Study in the United Kingdom, where usage of continuous combined therapy resulted in a relative risk of 0.71 (95% CI 0.56 to 0.90) (37).

It is unresolved whether protection from estrogens can be achieved when progestins are prescribed sequentially (usually defined as less than 10 to 15 days per month) as opposed to continuously. Although a number of studies indicate that the excess risk of uterine cancer can be significantly reduced if progestins are given for at least 10 days each month (27,38–40), several studies have shown that subjects prescribed progestins for less than 10 days per month experience some increase in risk, with only a slight reduction compared to estrogen-only users (27,38,40,41). The sharp contrast between the effects of <10 and ≥10 days of progestin use has led to the suggestion that the extent of uterine sloughing or of “terminal” differentiation at the completion of the progestin phase may play a critical role in determining risk (27). It remains questionable whether <10 days of progestin administration per month is sufficient for complete protection, particularly for long-term users (42). Few studies have had large numbers of long-term sequential users, and in two studies there has been evidence that this pattern of usage may result in some persistence of risk (27,41). Other studies, however, have not confirmed this (43).

Studies have shown that the effects of hormonal therapy (both unopposed estrogens as well as combination therapy) may vary by user characteristics, most notably by a woman's body mass. The Million Women Study showed that the adverse effects of unopposed estrogens were greatest in nonobese women and that the beneficial effects of combined therapy were greatest in obese women (37). Studies have also suggested that effects of unopposed estrogens are strongest in nondiabetic, normotensive, and nonsmoking women (26,31,44), but less information is available on how these other risk factors modify the effects of combination therapy. These findings suggest either that estrogen metabolism differs among certain women, or that risk is already high enough in women who are obese, diabetic, hypertensive, or smokers that exposure to exogenous estrogens has only a small additional effect.

Most data regarding effects of hormones derive from studies of users of pills. Unresolved is whether the use of estrogen patches, creams, or injections can affect risk; given relationships of risk with even low dose estrogens, it is plausible that these regimens may confer some increase in risk.

Tumors associated with estrogen use generally demonstrate favorable characteristics, including earlier stage at diagnosis, lower grade, and less frequent myometrial invasion (26,33). Estrogen users tend to be younger at diagnosis than nonusers, and the tumors are more frequently accompanied by hyperplasia or adenomyosis (45,46). The fact that estrogen remains linked to risk in studies limited to pathologically confirmed cases and that risk is increased for both early- and late-stage cancers (32,47) suggests that the increased risk is not related to pathologic overdiagnosis.

Tamoxifen

A number of clinical trials and one population-based case-control study have demonstrated an increased risk of uterine cancer among tamoxifen-treated breast cancer patients (48–50). This is consistent with tamoxifen's estrogenic effects on the endometrium. Elevated risks have been observed primarily among women receiving high cumulative doses of therapy, usually in the range of 15 g or greater. According to a recent investigation, the risk for malignant mixed müllerian tumors may be

especially high (51). One study documented a poor prognosis among long-term tamoxifen users who developed uterine cancer, presumably reflecting less favorable histologies and higher stages of disease at diagnosis (52). Whether this finding is generalizable to other populations remains unclear.

Anthropometry and Physical Activity

Obesity

Obesity is a well-recognized risk factor for uterine cancer and may account for up to 25% of cases (53–55). Very heavy women appear to have exceptionally high risks (55,56). Although studies have demonstrated significant positive trends of uterine cancer with both weight and various measures of obesity, including the Quetelet's index (weight/height²), height has not been consistently associated with risk. Obesity appears to affect both premenopausal and postmenopausal uterine cancer (55).

Although initial studies hypothesized that adolescent and long-standing obesity may be more important than adult weight, recent studies support that contemporary weight and weight gain during adulthood are the most important predictors of uterine cancer risk (55,56). Relationships with obesity appear stronger for postmenopausal disease and among women not exposed to exogenous hormones (56,57).

Recent interest has focused on determining whether the distribution of body fat predicts uterine cancer risk. A number of studies have shown that central obesity may have an effect independent of overall body size (56,58), although not all studies confirm this relationship.

Physical Activity

Recent investigations have focused on the role of physical activity in the etiology of uterine cancer. A potential relationship is biologically appealing given that physical activity can result in changes in the menstrual cycle, body fat distribution, and levels of endogenous hormones. Although several recent studies suggest a protective effect of physical activity on uterine cancer risk that appears independent of relationships with body weight (59–64), the apparent relationships are not as convincing as have been observed for breast cancer risk. For instance, recent results from the large European Prospective Investigation into Cancer and Nutrition (EPIC) indicate that the protective effect of physical activity may be restricted to premenopausal women (65). Further, other studies have not shown dose-response relationships, and the types of activities associated with risk reductions have varied across studies. Two recent reviews on the topic emphasize the need for further investigation to determine the types, characteristics, or time periods of physical activity that could optimally impact risk (66,67).

Dietary Factors

Despite the fact that obesity has been consistently related to uterine cancer, the role of dietary factors remains controversial. Geographic differences in disease rates (i.e., high rates in Western and low rates in Eastern societies) suggest that nutrition has a role, especially the high content of animal fat in Western diets. Armstrong and Doll (68) demonstrated a strong correlation between a country's total fat intake and uterine cancer incidence.

Dietary Fat

Although a number of studies have assessed uterine cancer risk in relation to consumption of dietary fat, the association remains unclear. A clear assessment of risk depends on careful

control for effects of both body size and caloric intake (energy). Several case-control studies have found a relationship with dietary fat intake (particularly animal fat) that appeared independent of other dietary factors (69–71). Another case-control study (53) found that the risk associated with fat calories was partially explained by body size. Several other case-control studies did not confirm a relationship with fat intake (72,73). In addition, a recent cohort study found an opposite trend; namely, some decrease in risk with relatively high intakes of saturated or animal fat (54).

Fruits, Vegetables, and Associated Micronutrients

A somewhat more consistent observation has been the reduction of uterine cancer related to high intakes of fruits and vegetables (53,69,73–75). There is some support for this relating to consumption of fruits and vegetables that are high in either beta-carotene (74) or lutein (53). Various other micronutrients have been implicated in the etiology of uterine cancer, although their independence from each other and from other risk factors has not been fully resolved (71–73). Further, not all studies support relationships with micronutrients, including a large Canadian prospective study (54).

Other Dietary Factors

Given the recognized role of diabetes in the etiology of uterine cancers, a number of studies have assessed risk in relation to carbohydrate intake, glycemic intake, and glycemic load, which are known to increase insulin and estrogen levels. There are suggestions that all three factors may relate to risk (76–79), although further studies are needed to sort out their independence from other risk factors, including obesity, diabetes, and physical activity levels.

Several studies have found that consumption of phytoestrogens and omega-3 fatty acids (found in fatty fish) may be protective (53,80,81), but confirmatory studies are needed. In addition, future studies are needed to assess whether risk reductions associated with certain dietary patterns reflect modified hormone metabolism, as suggested in both observational and intervention studies (82–85).

Alcohol Consumption

In several studies, regular consumption of alcoholic beverages has been linked to substantial reductions in uterine cancer risk (86–88). Several studies suggest more pronounced effects among premenopausal or overweight women, indicating that an attenuation in endogenous estrogen levels may be responsible for the reduced risk (86,88). However, other studies have failed to find a relationship between alcohol consumption and uterine cancer risk (89–91).

Cigarette Smoking

A reduced risk of uterine cancer among smokers has been reported, with current smokers having approximately half the risk of nonsmokers (90,92–94). Cigarette smoking has been linked to an earlier age at natural menopause in some populations and to reduced levels of endogenous estrogens. Reduced risk associated with long-term smoking is more pronounced in postmenopausal than premenopausal women (92). In addition, reduced risk associated with smoking may be most apparent in parous or obese patients (92,95).

At present, biologic mechanisms underlying the inverse relationship of smoking to uterine cancer risk remain elusive. Alterations in endogenous hormones or metabolites are likely involved. In one report, the inverse association of smoking with uterine cancer risk appeared to be more strongly related to

higher serum androstenedione levels than to lower serum estrogen levels, except perhaps among overweight women (96).

Medical Conditions

Numerous clinical reports link polycystic ovarian syndrome (PCOS) with an increase in the risk of uterine cancer, particularly among younger women (97–99); however, it is uncertain whether this risk is independent of obesity. In a follow-up study at the Mayo Clinic, women with chronic anovulation were found to be at a threefold increased risk of developing uterine cancer (100). Assessing histories of PCOS is challenging in case-control studies, but it is of interest that uterine cancer has been associated with histories of either hirsutism or acne (5,101), which are conditions often associated with hyperandrogenism.

A number of studies have noted a high risk of uterine cancer among diabetics, but again the issue is whether the association is independent of weight. Various cohort studies (102–105) and a number of case-control studies (5,106–108) suggest that the relationship persists when analyses are restricted to nonobese women or are adjusted for weight. However, in several other studies (109,110), the effect of diabetes on uterine cancer risk was apparent only among obese women, suggesting the possible involvement of selected metabolic abnormalities, including hyperinsulinemia. Further studies are needed to resolve the association, as well as to elaborate on how specific types of diabetes may be involved.

A variety of other conditions have been suggested as possibly predisposing to uterine cancer risk, including hypertension, arthritis, thyroid conditions, and cholecystectomy. In a number of studies, positive findings may be partially explained by the correlation of the diseases with other factors. Similar to relationships with breast cancer, patients with previous fractures have been found to have a reduced risk of uterine cancer (111,112), presumably reflecting the association of lowered bone density with altered endogenous hormone levels.

Host Factors

Although studies have shown that a family history of uterine cancer is a risk factor for the disease, particularly among younger subjects (113), this appears to explain only a small proportion of disease occurrence (114). In addition, subjects with a family history of colon cancer are at increased risk, an association that is now recognized as reflective of hereditary nonpolyposis colorectal cancer, a dominantly inherited syndrome associated with mutations in the DNA mismatch repair genes *MSH2*, *MLH1*, and *MSH6*.

A number of recent studies have focused on relationships of uterine cancer risk with common genetic polymorphisms, including those involved with hormone biosynthesis and metabolism (115–119), DNA repair (120), and folate metabolism (121). Additional studies are needed to resolve effects of these genes as well as their interactions with environmental factors.

Environmental and Occupational Risk Factors

Geographic variation in rates of uterine cancer, with high rates in certain industrial areas, has led to the suggestion that certain environmental agents may affect risk. Given the well-recognized influence of hormones on the disease, there has been particular concern about a potential role for certain endocrine disruptors, including dichlorodiphenyl-trichloroethane (DDT). Several studies have addressed this issue by comparing dichlorodiphenyldichloroethylene (DDE)

levels (the active metabolite of DDT) in the sera of cases and controls, finding no significant differences (122,123).

Studies assessing the relationship of uterine cancer risk to exposure to electromagnetic radiation (electric blanket or mattress covers) have been negative (124). Data for occupational exposures are limited. Elevated endometrial cancer rates have been found among teachers in California (125) and individuals exposed to animal dust and sedentary work in Finland (126). The extent to which these relationships reflect the influence of social class is unknown.

Biologic Mechanisms Underlying Risk Factor Associations

Many of the identified risk factors are thought to operate through alterations in various endogenous hormones. The majority of studies have found increased risks associated with higher levels of circulating estrogens among postmenopausal women that persisted after adjustment for the effects of body mass (127–130), although in one study associations were considerably reduced after adjustment for body mass (129). In this same investigation, estrogens appeared to be less predictive of premenopausal disease, suggesting that anovulation or progesterone deficiency might be more predictive of risk.

Less well investigated is whether other endogenous hormones are related to uterine cancer risk. Key and Pike (131) suggested that uterine carcinogenesis is dependent on uterine mitosis, which is increased by estrogens and reduced by progesterone, but risk associated with progesterone levels has not been well explored. Several studies have shown positive associations of uterine cancer risk with serum androstenedione and testosterone levels (128,129). It has been hypothesized that this may reflect a role of chronic anovulation and progesterone deficiency in premenopausal women, whereas after menopause, aromatase and local conversion of estrone from androstenedione may be involved (132).

Obesity, which is hypothesized to reflect elevated estrogen levels (131), seems to represent a key risk factor for both uterine carcinoma and endometrial hyperplasias, but the mechanisms mediating this are unclear. One case-control analysis of serum estrogen levels (129) reported that the risk associated with obesity was not entirely mediated by estrogen, especially among premenopausal women. In another cohort study of postmenopausal women, elevated serum estrogen levels appeared to account for the majority of the risk associated with obesity (130). A potential role for insulin and insulin-like growth factors (IGF) has been suggested, although studies generally have not found support for a role of either c-peptide (133) or IGF (134) levels.

Conclusions

A unified theory of how risk factors for uterine cancer might operate through one common hormonal pathway has been suggested. Estrogen promotes proliferation in the endometrium, which is opposed by progesterone. Therefore, exposure to estrogen, particularly bioavailable estrogen that is weakly bound or unbound to plasma protein, is viewed as carcinogenic. Functional ovarian tumors, PCOS, late menopause, and administration of exogenous estrogens and sequential oral contraceptives produce higher levels of estrogen exposure without the antiproliferative effects of progesterone. Obesity could also contribute in a variety of ways (135). Adipose tissue is the primary site for conversion of androstenedione to estrone, which is the primary source for estrogen after menopause. Obesity is associated with higher conversion rates and/or elevated plasma levels of estrogen. In addition, obesity is related to lower levels of SHBG and more frequent anovulatory menstrual cycles

TABLE 1.1
RISK FACTORS FOR UTERINE CANCER

Factors influencing risk	Estimated relative risk ^a
Older ages	2–3
Residency in North America, Northern Europe	3–18
Higher levels of education or income	1.5–2.0
White race	2
Nulliparity	3
History of infertility	2–3
Menstrual irregularities	1.5
Early ages at menarche	1.5–2.0
Late ages at natural menopause	2–3
Long-term use or high dosages of menopausal estrogens	10–20
Use of oral contraceptives	0.3–0.5
High cumulative doses of tamoxifen	3–7
Obesity	2–5
Stein-Leventhal disease or estrogen-producing tumors	>5
Histories of diabetes, hypertension, gallbladder disease or thyroid disease	1.3–3.0
Cigarette smoking	0.5

^aRelative risks depend on the study and referent group employed.

(i.e., less progesterone). Vegetarianism is associated with lower plasma estrogen levels, presumably on the basis of the relationship of diet composition to estrogen metabolism. The beneficial effects of combination oral contraceptives and cyclic progestins added to hormone replacement therapy presumably operate through the antiestrogenic effects of progesterone. The peculiar age incidence patterns for uterine cancer (i.e., extremely rare under age 45 years, followed by a rapid and progressive rise from ages 45 to 60 years) could also reflect the waning influence of progesterone. Nulliparity, hypertension, diabetes, the absence of smoking, and race may yet be added to the unifying scheme as knowledge of endocrinologic mechanisms in endometrial tissue increases.

Although there are a number of identified risk factors for uterine cancer (Table 1.1), important gaps in knowledge currently limit a full understanding of the proposed carcinogenic process. We need to understand when in a woman's life obesity matters most and how risk is influenced by weight loss; whether the number of adipocytes, their fat composition, or other factors determine peripheral conversion of androstenedione; and the precise hormonal mechanisms associated with vegetarianism. Perhaps the most important gap is in understanding the basic mechanism of estrogen carcinogenesis. It is unclear whether estrogens are complete carcinogens, classic "promoters" that affect initiated cells, or growth stimulants that act on vulnerable genetic material. The epidemiologic data are consistent with estrogens acting at a relatively late stage of carcinogenesis. If this reflects their position as tumor promoters, then the need to identify initiators of the process becomes even more crucial.

OVARIAN CANCER

Demographic Patterns

Ovarian cancer accounts for 3% of all incident cancers in U.S. women (1). Approximately 1 in 70 American women develops ovarian cancer during her lifetime. The average

annual age-adjusted incidence for all SEER areas between 2000 and 2004 was 13.5 per 100,000 women (2). An estimated 21,650 new cases will be diagnosed in the United States in 2008 (1).

Diagnosis usually occurs at advanced stages; the overall 5-year survival between 2000 and 2004 was only 45%. The average annual age-adjusted mortality rate is 8.9 per 100,000 women (2). The estimated 15,520 deaths due to ovarian cancer in 2008 will make it the fifth leading cause of cancer death among U.S. women (1).

After rising during the mid-20th century, age-adjusted mortality rates have since remained relatively constant (1). Incidence rates show little variation over the past 30 years, but both incidence and mortality rates may be declining for U.S. women under age 40 years (136). U.S. blacks and whites have nearly identical mortality rates, but incidence rates remain higher for U.S. white women (137) (Fig. 1.3).

The highest incidence occurs in North American, Scandinavian, and Northern European countries, whereas the lowest rates occur in African nations and some eastern countries, such as China (3). Age-standardized rates vary 4.5-fold across countries. Mortality data show a similar but slightly less dramatic pattern. The estimated age-standardized mortality rates are 6.2 in developed countries and 2.8 in developing countries (138).

Reproductive Risk Factors

Gravidity is consistently associated with a decreased risk of ovarian cancer (139–142). Compared with nulligravidous women, women with a single pregnancy have an RR of 0.6 to 0.8. Each additional pregnancy decreases risk another 10% to 15%. The number of full-term births seems most influential, but several studies have also found decreased risks associated with an increasing number of incomplete pregnancies (143,144). Most studies that adjusted for parity report no residual association with age at first or last birth (145), but some investigators argue that both number of births and timing matter (146,147).

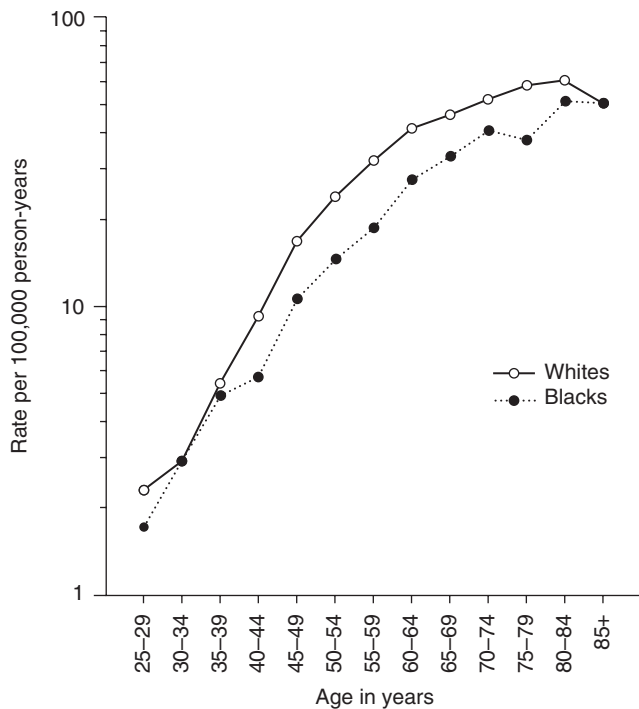

FIGURE 1.3. Age-specific incidence of cancer of the ovary by race. *Source:* Data from the Surveillance, Epidemiology, and End Results Program, 2000–2004.

Whether these risk relationships reflect a hazardous role for infertility or merely the protective role of pregnancy is unclear. Comparing subfertile women with ovarian abnormalities to subfertile women with normal ovarian function has thus far shown no increased risk for the former, but the data are not definitive (148). Studies with higher risks among infertile women support some role for abnormal endocrine factors (149). In one study (139), sexually active women who were not using contraceptives and had not conceived for 10 or more years were at a sixfold excess risk compared with other women. Another large study similarly found a high risk associated with nulliparity despite unprotected intercourse, especially in women with long periods of ovulatory experience (149).

Although several early studies showed substantial increases in ovarian cancer risk linked to use of fertility drugs (142,150), subsequent studies have generally not confirmed an association (151). The prospect that the causes of subfertility and infertility, not the associated treatments, are the causative factors appears to be gaining support (148,151,152).

A number of studies have found a reduced risk of ovarian cancer associated with breast-feeding, although the association has not always been shown to be independent of parity or to relate to risk in a dose-response relation (141,153–157). A recent pooling of two large cohort studies showed significant trends of risk with extended breast-feeding that were independent of parity effects (158). Notably, each month of breast-feeding decreased the relative risk of ovarian cancer by 2%. Suppression of ovulation and decreased gonadotropin levels were proposed as explanatory to the reduced risks, but further studies are needed to confirm this.

Menstrual Factors and Gynecologic Surgery

Numerous studies have noted reduced risks among women who have had a hysterectomy or tubal ligation (139,159–162). These patients' risks were 30% to 40% lower than the risks

among women who had not undergone surgery. Surgery offers an opportunity to remove abnormal-appearing ovaries, but this alone is unlikely to explain the protective effect (163). Partial devascularization and reduced ovarian function represent a possible alternative mechanism (164).

A number of studies have linked late age at natural menopause with an increased risk of ovarian cancer (139,165), although not all studies have confirmed this relationship (166). The marked flattening in the age-specific incidence curves shortly after menopausal ages is consistent with the conclusion that early or late menopause has little effect on ovarian cancer risk. Most studies have not found earlier ages at menarche to increase risk, but some have reported weak positive associations (139,165).

Hormonal Risk Factors

Oral Contraceptives

Almost all epidemiologic studies show a reduced risk of ovarian cancer among women who use oral contraceptives. Their use for only a few months introduces lasting protection, but long-term use generates the largest risk reduction (141,167). In one study, the protective effect of long-term use (≥ 10 years) reached 80% (168). The protection appears to persist for many years after their last use (167–170). The lower-dose formulations now in use seem to reduce risk at least as effectively as their higher dose predecessors (171–174). In addition, the androgenicity of the progestins used does not appear to differentiate risks (175).

Menopausal Hormones

Accumulating evidence links use of menopausal hormones to an increased risk of ovarian cancer (176–182). In most of these studies, risk has been highest among long-term users. Although most of the earlier studies focused on effects of unopposed estrogens, more recent studies have addressed effects of combined estrogen plus progestin therapy. There are inconsistent results regarding how risk is affected by regimen and mode of administration of hormones (177–179,181), which may reflect small numbers involved in many of the analyses. In the WHI clinical trial, women exposed to estrogen plus progestin therapy had a 58% nonsignificantly increased risk of ovarian cancer compared to those receiving a placebo (36). The recently published Million Women Study found no variation in risk according to type of preparation used, its constituents, or mode of administration (176). The study did note a higher risk of serous tumors related to use of exogenous hormones, a finding requiring further replication.

Endogenous Hormones

Recent interest has focused on the role of endogenous hormones in the etiology of ovarian cancer. Although one nested case-control study found higher levels of androgens and lower levels of gonadotropins among cases compared to controls (183), this was not confirmed in a more recent investigation (184). This latter study, however, found some suggestion that free testosterone might play a role in early onset ovarian cancers. Another investigation, which pooled data from three studies, reported null associations with estrogens, androgens, SHBG, IGF-1, and associated binding proteins (IGFBPs) (185,186). Despite these initial null results, the strong biologic rationale for these hormones in ovarian carcinogenesis warrants further investigation.

Medical Conditions and Medications

Several studies surveyed whether certain medical conditions predispose to ovarian cancer. Diabetes, hypertension, and thyroid diseases seem unrelated to risk (102,187). In line with a number of clinical studies showing simultaneous occurrences of endometriosis and ovarian cancer, several epidemiologic studies have found that women with a diagnosis of endometriosis have elevated risks for developing ovarian cancer (152,188,189). In one of these studies, the relationship was shown to be specific to clear cell and endometrioid ovarian cancers (189). As reviewed by Ness (190), the two conditions share a number of pathophysiologic processes, including estrogen excesses and progesterone deficits, immunologic responses, and inflammatory reactions. Pelvic inflammatory disease has also been found in several studies to be a possible risk factor for ovarian cancer (191,192). This finding supports a role for inflammation in ovarian carcinogenesis.

Medications recently surfaced both as potential risk and protective factors. Several studies showed increased risks among users of psychotropic medications, particularly those operating through dopaminergic mechanisms (193). However, subsequent studies that employed cohort designs or improved exposure assessment reported null associations (194–197). Other data suggested a reduced risk among women who used anti-inflammatory or other analgesic medications (198–201). However, as with the psychotropic medication data, subsequent studies showed, at most, a weak or inconsistent association. Chemoprevention via the use of these medications remains a premature concept.

Anthropometry and Physical Activity

Obesity has recently received increased scrutiny as a possible risk factor. Most studies fail to show a generalized effect (202), although some studies have shown possible inverse relationships (203). In those studies that do show positive relationships, it has usually been restricted to certain subgroups, including premenopausal women (204,205), nulliparous women (206), women who never used menopausal estrogens (207), or those who are physically inactive (208). Further, some studies have suggested that obesity is a risk factor only for certain types of tumors. However, the histologic subgroups identified as being increased among obese women have varied across studies (209,210). Further complicating assessment of effects are suggestions that increased risks may be restricted to women who are clinically obese (211) or who became obese when they were teenagers (212). These diverse results regarding the effects of obesity on ovarian cancer risk could reflect statistical chance or other systematic biases.

Studies have also examined effects of physical activity levels on ovarian cancer risk, although results are inconclusive. Case-control studies in China (213), Canada (214), and the United States (215) have reported inverse associations with increasing activity, but the cohort analyses published to date (216,217) suggest that increasing activity might put women at increased, rather than decreased, risk.

Dietary Factors

Correlations between ovarian cancer incidence and per capita fat availability and noted increased incidence rates among migrants who moved to areas with higher per capita fat availability have stimulated interest in dietary risk factors (68). Initial studies in unique populations, such as ovo-lacto-vegetarians (218) or meat abstainers (219), provided conflicting results.

Since then, studies have targeted a few classes of foods: lactose and dairy foods, fats, vitamins, fiber, fruits, and vegetables.

Lactose Consumption

Findings linking higher consumption of yogurt, cottage cheese, and other lactose-rich dairy products with an increased risk of ovarian cancer (220) were viewed with interest given that galactose-related enzymes can influence gonadotropin levels, which are hypothesized to be crucial ovarian cancer risk determinants. The majority of subsequent studies failed to show increases in risk with lactose consumption or galactose metabolism (221–225), although a few studies have provided some support for the hypothesis (226,227). Recent results from the Nurses' Health Study suggest that further attention may be warranted regarding effects for serous tumors (228).

Fat Intake

Although some case-control studies have reported higher risks of ovarian cancer associated with intake of fatty foods (e.g., butter and meats) as well as types of fat, the data on this are not entirely consistent (229–233). In contrast, most cohort studies have failed to find relationships with dietary fat consumption (226,229). The most recent analysis (234), a meta-analysis of 12 cohort studies, found no overall association with fat, cholesterol, or egg intakes, but some suggestion that very high levels of saturated fat intake might increase risk, a finding that merits further investigation.

Fruits, Vegetables, and Micronutrient Intake

Although some studies have suggested that ovarian cancer risk might be reduced by higher consumption of fruits and vegetables (221,226,235) or fiber (236,237), other studies, including a recent pooling project of 12 cohorts, fail to support these relations (238–241). Some studies showed inverse associations with particular vitamins, such as vitamins A, C, E, or beta-carotene (232,242–246), although results have not been consistent across studies. Further clarification of effects may require considering effects according to other risk factors and within histologic subgroups.

Alcohol and Coffee Consumption

A number of studies have examined effects on ovarian cancer risk related to alcohol consumption. Most have not found any convincing relationships (210,247–251), including a recent pooled analysis of ten cohort studies (252). Coffee consumption was linked to an elevated risk of ovarian cancer in early studies (253,254), but more recent studies have not replicated that association (210,248). One study actually suggested an inverse association with coffee consumption, but concluded that this was not due to caffeine intake since no relationship was observed with tea consumption (255).

Host Factors

A family history of ovarian cancer is the strongest risk factor identified to date. Which family member was affected is less important than the total number of affected relatives or their age at diagnosis (256). Women with two or more affected relatives or whose relative was diagnosed before 50 years of age experience the highest risks (257). Approximately 5% to 10% of ovarian cancer patients have a first-degree relative with ovarian cancer (256).

Inherited mutations in two autosomal dominant genes—*BRCA1* and *BRCA2*—are strongly linked to familial ovarian cancer (and breast and other cancers) (258). Whereas the lifetime probability of developing ovarian cancer in most women

is 2%, the probabilities in women with a family history or women with a *BRCA1/2* mutation are 9.4% (259) and 15% to 40% (260,261), respectively. Despite these increases, *BRCA1/2* mutations explain less than one third of the elevated risk in women with familial ovarian cancer (257). Other candidate high-risk genes have not been identified but are almost certain to exist (256).

In addition to assessing the role of high-penetrance genes, studies have begun to evaluate relationships of ovarian cancer risk with the more common genetic polymorphisms, including various genes involved in hormone metabolism. To date, no markers have been conclusively linked with risk increases (262,263).

Talc

Over-the-counter talc chemically resembles asbestos, a known cause of mesothelioma, and mesothelioma histologically resembles ovarian cancer. The published case-control studies generally report positive associations between ovarian cancer and perineal talc exposure. However, a lack of consistent statistical significance and inconsistent associations with different patterns of talc use raise questions about the validity of this association (264–268).

Cigarette Smoking

In general, cigarette smoking is not considered a major risk factor for ovarian cancer. However, a number of studies have found evidence that there may be an increased risk of mucinous tumors associated with smoking. In a recent systematic review, smoking was found to lead to a significant doubling in risk for mucinous tumors, but no increased risk for endometrioid or clear cell tumors (269). The risk of mucinous cancers increased with amount smoked but returned to that of never smokers within 20 to 30 years of stopping smoking. Fewer studies have evaluated effects of passive smoking on ovarian cancer risk, with no consensus as to whether this might alter risk or have histologic specificity (270,271).

Environmental and Occupational Risk Factors

Certain occupations came under scrutiny when studies linked hair dyes and triazine herbicides to ovarian cancer (272,273). Record linkage studies in Finland (274), Norway (275), Sweden (276), Canada (277), and the United States (125,278) have suggested a pattern of increased risks among certain professions (e.g., teachers, health care workers) or with particular occupational exposures (e.g., solvents, asbestos). Until additional data address the potential for inconsistent or chance findings and the challenge of finding large populations with sufficient data on other potential confounding variables, occupation will likely not be considered a major risk factor for ovarian cancer (279).

Conclusions

Much of the clinical and epidemiologic evidence concerning risk factors for ovarian cancer implicates ovulatory activity (Table 1.2). Conditions associated with reduced ovulation, for example, pregnancy and oral contraceptives, consistently reduce risk. Combining these and other menstrual factors into single “ovulatory age” or “lifetime ovulatory cycles” indexes has generally produced the expected associations with ovarian

TABLE 1.2

RISK FACTORS FOR OVARIAN CANCER

Factors influencing risk	Estimated relative risk ^a
Older ages	3
Residency in North America, Northern Europe	2–5
Higher levels of education or income	1.5–2.0
White race	1.5
Nulligravity	2–3
History of infertility	2–5
Early ages at menarche	1.5
Late ages at natural menopause	1.5–2.0
History of a hysterectomy	0.5–0.7
Use of oral contraceptives	0.3–0.5
Long-term use of menopausal estrogens	10–20
Perineal talc exposure	1.5–2.0
Female relative with ovarian cancer	3–4

^aRelative risks depend on the study and referent group employed.

cancer risk; that is, older ovulatory ages (280) or higher cycle counts (281) increase risk. However, the misclassification inherent in these indexes is sufficient to generate different risk estimates (282), and the magnitude of risk reduction for short-term oral contraceptive use or a single pregnancy exceeds the proportional decrease in ovulatory cycles that would be expected to be associated with these exposures.

The putative mechanisms behind ovulatory inhibition and the risk associated with “increased ovulation” (283) raise additional questions. An early report suggested, based on the associations with parity and infertility, that an unidentified endocrine abnormality predisposed women to relative or absolute infertility and ovarian cancer. The protection associated with oral contraceptives seems unlikely to fit this hypothesis unless, in some improbable manner, use induces an endocrine milieu similar to that underlying fertility.

A second popular unifying hypothesis is that ovarian cancer is the result of accumulated exposure to circulating pituitary gonadotropins (284). Although this is consistent with the parity, menopause, and oral contraceptive associations, a study that directly measured gonadotropin levels failed to find a relationship with subsequent development of ovarian cancer (183). This theory also fails to account for the risks associated with clinical infertility, and it predicts that menopausal hormone therapy use would decrease risk, because both exposures are associated with reduced gonadotropin levels.

A third explanation points to a biologic effect of ovulation on ovarian surface epithelium. Ovulation prompts a cascade of epithelial events, including minor trauma, increased local concentrations of estrogen-rich follicular fluid, and increased epithelial proliferation. Such proliferation, particularly near the point of ovulation, can recruit inclusions into the ovarian parenchyma. Some or all of these “incessant ovulation” events may lie on the causal path to ovarian cancer (285,286). This is consistent with most of the endocrine-related risk factors except for the risks associated with clinical infertility.

No single theory adequately incorporates the available data. A unifying hypothesis may lie in a combination of ovulation, hormones, and local effects. Additional factors, such as genetic alterations; androgens, progestogens, and other hormones

(283); inflammation (191); and endometriosis (190), also appear to be important.

Each hypothesis identifies testable possibilities. Discriminating between the roles of voluntary versus involuntary infertility could identify the mechanisms underlying the role of parity. Characterizing the specific reproductive abnormalities associated with clinical infertility could reveal new biologic mechanisms involved in ovarian carcinogenesis. Determining why hysterectomy and tubal ligation reduce risk could generate insights into the role of gynecologic conditions and ovarian carcinogenesis. Exploring the interactive contributions of the hormones along the hypothalamic-pituitary-gonadal axis could explain how specific hormones seem to influence risk at different time periods. In addition, verifying that inflammation or related conditions and pathways play an etiologic role in ovarian carcinogenesis could open new lines of inquiry.

Ovarian cancer epidemiology presents both simple and complex patterns. Rates have largely remain unchanged over the last 40 years, and virtually all studies show consistent associations with some exposures, such as oral contraceptives, parity, and family history. But where some uncertainty exists, it is substantial. Other reproductive or lifestyle factors that are consistently associated with other reproductive cancers—smoking, obesity, menopausal hormone therapy—have been published with such diversity that traditional attempts to quantitatively summarize the divergent data likely will not prove to be useful. Although it is tempting to attribute the differences to histology-specific associations, such hypotheses will require substantially more epidemiologic, clinical, genetic, and transitional data before their acceptance is certain. Careful a priori attempts to systematically assess the mechanisms of histologic differences may yet prove fruitful.

So where can epidemiology contribute to increasing the opportunities to reduce ovarian cancer's toll? The highly penetrant genes account for only a small proportion (10%) of women who develop ovarian cancer, but a better understanding of the mechanisms behind those risks could introduce immediate benefits for high-risk women. Continued close collaboration between geneticists and epidemiologists should pay dividends. A clear picture has emerged for some protective factors, such as oral contraceptives and parity, but risk associated with other important public health issues, such as smoking, obesity, and physical activity, remains uncertain. Continued attempts to account for the differences between studies should help delineate the spurious associations from the etiologically relevant risk factors. Doing so should help identify targets for improving detection, treatment, and prevention of this deadly tumor.

CERVICAL CANCER

It is now known that virtually all cases of cervical cancer and precancerous changes can be attributed to persistent infection with carcinogenic genotypes of human papillomaviruses (HPV) (287). Cervical cancer has a remarkably uniform etiology and pathogenesis worldwide. Consequently, the last two decades have witnessed the transformation of human HPV epidemiology from a narrow field of research to essential knowledge for gynecologists. Of the more than 100 genotypes of HPV, several dozen can infect the anogenital epithelium and approximately 15 to 20 (including types 16, 18, 26, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 66, 68, 73, 82) can cause anogenital cancer, although the types differ greatly in carcinogenic risk (287). HPV-16 is by far the most carcinogenic type, and accounts for half of cervical cancer cases. However, cervical infection with carcinogenic types of HPV, even HPV-16, is extremely common compared to the relatively rare development of cervical cancer. Thus, additional etiologic factors are involved, in particular, variability in the human host immunologic response. Other possible causal cofactors might act by affecting immunity or via genotoxic mechanisms. These include smoking, high parity, oral contraceptive use, and coinfection with other infectious agents (287, 288).

Key Aspects of HPV Natural History Related to Cervical Cancer Epidemiology

It is possible to define new prevention strategies using HPV-based technologies that are even more effective than cervical cytologic screening and colposcopy. These topics, including the pathogenesis, diagnosis, and prevention of cervical cancer precursors, are detailed by Wright in Chapter 19. Although the current chapter concentrates mainly on the descriptive epidemiology of invasive cervical cancer, and broad relationships with major demographic and behavioral risk factors, the epidemiology of cervical cancer is most coherently understood in terms of the effects that factors exert on the natural history of HPV infection, including (a) exposure/acquisition of infection, (b) persistence of HPV infection and progression to precancer (cervical intraepithelial neoplasia 3 [CIN 3]), and (c) development of invasion (Fig. 1.4) (289).

Cervical HPV transmission, which is primarily sexual, is studied best at the molecular level, because types must be distinguished for natural history studies and because most infections (more than two thirds) are not microscopically or

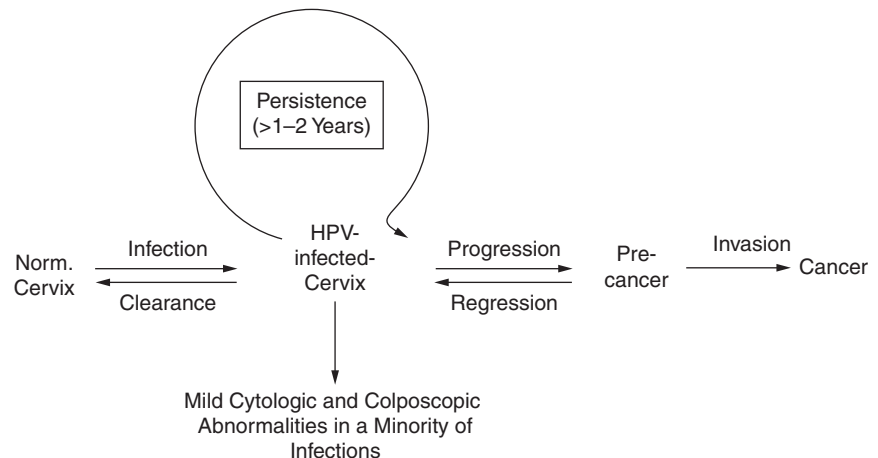

FIGURE 1.4. An epidemiologic model of the natural history of cervical carcinogenesis. The major steps in cervical carcinogenesis are human papillomavirus (HPV) infection (balanced by viral clearance), progression to precancer (partly offset by regression of precancer), and invasion. The persistence of oncogenic HPV types is necessary for progression and invasion. HPV infection is frequently, but not necessarily, associated with cytologic and histologic abnormalities. *Source:* From Schiffman M, Kjaer SK. Natural history of anogenital papillomavirus infection and neoplasia. *J Natl Cancer Inst Monogr* 2003;(31):14–19, with permission.

macroscopically evident (290). Each HPV type is a separate genetic entity and should be considered a separate sexually transmitted infection. Because all carcinogenic types are transmitted by the same sexual route, concurrent multiple-type infections are common. The available data, which are limited, seem to indicate that HPV types influence each other minimally (291, 292). The typical age of cervical HPV infection is similar to other sexually transmitted infections, with a large peak following sexual initiation.

Cervical HPV infections tend to clear after 6 to 24 months, as do warts anywhere on the body (291,293,294). Acquisition (293–296) and clearance dynamically oppose each other in each cohort of women to produce the characteristic age distributions as infections are transmitted sexually when women have new partners and are then cleared (297).

The immune response to HPV is an important determinant of viral clearance versus persistence and, by extension, a major determinant of cervical cancer risk. The key immune responses involved in the clearance of HPV infections are known to be cell mediated, but the specific immunological markers of immune protection are difficult to measure and poorly understood.

A major unresolved question of HPV natural history relates to viral latency. In follow-up studies lasting up to 10 years, virtually all HPV infections become nondetectable by sensitive HPV DNA tests, usually within 2 years, except for those that lead to precancer. Little else is known about latency, including what might cause re-emergence like that seen in renal transplant patients and HIV-immunosuppressed women, and what fraction of cancers (apparently small) arises following a period of latency. Answers to these questions will greatly affect prevention strategies reliant on HPV DNA detection.

It is the *overt persistence* of one of the carcinogenic types that is strongly linked to precancer, which histologically corresponds to CIN 3, including carcinoma in situ (298–302). Persistence of carcinogenic types of HPV and development of precancer are not identical, but thus far they are so closely linked that epidemiologists are only beginning to disentangle them. Part of the problem is that precancers begin as extremely small clonal lesions that may be below the limits of detection of microscopy. HPV type greatly affects both the absolute risk of viral persistence, and of progression to precancer associated with viral persistence (295,296,303). The most common carcinogenic type, HPV-16, is also the most common type in the general population, linked to its greater propensity to persist. However, even noncarcinogenic types like HPV-61 can also be persistent and common, although they do not cause malignant transformation (304).

The average time of viral persistence that leads to diagnosable precancer is not clear. Virgins who begin sexual activity can develop apparent precancers within a few years of initial HPV infection as detected by DNA. This short time period represents the leading edge of what is typically a longer incidence curve of precancer in persistently HPV infected women. The average age at microscopic diagnosis of precancer is approximately 25 to 30 years (305), approximately 5 to 10 years after the average peak ages of carcinogenic HPV prevalence and associated minor cytologic abnormalities in screening populations.

Noncarcinogenic HPV infections are capable of producing lesions falsely diagnosed as precancer, especially CIN2, showing that this level of abnormality is not a perfect surrogate for cancer risk (306). Still, because of the U.S. emphasis on safety and concern over loss to follow-up, treating precancer (except as appropriate in very young women, etc.) is a valid clinical strategy to provide a margin of safety, given that it is not yet possible to know which lesions pose a threat. Eventually, better accuracy based on molecular profiling is the goal.

Precancerous lesions (CIN 3, in particular) tend not to regress over short-term follow-up; however, even among precancerous lesions, risk and timing of invasion versus eventual regression are matters of probability. The absolute risk of untreated precancer developing into invasive disease is argued, with estimates averaging about 30% but ranging from 10% to 90%.

The high ratio of precancerous lesions to cancers supports the belief that many cases of precancer, particularly CIN2, would not invade but rather would regress if followed for many years. In any case, the epidemiologic risk factors for invasive cervical cancer among HPV-infected women are the same as mentioned above for precancer, except for age. Screened detected cases of invasive cancer, on average, occur approximately 15 to 20 years or more later than for precancer, suggesting a long sojourn time in the precancerous state. The median age moves toward even older ages as the quality of screening decreases, and the average stage of cancer at diagnosis also worsens due to this diagnostic delay.

Demographic Patterns

Cervical cancer is the second most common cancer of women worldwide, with 471,000 incident cases estimated in 2000 (307), and a 5-year prevalence of more than 1.4 million cases. Cervical cancer accounted for approximately 233,000 deaths worldwide in the year 2000, or about one tenth of the total number of female cancer deaths (307). The cancer burden (incidence and mortality) is disproportionately high (~80%) in the developing world.

The incidence rate per 100,000 women-years for invasive cervical cancer in various geographic areas is highly variable, linked to HPV infection and screening practices (287). The highest age-standardized rates, more than five times the rates in the United States and Canada, were reported from East Africa, Central America, and the Pacific Islands. Comparing regions without extensive effective screening, geographic studies using sensitive polymerase chain reaction (PCR) DNA testing methods to detect the carcinogenic HPV types have observed HPV prevalence rates to correlate with the population risks of cervical cancer.

An examination of age-specific cervical cancer incidence in countries prior to introduction of screening has demonstrated that rates begin to increase around age 25 (when cases are still quite rare), with an unusually early plateau or peak starting at age 40 to 50 (308). It is unusual for incidence rates of a cancer to plateau or fall with increasing age, and this age structure reflects that cervical cancers originate from HPV infections transmitted mainly in late adolescence and early adulthood.

It is estimated that 11,070 women will be diagnosed with and 3,870 will die from cervical cancer during 2008 in the United States (1). The corresponding average annual age-adjusted incidence for invasive cervical cancer in all SEER areas was 8.7 per 100,000 women for the period 2000 to 2004 (2). Previously striking regional differences in incidence, with excesses particularly in Appalachia, are now less visible, although high-incidence areas such as the Mexican-U.S. border still exist.

Cervical cancer rates began to fall during the early 20th century, before the advent of cytologic screening. Reduced parity may have contributed to this pattern, given that multiparity appears to be a cofactor for progression of HPV infection to cervical neoplasia. In the latter half of the last century, effective screening contributed to a further reduction in cancer incidence and mortality, particularly among women of 30 to 74 years because of targeting of this age group in many countries (309,310).

In the United States and many other developed nations, rates of squamous cell carcinomas, accounting for approximately

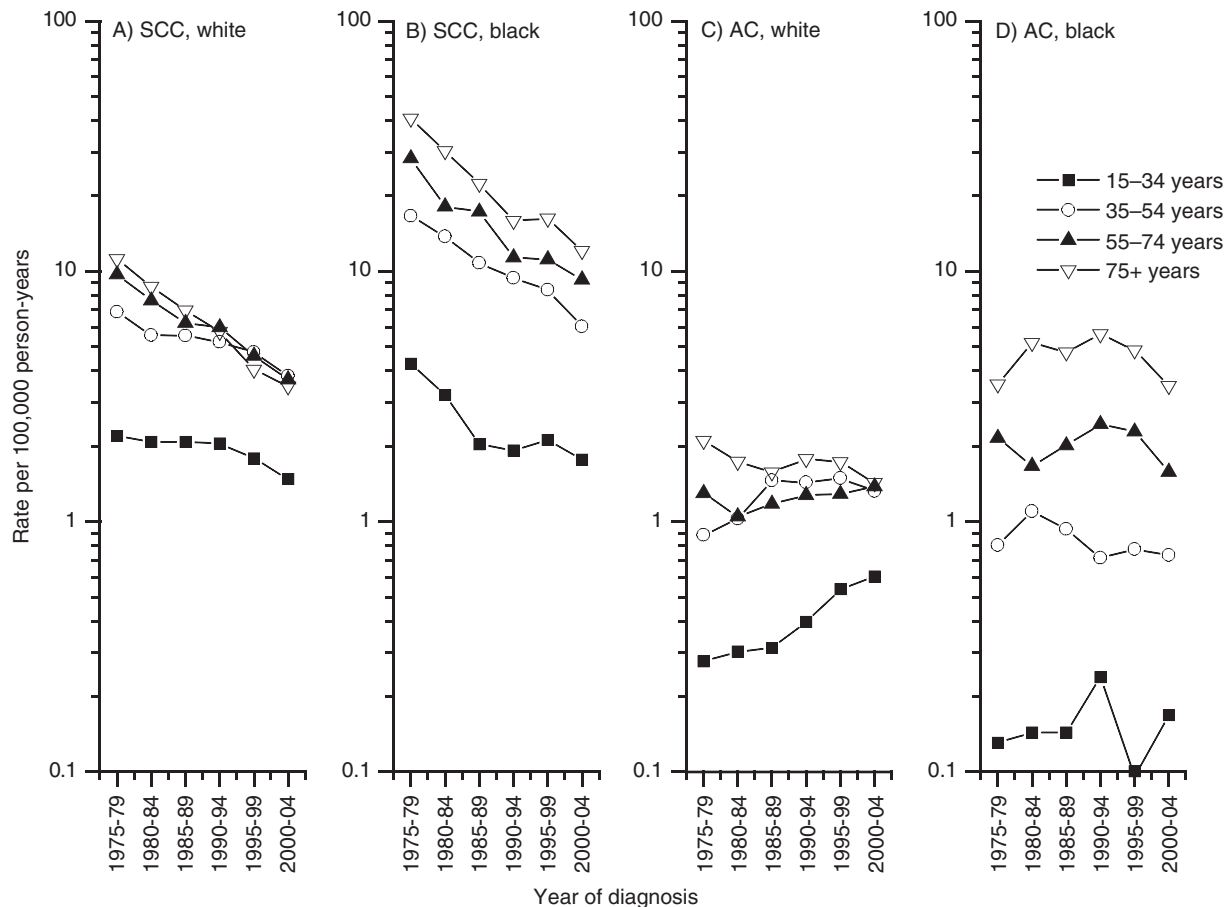

FIGURE 1.5. Incidence trends for cervical squamous cell carcinoma and adenocarcinoma by race. *Source:* Data from the Surveillance, Epidemiology, and End Results Program, 1976–1995, and from Wang SS, Sherman ME, Hildesheim A, Lacey JV, Devesa S. Cervical adenocarcinoma and squamous cell carcinoma incidence trends among white women and black women in the United States for 1976–2000. *Cancer* 2004;100;(5):1035–1044, with permission.

80% of invasive cervical cancers (310), have declined steadily since the introduction of Pap smear screening, while adenocarcinomas (accounting for approximately 15%) have not (311–318). In fact, rates of cervical adenocarcinomas have risen in the past two to three decades in various countries including the United States, both relative to rates of squamous cell carcinoma and in absolute numbers (Fig. 1.5).

The overall incidence and stage of invasive squamous cell cancer has declined substantially over the past 25 years, with the pace of decline having been more pronounced in black than white women (Fig. 1.6). Although rates for invasive carcinoma remain higher for blacks than whites, the difference has narrowed over time, with major differences now being observed only among older women.

The 5-year survival rate for cervical cancer is greater than 70%, with survival being highly dependent on stage at diagnosis. Younger women and white women are more likely than older women and black women, respectively, to be diagnosed with localized cancer that carries a good prognosis.

HPV Infection

For more than a century, epidemiologic studies have suggested an association between sexual activity and cervical cancer, but proof that HPV is the sexually transmitted agent responsible

for this association was not achieved until sensitive methods for detecting HPV DNA were developed. The epidemiologic association between HPV infection and cervical cancer fulfills all of the established epidemiologic criteria for causality. As a result, HPV is now accepted to be the central, necessary causal factor for virtually all cases of cervical cancer in the world. The recognition of the key etiologic role of HPV infection has profoundly altered the epidemiologic study of cervical cancer. It is increasingly clear which previously “established” epidemiologic risk factors for cervical cancer are correlates of HPV infection, which lead to infection, and which are HPV cofactors operating only in the presence of infection (319, 320). For example, because HPV is transmitted by direct physical contact, virgins (women without any sexual contact at all) almost invariably test negative for HPV (321,322) explaining their virtually negligible risk of cervical cancer regardless of other behaviors.

Numerous case-control and cohort studies have now shown that sexual behavior, specifically numbers of partners, is the main determinant of incident HPV detection and subsequent risk of cervical precancer and cancer (323–326). HPV infections are easily transmitted with few acts of sexual intercourse and, therefore, sexual frequency is not a major risk factor for cervical neoplasia. The variable “age at first intercourse” tends to weaken as a risk factor once HPV infection is taken into account (325,327) and remains an

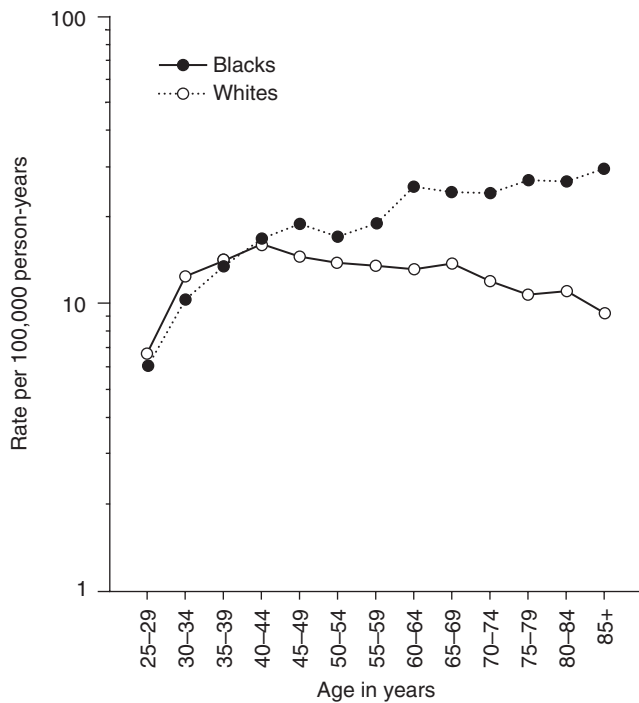

FIGURE 1.6. Age-specific incidence of invasive cancer of the cervix uteri by race. *Source:* Data from the Surveillance, Epidemiology, and End Results Program, 2000–2004.

apparent proxy for time of HPV infection (328), i.e., the start of viral “latency” (327).

A protective effect against cervical cancer risk has been noted for careful, consistent condom use. Condom use affords modest protection against HPV infection and resultant external warts (HPV-6 and HPV-11) and cervical lesions caused by carcinogenic HPV types (329). Given that users of condoms may not report sporadic unprotected contacts, and that the entire skin and mucosal genital area at risk for infection is not protected with this contraceptive method, only modest protection against transmission would be expected (330).

Historically, and still in many regions of the world, female monogamy has been valued more than male monogamy. Thus, cervical cancer risk from HPV infection transmitted from a male partner to his monogamous partner can properly be seen as “the male factor.” Confirmed associations supporting this view include the geographic clustering of cervical and penile cancer, the increased risk of cervical cancer among wives of men who have penile cancer, the increased risk among partners of men who have had a previous partner who died of cervical cancer, and the increased risk among women whose partners travel (331). Circumcision is associated with a reduced risk of HPV detection in penile samples, and the wives of men with a history of multiple partners were at lower risk of cervical cancer if the men had been circumcised (331). Circumcision appears to reduce male HPV infection, but studies to understand details of HPV transmission between sexual partners have proved challenging. Contact between women and multiple partners at different times, clearance of infection in one partner but not the other, and difficulties in collecting satisfactory specimens for HPV testing from men all complicate the demonstration of concordant infection among partners (332).

Transient HPV infections are ubiquitous among sexually active young women, but progression to a cervical cancer precursor requires persistence of carcinogenic types (296,299,300,333,334). This has prompted epidemiologic studies to

investigate “cofactors” that influence persistence and progression to precancer. Persistence and progression to CIN 3 occur concurrently, complicating the independent examination of these two processes.

Viral Factors Associated with Persistence and Progression

HPV type is by far the strongest predictor of risk of precancer (see Wright, chapter 19). Persistent HPV-16 infection is an extremely strong risk factor for subsequent diagnosis of CIN 3 and invasive cancer. HPV types, are more predictive of risk than subtleties of minor and equivocal cytopathic effects, colposcopic findings, or behavioral cofactors like smoking. However the existence of many HPV types prevents easy-to-follow clinical protocols. Furthermore, intratypic sequence variants of HPV-16 and possibly other types have been associated with altered risk, although these risk modifications are weaker than the intertypic variation. The role of elevated viral load (i.e., HPV content in samples obtained from infected women) in predicting persistence and progression of infection is complicated and varies by HPV type. A clear trend of increasing prospective risk with increasing viral load has been demonstrated only for HPV-16. Viral load assessment is not useful clinically. Although studies suggest that women with prevalent infections may be more likely to acquire additional infections, infection with one HPV type does not seem to influence the risk of persistence and development of precancer from another concurrent infection (291,335). Finally, while the state of the virus (integrated into human host DNA vs. episomal), methylation status, and transcript levels for the oncogenes E6 and E7 may be associated with risk of persistence and subsequent neoplasia, clinically useful assays and protocols are not yet available.

Host Factors Associated with Persistence and Progression

Immunity

Whereas humoral (antibody-mediated) immunity appears to play a central role in preventing HPV infection (leading to the prophylactic vaccines), elimination of HPV seems more closely related to mounting an effective cellular immune response (336–338). Impaired cellular immunity, attributable to human immunodeficiency virus (HIV) infection, transplantation, or immunosuppressive drugs, has been shown to increase HPV prevalence, persistence, warts, CIN, and cancer (339,340). In contrast, deficiencies in humoral immunity appear unrelated to these conditions. The U.S. Centers for Disease Control and Prevention (CDC) has identified cervical cancer as an acquired immune deficiency syndrome (AIDS)-defining illness among women infected with HIV. Compared to the general population, women with AIDS have a fivefold excess risk of carcinoma in situ of the cervix, with risk increasing over time (341). Although risk was similarly elevated for invasive cancers, rates did not increase over time, suggesting that HIV infection probably has a limited impact on the transition from in situ to invasive disease. Although highly active antiretroviral therapy (HAART) improves CD4 levels, this has not been associated with regression of cervical cancer precursors (339).

Human Leukocyte Antigens

Human leukocyte antigens (HLAs) are important determinants of the efficiency of antigen presentation to immune effector cells and, therefore, may influence the outcome of HPV infections. Both class I HLA genes (those that encode

HLA molecules that are present in all nucleated cells) and class II HLA genes (those that encode HLA molecules that are present in lymphocytes and other immune-related cells) are involved in immune presentation. To date, HLA class II genes have been more extensively studied than HLA class I genes for their association with cervical cancer. A protective association with HLA DRB1*13 and/or DQB1*603 has been found consistently among studies, whereas specific HLA class II markers of increased risk have not been identified. Data for risk associations with polymorphic variants of HLA class I antigens are sparse; a protective association with HLA C*0202 was reported in an analysis combining data from three diverse populations (342). Since the C*0202 allele is involved not only in acquired immune response to viruses (i.e., the antigen-specific, memory immune responses associated with T cells of the immune system) but also in the innate immune response to foreign pathogens (i.e., nonspecific, inflammatory immune responses), this finding has prompted the speculation that not only the HPV-type specific T-cell mediated immune responses but also nonspecific innate immune responses might be important in the immune response to HPV infections and in cervical cancer pathogenesis. Results regarding other genes involved in the immune response are still inconclusive.

Familial Factors

Whatever the mechanism, studies conducted largely in Scandinavian countries with established nationwide tumor, twin, and other family registries clearly indicate that cervical cancer aggregates in families (343–349). In general, an approximate twofold increase in risk of precancer or invasive cervical cancer relative to general population risk is observed in family members of cervical cancer patients. It is not settled how much of this elevation in risk among relatives of individuals affected with cervical cancer can be attributed to shared environment versus genetic effects (343,347).

Behavioral Factors Associated with Persistence and Progression

Socioeconomic Status

Internationally, women defined as low social class were found in a recent meta-analysis to have twice the risk of cervical cancer compared to women defined as belonging to a high social class (350). In the United States, the inverse relationships of risk with income and education prevail among both whites and blacks, and among HPV-infected women (351). In one analysis, when adjustment was made for socioeconomic variables, the relative risk of cervical cancer among blacks compared to whites was substantially reduced (352). On the other hand, controlling for race or ethnicity, or exposure to HPV infection does not account for the socioeconomic status (SES) association entirely (351). The correlates of low socioeconomic level that are HPV cofactors for cervical cancer are not known. Of note, another socioeconomic variable formerly linked to cervical cancer risk, religion, has not been reassessed in studies incorporating accurate HPV testing.

Cigarette Smoking

Case-control and cohort studies among groups of women infected with carcinogenic HPV have shown that smokers are at increased risk compared with infected women who do not smoke (288,327,353–355). Current smoking is the main risk factor, not past smoking, with no clear trend with time since stopping smoking. Among current smokers, evidence of increasing risk has been found with increasing intensity and

duration (or early start) of smoking. Several investigations have attempted to define possible mechanisms by which smoking might alter cervical epithelium. Tobacco-derived carcinogens are secreted into the cervix at levels higher than in serum (356–359), suggesting possible genotoxicity. The immunosuppressive effects of smoking (360) might enhance the persistence of HPV infection (361). In a randomized clinical trial, quitting smoking was associated with increased regression rates of microscopically identified HPV infections, possibly due to an effect on cell-mediated immunity (362).

Parity and Other Obstetrical and Gynecologic Events

HPV-infected women who have many live births are at increased risk of cervical cancer and precancer. There is a dose-dependent increase in risk with numbers of live births, most evident among women with many live births (288,363–367). Although this epidemiologic association is firmly established, the explanatory mechanism is not clear. Mechanisms underlying the association between parity and cervical neoplasia include trauma during parturition, hormonal changes associated with pregnancy, immunosuppression, and possibly altered anatomy of the transformation zone, specifically eversion. Other menstrual and reproductive factors, including miscarriages, abortions, stillbirths, ectopic pregnancies, cesarean sections, age at first pregnancy, age at menarche, and age at menopause, are not independently associated with risk (365,368).

Oral Contraceptives

Studies examining the relationship of oral contraceptive use to cervical cancer risk among HPV infected women are especially complex, with questions arising about the potential for confounding, particularly by the duration of HPV infection and screening behavior (288,369–373). Use of oral contraceptives could plausibly potentiate the carcinogenicity of HPV infection, because transcriptional regulatory regions of HPV DNA contain hormone-recognition elements and transformation of cells in vitro with viral DNA is enhanced by hormones (374). A recent large multi-center case-control study and meta-analysis found an elevated risk of invasive cervical cancer among HPV-positive women who used oral contraceptives for more than 10 years (288, 373). Shorter durations of use were not associated with elevated risk. There is not yet prospective confirmation of the risk of precancer among HPV-infected women taking oral contraceptives. Evidence linking oral contraceptives to cervical abnormalities has raised concern about long-acting steroid preparations, notably depot-medroxyprogesterone acetate (DMPA). Although these agents are widely used in many countries, studies evaluating their effects, particularly among HPV-infected women, are limited (328,375).

In sum, Bosch et al. (376) concluded that HPV infection associated with one or more leading candidate cofactors (pregnancy, smoking, and oral contraceptive use) might account for about 75% of cervical cancer. This interesting analysis has not been replicated sufficiently; thus, the search for other cofactors continues.

Infectious Agents Other than HPV

In the 1970s, herpes simplex virus (HSV-2) was hypothesized to be the sexually transmitted cause of cervical cancer (377). Now, HPV infection is known to be the central, necessary cause of cervical cancer, but other sexually transmitted agents could increase the risk of cervical cancer among HPV-infected women. Of the other agents examined, there is still some interest in HSV-2, but most attention now is focused on *Chlamydia trachomatis*. Although residual confounding by some aspect of HPV infection has not been completely ruled out, despite adjusting for HPV exposure using DNA tests and/or serology, *C. trachomatis*

seropositive women are sometimes observed to be at increased risk compared to seronegative women (377–380). No consistent association with cervical cancer risk has been observed for other sexually transmitted agents (except for HIV, related to immunosuppression). It is interesting that the mildly immunosuppressive retrovirus HTLV-1 has not been linked to an increased risk of precancer and cancer among HPV-infected women (381). One investigation (382) but not another (383) noted a rise in risk of cervical cancer with multiple, concurrent infections, consistent with the hypothesis and some epidemiologic evidence (384) that long-term cervicovaginal inflammation (dominated by neutrophils), regardless of causal agent, might increase the carcinogenicity of HPV infection.

Nutrients

The influence of nutrient status on risk of cervical neoplasia has received substantial research attention (385,386). Although epidemiologists continue to suspect that diet, e.g., antioxidant micronutrient intake, is important in cervical carcinogenesis, no firm associations between a specific aspect of nutritional status and HPV infection or cervical cancer risk has been established or completely discarded, perhaps due to methodologic difficulties. Low folate levels or high homocysteine levels have been linked to risk of cervical cancer, leading to interest in markers of one-carbon metabolism and DNA repair (384,387). Unfortunately, seven phase 3 chemoprevention trials giving folic acid or beta-carotene failed to significantly ameliorate HPV lesions and precancers, although topical administration of retinoic acid did lead to lesion regression, similar to its therapeutic utility on facial warts (384).

Risk Factors for Cervical Adenocarcinoma

While infection with a carcinogenic HPV is a necessary cause of both squamous cell carcinomas and adenocarcinomas, the distribution of carcinogenic HPV types and variants detected in these two tumor types vary, with HPV-18 accounting for a relatively higher percentage of adenocarcinomas as compared to squamous cell carcinomas (388).

Interpreting increasing rates of cervical adenocarcinomas over time poses challenges because of gradual improvements in clinical practices (including the use of devices to obtain better endocervical sampling), stricter criteria for adequate Pap tests, development of cytologic criteria for recognizing adenocarcinoma in situ (AIS), and recently, formal inclusion of the AIS category in the new Bethesda System (314,315,389). In addition, proposed but unsubstantiated explanations for these upward trends include increased rates of HPV infection without improved cytologic detection of AIS, a specific increase in rates of HPV-18 infection, and increased exposure to HPV cofactors specific to adenocarcinoma.

Although our understanding of the etiology of cervical adenocarcinoma is incomplete, a picture is emerging in which adenocarcinoma seems to share some risk factors with cervical squamous carcinomas (acquisition of HPV through sexual contact) and others with uterine carcinoma (a tumor etiologically related to hormones). Two strongly linked factors for squamous carcinoma, parity and smoking, have not been shown to increase the risk for adenocarcinoma (390–392); in fact, there is some evidence that both factors might be associated with decreases in risk. In contrast, increased weight (or related measures) appears to be related to increases in the risk of cervical adenocarcinomas (391,393,394). Oral contraceptives have been linked to an increased risk for AIS or adenocarcinoma in a number of studies (391,395–398). The increased risk of cervical adenocarcinoma associated with obesity and reduced risk with parity and smoking resemble

the epidemiology of endometrial adenocarcinoma. However, the relationship between cervical adenocarcinoma and oral contraceptives is more similar to reported results for squamous carcinomas of the cervix. The association between estrogen replacement therapy and increased risk for adenocarcinoma has been inconsistent (399,400).

Conclusions

Knowledge of the epidemiology of HPV and its causal role in cervical carcinogenesis has been successfully translated into clinical practice (401–405), particularly to reduce rates of squamous lesions. In many developed countries, women with equivocal cytology are tested for HPV DNA; a negative result provides strong reassurance that immediate follow-up is not required and can reduce patient anxiety and health costs (406). Comparison of HPV test results with cytologic interpretations provides important quality assurance for both tests (407,408). Repeated HPV testing is also finding application in following women without intervention and in determining the risk of recurrence among those treated for CIN. HPV testing as an adjunct to primary screening has been adopted in the United States, and screening studies are under way to develop new optimized approaches that focus resources on at-risk women (409). Finally, encouraging early results from vaccine trials suggest that primary prevention of HPV infection may be possible, potentially allowing eradication of cervical cancer in even the poorest nations of the world (410,411). Following these accomplishments, the epidemiologic study of HPV and cervical cancer will continue in order to target public health strategies, improve patient management, and monitor success in prevention.

VULVAR CANCER

Demographic Patterns and the Importance of Pathologic Classifications

Carcinoma of the vulva is a rare genital neoplasm with an average annual age-adjusted incidence in all SEER areas during 2000 to 2004 of 2.2 per 100,000 women (2). During 2008, an estimated 3,460 women will develop the disease and 870 will die as a consequence of it.

Vulvar cancer is etiologically heterogeneous, and pathologic subtypes have distinct epidemiologic features. The great majority of cases are squamous, but two subclassifications of squamous cancers, basaloid and warty, are more linked to HPV than keratinizing squamous tumors (412). Most vulvar intraepithelial neoplasias, similar to CIN, show risk factors that resemble basaloid and warty carcinomas. The HPV-associated subtypes are associated with younger age and black race (413). The non-HPV-associated types are associated with chronic inflammatory states such as lichen sclerosus.

Because vulvar cancer is heterogeneous, and because epidemiologic data usually do not separate the subtypes, compiled summary data must be interpreted very cautiously. Although vulvar cancer has been noted in clinical series to occur frequently among blacks, recent incidence data do not support any substantial differences in *overall* incidence by race (2.3 per 100,000 for white women and 1.9 per 100,000 for black women). Although the disease occurs primarily among older women (a mixture of HPV- and non-HPV-related pathologies), recent analyses of SEER data indicate substantial increases in the incidence of in situ vulvar carcinomas (mainly HPV related), which generally occur at much younger ages than invasive diseases (414).

Cancer of the vulva occurs significantly more frequently among women with primary cancers of the cervix, and the two diseases often occur simultaneously (415,416). Approximately 15% to 20% of women with vulvar cancer have a second primary cancer occurring simultaneously or nonsimultaneously in the cervix, vagina, or anogenital area. As many as 10% to 15% of women with cancer of the vulva have a second primary lesion of the cervix. This association probably reflects multifocal HPV infection. When multiple primaries are not diagnosed simultaneously, cancer of the cervix usually precedes cancer of the vulva. Many patients with vulvar cancer have multifocal genital lesions, commonly including a mixture of condyloma acuminatum planum and intraepithelial neoplasia. They may also have similar changes at other anogenital sites, including the vagina, cervix, and perianal region (417).

SEER incidence data indicate nearly a doubling in the rate of vulvar cancer between 1973 and 1976 and between 1985 and 1987 (418). This is in contrast to rates of invasive squamous cell carcinomas, which have remained relatively stable. Given that *in situ* cancers develop on average significantly earlier than invasive vulvar cancers, it may be that changes in certain risk factors (e.g., increased sexual activity and HPV infection) may have been too recent in order for effects to be seen for invasive cancers. Alternatively, successful treatment of *in situ* tumors may have prevented the occurrence of invasive disease. Again, the most likely explanation for the patterns observed is etiologic differences, with HPV being important for a larger proportion of *in situ* cancers (412).

HPV and Smoking

Early case-control studies reported higher risks among women reporting multiple sexual partners (419,420). Subsequent studies postulated a role for HPV in the etiology of the tumors, finding high rates of detection of the virus in vulvar tumor tissue and high subsequent disease risks among patients with seropositive tests to HPV-16 (421–423). HPV-16 appears to be the most predominant type detected among vulvar cancer patients (376).

Findings of elevated risks of vulvar cancer associated with cigarette smoking (419,423–425) have prompted several studies to examine interactions with HPV infection status. Two studies have found particularly high risks associated with HPV seropositivity among cigarette smokers, suggesting that the effect of HPV may depend on smoking as a cofactor (422,423).

Social Class

Although the incidence of vulvar cancer has been discussed in relation to social class, results from one case-control study indicated that control for sexual factors eliminated this effect (419). Suggestions that the risk of vulvar cancer is elevated among nulliparous women and those with late ages at first birth were also not confirmed in this study.

Medical Conditions

Vulvar carcinomas often arise within genital warts, but more specific temporal associations between the two remain unclear. Several studies have suggested that a history of vulvar warts is associated with an elevated risk of vulvar cancer, with RRs ranging from 15 to 23 (419,426). In one study, a particularly high risk was associated with multiple episodes of genital warts, possibly reflecting poor immunologic response to HPV infection among these women (419). However, the HPV types that

cause vulvar warts, HPV-6 and HPV-11, are not genetically close to the major types in vulvar cancers and preceding vulvar intra-epithelial neoplasia (predominantly HPV-16), so the exact relationship between warts and cancer is somewhat obscure.

Several clinical studies have suggested that vulvar cancer may be elevated among women with diabetes, obesity, or hypertension, but this has not been confirmed in the one epidemiologic study assessing these factors (419). An excess risk of vulvar cancer among users of oral contraceptives was found in one study but not in another (419,425).

Host Factors

Recent attention has focused on the possible etiologic role of genetic factors. Although it has been hypothesized that some carcinogen-metabolizing genes might be involved, particularly those involved in the metabolism of cigarette smoke, studies have failed to find relationships of risk with either glutathione S-transferase (GST) or debrisoquine 4-hydroxylase (CYP2D6) genetic polymorphisms (427,428).

Conclusions

The cervix and vulva are covered by squamous-cell epithelium with a common embryologic origin from the cloacogenic membrane. These similarities have led to the theory that the entire lower genital tract responds to various carcinogens as a single tissue field, resulting in a relatively high proportion of multicentric squamous carcinomas (429). The multicentric nature of the disease; its association with cervical, vaginal, and perianal malignancies; and several risk factors common to it and cervical cancer suggest that the etiologic mechanisms for a fraction of vulvar cancer and cervical cancer may be similar, linked to HPV infection.

VAGINAL CANCER

Demographic Patterns

Cancer of the vagina is also rare, with an average annual age-adjusted incidence of 0.7 per 100,000 women in the SEER areas for the period from 2000 to 2004 (2). The incidence is higher for blacks (1.1 per 100,000 for blacks vs. 0.7 per 100,000 for whites), but the reasons for the discrepancy are unknown. During 2008 it is estimated that 2,210 women will develop the disease and 760 will die from it (1). The average 5-year survival rate is 52% for whites (50% for all races). The majority of vaginal cancers are squamous-cell carcinomas and occur in the upper part of the vagina.

Vaginal cancer is primarily a disease of older women (430), with almost 60% occurring among women 60 years of age or older. In the past, carcinoma of the vagina was only rarely reported in infants and children but, beginning in the late 1960s, cases of clear-cell adenocarcinoma of the vagina, an uncommon cancer in any age group, began to be observed with much greater frequency than expected among women between 15 and 22 years of age. Most of these cases have been related to prenatal exposure to diethylstilbestrol (DES).

Medical and Sexual Risk Factors

The rarity of vaginal cancer has limited the conduct of definitive epidemiologic investigations. One case-control study of vaginal cancer, based on relatively few cases, found associations of risk

with low socioeconomic status, histories of genital warts or other genital irritations, and previous abnormal Pap smears (431). A more recent and larger study linked risk with histories of multiple sexual partners, early ages at first intercourse, and current cigarette smoking (432). Epidemiologic studies have also shown high risks associated with prior hysterectomies, although this apparently is due to the predisposition of women with anogenital cancers (particularly those with cervical cancer) to subsequently develop vaginal cancers (432).

HPV Infection

Findings that vaginal cancer is frequently found as a synchronous or a metachronous neoplasm with cervical cancer have led to the suggestion that there may be shared etiologic features between vaginal and cervical cancers. HPV has been related to disease through findings of HPV antigens or DNA in vaginal cancer tissue. In the largest study of this issue, HPV DNA was found in tumor blocks in over 80% of patients with *in situ* and over 60% of patients with invasive cancers (432). In addition, serologic antibodies to HPV have been linked to subsequent disease risk (421).

Diethylstilbestrol and Clear-Cell Adenocarcinomas

In 1971, seven clear-cell carcinomas of the vagina and one closely related endometrioid carcinoma developed in young women (ages 15 to 22 years) (433). An epidemiologic study found that the mothers of seven of the eight women had taken DES during the first trimester of pregnancy as opposed to none of the mothers of 32 matched controls. The relationship between DES exposure *in utero* and adenocarcinoma of the vagina was soon confirmed in New York State and at the Mayo Clinic (434,435). Since then, a registry of clear-cell cancer of the vagina and cervix has been established, and many more cases have been reported (436). Among these patients, about twice as many have clear-cell adenocarcinoma of the vagina as have clear-cell adenocarcinoma of the cervix.

Recent data from an assembly of all established DES cohorts indicate that the majority of patients with vaginal or cervical adenocarcinomas are diagnosed prior to age 25, with the incidence after this age decreasing by 80% (437). The estimated attack rate for clear-cell adenocarcinoma of the vagina and cervix through 39 years of age was estimated to be 1.6 per 1,000 DES-exposed daughters. Thus, DES exposure leads to a large relative increase in risk, but it affects only a small proportion of all exposed women. It remains to be seen what risk will be encountered by DES daughters when they reach their 50s and 60s, the peak ages of adenocarcinomas of the vagina in women unexposed to DES.

Conclusions

Even less is known about risk factors for vaginal cancer than is known for vulvar cancer. It has recently been suggested that there may be two types of vaginal cancers with age-related etiology (438). In young patients, the etiology may be similar to cervical cancer and relate to HPV, smoking, and low socioeconomic status, while the most common occurrences in older women may be due to hormonal factors or trauma to the vagina. Further attention should focus on the relative contributions of these factors.

The rare occurrence of vaginal adenocarcinoma in young women is distinctive in being essentially an iatrogenic disease related to *in utero* exposure to DES and other estrogens.

A proposed mechanism involves nests of abnormal cells of müllerian duct origin, which are stimulated by endogenous hormones during puberty and promoted into adenocarcinomas.

GESTATIONAL TROPHOBLASTIC DISEASES

Gestational trophoblastic diseases (GTDs) (which include hydatidiform moles, invasive moles, and choriocarcinoma) encompass a range of interrelated conditions characterized by abnormal growth of chorionic tissues with various propensities for local invasion and metastasis (439). Hydatidiform moles can be either complete or partial and have distinctive pathologies and etiologies. Complete moles have paternally derived nuclear DNA but maternally derived cytoplasmic DNA. In contrast, partial moles generally have a triploid karyotype, with the extra haploid set of chromosomes being of paternal origin.

Demographic Patterns

Choriocarcinoma is a rare malignancy in the United States, with a reported incidence in all SEER areas of 0.1 per 100,000 women, or approximately 1 per 25,674 live births (440). Hydatidiform moles occur about once in every 1,000 pregnancies, and approximately one of six occurrences results in invasive complications (either invasive mole or choriocarcinoma). Trophoblastic diseases have been reported to be more common in certain parts of the world, although some of the differences may be due to a variety of selection, detection, and reporting biases (441), including whether risk is expressed in relation to women at risk, conceptions, or live births. In the United States, incidence rates have declined over time, and survival improved, but blacks continue to have higher incidence and lower survival than women of other ethnicities (442).

The epidemiologic study of choriocarcinoma has been complicated by its relative infrequency. Most studies have, therefore, focused on defining risk factors for hydatidiform moles, but it is uncertain the extent to which these findings can be extrapolated to malignant trophoblastic disease.

Host Factors

Trophoblastic disease rates are considerably higher in Asian and African countries, but the true extent of difference from Western rates is difficult to decipher because of variations in reporting practices (443). A survey in Britain showed that the incidence of gestational trophoblastic diseases in Asians was nearly twice as high as among non-Asians (444). One incidence survey in the United States showed that, even after adjustment for age and birth distribution effects, blacks had a 2.1-fold greater risk and other nonwhite races had a 1.8-fold greater risk than whites (445). American Indians and Alaskan natives have also recently been shown to have high rates of GTDs (446).

One clearly established risk factor for choriocarcinoma and hydatidiform moles is maternal age. A recent study showed women at extreme maternal ages (either very early or late) to have nearly twofold elevated rates, with even further age differences noted for the occurrence of complete moles (444).

A history of hydatidiform moles is also a strong risk factor. The risk of another molar pregnancy in a subsequent conception is about 1% and the risk appears to increase to about 25% in women who have had more than one previous hydatidiform mole (447). Although two studies have reported a higher risk of hydatidiform moles associated with a history of a complete mole (448,449), other studies have not confirmed

this. Hydatidiform moles are associated with a 1,000 to 2,000 times increase for development of subsequent choriocarcinoma, with an even further enhancement after a complete molar pregnancy (2,500 times higher than after a live birth). One study suggested that some women might have multiple episodes of hydatidiform moles despite different male partners, suggesting either a role for oocyte defects or environmental factors (450).

Two studies have found an association between blood group A and choriocarcinoma (451,452). The combination of mother's group A and father's group O generated over a 10-fold increased risk. Blood groups A and AB were associated with elevated risks of hydatidiform moles in one study but not in another (453,454). These findings may support a role for genetic factors or immunologic factors related to the histocompatibility of maternal and trophoblastic tissues.

Menstrual, Reproductive, and Anthropometric Risk Factors

In several studies that have adjusted for the effects of late maternal age, parous women have remained at a substantially reduced risk of GTDs compared with nulliparous women, with some evidence of further reductions in risk with multiple births (453,455,456). Several studies have found an increased risk associated with a prior spontaneous abortion, although this has not been consistently observed (453,455–457). An increased risk of GTDs has been found related to a history of induced abortions in a number of studies, although information was not available on reasons for the terminations (455). A history of infertility has also been suggested as a risk factor for gestational trophoblastic disease, although not confirmed in all studies (453,455,457). In one study, Chinese patients reporting the use of herbal medicines during the first trimester of a previous pregnancy were at elevated risk (455).

Low body mass, unrelated to dieting or exercise, has been reported as a risk factor for choriocarcinoma in one study (458). Patients also had later onset of menarche and lighter menstrual periods than controls, possibly reflecting lower estrogen levels.

Exogenous Hormones

Several studies have found an increased risk of trophoblastic diseases associated with long-term use of oral contraceptives (455,459,460). Two other case-control studies, however, found no influence of oral contraceptives on risk (453,457). In one study, the association was considerably stronger for partial than complete moles (461). Others have suggested that oral contraceptives may increase the risk of malignant sequelae after mole evacuation through a tumor-stimulating effect (462,463). In one study, this effect was restricted to users of high-dose estrogens, although in others there were no effects of the pill on postmolar complications (459,464,465).

Other Risk Factors

Late paternal age was suggested in one study to increase the risk of trophoblastic diseases, but other investigations failed to confirm this (453,455,466). Cigarette smoking has also been linked with the occurrence of trophoblastic disease (457). One study suggested that low carotene intake affected the risk of hydatidiform mole, but no specific dietary associations were observed in another study (455,459).

Conclusions

Although a genetic role in the development of hydatidiform moles is now certain, little is known about genotypes that predispose to hydatidiform moles or environmental factors that may increase the risk of defective ova. Except for the possible role of oral contraceptives, few potential environmental promoters have been identified.

The trophoblast plays an active role in pregnancy, including metabolizing and detoxifying xenobiotic substances, regulating nutrient and waste product transfer, synthesizing steroid and protein hormones, and controlling the immune response of the maternofetal unit. Injury to the trophoblast can occur in pregnancy as a result of environmental exposure (e.g., heavy metals and polycyclic hydrocarbons), resulting in the breakdown of trophoblastic processes. When the trophoblast malfunctions, mutagenic, teratogenic, lethotoxic, and carcinogenic compounds may gain access to the developing embryo, causing injury and death. The genotype of hydatidiform moles results in a trophoblast that malfunctions, and exposure to certain environmental agents during the molar pregnancy may promote choriocarcinoma. Before implantation, the trophoblast forms most of the embryonic tissue, which already metabolizes environmental agents. Even preimplanted moles, with their impaired metabolic capabilities, may increase the toxicity of environmental agents and promote carcinogenesis.

Recent advances in identifying genetic and molecular markers involved with partial versus complete moles (439) open a number of avenues for assessing the interaction of these markers with a variety of proposed environmental risk factors. This could include a focus on early stages in the disease process or on factors involved in the progression of molar pregnancies to more invasive complications.

SUMMARY

The goal of both medical practice and epidemiology is to reduce morbidity and mortality. For many diseases, the focus has turned to the ultimate aim of prevention. The link between identification of etiologic factors and possibilities for prevention is well illustrated for tobacco- and alcohol-related tumors and for those associated with specific pharmaceutical, radiogenic, and occupational exposures. Fortunately, for gynecologic cancers, there are a number of identified etiologic factors that are also amenable to preventive approaches.

Undoubtedly, the prospects for prevention are best for cervical cancer. For some time, secondary prevention in the form of screening for pathologic precursors of invasive disease has been the hallmark of the public health approach to this malignancy. The establishment of HPV as a central etiologic agent for the disease presents other avenues for prevention, including application of recently developed vaccines against the virus (410). Knowledge of when and how infection and other factors operate in the natural history of the disease has revolutionized screening strategies and shifted treatment from cell ablation to antiviral therapies. As always, combined laboratory, clinical, and epidemiologic research is needed to realize these propositions.

Many believe that more is known about the cause of endometrial carcinoma than for almost any other tumor. A unified theory of how all risk factors may operate through a final common estrogenic pathway is popular and well supported. A woman's hormonal milieu may prove to be favorable to modification at a practical level. There is substantial evidence that elimination of obesity an intervention actively promoted for other reasons—should also reduce endometrial cancer risk. After the epidemic of endometrial cancer due to estrogen replacement therapy, changes in the management of menopause occurred, resulting in a marked decline in the rates of endometrial cancer.

More care is devoted to identifying women who truly need estrogen therapy, treatment of menopausal symptoms is for a much shorter period of time, the use of cyclic progestin in combination with estrogen is advised if indicated, and regular endometrial sampling is frequently practiced for long-term estrogen users.

Although past alterations in patient management led to a decline in endometrial cancer, current events make future patterns less clear. Previous enthusiasm for long-term treatment of large segments of the population of menopausal women with hormones to control symptoms and prevent osteoporosis and heart disease may have implications for endometrial cancer in the future. On the other hand, current patterns of use of oral contraceptives could lead to reductions in endometrial cancer rates in the general population. The impact of widespread oral contraceptive use at young ages on endometrial cancer risk at older ages is not well studied. However, if it is anywhere near the reduced risk seen at young ages, the resulting reduction in endometrial cancer overall could be substantial.

With further research, it is also possible that pharmacologic interventions aimed specifically at groups at high risk for endometrial cancer due to endogenous hormonal factors could be justified. More must be learned about the associations of risk for endometrial cancer and the quantitative levels of estrogens and other hormones and their relative proportions. Once these factors are known, women with PCOS, diabetes, morbid obesity, or other predisposing conditions could be evaluated for unfavorable hormone profiles and appropriately targeted for treatment.

Although a substantial amount has been learned about ovarian cancer risks, the prospects for meaningful preventive measures aimed at this tumor are probably worse than for the other gynecologic malignancies. Although several ovarian cancer risk factors seem to indict ovulatory activity as a common pathway to increased risk, the mechanism by which this occurs is unknown. Even if some of the hypothesized mechanisms prove to be correct (e.g., levels of circulating gonadotropins), it is unclear how reasonable any interventions may be. However, if the long-term effect of oral contraceptive use on ovarian cancer risk is similar to its short-term effect, a substantial decline in ovarian cancer rates should result from pill use patterns of the past 40 years. Another reason for the limited prospects for prevention is that for several risk factors (e.g., protection associated with hysterectomy), no credible mechanism has been suggested. The associations promising the greatest opportunities for preventive actions are several recently suggested dietary relationships, specifically, decreased risks with consumption of diets high in fruit and vegetable and certain micronutrients. However, these observations need to be replicated in additional studies. Because of the preventive implications, attempts at confirmation should have high priority.

For cervical cancer, endometrial cancer, and ovarian cancer, much is known about the risk factors. Less is known about the precise biologic mechanisms through which the known risk factors operate. There is substantial enthusiasm for current interdisciplinary studies that incorporate state-of-the-art laboratory assays into robust epidemiologic research designs focused on answering these mechanistic questions. Even among some of the more conservative etiologists, there is a belief that the gynecologic oncologist may soon be able to intervene much earlier in the natural history of these diseases and, in some instances, engage in primary prevention.

CHAPTER 2 ■ CLINICAL GENETICS OF GYNECOLOGIC CANCER

STEVEN A. NAROD

GENETICS IN CLINICAL PRACTICE OF GYNECOLOGIC ONCOLOGY

The identification of *BRCA1* in 1994 and *BRCA2* in 1995 has introduced a new component to the practice of gynecologic oncology. Genetic testing for predisposition to ovarian cancer became available by 1996 and is now well established. There are five genes for ovarian cancer susceptibility that are now in clinical use (*BRCA1*, *BRCA2*, *MLH1*, *MSH2*, and *MSH6*). *BRCA1* and *BRCA2* are responsible for the hereditary breast-ovarian cancer syndrome (13% of all ovarian cancers) and *MLH1*, *MSH2*, and *MSH6* are responsible for the hereditary nonpolyposis colon cancer syndrome (2% of ovarian cancers). Our ability to use laboratory testing to predict the later development of ovarian cancer requires that clinicians have a clear understanding of the role of genetic testing in risk assessment and in patient care. Advances in preventive oncology have had the effect of increasing the number of healthy women who seek advice from a gynecologic oncologist. Increasing numbers of prophylactic salpingo-oophorectomies are performed on healthy women by surgeons who, for the most part, had previously treated patients for cancer. Information is now available to support the practice of genetic testing for *BRCA* mutations as a means to prevent ovarian cancer in high-risk women. Current strategies for prevention include prophylactic surgery and chemoprevention with oral contraceptives. Screening for ovarian cancer is widespread, but its utility has not been proven.

OVARIAN CANCER

Genetic Epidemiology

Approximately 13% of all women with invasive ovarian cancer carry a *BRCA1* or *BRCA2* mutation (1–3) and it is reasonable to offer genetic testing to all women diagnosed with invasive epithelial ovarian cancer (women with mucinous cancer may be exempted). In the event of a positive genetic test, testing is extended to unaffected female relatives. However, if there is no living affected relative, then testing may begin with an unaffected woman.

The frequency of *BRCA* mutations among ovarian cancer patients is not the same for all ethnic groups. In some populations, there are recurrent (founder) mutations. In these populations, the overall frequency of *BRCA1* mutations tends to be high and a large proportion of mutations will be accounted for by one, or a small number, of specific mutations. For example, approximately 30% to 40% of Jewish women with

ovarian cancer carry one of three founder mutations (two in *BRCA1* and one in *BRCA2*) (4,5). Moslehi et al. (4) found that 41% of Jewish women with ovarian cancer from North America carried a mutation, including the majority of those diagnosed between the ages of 40 and 60. Modan et al. (5) found one of the three mutations in 29% of 840 Jewish women with ovarian cancer in Israel. In Poland, 13.5% of unselected patients with ovarian cancer carry one of three common *BRCA1* mutations (6) (one of these [5382insC] is also one of the Jewish founder mutations). Three mutations account for 86% of all *BRCA* mutations found in Poland (7). The frequency of *BRCA* mutations has been estimated at 1 in 12 cases of ovarian cancer in French-Canadians (8) and one in six cases in Pakistan (9). In these populations, it may be possible to offer testing for a limited number of mutations.

The excess risk of ovarian cancer in Jewish families with multiple cases of breast or ovarian cancer appears to be almost entirely due to the three Jewish founder mutations. Liede et al. studied a cohort of 290 Jewish women undergoing surveillance for ovarian cancer because of a family history of breast or ovarian cancer (10). Among women with a *BRCA* mutation, the ovarian cancer incidence was 32 times greater than expected. However, among women who did not carry a mutation, no excess risk of ovarian cancer was observed. Kauff et al. followed 199 women from site-specific *BRCA*-negative breast cancer families (11). They observed an elevated risk for breast cancer (standardized incidence ratio [SIR] = 3.1; $p < 0.001$), but not for ovarian cancer (SIR = 1.5; $p = 0.5$) (11). Phelan et al. screened 160 Jewish families with site-specific breast cancer or the breast-ovarian cancer syndrome (12). These families had previously been found to be negative for the three Jewish founder mutations. Only a single nonfounder mutation was identified. Together, these studies indicate that if a founder mutation is not identified through screening of a Jewish family, it is exceedingly unlikely that a different mutation will be found. This also implies that a Jewish woman without one of the three mutations should not be considered to be at increased risk for ovarian cancer (although she may be at higher than average risk for breast cancer). Testing for mutations other than these three in Jewish women should be conducted in exceptional circumstances—an example would be a family with four or more cases of early-onset breast cancer or invasive ovarian cancer.

In the ethnically mixed populations of North America, approximately 13% of all patients with invasive ovarian cancer carry a mutation in *BRCA1* or *BRCA2* (1–3). However, the range of mutations is wide and genetic testing must be comprehensive (full genomic screening). In Ontario, Canada, a mutation was found in 129 of 977 (13.2%) unselected cases of ovarian cancer (2). There were 75 *BRCA1* mutations and 54 *BRCA2*

TABLE 2.1
LIFETIME RISKS OF CANCERS ASSOCIATED WITH SPECIFIC GENES

mutations. Women with *BRCA1* mutations were diagnosed with ovarian cancer at an average age of 52.6 years, compared to 58.8 years for carriers of *BRCA2* mutations and 57.3 years for the nonhereditary cases. *BRCA1* mutations represented 71% of the mutations found in women diagnosed under age 50 and *BRCA2* mutations represented 62% of those diagnosed after age 60.

Among *BRCA1* carriers, the risk of ovarian cancer is significant in women above the age of 35 (13) (approximately 1% per year) and preventive measures must be initiated early. Women who carry a pathogenic mutation in the *BRCA1* gene have a lifetime risk of approximately 40% for developing invasive ovarian cancer (14–18) (Table 2.1). Among *BRCA2* carriers, the risk is much lower and ovarian cancer rarely occurs below age 50. Antoniou et al. estimated the lifetime risk for *BRCA2* carriers to be 11% (15); Satagopan et al. estimated the risk of ovarian cancer to be 21% (17). A recent meta-analysis (which included these two studies) estimated the risk of ovarian cancer to be 16% (18). Also, among *BRCA2* carriers, the risk of ovarian cancer varies with the position of the mutation. Thompson et al. (16) estimated that the risk of ovarian cancer to age 70 was 20% for carriers of *BRCA2* mutations within the Ovarian Cancer Cluster Region (OCCR: nucleotides 4075–6503) and was 11% for mutations outside of this region. This assignment was confirmed by Lubinski et al. in 2004 (19). These investigators studied 440 families with a *BRCA2* mutation. They found that families with a mutation in the OCCR (nucleotides 3035–6629) were twice as likely to contain one or more cases of ovarian cancer than were families with a *BRCA2* mutation located outside of this region (odds ratio [OR] = 2.2; $p = 0.0002$).

Metcalfe et al. followed a cohort of women with breast cancer and a *BRCA1* or *BRCA2* mutation (20). In the ten-year period following the cancer diagnosis, the risk of ovarian cancer was 13% for *BRCA1* carriers and 7% for *BRCA2* mutation carriers. In this study, 25% of the deaths in women with stage I breast cancer were due to subsequent ovarian cancer.

Pathology and Surgical Presentation of Hereditary Ovarian Cancer

Ovarian cancers that occur in women with a *BRCA* mutation appear to be similar to their sporadic counterparts (1,2,21,22), with the exception that mucinous tumors and tumors of low malignant potential (or “borderline” tumors) are rarely observed in women with a *BRCA* mutation. The great majority of *BRCA*-linked ovarian cancers show moderate to poor differentiation. Most hereditary ovarian tumors present at an advanced surgical stage (4,21), but stage I or II tumors are now being discovered in the context of high-risk screening programs, or as an incidental finding associated with a prophylactic

oophorectomy in an asymptomatic woman. Several studies have reported on the presence of early ovarian cancers among pathology specimens obtained at the time of prophylactic surgery (23–30). In one study (23), 4 of 33 women (12%) at high risk were found to have clinically unsuspected ovarian cancer at the time of prophylactic oophorectomy. In a second study (24), two of eight women with germ-line *BRCA1* mutations had ovarian cancer at the time of prophylactic oophorectomy. Salazar et al. (25) reviewed the ovaries of 20 women who had a prophylactic oophorectomy and found two cases of microscopic cancer. Finch et al. described a series of 159 female *BRCA1* or *BRCA2* carriers who underwent prophylactic oophorectomy (26). Six of 94 *BRCA1* carriers were found to have an occult cancer (6.4%). In contrast, only one of the 65 *BRCA2* carriers was found to have an occult cancer (1.5%). Three of the seven cases of occult malignancy involved the fallopian tube and not the ovaries.

In a study from Boston, 122 of *BRCA1* and *BRCA2* carriers underwent preventive ovarian surgery (27). Seven cancers were found (6% of total). All cancers were found in the distal portion of the fallopian tube. Powell et al. found seven cancers among 67 women who underwent a prophylactic oophorectomy (28). Seven cancers were found: four in the fallopian tubes and three in the ovaries. These studies support the theory that the distal fallopian tube is the site of origin of the majority of ovarian/fallopian cancers in high-risk women (30–32). Carcinoma of the fallopian tube has also been noted in several *BRCA*-linked breast and ovarian cancer kindreds. In a population-based study of unselected cases of carcinoma of the fallopian tube, 7 of 44 (16%) tested patients were found to harbor a germ-line *BRCA* mutation: five in *BRCA1* (11%) and two in *BRCA2* (5%) (33). It is necessary that the fallopian tube be completely removed and serially sectioned when a prophylactic oophorectomy is performed.

Several study groups have asked whether morphologic alterations of the ovarian surface epithelium are prevalent in women with ovarian cancer (34–37) or who are at high genetic risk for ovarian cancer (38). Alterations of these types are common and it has not yet been proven that they are present at a higher frequency than expected in cancer-prone ovaries.

Clinical Outcome and Treatment Effects

Several studies have reported that the survival of patients with *BRCA*-associated ovarian cancer is improved, compared to women with sporadic ovarian cancer (21,39–43). A study of consecutive cases of ovarian cancers, which compared *BRCA*-associated to sporadic ovarian cancers from the same institution, found that *BRCA* mutation status was a favorable and independent predictor of survival for women with advanced disease (21). It is not yet clear if the improved survival rate is the result of a difference in the natural history of ovarian cancer in the two subgroups or a better response of *BRCA*-associated tumors to current therapies. Cass et al. reported that *BRCA1* carriers with ovarian cancer had a higher response rate to primary therapy than did matched noncarriers, and carrier patients with advanced disease had improved survival (91 months for *BRCA1* carriers vs. 54 months for noncarriers; $p = 0.05$) (41).

Prophylactic Oophorectomy

In 1995, a consensus panel of the National Institutes of Health (NIH) recommended prophylactic oophorectomy for high-risk women at age 35 years, or after childbearing is complete (44). It seems logical that prophylactic oophorectomy should eliminate the incidence of ovarian cancer, but there are two reasons

for potential failure of prophylactic oophorectomy. First, it is possible that the removed ovaries or fallopian tubes contain foci of occult carcinoma and that the cancer has spread locally to the peritoneum at the time of the resection. In this case, the peritoneal cancer is not, in fact, a primary cancer, but a metastatic ovarian cancer. Second, it is possible that *de novo* cancer arises in the peritoneum after oophorectomy. The peritoneum is derived from coelomic epithelium, of the same embryologic origin as the surface epithelium of the ovary.

Liede et al. (10) followed a cohort of 33 Jewish women with *BRCA* mutations for a mean of eight years. Five cases of primary peritoneal cancer were diagnosed. The ten-year risk of peritoneal cancer was 16%. However, the women in this study had both ovaries intact and the peritoneal origin of the tumors was not definite. It is difficult to measure the risk of peritoneal cancer in women with intact ovaries. Peritoneal, fallopian, and serous ovarian cancers are histologically indistinguishable, and symptomatic women often present with multiple foci of cancer involving the peritoneum, tubes, omentum, and ovary. Tubal cancer is difficult to discriminate from ovarian cancer and is often misclassified as ovarian cancer (45). It is easier to make the diagnosis of primary peritoneal cancer in women without ovaries. New serous cancers that arise in the abdominal peritoneum, following an oophorectomy, and with normal ovaries on pathological examination are generally considered to be primary peritoneal cancers.

Piver et al. (46) reported that 6 of 324 women who underwent prophylactic oophorectomy experienced primary peritoneal cancer. The mutation status of these women was unknown and there was no standard period of follow-up. Struewing et al. (47) reported that the cancer risk in women after prophylactic oophorectomy was 13 times greater than that expected from population-based rates, but this was based on only two observed cases of peritoneal cancer. Kauff et al. (48) followed 170 *BRCA* carriers for an average of two years. They observed one peritoneal cancer among 98 women who chose salpingo-oophorectomy, versus five ovarian/peritoneal cancers in 72 women with intact ovaries. In a historical cohort study of 551 *BRCA1* and *BRCA2* carriers, Rebbeck et al. (49) reported that the incidence of ovarian or peritoneal cancer was diminished by 96% (95% confidence interval [CI], 84% to 99%) in women who underwent prophylactic oophorectomy, compared to those with intact ovaries.

Finch et al. followed 1,045 women with a mutation who underwent a bilateral prophylactic salpingo-oophorectomy and compared the cancer risk with 783 women who did not undergo the procedure (13). After a mean follow-up of 3.5 years, 50 incident ovarian, fallopian tube, or peritoneal cancer cases were reported in the cohort. There were 32 incident cancers diagnosed in women with intact ovaries. Eleven cancer cases were identified at the time of prophylactic oophorectomy, and seven were diagnosed following prophylactic oophorectomy. The overall reduction in cancer risk associated with bilateral oophorectomy was 80% (hazard ratio = 0.20; 95% CI, 0.07 to 0.58; $p = 0.003$). The estimated cumulative incidence of peritoneal cancer was 4.3% at 20 years after oophorectomy.

An additional benefit of prophylactic oophorectomy is a marked reduction in the risk of breast cancer (48–50). Oophorectomy performed at a relatively early age (<40) is associated with a greater degree of protection than surgery performed near the age of menopause. In the largest study to date, Eisen et al. found that oophorectomy was associated with a significant reduction in breast cancer risk of 56% for *BRCA1* carriers and 46% for *BRCA2* carriers (50). The risk reduction was greater if the oophorectomy was performed before age 40 (OR = 0.36) than after age 40 (OR = 0.53) and the protective effect was evident for 15 years post-oophorectomy. Reductions of similar magnitude have been reported in other studies (48,49).

Hormone Replacement Therapy

Premenopausal oophorectomy is associated with the induction of acute menopause. There is concern that the use of hormone replacement therapy in these women may be associated with an increased risk of breast cancer, or may offset the protective effect of the oophorectomy itself. There is one study of hormone replacement therapy in *BRCA1* and *BRCA2* carriers. Rebbeck et al. estimated the effect of oophorectomy on breast cancer risk in a study of 462 *BRCA1* and *BRCA2* carriers (51). They found that the odds ratio for breast cancer associated with oophorectomy in the entire study group was 0.40 (95% CI, 0.18 to 0.92) and was 0.37 (95% CI, 0.14 to 0.96) in the subgroup of women with oophorectomies who used hormone replacement therapy. This single study suggests that it is safe to offer hormone replacement therapy, but this is a relatively small sample and additional studies are required.

Oral Contraceptives and Tubal Ligation

A protective effect of oral contraceptives against ovarian cancer has been reported in *BRCA* carriers (52–54). In a recent matched case-control study of 799 ovarian cancer cases and 2,424 controls, three to five years of oral contraceptive use was associated with a 64% reduction in the risk of ovarian cancer ($p = 0.0001$) (53). In a second, smaller study (54), six or more years of use of oral contraceptives was associated with a decrease in risk of 38% (OR = 0.62; 95% CI, 0.35 to 1.09). Tubal ligation has been found to be protective against ovarian cancer in the general population. There is some evidence that it is also effective among *BRCA1* carriers (53). McLaughlin et al. reported an adjusted relative risk of 0.78 (95% CI, 0.61 to 1.0) for tubal ligation and subsequent ovarian cancer (a risk reduction of 22%) (53).

Screening for Hereditary Ovarian Cancer

Screening for ovarian cancer using serial CA-125 levels and abdominal ultrasound has been proposed as a method of reducing mortality through early detection. There have been no randomized trials of screening in *BRCA1* carriers, but observational cohort studies have been disappointing. Liede et al. (10) identified seven incident ovarian/peritoneal cancers in a historical cohort of 33 *BRCA* carriers who underwent regular screening examinations. Six of the seven cases were stage III at the time of diagnosis. For the majority of cases, the ultrasound findings were normal prior to diagnosis and the women presented with pain or abdominal distension. In a randomized trial of CA-125 and ultrasound in women at average risk, Jacobs et al. (55) identified 16 ovarian cancers in the screened group. Eleven of the 16 tumors were diagnosed at stage III or IV. Neither CA-125 nor ultrasound has proven to be a sensitive means of detecting stage I and stage II ovarian cancers.

ENDOMETRIAL CANCER

The most important factor in the etiology of endometrial cancer is prolonged estrogen exposure, but inherited factors are important for a small proportion of cases as well. Susceptibility genes for endometrial cancer include *BRCA1*, *PTEN*, and the three mismatch repair genes *MSH2*, *MLH1*, and *MSH6* (Table 2.2). These genes are responsible for the hereditary breast-ovarian cancer syndrome, Cowden syndrome, and hereditary nonpolyposis colon cancer, respectively (discussed later).

TABLE 2.2
GENES ASSOCIATED WITH COMMON CANCERS

Breast	Ovary	Colon	Endometrial
<i>BRCA1</i>	<i>BRCA1</i>		
<i>BRCA2</i>	<i>BRCA2</i>	<i>APC</i>	
<i>ATM</i>	<i>MSH2</i>	<i>MSH2</i>	<i>MSH2</i>
<i>CHEK2</i>	<i>MLH1</i>	<i>MLH1</i>	<i>MLH1</i>
<i>NBS1</i>	<i>MSH6</i>	<i>MSH6</i>	<i>MSH6</i>
<i>TP53</i>			<i>PTEN</i>

The Breast Cancer Linkage Consortium reported that some endometrial cancers were due to mutations in *BRCA1* (56) but none were due to mutations in *BRCA2* (57). Among *BRCA1* carriers the risk for endometrial cancer was reported to be 2.6 times higher than expected (95% CI, 1.7 to 4.2). However, two smaller studies (one of patients with papillary serous endometrial tumors [58] and one on patients with endometrial carcinomas in general [59]) concluded that the risk of endometrial carcinoma in women with a germ-line *BRCA1* mutation was not increased. These findings suggest that it is likely that some cases of endometrial carcinoma are due to an inherited *BRCA1* mutation, but the penetrance of *BRCA1* mutations for endometrial carcinoma is low and the hereditary fraction is small.

Beiner et al. prospectively followed a cohort of *BRCA1* and *BRCA2* carriers who had an intact uterus (60). After an average follow-up period of 3.3 years, six women were diagnosed with endometrial cancer, compared to 1.1 cancers expected (SIR = 5.3, $p = 0.001$). Four of the six patients had used tamoxifen in the past. Among the 226 participants who had used tamoxifen (220 as treatment and six for the primary prevention of breast cancer) the relative risk for endometrial cancer was 12 ($p = 0.0004$). The risk among women who were never exposed to tamoxifen treatment was not significantly elevated. These data suggest that the excess risk of endometrial cancer among *BRCA* carriers can be attributed to past tamoxifen use, and not to the effect of the gene.

Somatic mutations in *PTEN* are common in endometrial cancers (61) and, rarely, inherited constitutional mutations in *PTEN* are present in women with endometrial cancer. In the latter case, endometrial cancer is seen in the context of Cowden syndrome—a rare dominant disease of the skin that is associated with increased risks of cancer of the breast, thyroid, and endometrium (62).

Women in families with the syndrome of hereditary familial nonpolyposis colon cancer (HNPCC) are also at elevated risk for endometrial and ovarian cancer (63). This syndrome is characterized by an autosomal dominant inherited tendency to develop colon and other cancers. The colon cancers tend to be of young onset, are right-sided, and are often multicentric. Adenomatous polyps are seen, but florid polyposis is rare. Individuals in families with HNPCC are at risk for a range of cancer types, and endometrial cancer is the second most frequent site of cancer among women (63,64). Genes that are responsible for the repair of mismatched DNA (mismatch repair) are defective in families with this syndrome. *MSH2*, *MLH1*, and *MSH6* are the three major genes responsible. The risk of colon cancer is high in families with a mutation in any of these genes, and the lifetime risk for endometrial cancer in women from these families is reported to be from 40% to 60% (63,64). The risk of endometrial cancer also depends on which gene carries the mutation. Mutations in *MSH2* and

MSH6 have been implicated in most HNPCC families with endometrial cancer, but families with *MSH1* mutations have been reported as well. Germ-line mutations in *MSH6* are relatively rare in HNPCC but are overrepresented in families with multiple cases of endometrial cancer (65). Goodfellow et al. reported that an inactivating germ-line *MSH6* mutation was present in 7 of 441 women with unselected ovarian cancer (1.6%) (66). Cancers were diagnosed in women with mutations on average ten years earlier than in women without mutations. Malander et al. studied 128 women with ovarian cancer, unselected for age of diagnosis or family history (67). They found one mutation in *MLH1* and one mutation in *MSH2*. This small study suggests that about 2% of unselected cases of ovarian cancer are due to mutations in the mismatch repair genes.

It is possible that other genetic variants in the genes in the mismatch repair pathway may also contribute to ovarian cancer. This may be due to the effect of common variants associated with lower penetrance. To test this hypothesis, Beiner et al. studied 672 unselected cases of endometrial cancer for a variant in the *MLH1* gene (nt-93 A) (68). They found that women who carried this variant were at 1.5-fold increased risk of endometrial cancer (OR = 1.5; 95% CI, 1.2 to 2.0). A positive association was also seen for ovarian cancer (OR = 1.5; 95% CI, 1.3 to 3.9) (69). A similar association has been seen for colon cancer with microsatellite instability (70).

The majority of tumors in individuals from HNPCC families demonstrate microsatellite instability. Microsatellite instability is a feature of tumors that are genetically unstable, i.e., that are associated with error-prone DNA replication during cell division. Microsatellite instability is limited to tumor DNA and the phenotype is visualized in the laboratory by comparison of tumor and lymphocyte DNA from the same individual. Microsatellite instability is highly predictive of colon and endometrial cancers that are attributable to mutations in one of three mismatch repair genes (*MSH2*, *MLH1*, and *MSH6*). These mutations may be germ-line (inherited), but are more often somatic (restricted to tumor tissue only). Approximately one quarter of women with nonhereditary endometrial cancer (sporadic cancer) have tumors that demonstrate microsatellite instability (71). If the mutation is present in the germ line, it may be transmitted from the carrier parent to child. In this case, genetic counseling is warranted. Counseling should include a full pedigree review, and may involve predictive genetic testing for unaffected individuals. Other individuals found to carry the family mutation should be apprised of the risks and the range of tumor types involved. It is not necessary that genetic counseling be undertaken when the mutation is limited to the tumor tissue only, as this situation does not pose a risk to relatives. The gene may also be silenced by methylation of the gene regulatory regions. The *MLH1* gene is usually silenced through methylation in the tumor tissues (72).

Individuals with an inherited mutation in one of the mismatch repair genes are also at risk for additional cancers, including ovarian, gastric, urologic tract, and small bowel cancers, but the risk for these is much less than the risk for colon or endometrial cancer. Members of the International Collaborative Group on HNPCC collected information on 80 women with ovarian cancer who were members of HNPCC families (64). The mean age of diagnosis was 43 years. The majority of cancers were moderately or well differentiated and 85% were stage I or II. Synchronous endometrial cancer was reported in 22% of cases.

There is currently no consensus on the screening and management of women with inherited mutations in the mismatch repair genes. Annual endometrial ultrasound surveillance has been recommended by the International Collaborative Group on HNPCC, but the effectiveness of this screening regimen has

not been established. Although there are no data on the effectiveness of hysterectomy as a preventive measure for hereditary endometrial cancer, there have been no reports of failures of hysterectomy to prevent endometrial cancer. Because of the high lifetime risk of endometrial cancer in women with mutations in the mismatch repair genes, preventive hysterectomy may be warranted.

CHAPTER 3 ■ THE BIOLOGY OF GYNECOLOGIC CANCER

KRISTIN K. ZORN, GINGER J. GARDNER, JOHN H. FARLEY, AND MICHAEL J. BIRRER

INTRODUCTION TO THE BIOLOGY OF GYNECOLOGIC NEOPLASIA

A neoplasm represents new growth and may be defined as an abnormal mass of tissue, the growth of which exceeds and is uncoordinated with that of the normal tissues. Growth persists in the same excessive manner after cessation of the stimuli that evoked the change (1). Neoplasia traditionally has been classified as benign or malignant on the basis of structural and growth characteristics. Most benign tumors mimic their tissue of origin in both cellular form and function. Cancerous tumors exhibit a spectrum from well differentiated to anaplastic (undifferentiated, characterized by both cytologic pleomorphism and architectural disorganization). Benign masses are typically well demarcated, with a broad, expansive front, and do not invade local normal tissues. Although some malignancies grossly appear to be encapsulated, they may infiltrate adjacent noncancerous tissue. In addition, malignancies tend to have a faster growth rate that is, in general, inversely related to the degree of differentiation. Finally, the ability to metastasize, a behavior that many malignant tumors exhibit, is a feature that benign tumors uniformly lack (2).

Nonneoplastic processes can alter the structure and/or function of a tissue, but are usually reversible. These conditions represent an adaptation to stress, such as an injury or infection, or a physiologic response to biochemical (e.g., hormonal) stimulation. *Hypertrophy* refers to an increase in cell size within a tissue, whereas *hyperplasia* is an increase in cell number. *Metaplasia* describes the process by which one differentiated cell type is replaced with another. *Dysplasia* is disordered cellular proliferation characterized by structural variability and disorganization of tissue architecture. When the full thickness of an epithelium is involved through this process, it is termed carcinoma *in situ*, and is considered to be a preinvasive process (2).

Biologic Properties of Transformed Cells and Tumors

Our understanding of the biologic behavior of malignant cells has been derived from *in vitro* comparisons of normal and transformed cells, the study of cell lines established by culturing human cancer cells, and the evaluation of tumors transplanted or induced in animals. Normal human cells display a finite ability to proliferate in cell culture, stopping after about 50 generations of cell division. These cells have specific requirements for growth, including the availability of nutrients and growth factors, attachment to a substratum, and lack of

contact with other cells. In the event of temporary nutritional deprivation, they will arrest in a nonproliferative state but retain the capacity to resume replication with replenishment of growth-promoting substances.

Malignant cells, in contrast, demonstrate decreased reliance on exogenous growth factors, anchorage independence, and a lack of contact inhibition. As a result, transformed cells generally require less serum and supplements to grow, demonstrate nonadherent growth (such as growth in suspension or in a semisolid medium), and exhibit greater cell-population density. Cellular transformation produces disorganization of actin filaments, which results in more rounded, refractile cells.

Depending on location and accessibility to physical examination or imaging techniques, most tumors become clinically detectable at a mass of 1 to 10 g (10^9 to 10^{10} cells). A tumor mass of 1 kg (10^{12} cells) represents approximately 40 doublings and is generally lethal to the host in animal models. The time it takes for a given human malignancy to double in volume is usually constant, consistent with an exponential growth pattern (Fig. 3.1). Tumors frequently demonstrate a growth deceleration generally attributed to inadequate nutrition as they enlarge. Extrapolation into the preclinical phase reveals a slower rate of growth during this portion of the tumor's life span as well, which may be related to the early growth requirements of establishing a supporting vascular network and overcoming the host's immune surveillance.

Doubling times for human malignancies range from a few days for certain lymphomas and leukemias to up to several months for epithelial tumors such as lung and colorectal carcinomas. The growth rates for tumors of identical origin and histology may also be quite variable. A formula that includes the growth fraction and duration of DNA synthesis may be used to estimate the theoretical doubling time for a given tumor. This potential tumor doubling time is often considerably shorter than the actual doubling time seen clinically (3). Reasons for this discrepancy include tumor cell death (apoptosis or necrosis) or lowered growth fraction due to cellular senescence, in part due to the lack of an adequate vascular supply.

Cell Cycle, Senescence, Apoptosis, and Necrosis

Cell Cycle

During the process of replication, a cell passes through a series of phases beginning with DNA synthesis (S phase) and culminating in mitosis (M phase), the process by which the cell actually divides (Fig. 3.2). These two periods are separated by the presynthetic (G_1) and premitotic (G_2) phases. Cells that

FIGURE 3.1. An exponential growth curve with preclinical lag and terminal growth deceleration. The abscissa represents time of tumor growth in days. The ordinate displays tumor volume in square centimeters. A slower rate of tumor growth is shown during the tumor's preclinical phase as well as when it attains a large volume.

are not actively proliferating are in the G_0 phase. Some of these nonproliferating cells retain the ability to progress through the cell cycle given the appropriate stimulus and environmental conditions. Others have lost the capacity for replication, which occurs secondary to terminal differentiation or damage sufficient to result in eventual cell death. The proportion of cells in a tumor that are actively proliferating is known as the tumor's growth fraction (3).

Entry into and transit through the cell cycle appear to be controlled by a number of regulatory proteins (3). Events necessary for G_0/G_1 cells to enter the S phase include the transduction of growth factor signals to the nucleus and the activation of "early response" genes, whose products bind to DNA and regulate the expression of other genes necessary for progression through the cell cycle (Fig. 3.3). The proteins necessary for this progression include the cyclins, cyclin-dependent kinases (CDKs), and the CDK inhibitors (4,5). It is now abundantly clear that progression through the cell cycle requires the interaction of these proteins in a coordinated fashion.

The cyclins are a group of proteins that are synthesized and degraded during the cell cycle. They can be divided into two major classes depending on where in the cell cycle they are active: the G_1 cyclins include cyclins D, A, and E, whereas the mitotic cyclins include cyclins A and B. The cyclins bind to and

FIGURE 3.2. The cell cycle. The normal cell cycle, with relative time spent in each phase, is illustrated. G_0 cells are "resting," with an ability to replicate given the appropriate conditions and stimulus, or they have lost the ability to proliferate secondary to damage, death, or differentiation. G_1 represents the presynthetic phase; DNA synthesis occurs during the S phase; G_2 is the premitotic phase; and M represents mitosis, the briefest portion of the cycle.

activate the CDKs. The cyclin/CDK complex is critical for the phosphorylation and activation of proteins and enzymes involved in DNA replication. For instance, the cyclin D/CDK4, cyclin D/CDK6, cyclin E/CDK2, and cyclin A/CDK2 complexes phosphorylate the retinoblastoma gene product (pRb) (6). pRb is a protein with tumor-suppressor function. The Rb protein and a structurally related protein, p107, are modified by a variety of different cyclins and CDKs (7). Their phosphorylation results in the release of transcription factor E2F, which then drives the transcription of "growth genes" (8–10). Another example is the activation of the protein kinase p34^{cdc-2} by dephosphorylation and binding to a regulatory cofactor, which appears important for cell cycle transit. Kinase activity is maximal during mitosis, when p34^{cdc-2} is bound to the protein cyclin B.

The stimulatory activity of cyclin/CDK complexes is opposed by CDK inhibitors (4). The CDK inhibitors are a group of small proteins that are able to directly inhibit the activity of the cyclin/CDK complex. The G_1 cyclin/CDK complexes are inhibited by p15, p16, and p27.

The interaction of cyclins, CDKs, and CDK inhibitors provides for a regulated progression through the cell cycle (5). The cell passes through a number of checkpoints where assurance of proper completion of prior phases is required (11,12). If this assurance is not achieved, the cell arrests. The p53 protein mediates two of these checkpoints (13). Overexpression of wild-type (nonmutated) p53 arrests cell cycle progression in G_1 at or near a restriction point regulating the G_1/S transition, in part by transcriptionally activating the expression of the CDK inhibitor p21 Waf1/Cip1 (13). Although routine cellular functions may not require the presence of p53, conditions such as DNA damage and cellular stress stimulate the expression of p53 and produce a G_1 arrest (5). If the DNA damage is minor, it is repaired during this arrest; extensive damage causes the cell to undergo apoptosis (discussed below) (14). Elevated levels of p53 can also produce a G_2/M arrest, providing another period of rest for the cell during which it can repair damaged chromosomes. Although the mechanism for G_2 arrest is less clear than that involved in the G_1 checkpoint, it appears to involve the inactivation of mitotic cyclins A and B (15–17). The formation of a functional mitotic spindle is critical for successful cell division. It is not surprising, therefore, that a checkpoint exists during mitotic spindle formation (18). The genes involved in this process have only recently been characterized, but some appear to be involved in human cancers (19).

Senescence

Cell growth slows as the finite number of cell doublings, known as the Hayflick limit, approaches (20). This process is governed by the loss of telomeres on chromosomal ends. Telomeres are protective DNA sequences rich in TTAGGG repeats that are shortened with successive replications. When the ends become critically shortened, the cell enters replicative senescence or mortality stage 1. In epithelial cells, the first barrier appears to be mediated by stress-induced cyclin-dependent kinase inhibitors (CKIs) (p16, p21) inhibiting Rb inactivation (21). Some cells escape senescence and continue to divide until they undergo crisis, which is also known as mortality stage 2. The rare cell that emerges from this stage still able to replicate is considered to be immortalized because it has acquired the ability to proliferate indefinitely. Continued telomere erosion in cells that overcame the first barrier eventually leads to unprotected telomeric ends generating widespread genomic instability. Immortalized cells are able to continue dividing because they maintain telomere length, usually through reactivation of telomerase (21,22). Telomerase is an RNA-dependent DNA polymerase that synthesizes the telomeric DNA sequences. It consists of an RNA template, which is universally

FIGURE 3.3. Signal transduction, regulation of the cell cycle, ubiquitin proteasome protein degradation, and apoptotic pathways. The covalent modification of intracellular constituents is illustrated by receptor and nonreceptor protein tyrosine kinases. Input from tyrosine kinases results in increased generation of activated ras bound to GTP, which in turn associates with ras effectors: raf, Rho, Rac, and RassF1. Raf (MAPKKK) propagates the signal to microtubule-associated protein kinase kinase (MAPKK), which activates MAPK. MAPK phosphorylates a host of substrates, including cytoplasmic phospholipase A₂, cytoskeletal components, protein synthesis machinery, and, most importantly, transcription factors such as myc, cJun, and ATF. Parallel pathways exist that use different MAPKKs, MAPKKs, and MAPKs. Different MAPKs, such as ERK, JNK, and p38, phosphorylate and activate downstream targets that ultimately drive the cell cycle. The upstream activators of the MAPKKK are not as well characterized as other portions of the cascade; as such, only ras, PAK 1, and rac have been listed for simplicity. Although the MAP kinase cascades are parallel in nature, there is extensive cross talk between these pathways. The generation of “secondary messengers” that act upon intracellular receptor sites is exemplified by G-protein-coupled receptors. G-proteins interact with adenylate cyclase and certain phospholipases. Consequent hydrolysis of membrane phosphatidylinositol 4,5-bis-phosphate yields inositol 1,4,5-tris-phosphate (IP₃), which releases Ca²⁺ from internal stores, and diacylglycerol (DAG), which activates protein kinase C (PKC). Activation of PI3K by tyrosine kinases increases IP₃ levels, allowing cross talk between growth factor and G-protein-coupled receptors. The ultimate effect of growth factors is to trigger the enzymatic cascade involving cyclins and cyclin-dependent kinases (CDKs) that play critical roles in stimulating cells to enter and transit through the cell cycle. The protein levels of cyclins and CDKs are controlled by ubiquitylating enzymes. Ubiquitin (Ub) is a small 8-kDa protein, which is covalently attached to the target protein by E3 ubiquitin ligase, leading to the formation of a polyubiquitin chain. The polyubiquitylated protein is recognized by the 26S proteasome, and is destroyed in an ATP-dependent manner. Extrinsic apoptotic pathways are triggered by activation of a variety of receptors (Fas, TNF-R) containing death domains, which leads to the activation of caspases and programmed cell death (apoptosis). Intrinsic apoptotic pathways are activated by a wide range of stress stimuli and result in an up-regulation of proapoptotic mediators (BCL-2 members) on the outer mitochondrial membrane, with subsequent apoptosome assembly and activation of caspases and apoptosis. These pathways have extensive cross talk with other cellular pathways, including the one depicted here. Elevated activity of PI3K leads to activation of AKT, which in turn phosphorylates Bad, leaving its protein partner Bcl-2 available to inhibit apoptosis.

expressed, and a catalytic component termed hTERT, whose expression is usually repressed after embryogenesis is complete. Approximately 90% of human tumors, however, express telomerase as a result of the upregulation of hTERT. Other tumors undergo a process independent of telomerase activation known as alternative lengthening of telomeres, which is less well understood. Although immortalized, these cell lines are generally not tumorigenic when implanted into animals. Further genetic alterations are required to convert these into tumor-forming cell lines.

Apoptosis

Apoptosis is an active and intricately regulated process in which cells undergo programmed cell death. It is a normal physiologic condition that is associated with involution and tissue remodeling during morphogenesis and a number of immunologic responses (23,24). Apoptosis consists of three phases known as the initiation, effector, and degradation phases. In the initiation phase, the cells receive a stimulus that triggers the apoptotic process. Hypoxia, ionizing radiation, chemotherapeutic agents, and viral infection can induce the process (25–28). Additionally, cytotoxic lymphocytes, mediated by the Fas ligand, and p53, mediated by *bax*, can induce apoptosis (29–33). The entire process is regulated by a number of oncogenes and tumor-suppressor genes (p53, *Rb*, *ras*, *raf*, and *c-myc*) (34). Apoptosis is still reversible in the effector phase; once degradation begins, though, the process is no longer reversible and cellular death ensues (24, 28).

Histologically, apoptotic cells are characterized by cell shrinkage, chromatin condensation, and internucleosomal degradation of cellular DNA. This appearance differs from that of hypoxic necrosis, which is characterized by cellular swelling. The swelling is attributed to the loss of selective cell membrane permeability and to mitochondrial swelling, resulting in plasma membrane rupture with DNA, RNA, and protein degradation from the release of lysosomal hydrolases. The enzymatic degradation leads to an intense inflammatory response in the surrounding tissue, resulting in cellular necrosis (23,24,35). In contrast, this inflammatory response does not occur with apoptosis. During the final stages of apoptosis, the cell becomes convoluted and breaks into several membrane-bound vesicles containing intact organelles and nuclear fragments. Typically 180 to 200 base pairs in length, DNA fragments are the biochemical hallmark of apoptosis and can be used for morphologic analysis (24,35). Although apoptotic cells can be visualized and quantified with routine staining of tumor material, techniques using labeling of the 3' free ends of the DNA fragments by radioactive or nonradioactive means allow for accurate identification of single apoptotic cells and quantification of the extent of apoptosis in tumor material via an apoptotic index (24,36,37). The index commonly measures either the number of apoptotic cells per 1,000 tumor cells or per ten high-power fields (24,38,39).

Apoptosis can be induced by cytotoxic lymphocytes (CD8⁺ T lymphocytes) via the Fas ligand/receptor pathway (30,31). Fas (or Apo-1) is a glycosylated transmembrane receptor belonging to the tumor necrosis factor (TNF) receptor family. The binding of Fas receptor to Fas ligand (FasL), a transmembrane protein present on cytotoxic T lymphocytes, activates a pathway eventually leading to apoptotic cellular death (30,31). Downstream of the Fas receptor is FADD (Fas-associated death domain), which binds to a conserved amino acid sequence known as the "death domain" of the cytoplasmic end of the Fas receptor. Together, these two proteins form an apoptotic signaling complex with FLICE (FADD-like interleukin-2 converting enzyme [ICE], also known as caspase-8). Recently, caspases have been identified as the "common final pathway" in the execution of apoptosis in highly divergent systems (31). Caspase

assays have been developed that, as with the DNA fragmentation index, provide a method of identifying cells undergoing apoptosis.

The *bcl-2* family of proteins has been shown to play a major role in apoptosis. The *bcl-2* protein was initially discovered as an overexpressed protein in B-cell lymphomas. For this reason, *bcl-2* is considered to be an oncogene. Members of the *bcl-2* protein family are both apoptosis inhibiting (*bcl-2*, *bcl-xl*, *bcl-w*, *bfl-1*, *brag-1*, *mcl-1*, and *A1*) and apoptosis promoting (*bax*, *bak*, *bcl-xS*, *bad*, *bid*, *bik*, and *Hrk*) (24,40–45). Their actions can be independent of or in competition with one another. For instance, when *bax* is in excess, the *bax* homodimers predominate, favoring apoptosis. However, an excess of *bcl-2* leads to *bcl-2/bax* heterodimers that inhibit apoptosis. In other examples, *bcl-xl* inhibits apoptosis by binding and sequestering *bax*, whereas *bad* promotes apoptosis by binding *bcl-2* and *bcl-xl*, thereby releasing *bax* (24,43,44). The exact mechanism of action of each family member is currently under investigation. However, *bcl-2*, *bcl-xl*, and *bax* appear to exert their effects on the cell mitochondria either as ion channel or adapter/docking proteins. As these proteins form ion channel pores on the membrane surface of the mitochondria, disruption of the transmembrane potential releases caspase-activating substances, thereby activating the final common pathway in apoptosis (23,24,46).

Tumor-suppressor genes as well as other oncogenes besides *bcl-2* are associated with the regulation and execution of apoptosis, including p53, *Rb*, *ras*, *raf*, and *c-myc* (24,34). As discussed previously, p53 monitors the status of DNA (Fig. 3.3). With DNA damage, p53 stalls the cell cycle through the induction of CIP/WAF/p21, a protein that prevents phosphorylation of CDKs (24,34,47,48). CDKs are positive regulators of the cell cycle. In the absence of this phosphorylated (active) CDK, *Rb* will remain unphosphorylated, and the cell cycle will halt until the DNA is repaired. If the DNA is not repaired, p53 can promote apoptosis through the upregulation of *bax* and the downregulation of *bcl-2* (24,34,49,50). Cells lacking p53 are resistant to some apoptotic induction events, such as ionizing radiation, chemotherapeutic agents, loss of *Rb*, and expression of *c-myc*. The effect of *c-myc* on the apoptotic process is growth-factor dependent. It induces proliferation in the presence of growth factors, but in their absence has apoptotic effects (24,51). Overexpression of *ras* may lead to increased or decreased apoptosis (24,52–54). Additionally, *ras*-induced apoptosis is inhibited by *bcl-2*. However, phosphorylation of *bcl-2* negates its capacity to protect cells from *ras*-induced apoptosis (24,55).

Several investigators have examined differing aspects of apoptotic mechanisms in gynecologic malignancies (56–61). In general, overexpression of the oncogenes *bcl-2* and *bcl-xl* protects many cell types against inducers of apoptosis (hypoxia, ionizing radiation, chemotherapeutic agents, and viral infection), and therefore promotes tumorigenesis. Additionally, downregulation of the p53 tumor-suppressor gene or of the proapoptotic *bax* gene also promotes tumorigenesis. In gynecologic malignancies, *bcl-2* is strongly expressed in normal endometrial epithelium and is downregulated in atypical hyperplasia and endometrial adenocarcinoma. However, the use of *bcl-2* expression as a prognostic factor is not well established (59). With respect to p53, immunohistochemical detection of p53 in tissue correlates closely with the presence of mutations in the gene, which is attributable to a much longer half-life of the mutated protein. Mutations of p53 are absent in normal endometrium but present in endometrial cancer, particularly the endometrioid subtype; p53 expression in endometrial cancer has been shown to correlate with tumor type, stage, and grade but not significantly with prognosis (57,60,62–66).

Necrosis

Historically, three types of cell death have been distinguished in mammalian cells by morphological criteria. Type I cell death, better known as apoptosis, is defined by characteristic changes in the nuclear morphology, including chromatin condensation (pyknosis) and fragmentation (karyorrhexis) (67). All of these changes occur before plasma membrane integrity is lost. Type II cell death is characterized by a massive accumulation of two-membrane autophagic vacuoles in the cytoplasm. Type III cell death, better known as necrosis, is often defined in a negative manner as death lacking the characteristics of the type I and type II processes, and is usually considered to be uncontrolled (67). Necrosis can include signs of controlled processes such as mitochondrial dysfunction, enhanced generation of reactive oxygen species, adenosine 5'-triphosphate (ATP) depletion, proteolysis by calpains and cathepsins, and early plasma membrane rupture (67). Recent research suggests, however, that the process of necrosis might be tightly regulated. Specific processes thought to be involved in the regulation of necrosis include receptor-induced necrotic cell death through receptor interacting protein RIP1 and cyclophilin D. RIP kinases constitute a family of seven members and are crucial regulators of cell survival and death (68). RIP kinases are classified as serine/threonine kinases and are closely related to members of the interleukin-1 receptor-associated kinase (IRAK) family. RIP1 and RIP2 (CARDIAK/RICK) also bear a C-terminal domain belonging to the death domain, allowing recruitment to large protein complexes initiating different signaling pathways (68). Cyclophilin D is a mitochondrial matrix protein that can interact with inner membrane proteins and participate in the opening of nonspecific channels, causing dissipation of the inner mitochondrial transmembrane potential (67). Knockout of the cyclophilin D gene induces resistance to necrotic cell death.

In Vivo Biology

Proliferation Indices

Various methods have been developed to measure the percentage of cells actively proliferating, the percentage of cells in specific phases of the cell cycle, the duration of different phases, and the total cell-cycle time. The labeling index (LI) is a crude estimate of the percentage of proliferating cells within a tumor. The LI identifies the proportion of cells that have completed S phase during the assay by using autoradiography to detect ^3H -thymidine that has been incorporated into cellular DNA. Another crude estimate of proliferation is given by the mitotic index (MI), which relies on enumeration of mitotic figures. This measure is limited by the relatively short duration of mitosis and the ability to correctly identify cells in mitosis. The percent labeled mitosis (PLM) method is used to estimate the duration of the cell cycle and its component phases. Serial biopsies are obtained after thymidine injection to follow the labeled cohort of cells as it passes through the cell cycle. Ideally, waves of labeled mitoses of width T_S (S-phase duration) are separated by T_C (cell-cycle duration). Phase duration variability, however, causes dampening of these waves. Computer models are required to generate approximations of the phase and cycle times. Drawbacks of the PLM method include the preferential collection of data from the cells with shorter cycle times and the inability to distinguish nonproliferating from slowly proliferating cells (3).

Flow cytometry has been used to analyze the cell cycle and growth fraction. The histogram generated by fluorescent emission allows estimation of the proportion of cells with DNA content that is diploid (G_1 and G_0 cells), tetraploid (G_2 and

M cells), or intermediate (S-phase cells). The S-phase fraction (SPF) provides an approximation of the growth fraction. Phase determination may be complicated by background contamination due to cellular debris and by the imprecision involved in interpreting DNA distribution, especially in the presence of aneuploidy. A more specific method for estimating the SPF involves the administration of a nonradioactive DNA precursor, such as 5-bromodeoxyuridine or 5-iododeoxyuridine, followed by treatment with a DNA-intercalating fluorescent dye. The precursor may be recognized in denatured DNA by a fluorescent-labeled monoclonal antibody. Two-parameter flow cytometry is used to follow the labeled cohort of cells as it traverses the cell cycle. This method can generate estimates for T_S and LI from a single biopsy performed at a known interval after administration of the precursor. Similar to the PLM method, however, these flow cytometric measurements favor data collection from the most rapidly dividing cells. Another application of flow cytometry is the estimation of growth fraction via fluorescent-labeled antibody recognition of cellular antigens expressed only by actively proliferating cells (proliferation-dependent antigens) (3).

Estimates for the LI or SPF of solid human malignancies are generally in the range of 3% to 15%, a proliferation rate lower than that of normal bone marrow and intestinal epithelium, but higher than that of other normal tissues such as liver and lung (31). Typical values for tumor T_S and T_C are 12 to 24 hours and 2 to 3 days, respectively. These values are somewhat longer than comparable estimates for nonmalignant, rapidly proliferating tissues. Many studies have addressed indices of proliferation for gynecologic malignancies. The PI (proliferation index, generally defined as %S + G_2 cells) and SPF are the measures that are commonly used. SPF and PI have been used as both discrete and continuous variables when establishing levels of significance.

Some retrospective investigations of epithelial ovarian cancer have found the SPF or PI to be prognostic indicators, while others have not (69–72). A prospective evaluation of 47 cases of ovarian carcinoma of all stages assessed SPF and expression of Ki-67, a proliferation-dependent nuclear antigen. Expression of Ki-67 and elevated SPF were both found to confer an adverse prognosis. When the cases were stratified by disease dissemination, stage I/II versus stage III/IV, the SPF retained its significance within both groups (73).

Increasing SPF and PI have been noted to accompany increasing severity of endometrial hyperplasia (74); several investigators have also found a correlation between advanced grade and elevated indices in endometrial carcinoma (75–77). Two prospective studies, including 304 evaluable clinical stage I/II patients and 101 patients of all stages of endometrial cancer, reported SPF to be of independent prognostic significance in multivariate analyses (75,77). Another prospective study of 209 clinical stage I/II cases, however, found a high PI not to have adverse implications (78).

Increasing proliferative activity, as measured by mitotic index, has been reported to correlate with increasing degree of cervical dysplasia (79). One prospective evaluation of 242 squamous cell carcinoma patients of all stages found SPF to be significantly related to survival in both univariate and multivariate analyses, whereas another prospective study of 195 similar cases determined that SPF alone did not predict survival (80,81). A few investigators have noted the subset of diploid cases with high proliferative indices to have a significantly worsened prognosis (81–83).

Some studies of proliferation have assessed the less commonly occurring gynecologic malignancies. Retrospective analyses of uterine sarcomas have revealed the mitotic index or SPF to be useful for predicting clinical outcome (84–86). For discriminating molar versus nonmolar hydropic gestations, elevated SPF was found to be useful in one study, but

not in another (87,88). In an evaluation of 51 complete mole patients with available follow-up, no significant difference was noted in the SPF for those with persistent disease versus those without (88). A retrospective evaluation of 42 cases with all stages of squamous cell carcinoma of the vulva failed to show a significant association between SPF and recurrence or overall survival (89).

Precursor Lesions

A wide range of neoplasia is encountered in gynecology. Squamous cell carcinoma of the cervix has the most well-defined precursor lesion among the gynecologic malignancies in the form of cervical dysplasia. High-grade cervical dysplasia has a known high propensity for eventual infiltration into the subepithelial tissue, whereas most low-grade dysplasia will spontaneously regress (90). Endometrial cancer has two forms of precursor lesions: endometrioid endometrial cancer is associated with atypical hyperplasia arising in a setting of estrogen excess, whereas serous and some clear cell endometrial cancer arises from endometrial intraepithelial neoplasia (EIN) in a setting of atrophy (91). A precursor lesion for epithelial ovarian cancer has not been identified consistently, although some researchers have found dysplasia of the ovarian surface epithelium, particularly in ovarian inclusion cysts, to be associated with ovarian cancer (92). Atypical endometriosis appears to be a preinvasive lesion for 28% of endometrioid and 49% of clear cell ovarian cancers (92). Further evaluation of all of these precursor lesions is under way to define the critical events that cause a small fraction of them to progress to overt cancer while the rest remain premalignant or even regress.

Gynecologic neoplasms range from noninvasive benign tumors, such as uterine leiomyomata, to aggressive malignancies, such as high-grade epithelial ovarian carcinoma. Ovarian tumors of low malignant potential (LMP, also called borderline tumors) are relatively unique with respect to the criteria distinguishing benign from malignant neoplasia. Although originally thought to represent a preinvasive stage in ovarian malignancy, recent molecular evidence suggests a more complicated relationship between LMP and invasive tumors. Serous LMP tumors do not have p53 mutations and display loss of heterogeneity (LOH) on the long arm of the inactivated X chromosome, whereas invasive serous ovarian cancer frequently displays p53 mutations and has a different pattern of LOH involving multiple chromosomes (93). Mucinous LMP tumors, on the other hand, have similar patterns of *K-ras* mutation and LOH as invasive mucinous ovarian cancer (92). These results suggest that, whereas mucinous LMP tumors may progress to invasive cancer, serous LMP tumors do not and, in fact, likely represent a distinct disease process. Other gynecologic neoplasms such as advanced endometriosis, with its ability to invade structures such as the bowel and ureter despite being a benign lesion, and pseudomyxoma peritonei, with an indolent but nevertheless potentially lethal course, also blur the boundaries between the behavior of benign and malignant tumors.

Stem Cells

Stem cells are a recent focus of intense research that ultimately may contribute to our understanding of the pathogenesis of ovarian cancer, as well as strategies for its prevention and treatment. Somatic stem cells divide asymmetrically, giving rise to a cell that can replace normal differentiated tissue cells and another stem cell. Somatic stem cells are thought to play a role in the normal function of organs and in normal tissue repair. Because of these repeated cycles of division, the stem cells are prone to accumulating genetic mutations over time. Cellular transformation may occur, creating a population of cancer stem cells (reviewed in Ref. 94). The properties of stem

cells may explain some of the clinical features of tumors; their ability to differentiate may explain the heterogeneous nature of many tumors, while their ability to remain quiescent in a niche until stimulated to undergo potentially limitless self-renewal may help explain the process of recurrence.

Cancer stem cells, also referred to as "side population" cells, were described first in leukemia and breast cancer. Goodell et al. first identified a subset of cells in murine bone marrow on the basis of their ability to efflux the Hoechst 33342 vital dye with dual-wavelength flow cytometry. These side population cells were found to have the features of hematopoietic stem cells (95). Recent work has identified side population cells in epithelial ovarian cancer animal models, cell lines, and patients. Animal models for ovarian cancer have progressed significantly with the identification of the müllerian inhibiting substance type II promoter in a mouse model of serous ovarian cancer as well as the *Kras/PTEN* Cre recombinase mouse model for endometrioid ovarian cancer (96,97).

Szotek et al. utilized these two models to identify side population cells. One cell line derived from each model was found to have side population cells based on a sort using Hoechst 33342. These cells, in turn, were capable of forming tumors when injected into the dorsal fat pad of nude mice. In addition, side population cells were identified in three of four human ovarian cancer cell lines and the ascites from four of six patients with ovarian cancer (98).

Bapat et al. also examined the tumor cells in ascites from a patient with advanced ovarian cancer for evidence of cancer stem cells. Initially, one tumorigenic clone was identified, but another spontaneously transformed in culture. Both clones were capable of producing anchorage-independent spheroids that self-renewed. They also induced serous tumors when injected subcutaneously or intraperitoneally into nude mice. These features suggest that the clones represent true cancer stem cells (99).

Genetic Alterations

Chromosomal Abnormalities

Karyotypic and molecular biologic analyses have provided evidence that most cancers arise in association with clonal genetic changes. Multiple genetic alterations appear necessary for conversion from the normal to the cancerous state, with primary events that are responsible for tumor initiation and secondary changes that account for tumor progression and heterogeneity. Gross chromosomal abnormalities include translocations, deletions, inversions, and amplifications affecting entire sections of a chromosome (100). Most forms of malignant neoplasia demonstrate both intertumoral and intratumoral heterogeneity with respect to chromosomal aberrations. Molecular chromosomal abnormalities in cancer consist of point mutations affecting a specific locus on the chromosome, frequently involving dominant (e.g., *ras*) or recessive (e.g., p53) oncogenes (101).

Classic examples of chromosomal abnormalities found in cancer are the reciprocal translocations that occur in chronic myelogenous leukemia (CML) [t(9;22)] and Burkitt's lymphoma [t(8;14)] and the inherited deletions of 13q14 in retinoblastoma (102). In CML, the protooncogene *abl* is translocated from chromosome 9 to 22. This results in the formation of a new protein that represents a fusion of the *abl* and *bcr* gene products. Experimental infection of mice with retroviruses carrying the gene encoding this fusion protein has produced a CML-like condition in these animals. In Burkitt's lymphoma, the *myc* protooncogene is repositioned near genes encoding the immunoglobulin heavy or light chains and is constitutively activated. Deregulated expression of the *myc*

gene results in cellular proliferation. Characterization of chromosomal abnormalities at 13q14 in hereditary retinoblastoma resulted in the identification of the retinoblastoma gene (*Rb*). The identification of allelic loss in tumors from patients heterozygous at this locus (loss of heterozygosity or LOH analysis) has provided evidence that similar molecular mutations appear to be operating in the hereditary and sporadic forms of the disease. The Rb protein appears to have a major role in regulating cell division; the consequences of alterations at the Rb locus have led to its characterization as a tumor-suppressor gene.

Gross chromosomal alterations have been described in both benign and malignant gynecologic neoplasia, but are more frequent and generally more extensive in the latter. In uterine leiomyomata, clonal chromosomal aberrations have been reported in 15% to 54% of tumors studied, with abnormalities involving chromosomes 12 and 14 being most frequently detected (103,104). In uterine sarcomas, up to 71% of tumors have demonstrable and often multiple abnormalities, with chromosomes 1, 7, and 11 most commonly involved, especially 11q22 (105,106). Cervical carcinoma is characterized by chromosome 1 alterations in greater than 90% of tumors, as well as by frequent deletions involving 3p, 11q, and 17p (107–110), while karyotypic analysis of epithelial ovarian cancers reveals frequent abnormalities of chromosomes 1, 3, 7, 11, and 12 (111–113).

In general, less aggressive malignancies are associated with less complex karyotypic changes. Simple chromosomal abnormalities have been reported for some granulosa cell tumors, tumors of low malignant potential, low-grade epithelial ovarian cancer, and early-stage endometrial and ovarian carcinomas, whereas advanced epithelial ovarian carcinoma frequently demonstrates complex chromosomal changes (112–118). In addition, specific changes for certain tumors may represent a later event in tumorigenesis or may confer a worse prognosis. The frequency of polysomy for chromosome 1 increases as the severity of cervical intraepithelial neoplasia increases (109). Gallion et al. detected LOH on 17p in benign, borderline, and invasive epithelial ovarian tumors, but found allelic loss on 11p in the invasive cancer cases only (119). LOH on 13q was noted in 58% of informative cases overall, including 80% of stage I tumors. Worsham et al. analyzed six squamous cell carcinomas of the vulva, each containing multiple chromosomal rearrangements (120). Two specific deletions, 10q23–25 and 18q22–23, were present in all four of the patients who died of disease but in neither of the long-term survivors.

Somatic Versus Germ-Line Mutations

In addition to the above classification, genetic changes may be characterized as germ-line versus somatic. Whereas all of the cells in an individual with a germ-line mutation will manifest the genetic alteration, somatic mutations occur in a single cell and are detectable in tumors secondary to clonal proliferation. Germ-line genetic changes have been shown to be the basis of the hereditary cancers seen in syndromes such as *BRCA1*, *BRCA2*, and hereditary nonpolyposis colon cancer (HNPCC). In general, these hereditary syndromes are thought to account for only a minority of gynecologic cancers. Somatic mutations, on the other hand, occur in the majority of cancers.

Clonality

Many human tumors exhibit extensive heterogeneity with respect to cellular properties such as morphology, surface markers, and chromosomal abnormalities. This diversity has raised the question of whether tumors originate from a monoclonal or polyclonal origin. One method of assessing clonality evaluates

X-linked gene products such as the isozymic expression of glucose-6-phosphate dehydrogenase (G6PD) (121). Another technique utilizes restriction fragment length polymorphism (RFLP) analysis, exploiting the differential methylation patterns of X-linked genes such as hypoxanthine phosphoribosyl transferase (*HPRT*), phosphoglycerate kinase (*PGK*), and the human androgen receptor (*HUMARA* assay) (122). The use of proliferation-independent X chromosome-linked markers is based on lyonization, the phenomenon of random inactivation of one X chromosome in the embryonic cells of mammalian females. The somatic cells of heterozygous women will be mosaics, with approximately equal numbers of cells expressing either the maternal or paternal allele, but no cells expressing both. A tumor arising in a woman heterozygous for an X-linked gene would be expected to express only one allele if it originated from a single antecedent cell, but to express both alleles if its origin were polyclonal (121). Although the studies utilizing these techniques have generally suggested a monoclonal origin for tumors, the interpretation of the results is complicated by technical issues with the assays, particularly the presence of monoclonal patches in many of the surrounding normal tissues, raising the possibility that the monoclonal tumor simply reflects the clonal composition of the normal tissue.

Genetic markers acquired secondary to somatic events have also been studied to assess clonality. Examples include the rearrangement of immunoglobulin and T-cell receptor genes in lymphoid malignancies (120), the allelic loss on autosomes described for a number of different cancers (123), and point mutations. Immunohistochemistry or molecular probes are used to determine if the same gene product or gene arrangement is present in all of the cells within the tumor, suggesting their origin from a common precursor cell. LOH analysis is employed to discern whether the pattern of allelic loss is identical in all of the cells in a given tumor. Point mutations may be assessed by techniques such as RFLP analysis using restriction endonuclease digestion. Studies using these techniques have been performed on acute myelogenous leukemia, Burkitt's lymphoma, and many epithelial tumors. The results have provided overwhelming evidence for a monoclonal origin of most human malignancies.

Many studies have analyzed the clonal nature of gynecologic malignancies. Fialkow reported the use of G6PD analysis for a variety of tumors, including cervical carcinoma, but this method was thought to be inconclusive, owing in part to its inability to reliably exclude the presence of contaminating normal tissue in the assay (120,124,125). Other problems noted with this method included the requirement for a relatively large amount of tissue and the low frequency of G6PD polymorphism in the female population. In contrast, Vogelstein et al. demonstrated that RFLP analysis of the *HPRT* and *PGK* genes could be used to assess the clonality of tumors in greater than 50% of American women. Of 92 tumors tested with the *HPRT* and *PGK* probes, the X-inactivation patterns seen reflected clonality accurately in greater than 95% (122). Sawada et al. evaluated the clonality of 25 gynecologic malignancies (4 cervical, 11 uterine, 7 ovarian, and 3 tubal) in women heterozygous for the *BstXI* polymorphism of the *PGK* gene. All 25 tumors were determined to be monoclonal, whereas adjacent normal tissue was polyclonal. DNA preparations from separate areas of the same primary tumor and from corresponding metastatic lesions again revealed identical allelic inactivation (125). The differential methylation patterns of the *PGK* gene on which this RFLP analysis is based could potentially limit the utility of this approach, however, since DNA methylation patterns are sometimes altered in malignancy.

Several investigators have employed a strategy of combined X-chromosome inactivation and autosomal LOH analysis to assess the clonality of metastatic epithelial ovarian cancer.

Jacobs et al. investigated the primary tumor and metastatic implants for LOH at five loci on chromosomes 5, 11, 13, and 17 and sequenced exons 5–8 of the p53 gene in 17 cases. X-chromosome inactivation of the *PGK* gene could be assessed in five of these patients. Strong evidence for a single precursor cell was presented for 15 of 17 cases. In two cases, data were thought to be compatible with either a monoclonal origin or origin from two primary ovarian carcinomas (126). Tsao et al. tested for LOH at 12 loci on chromosome 17 in 16 patients and were able to evaluate allelic inactivation of the *HPRT* gene in four of these 16. In all cases, the X-chromosome inactivations and LOH patterns were identical for all tumor deposits tested in each individual patient (127). Li et al. examined eight cases of invasive and one case of borderline ovarian carcinoma. Analysis of LOH at 86 polymorphic autosomal loci and X-chromosome inactivation patterns of the RFLP DXS255 in five informative patients strongly suggested a monoclonal origin for all of the tumors tested (128).

In contrast, Muto et al. have provided evidence for a polyclonal origin in four of six cases of papillary serous carcinoma of the peritoneum. Eight loci on chromosomes 1, 3, 4, and 17 were assessed for LOH at five or more different tumor sites within each patient. Screening for p53 mutations was also performed. Four of the six patients demonstrated selective allelic loss at all sites tested. One of these four patients also had a p53 mutation detected by single-strand conformational polymorphism (SSCP) analysis and confirmed by DNA sequencing at only half of the distinct anatomic sites tested (129). Recent analysis of borderline tumors has also determined that a small subset of these malignancies is multiclonal in origin (130). Additional studies of primary peritoneal serous carcinoma and borderline tumors are needed to clarify their clonal origin and their relationship to, or distinction from, primary ovarian serous carcinoma (131).

Ploidy

The cells in a tumor may be described in terms of their overall DNA content as compared to that of normal tissue. Normal tissue primarily contains cells that have a diploid ($2n$) complement of chromosomes, a subset of cells that have undergone DNA synthesis ($4n$) but have not yet divided, and a smaller number of cells with an intermediate amount of DNA. Deviation from this distribution is termed aneuploidy and occurs in approximately 70% of human tumors (132). Tumor ploidy status is frequently described by a ratio known as the DNA index. The numerator is the DNA content in tumor cells that are either not actively proliferating or are in the process of replicating but have not yet undergone DNA synthesis, whereas the denominator is the DNA content of normal diploid cells. Index values deviant from 1 are used to define aneuploidy (3).

Flow cytometry and, more recently, image cytometry are methods that have been used to assess the ploidy status of tumors. In flow cytometry, a DNA intercalating fluorescent dye, such as propidium iodide, is applied to a single-cell suspension. Laser excitation of the stained nuclei, which have been isolated from the cell, generates a fluorescent emission proportional to the amount of DNA in each cell. A histogram is generated, which is analyzed for evidence of tumor aneuploidy (Fig. 3.4) (3). Flow cytometry may be applied to paraffin-embedded as well as fresh-frozen tissue. In addition, because of the large number of cells evaluated, it may be used to describe other cellular parameters, such as the cell-cycle composition of the tumor cell population. Potential confounding factors associated with this method include cellular debris and normal cells contained in the suspension. In image cytometry, touch imprints of the tumor are stained with a stoichiometric nuclear dye, such as feulgen. To quantify DNA staining, a computer measures the optical density in intact cells that have been prescreened by light microscopy to exclude nontumorous cells. The number of cells analyzed is usually 100 to 200, which is in contrast to the 20,000 to 50,000 required by flow cytometry. Both paraffin-embedded and fresh-frozen tissue may be used for image cytometry. Other applications of image cytometry include the description of nuclear architecture and the quantification of hormone receptors (133–135). Although flow cytometry and image cytometry have provided comparable estimates of aneuploidy between series of cancer cases, the classification within series of cases evaluated by both methods may differ by as much as 15% (135).

Several important caveats regarding the use of ploidy status should be noted. Normal ploidy status should not be equated with a normal karyotype. Because ploidy determination provides an estimate of overall DNA content only, tumors with structural chromosomal abnormalities may still manifest a normal DNA content. Also, different areas of the same tumor may manifest heterogeneity with respect to ploidy status (71,136,137). Thus, differences in sampling techniques such as obtaining single versus multiple tissue specimens may partially explain the discrepant results of various investigators examining the same tumor type.

Ploidy studies of epithelial ovarian cancer have detected aneuploidy in 0% to 34% of LMP tumors and in 50% to 80% of invasive carcinomas (70–73,113,134–143). The three largest published series of LMP tumors are case-control studies that reached conflicting conclusions regarding the significance of aneuploidy and prognosis (139–141). In invasive disease, studies have suggested that ploidy status may be of prognostic importance. Several studies have found ploidy status to be of independent prognostic significance in early-stage invasive disease (70,73,142,144,145). Many investigations that have included advanced-stage invasive disease have also reported a significant adverse association between aneuploidy and

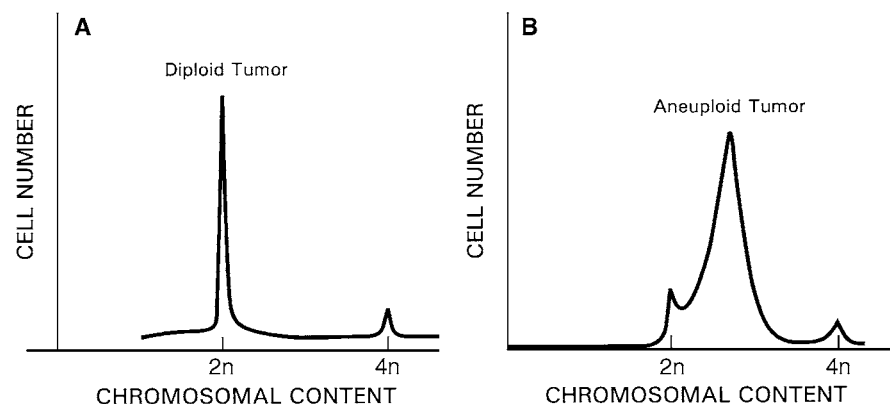

FIGURE 3.4. DNA histograms for (A) diploid and (B) aneuploid tumors. **A:** The normal distribution of cells in somatic tissue is shown, with the majority possessing a $2n$ DNA content, and a smaller fraction having a $4n$ or intermediate amount of DNA. **B:** In contrast, a tumor-cell population is shown that contains a prominent population of cells with an intermediate DNA content.

median time to recurrence or long-term survival (70–73,144, 146,147). Subset analysis by stage in some of these studies, however, has shown the association to be significant only in patients with early-stage tumors (73,144). Suboptimal tumor debulking at the primary surgery, a higher frequency of positive second-look laparotomies, and a greater likelihood of recurrence after a negative reassessment procedure have all been associated with aneuploidy, although the relationships have not always been statistically significant (69–73,77,78,80–83,133, 135,136,138–150). Overall, it appears that cytometric analysis of tumor DNA content is an important prognostic indicator in ovarian cancer and is associated with a shortened median time to recurrence and long-term survival. This association appears particularly true in early-stage tumors.

The clinical value of DNA ploidy status has also been analyzed in both endometrial hyperplasia and carcinoma (74,78,151–153). Norris et al. defined a set of combined morphometric and DNA content criteria to help distinguish between various forms of endometrial hyperplasia and carcinoma (154). Lindahl and Alm prospectively evaluated 156 patients with endometrial hyperplasia (109 cystic glandular, 35 adenomatous, and 12 atypical). The frequency of aneuploidy was 21%, 20%, and 33%, respectively. Follow-up at 24 months for a subset of patients treated with dilatation and curettage only revealed nonhyperplastic endometria in 64% of those whose hyperplasias were initially diploid compared to 36% of those whose lesions were nondiploid. The difference was not statistically significant, but they noted that this may have resulted from the small number of cases analyzed because a number of patients were lost to follow-up (74). Whereas earlier studies produced conflicting results with respect to the clinical value of DNA ploidy status on prognosis in endometrial carcinoma, more recent studies have shown DNA ploidy status to be an important prognostic indicator with respect to survival (78,151–153). In a subgroup of 293 women with early-stage disease from a Gynecologic Oncology Group protocol, Zaino et al. found a significant increased risk of disease-related death for patients with aneuploid tumor type as compared to patients with diploid tumor type (151). Although this study examined early-stage disease, Nordstrom et al. recently examined DNA ploidy status in 266 patients with advanced-stage or early-stage grade 3 tumors. In this study, World Health Organization (WHO), International Federation of Gynecology and Obstetrics (FIGO), and nuclear grading were evaluated for prognostic impact in relation to clinical variables and DNA ploidy. Patients with clinical stage I (grades 1–2) tumors were excluded. In univariate Cox analyses, WHO, FIGO, and especially nuclear grading ($p < 0.001$), as well as age, stage, and ploidy, were prognostic regarding survival. In the multivariate Cox analyses, WHO and FIGO grades yielded little further independent information beyond nuclear grade. When DNA ploidy was added to the analyses, nuclear grade lost most of its impact because aneuploidy was a powerful factor ($p < 0.001$) that covaried with nuclear grade (152). Thus, it appears that recent data would suggest aneuploidy as being an independent indicator of poor prognosis with respect to endometrial carcinomas.

Preinvasive and invasive cervical diseases have also been evaluated for the prognostic significance of aneuploidy (155–164). A good correlation has been demonstrated between normal or dysplastic Papanicolaou smears and normal or aneuploid DNA histograms, respectively (158,159). An increasing DNA index and a higher frequency of aneuploidy have been reported for increasing degrees of cervical intraepithelial neoplasia (CIN) (158,160–162). Some investigators have suggested defining a subset of CIN at high risk for progression by quantitating the degree of aneuploidy (161,163). Bibbo et al. (164) found that polyploid CIN was more likely to revert to normal histology than aneuploid, nonpolyploid CIN.

Additionally, in a prospective study examining the natural history of CIN, Kashyap et al. (162) noted that aneuploid CIN 1 and CIN 2 lesions were more likely to progress to CIN 3 than euploid lesions. Retrospective and prospective studies of invasive cancer, however, have not demonstrated a consistent relationship between aneuploidy and prognosis (81–83, 154–156). Other gynecologic malignancies such as uterine sarcoma, gestational trophoblastic disease, granulosa cell tumors, vulvar cancer, and fallopian tube cancer have not shown a consistent relationship between ploidy status and prognosis (84–86,88–89,165–169).

Genomic and Proteomic Analysis Techniques

Recent advances in molecular techniques have provided new genomic and proteomic approaches that allow for a more precise analysis and definition of the genetic lesions within cancer cells (170). Loss of genetic material may reflect the presence of tumor-suppressor genes, whereas gain of chromosomal regions identifies the presence of dominant oncogenes.

Fluorescent *In Situ* Hybridization. Gross chromosomal abnormalities are detected by the examination of cultured tumor cells arrested in mitosis by spindle poisons using standard cytogenetic techniques. Fluorescent *in situ* hybridization (FISH) is an excellent technique for identifying the copy number and location of specific genes (or chromosomal regions) within a tumor. A nucleic acid probe that recognizes a specific gene (chromosomal region) is labeled with a fluorescent dye and hybridized to chromosomal spreads. A control for chromosome number is accomplished by using a centromeric probe labeled with a different fluorescent dye (Fig. 3.5). Using these probes, total and relative (per chromosome) gene copy number can be derived. Loss of genetic material may reflect the presence of tumor-suppressor genes, whereas gain of chromosomal regions identifies the presence of dominant oncogenes.

A related technique known as comparative genomic hybridization (CGH) allows a much broader assessment of chromosomal imbalances (171). CGH represents the first approach to scanning the entire genome for DNA copy number abnormalities. The technique utilizes total genomic DNA from control and test samples, which are then labeled with different fluorescent dyes, mixed, and hybridized to normal metaphase spreads. A region that is deleted in the test sample will not hybridize to its chromosomal location, causing the control sample's dye to be in excess. Conversely, the test sample's dye will be in excess if a region is amplified. Thus, a global assessment of chromosomal imbalances can be determined. A more recently developed version of CGH utilizes microarrays (see below) that contain genomic DNA probes. Hybridization of the above-described labeled probes to microarrays containing genomic DNA from a variety of chromosomal regions can provide a quantitative evaluation of chromosomal imbalances.

Whereas FISH allows a specific locus of interest to be identified, CGH represents an advance in its ability to assess the whole genome for gene copy number alterations. FISH has demonstrated that 3q26 has increased copy number in 40% of ovarian cancers (172). Various studies utilizing CGH have consistently revealed aberrant gains in 3q26-qter, 7q32-qter, 8q24-qter, 17q32-qter, and 20q13.2-qter and losses in 4, 13q, 16qter, 18qter, and Xq12 in the genome of fallopian tube and ovarian cancers (173–175). CGH analysis has also been used to evaluate for copy number abnormalities in *BRCA1* and *BRCA2* mutation carriers compared to sporadic ovarian cancer cases (176–178). Inconsistent results have been obtained so far, likely due to small sample sizes and varying inclusion of specific mutations. However, two studies have shown increased copy numbers on 2q (176,178), while two have shown losses on chromosomes 9 and 19, particularly in the *BRCA1* group (177,178), and merit further evaluation.

FIGURE 3.5. FISH analysis of advanced ovarian cancers for cyclin E. The BAC clone containing the CCNE1 (cyclin E) gene was labeled with spectrum orange, whereas the BAC clone containing the INSR gene (to control for aneusomy) was labeled with spectrum green.

Microarrays. Subsequent advances in technique have allowed genomic segments spotted onto arrays to be substituted for the metaphase spreads used in the CGH technique. Microarrays allow for increased resolution, and the potential to improve efficiency and reproducibility. The first array platforms utilized bacterial artificial chromosomes (BAC) as large inserts. Investigators then developed cDNA microarrays. Currently, commercially produced oligonucleotide arrays or single nucleotide polymorphism (SNP) arrays are widely used. Arrays can be designed to focus on a specific area, such as a particular chromosome or region of a chromosome, or can include a large number of genomic segments to assess across the entire genome.

Using microarrays, expression profiles can be established for tumors of different histology, stage, and grade and compared to those of normal tissues. These comparisons can identify genes whose aberrant expression is present in the malignant cell compared to that of its normal counterpart. The selection of the appropriate control sample is critical as it serves as the basis for this analysis. For ovarian tumors, the control sample can be selected to include RNA harvested from the whole ovary or RNA isolated solely from the ovarian surface epithelium. Since the majority of ovarian cancers are thought to be of epithelial origin, the surface epithelium may provide a more specific normal counterpart. Alternatively, there is the potential loss of genetic alterations in the ovarian stroma, the local host

microenvironment, which may be important to the adjacent tumor cell growth. This question was evaluated by profiling the five tissues typically selected as a normal ovarian control in ovarian cancer microarray studies (179). Each normal tissue's comparison to the same set of ovarian cancer samples generated a unique set of differentially expressed genes, emphasizing the importance of the normal control when assessing the list of genes found to be up- or down-regulated in a comparison to cancer. Although there is no broadly accepted standard for the optimal normal ovarian control, this data indicates the potential hazards in cross-comparison between microarray studies if different normal controls are used.

Ovarian cancers of different histologic subtypes have been profiled (180–185). The expression of genes unique to a particular histologic subtype may help explain clinical and biologic characteristics of these subtypes and generate the basis for additional study. For example, clear cell carcinoma of the ovary has traditionally been associated with chemoresistance and an overall poor clinical outcome. Using oligonucleotide arrays, Schwartz et al. analyzed the four major histologic types of ovarian cancer among 113 separate tumors. A unique expression profile of 73 genes was demonstrated in the clear cell ovarian cancers (180). Similarly, other investigators have also noted a distinct profile among clear cell ovarian cancers compared to ovarian cancers of other histologic subtype (181). One study compared the expression profiles of ovarian cancers of different histologies to the analogous subtypes of endometrial cancer. This analysis showed a strong influence of the organ of origin for papillary serous and endometrioid histologies. In contrast, tumors of clear cell histology demonstrated a striking similarity despite different organs of origin, even when renal clear cell carcinomas were included in the analysis, which implies a unique cell of origin and/or biology for all clear cell cancers (182). Collectively, this data suggests that there may be a benefit to subtype-specific diagnostic and therapeutic strategies for ovarian cancer. Subsequent validation studies with clinical correlation have identified up-regulation of the *ABCF2* gene in clear cell ovarian cancers (183). *ABCF2* belongs to the ATP-binding cassette gene superfamily. Currently this gene requires further characterization as it may represent a useful prognostic marker or a potential therapeutic target in clear cell ovarian malignancy.

Other investigators have focused on the molecular signature identified in mucinous ovarian tumors. Microdissection of mucinous cystadenomas, mucinous tumors of low malignant potential, and mucinous adenocarcinomas was performed. The tumors were compared to normal ovarian surface epithelium and a series of microdissected serous ovarian tumors. Hierarchical clustering showed a close association of mucinous tumors. Analysis of the gene expression profiles in mucinous tumors demonstrated an up-regulation of genes involved in cytoskeletal function, which was confirmed with reverse transcriptase polymerase chain reaction (RT-PCR) (184). Other investigators have utilized whole tissue samples to demonstrate a distinct pattern of gene expression among mucinous tumors (185). One gene highly overexpressed in mucinous ovarian cancers is *LGALS4*, an intestinal cell surface molecule. Interestingly, *LGALS4* is located at 19q13.3, a region previously identified to harbor a high frequency of loss of heterozygosity in mucinous ovarian cancers (186).

Other research has focused on clarifying whether a continuum from normal to premalignant to malignant tissue exists for ovarian cancer as it does for other malignancies such as colorectal and cervical cancer. For instance, tumors of low malignant potential (LMPs), also known as borderline tumors of the ovary, have metastatic potential and some histologic features similar to invasive ovarian cancers; however, LMPs generally demonstrate a slow growth rate and an indolent clinical course. Recently, gene expression profiling was applied to

FIGURE 3.6. Hierarchical clustering analysis of the 14,119 probe sets passing the filtering criteria for LMP, low-grade, high-grade, and OSE specimens and binary tree validation. Clustering analysis was completed using the 1 – correlation metric with centroid linkage. Overall tree structure was retained despite the association of low-grade tumors with LMP tumors and the grouping of early-stage and late-stage high-grade lesions. Low-grade and early-stage high-grade samples are indicated in bold. Misclassified specimens are bold and italicized.

define the relationship between LMPs and invasive ovarian cancers (Fig. 3.6). Microdissected LMPs and invasive ovarian cancer of both serous and mucinous histology were compared to normal ovarian surface epithelium. Unsupervised clustering of the expression profiles demonstrated that the serous LMPs cluster separately from high-grade tumors and closer to normal epithelial cells. Interestingly, the majority of low-grade serous invasive tumors clustered with serous LMP tumors, with p53-dependent genes prominently represented on the gene lists. The high-grade invasive tumors showed enhanced expression of genes linked to proliferation, chromosomal instability, and epigenetic silencing compared to the low-grade tumors and LMPs (187). These findings strongly support the concept that serous LMP tumors develop via a pathway that includes the low-grade tumors, whereas high-grade tumors develop along an independent route. In contrast, analysis of mucinous tumors revealed a much closer relationship between LMP tumors and their invasive counterparts. In fact, a molecular continuum from benign mucinous cystadenoma to mucinous LMPs to invasive cancer seems to exist. This supports the idea that a benign mucinous cyst can progress via a borderline lesion to invasive tumor, whereas a serous cyst typically will not undergo transformation to a high-grade ovarian cancer. Additional insights from profiling research such as these may identify the specific molecular events involved in the etiology of each type of ovarian tumor. Understanding these molecular events can then be utilized as targets for screening strategies or for therapeutic intervention.

Gene expression profiling has also been used to identify expression gene patterns in ovarian cancer that correlate with important clinical outcomes. One study employed an oligonucleotide array with over 40,000 features to achieve a whole-genome assessment in which 1,191 genes demonstrated differential expression when compared to normal ovarian

surface epithelium. RT-PCR was utilized as a confirmatory analysis on 14 randomly selected genes. The differentially expressed genes include those associated with cell growth, differentiation, adhesion, apoptosis, and migration (188). With regard to other known clinical prognostic markers, unique gene expression profiles have been demonstrated for early- versus late-stage disease, tumor grade, and surgical resectability (189–191).

Recently, correlation of gene expression profiles with ovarian cancer chemoresistance has been defined (192–194). Unique profiles are associated with primary ovarian cancers that subsequently demonstrate either sensitivity or resistance to chemotherapy. Intrinsic and acquired chemoresistance yield different patterns of gene expression. Further, gene expression profiles have been used to predict early recurrence and positive second-look surgical findings, clinical markers of chemoresistant disease (195,196).

Serial Analysis of Gene Expression. Serial analysis of gene expression (SAGE) is one of several new techniques that allow determination of the expression patterns of thousands of genes simultaneously. SAGE was developed on the basic principles that a short sequence tag (10 base pairs) contains sufficient information to uniquely identify a transcript and that the concatenation of tags in a serial fashion allows for increased efficiency in a sequence-based analysis. The procedure involves the synthesis of cDNA, which is then cleaved. The fragments eventually are amplified via polymerase chain reaction (PCR), concatenated, and sequenced. The identity and abundance for individual transcripts in a tissue can thus be determined (197). The advantage of SAGE is that it is an “open” technique that does not require prior knowledge of the sequences to be analyzed. Microarray technology requires the knowledge of the target sequences (cDNAs or oligonucleotides printed on the microarrays). However, microarrays tend to be easier to utilize.

Carcinogenesis

Initiation and Promotion

The biologic processes of tumor initiation and promotion were first characterized from experiments that involved the induction of skin tumors in mice (198). Animals given high doses of an agent such as a polycyclic aromatic hydrocarbon (initiator or carcinogen) would eventually develop a low number of skin papillomas. If subtumorigenic doses of this agent were followed by multiple administrations of substances that by themselves could not produce tumors (promoters), such as croton seed oil, the animals developed papillomas at a high rate. Further treatment of these animals with a carcinogen converted some of the papillomas to carcinomas. From these classic studies, data from other animal models, and the direct study of human cancers, it has become clear that carcinogenesis is a multistep process.

Initiation is the first stage of carcinogenesis and is characterized by irreversible changes in the cellular DNA. Initiators can be chemical, physical, or viral agents. Chemical carcinogens are usually identified by their ability to cause malignancies when given as a single agent to animals or by epidemiologic studies of environmental/occupational exposures. Their mechanism of action stems in part from their ability to form reactive electrophilic species that can form covalent adducts with nucleophilic sites found in nucleic acids. These adducts can cause DNA structural distortions and, if not repaired prior to subsequent DNA synthesis, heritable mutations. The activity of a chemical carcinogen may vary depending on the dose received and host factors, such as age, sex, species, and target organ specificity. Examples of chemical carcinogens are aromatic amines, nitrosamines, hydrazines, chlorocarbons, reactive alkylating agents, and some natural products, including heavy metals such as cobalt, chromium, and nickel (198). Physical carcinogens include ionizing and ultraviolet radiation, which produce DNA mutations and chromosomal abnormalities through the formation of intermediates such as free radicals and pyrimidine dimers, respectively. Agents such as ultraviolet light, x-rays, certain viruses and chemicals, and tumor-cell DNA can be used to produce cell lines that are not only immortalized but capable of forming tumors in immunocompromised animals (199).

Promotion, the second stage of carcinogenesis, involves a series of generally reversible cellular and tissue changes that inevitably involve cellular proliferation. This proliferation results in the clonal expansion of initiated cells, which then accumulate more mutations, resulting eventually in a transformed cell. Most tumor promoters do not form electrophilic species. Activities associated with tumor promoters include changes in phospholipid, polyamine, and nucleic acid synthesis; enzyme induction; and release of prostaglandins, with concomitant alterations in cell morphology, differentiation, and mitotic rate. Some promoters bind to protein kinase C, a known second messenger in signal transduction pathways (198). Examples of substances classified as promoters include phorbol esters, phenobarbital, saccharin, and hormones such as estrogen (198,200).

The molecular mechanisms of tumor promotion involve proliferative stimuli from growth factors and hormones, the activation of second messenger cascades, stimulation of transcription factor activities, and ultimately changes in the expression of effector genes involved in the biologic processes of cellular growth and/or differentiation. The net effect is to alter cell division, produce clonal expansion of initiated cells, and allow for the continued accumulation of key mutations necessary for the development of the fully transformed phenotype (201).

Potential tumor promoters have been identified for gynecologic malignancies. For example, monocyte products interleukin (IL)-1, IL-6, and TNF- α have all been demonstrated to stimulate the growth of ovarian cancer cells (202). The role of these and other growth factors in the development of gynecologic cancer

is more fully described above. In addition, another example is provided by the well-known growth stimulatory effect of estrogen on endometrial glands.

Occupational/environmental exposure to chemicals has not been identified as an important risk factor for the development of gynecologic malignancies, unlike other cancers such as those of the lung and bladder. The limited data that exist have been derived primarily from animal studies. Multiple chemicals have been shown to have the potential for causing ovarian granulosa cell tumors, benign mixed neoplasms, or nonneoplastic toxic changes in some, but not all, rodent species tested (203,204). Examples of such agents include 1,3-butadiene, benzene, and tricresylphosphate. Chemical agents given in conjunction with an estrogen have also been used to generate endometrial carcinoma and uterine sarcoma in rodents (205,206).

Physical carcinogens may play a role in the development of some gynecologic tumors. A history of prior pelvic irradiation is associated with the development of uterine sarcoma, particularly malignant mixed mesodermal tumor. Case series of patients developing endometrial adenocarcinoma following irradiation for cervical cancer have also been reported, with a disproportionate number of cases of papillary serous histology (207).

Agents that function as tumor promoters in the development of female genital cancers have been better characterized. Unopposed estrogen, whether exogenous or endogenous, is a well-known risk factor for endometrial carcinoma. More recently, concern has been raised over the partial agonist activity of the antiestrogenic agent tamoxifen, which is used most often in the prevention and treatment of breast cancer. Also, sequential oral contraceptives (OCPs) have been associated with an elevated risk of endometrial cancer, but have been replaced by combination preparations, which, in contrast, impart protection against both uterine and ovarian epithelial carcinoma.

Exposure to some hormonal agents has been associated with an increased risk for the development of other gynecologic malignancies as well, although their precise role (initiator vs. promoter) in the pathogenesis remains unclear. For example, several studies have reported an increased rate of cervical cancer among long-time users of OCPs. Also, intrauterine exposure to diethylstilbestrol is associated with an increased risk of developing clear cell adenocarcinoma of the vagina and cervix.

Viral Carcinogenesis

Experiments in the early 1900s in which inoculations of filtered, cell-free extracts from the cancer cells of one animal could induce a tumor in a healthy recipient provided evidence for the role of a transmissible agent in some forms of animal carcinogenesis (208). This phenomenon was initially demonstrated for chicken leukemia and sarcoma, with the responsible infectious agents isolated known as avian leukemia viruses (ALVs) and avian or Rous sarcoma viruses (ASV or RSV), respectively. Subsequently, the mouse mammary tumor viruses (MMTVs) were shown to transmit mammary carcinomas from nursing mothers to newborn mice via breast milk, and murine leukemia viruses (MuLV) were found to spread horizontally by means of cell-free extracts. These viruses are all examples of RNA-containing retroviruses.

The general structure and life cycle of a retrovirus are depicted in Figure 3.7. A retrovirus consists of an outer envelope and an inner core, within which resides the viral genome. The envelope is a lipid bilayer containing viral glycoproteins encoded by the *env* gene. The core contains capsid proteins specified by the *gag* gene, and two identical single viral RNA strands with bound reverse transcriptase enzyme encoded by the *pol* gene (208). A retrovirus enters a host cell by absorption and endocytosis via specific cell-surface receptors. For example, the human immunodeficiency virus (HIV) is a retrovirus with a known specificity for CD4⁺ cells. Inside the host cell cytoplasm, the viral RNA is released from the envelope

FIGURE 3.7. The structure and life cycle of a retrovirus. The outer envelope of a retrovirus is a lipid bilayer containing viral glycoproteins encoded by the *env* gene. The inner core consists of capsid proteins, specified by the *gag* gene, and two identical single viral RNA strands with bound reverse transcriptase enzyme encoded by the *pol* gene. After entry into the host cell cytoplasm via absorption and endocytosis, the viral RNA is released from the viral particle and reverse transcribed into DNA. An extension of a nucleotide repeat sequence of the ends of the viral RNA is also synthesized, forming a long terminal repeat (LTR) on the DNA that contains sequences necessary for viral RNA synthesis. The DNA then localizes to the nucleus and is randomly integrated into the host genome. The viral genome is replicated and mRNA encoding viral proteins are produced and translated. New virions are assembled from their component parts and released from the cell.

and capsid proteins are then reverse transcribed into DNA. An extension of a nucleotide repeat sequence on the ends of the viral RNA is also synthesized, forming a long terminal repeat (LTR) on the DNA that contains promoter, enhancer, and polyadenylation sequences required for viral RNA synthesis. Between the LTRs are located the *env*, *gag*, *pol*, and various other genes, depending on the type of retrovirus. This DNA localizes to the nucleus and is randomly integrated into the host genome by means of sequences at the ends of the LTR. The integrated DNA serves as a transcription template to replicate the viral genome or produce mRNA for structural and functional viral proteins. Virions are assembled from the viral RNA and processed proteins and are then released (208).

Transforming retroviruses may be classified into two basic types based on their mechanism of action (209). The first group consists of the acute transforming viruses, which can transform cells in culture within several days. These viruses contain viral oncogenes (*v-onc*) derived from normal host cell sequences called protooncogenes (*c-onc*) through the process of transduction, which involves recombination of viral and host genomes during viral integration. In the process of transduction, viral sequences necessary for reproduction are replaced by cellular DNA (*c-onc*), rendering the retrovirus replication defective and dependent on competent “helper viruses” to complete the replication process. In fact, oncogenes were first identified by the study of tumor-causing viruses. *V-oncs* frequently differ from *c-oncs* by containing mutations and no intervening/noncoding sequences (introns). Protooncogene products include a wide range of proteins that are critical for the control of cell growth. They include growth factors and their receptors, nuclear transcription factors, and signal transduction proteins. Because retroviruses carrying these genes will express high levels of these products upon infection, the effects of these retroviruses on cell function are seen acutely.

Chronic or slow-acting retroviruses constitute the other major class of transforming retroviruses. They contain no oncogenes, are replication competent, and are associated with a long latency period. The mechanism of transformation by these viruses is via insertional mutagenesis (209). Random and rare viral genomic integration near a protooncogene or

growth-effector gene (e.g., *c-erbB*, *c-K-ras*, or *IL-2*) results in abnormal transcriptional activation of the cellular gene. If the integration is upstream of the gene and in the same orientation for transcription as the gene, it is considered functionally a promoter insertion. When the integration occurs downstream from the target or upstream but in an opposite transcriptional orientation, the viral LTRs are thought to operate through enhancer insertion. An example of insertional mutagenesis is demonstrated by ALV, which can induce bursal lymphoma in chickens following integration of viral LTRs near the *c-myc* protooncogene by either promoter or enhancer insertion.

Viruses containing linear or circular double-stranded DNA have also been implicated in carcinogenesis. The Shope papillomaviruses, extracted from the warts of cottontail rabbits and transmitted horizontally to tumor-free animals, were the first such viruses isolated. Another early isolate was the polyoma virus, capable of causing murine salivary gland adenocarcinoma (208). The structures and activities of the DNA tumor viruses are more complex than those of the retroviruses. In general, the mechanisms of transformation may be direct or indirect (210). Direct methods include activation of cellular or viral oncogenes, alteration of host cell protein expression at the site of viral integration, and the interaction of viral oncoproteins with cellular proteins, such as the products of tumor-suppressor genes (210,211). Indirect actions include altering the host cell genome without persistence of the viral DNA or induction of host immunosuppression.

One example of a DNA tumor virus is simian virus 40 (SV40), a member of the papovavirus family (208). Although nonpathogenic in its natural adult monkey host, it can cause tumors when inoculated into newborn hamsters and certain strains of neonatal mice. Cell culture studies have shown that papovaviruses can cause either a lytic infection, in which the virus undergoes replication and subsequent release from the host cell via lysis and cell death, or an abortive infection, characterized by cell survival but with a subset undergoing transformation with viral DNA integrated in the host cell genome. Permissive cells that can support viral replication, like adult monkey cells, are subject to lytic infection. Nonpermissive or semipermissive cells, such as hamster cells, will typically be transformed.

Cells transformed by papovaviruses will often contain only a portion of the viral genome. The only consistent segment integrated in cells transformed by SV40 is the early viral region encoding proteins known as large-T and small-T antigens. The role of the small-T antigen is not well characterized, but several functions have been ascribed to the large-T antigen. By studying experimental mutants, functional domains of large-T have been identified. At least two domains appear to be involved in transformation. One of these includes amino acids 105–114, a segment necessary for binding to pRb (the product of the retinoblastoma tumor-suppressor gene) and p107 (a 107-kD cellular protein). Mutations within this domain will destroy the ability of SV40 to transform cells. Another domain includes that of amino acids 272–625, which contains binding sites for the p53 protein, DNA polymerase- α , and ATP, and is involved with helicase and self-oligomerization activities. Mutations within this portion of the SV40 genome will abolish its transforming ability in some, but not all, cell lines. Large-T antigen is also instrumental in the initiation and regulation of viral DNA replication and transcription.

The adenoviruses constitute another group of DNA tumor viruses studied in animal models and cell culture (208). In humans, they can cause acute infections of the eye and upper respiratory and intestinal tracts, whereas in rodents, they can cause tumors in neonates or transform cultured rodent cells. Similar to SV40, only a portion of the viral genome is consistently integrated. For the adenoviruses, this is represented by the *E1A* (early region 1A) and *E1B* gene sequences. Multiple gene products can be produced from both *E1A* and *E1B* as a result of differential splicing of transcripts. *E1A* products can immortalize cells but require the presence of *E1B* or an activated ras in cell culture to cause transformation. *E1A* can also regulate cellular and viral transcription. There are three conserved amino acid sequence domains for *E1A*. The first two are required for transformation and contain the binding sites for pRb. In addition, *E1A* can bind p107 and a 300-kD cellular protein, whereas *E1B* binds p53.

Despite extensive investigations of the role of transforming viruses in animal models and in *in vitro* cell culture, their role in human cancer remains speculative. Human T-cell leukemia virus (HTLV-1) is a retrovirus that confers risk for human adult T-cell leukemia (ATL) (211). Infection is specific for CD4⁺ lymphocytes, and can be transmitted vertically through breast milk or horizontally via sexual intercourse or blood transfusions. After random integration into the host genome, polyclonal expansion of T cells occurs during a latency period, which can last several years. Only a subgroup of infected patients actually develops leukemia, which is manifested by a clonal cell population that has the same viral site of insertion within all of the malignant cells of a given patient. In addition to the *env*, *gag*, and *pol* genes typical of retroviruses, the HTLV-1 genome encodes proteins known as Tax and Rex (212). The mechanism of transformation by HTLV-1 appears to involve Tax protein transcriptional activation of cellular genes. Genes whose expression is altered include *IL-2*, *c-sis*, *c-fos*, granulocyte-macrophage colony-stimulating factor, and a subunit of the IL-2 receptor.

Acquired immune deficiency syndrome (AIDS) patients are known to be at increased risk for developing certain malignancies, such as lymphoma and Kaposi's sarcoma (KS). HIV is a CD4⁺ tropic retrovirus that causes AIDS, but its relationship to the above cancers remains unclear. For instance, although KS is commonly found in AIDS patients, its tumor cells lack evidence of viral genomic integration. However, supernatants from HIV-infected cells have been shown to be growth enhancing for the KS cells of AIDS patients secondary to the presence of the *tat* gene product encoded by the virus. In addition, germ-line insertion of the *tat* gene into mice precipitates skin tumors resembling KS (61). HIV, therefore, may act indirectly to

induce and/or promote the development of KS. An increasing incidence of aggressive B-cell lymphomas has also been noted in HIV patients. Whether this is a result of reactivation of other viruses or an alteration in immune surveillance is unknown. Epstein-Barr virus (EBV) and c-myc overexpression appear to be involved in a large number of these cases (213).

EBV is a member of the DNA herpesvirus family. In addition to causing mononucleosis by acute infection, it has been associated with Burkitt's lymphoma (BL), lymphoma of the immunocompromised host, and nasopharyngeal carcinoma (214,215). The mechanisms of these associations remain to be defined. It is known that B cells and nasopharyngeal epithelium contain the cell-surface receptor CR2, which serves as a receptor for both C3d serum complement and EBV. In addition, B lymphocytes can be immortalized by EBV infection *in vitro*. Viral genes encoding EBV nuclear antigen 1 (*EBNA-1*), *EBNA-2*, and latent membrane protein (*LMP*) are the most likely candidates for effectors of immortalization (208). Although *EBNA-1* has been the only latent gene consistently expressed in BL, experiments with *LMP* mutants have suggested that *LMP* is required for the transformation of B lymphocytes, but which domain is necessary is currently unclear (216,217). BL characteristically contains chromosomal translocations, primarily t(8;14) but also t(2;8) and t(8;22), which reposition the protooncogene *c-myc* near immunoglobulin (Ig) genes. The resulting deregulation of *c-myc* favors cellular proliferation. Magrath et al. have proposed a theory regarding the development of BL in African children (217). Infectious diseases such as malaria may alter the relative and absolute numbers of B-cell precursors in the bone marrow and perhaps mesentery, which are cells that are susceptible to the translocations found in BL. Ig enhancers may increase the frequency of translocations, and therefore play a role in *c-myc* deregulation. Magrath et al. believe that EBV probably increases Ig enhancer activity. BL is seen as a consequence of collaboration between EBV infection and these chromosomal aberrations. EBV may also cooperate with HIV in the development of some other B-cell lymphomas. When B lymphocytes from EBV-seropositive donors are infected with HIV, a subset of these cells is subsequently transformed. These transformed cells show marked elevations of *c-myc* transcripts and protein, as well as EBV DNA and RNA (213).

Another DNA virus associated with a human cancer is the hepatitis B virus (HBV). Chronic HBV infection is strongly associated with the development of hepatocellular carcinoma. HBV is hepatotropic secondary to the presence of HBV receptors on liver cells that recognize the viral coat protein. Acute infection is frequently hepatotoxic, resulting in destruction of liver cells. Chronic infection is associated with viral integration. The precise mechanism by which HBV increases the risk of developing hepatocellular carcinoma remains unknown. Although HBV is not an acutely transforming virus, two viral genes can be consistently demonstrated after integration. They are *ORF* (open reading frame) X, and *preS2/S*, which encode proteins that can function as transcriptional activators (208). Insertional events may be important in the role of HBV in the pathogenesis of liver cancer. Modification of cyclin A has been reported secondary to HBV viral genomic integration into an intron of the cyclin-A gene in cancerous liver cells. The resultant hybrid HBV-cyclin A transcript encodes a stabilized cyclin A resistant to degradation. This may play a role in the process of carcinogenesis, as cyclin A is intimately involved with cell-cycle control through its association with protein kinases such as p34^{cdc-2} and is a component of protein complexes involving E2F transcription factor and p107 (218,219). Insertional mutagenesis involving the retinoic acid receptor- β gene and the mevalonate kinase gene owing to EBV integration has also been reported (220).

Historically, herpes simplex virus 2 (HSV-2) was the first viral agent suspected of playing a role in the pathogenesis of

gynecologic malignancies. It is a member of the herpes family of DNA viruses. Epidemiologic studies showing a higher frequency of HSV-2 antibodies in women with cervical cancer than in healthy women suggested a possible link between HSV-2 infection and cervical cancer. Fragments of the HSV-2 genome have been identified in some cases of cervical and vulvar carcinoma, but are usually not integrated into the host genome (221,222). Genital keratinocytes previously immortalized by integration of human papillomavirus 16 have been transformed in cell culture by transfection with a subgenomic region of HSV-2 known as BglIII N (223). However, with subsequent cell passages, the transformed phenotype was maintained despite loss of the HSV-2 genetic material. In addition, normal epithelial cells transfected with HSV-2/BglIII N were not transformed. These data support the hypothesis that if HSV-2 plays a role in the development of cervical cancer, it most likely functions indirectly as a cofactor.

The study of viral infections as possible contributors to the process of gynecologic carcinogenesis is now focused primarily on human papillomavirus (HPV). HPVs are epitheliotropic DNA viruses and members of the papovavirus family (224). The HPV viral particle consists of an approximately 8,000-base pair (bp) circular double-stranded DNA molecule surrounded by an icosahedral capsid structure (225). The viral DNA contains seven early (E1–E7) and two late (L1 and L2) open reading frames (ORFs), plus a noncoding region (NCR) of about 1,000 bp involved in the control of replication and transcription (Fig. 3.8). E1 contains the DNA sequences for at least two proteins involved in DNA replication. Genes encoding activator and repressor proteins, which regulate viral mRNA synthesis, are located in E2. E4 may play a role in the maturation of viral particles. The E5 and E6/E7 ORFs were originally identified by their participation in the *in vitro* transformation of rodent cells by fragments of the bovine papillomavirus genome. L1 and L2 contain genes that encode the viral capsid proteins.

FIGURE 3.8. The HPV genome. The HPV genome is an approximately 8,000-bp circular double-stranded DNA molecule containing seven early (E1–E7) and two late (L1 and L2) open reading frames (ORFs), plus a noncoding region (NCR) involved in the control of replication and transcription. E1 contains sequences for proteins involved in DNA replication. E2 encodes activator and repressor proteins that regulate viral mRNA synthesis. E4 is thought to be involved in the maturation of viral particles. E6 and E7 can immortalize human keratinocytes and cooperate with oncogenes in the process of malignant transformation. L1 and L2 encode viral capsid proteins.

Over 60 HPV types have been identified by cross-hybridization procedures demonstrating less than 50% DNA sequence homology between any two types (224). Approximately 20 of these have been isolated from the anogenital tract. The lesions associated with HPV infections vary depending on the viral type involved. Lorincz et al. analyzed the relationship between 15 common anogenital types of HPV and cervical dysplasia in 2,627 women (226). Evidence of HPV viral DNA was found in 84% of the 153 invasive carcinoma cases, predominantly HPV-16, -18, -45, or -56, with about 10% containing HPV-31, -33, -35, -51, -52, or -58. They referred to the former group of HPV types as “high risk” and to the latter group as “intermediate risk.” Of the 261 cases of high-grade intraepithelial lesions (HGSILs), 54% contained high-risk HPV, 24% had intermediate-risk types, and 4% included viral DNA from their designated “low-risk” group, which included HPV-6, -11, -42, -43, and -44. The 377 low-grade intraepithelial lesions (LGSILs) contained high-risk types in 23%, intermediate-risk HPV in 17%, low-risk types in 20%, and no evidence of HPV in 30%. Nine percent of the LGSIL cases could not be classified. Multiple other investigators have also demonstrated the frequent association of HPV-16 and -18 with HGSILs and invasive carcinoma, while HPV-6 and -11 are more often found in condylomas and low-grade dysplasia. Squamous cell histology has been studied more extensively than that of adenocarcinoma and adenosquamous carcinoma. The prevalence of HPV DNA in these less common types of cervical cancer has varied from 20% to 80%, depending on the method of detection used (226). The vast majority of vulvar condylomata acuminata are also associated with the low-risk HPV types, whereas high-risk types have been demonstrated in invasive vulvar carcinoma.

HPV DNA has been detected in host cells in both integrated and nonintegrated (episomal or extrachromosomal) states (225,226). Episomal viral DNA is characteristic of benign cervical precursor lesions, although integrated HPV is sometimes found in HGSILs. Invasive carcinoma almost always contains integrated viral DNA, but episomal forms of the viral genome have also been detected. Although integration has occurred near cellular protooncogenes, in general the site of viral integration appears to be random with respect to the host genome. However, there is a consistent pattern with respect to the site of disruption of the circular viral genome in the process of integration. The viral DNA is usually interrupted in the E1/E2 region, which is the viral transcriptional regulatory system. Upon integration into the host genome, two ORFs, E6 and E7, are consistently retained (224).

Human keratinocyte cell cultures and tumor cell lines have illustrated the participation of the HPV E6 and E7 proteins in the processes of immortalization and transformation. Transfection of human foreskin keratinocytes with high-risk HPV DNA, but not with low-risk HPV DNA, has been demonstrated to immortalize these cells (227). Integration and expression of both E6 and E7 are usually required for efficient immortalization, since E7 alone has weak activity and E6 alone has none (227). The role of HPV in the multistage process of cervical/vulvar carcinogenesis would appear to be early in the course of the disease since the effect of HPV has generally been limited to immortalization. Progression to the fully transformed phenotype has been described in an HPV-18-immortalized keratinocyte cell line after multiple passages, but in general, this phenomenon is quite rare (228). The transfection of an activated *Ha-ras* oncogene into HPV-16-immortalized cervical cells can render them tumorigenic, demonstrating the ability of HPV to cooperate with another cellular insult to effect carcinogenesis (229). Persistent expression of E6 and E7 appears to be necessary to maintain the transformed phenotype. The application of synthetic anti-E6 and anti-E7 oligonucleotides to cervical and oral cancer cell lines containing HPV-18 significantly inhibits cell growth (230). Treatment of the cells with both antisense

oligonucleotides inhibits growth more effectively than either one applied alone.

An important property of the *E6* and *E7* oncoproteins is their biochemical interaction with tumor-suppressor gene products. Similar to adenovirus E1A and the SV40 large-T antigen, HPV *E7* can bind pRb. The *E7* proteins from HPV-16, -18, -6, and -11 have all been demonstrated to bind pRb *in vitro*, although the binding affinities of the high-risk HPV types are higher (231). The *E6* proteins of HPV-16 and -18 have been shown to bind p53 *in vitro*, which is analogous to adenovirus E1B and SV40 large-T (231). Inactivation of p53 and pRb, secondary to protein binding or mutation, may disrupt control of cellular proliferation. The small proportion of cervical cancer that is HPV-negative frequently harbors a demonstrable p53 mutation. By use of p53-responsive reporter plasmids and a HeLa cervical cancer cell line, Hoppe-Seyler and Butz have shown that HPV-16 *E6*, as well as mutant p53, can disrupt p53-mediated transactivation (232). Additional investigation is needed to further define the specific role of HPV in cellular transformation.

Molecular Basis of Carcinogenesis

Early epidemiologic studies suggested that the development of human epithelial cancers is a complex multistage process. The study of tumors that rise in frequency with age has revealed that cancer incidence is proportional to the n th power of age (233). This relationship may be interpreted to suggest that some n events, each time dependent but independent of each other, must occur before a tumor can develop. Two models have been proposed to explain how these events might take place. One proposal is that a single cell accumulates multiple genetic lesions (single target, multihit). The other suggests that multiple cells receive a single insult (multiple targets, single hit). Because of evidence suggesting that most human tumors have a monoclonal origin, the former theory has received the most support. Whether or not the n events need to occur in a certain order for a given malignancy to develop is unclear.

These epidemiologic data, combined with results from the aforementioned animal models of carcinogenesis, strongly suggest that human cancer results from a complex, multistage process. The application of modern molecular biologic techniques to the biologic mysteries of cancer has supplied additional critical evidence for the multistage hypothesis. The identification and characterization of oncogenes as cancer-causing genes has provided the structural link between the carcinogen/promoter model of malignancy and the biochemical pathways known to be activated in the process of cellular transformation. A recent review proposed that despite the enormous variety of human cancers, five basic rules exist for making human tumor cells (234). According to these rules, malignant cells must have the ability to generate their own mitogenic signals, to resist exogenous growth-inhibitory controls, to evade apoptosis, to proliferate without limits, and to acquire vasculature. In addition, advanced tumors acquire the ability to invade and metastasize.

Oncogenes have been described by (a) identification as transforming sequences found within retroviruses; (b) gene transfer experiments in which DNA sequences from tumor cells were shown to transform normal recipient cells; (c) characterization of fusion genes at chromosomal breakpoints; and (d) identification by nucleic acid sequence homology. Protooncogenes are cellular genes that play important roles in cellular proliferation. Activation of protooncogenes occurs secondary to point mutation, gene amplification, or loss of normal control mechanisms regulating gene expression. Overexpression or overactivity of the protein product results in the transformation of normal cells (235). Protooncogenes that have been well characterized include growth factors and

their receptors, nuclear transcription factors, and components of signal transduction pathways (235).

Multiple activated oncogenes have been detected within gynecologic malignancies, some of which have been previously described in this chapter (236). For example, overexpression of *c-erbB2*, which encodes a transmembrane tyrosine kinase with 40% sequence homology to the epidermal growth factor (EGF) receptor, occurs in approximately 30% of epithelial ovarian carcinomas. The *ras* family of oncogenes encodes a protein with GTPase activity and is activated by point mutation. Activation of *ras* genes has been detected in endometrial carcinomas and ovarian LMP tumors. Overexpression of the nuclear transcription factor *c-myc* has been described in a large number of female genital cancers.

Another type of oncogene known to be important in carcinogenesis is the tumor-suppressor gene. Historically, two independent lines of evidence supported its existence (235). Somatic cell hybrids, formed by the fusion of tumor cells with normal cells, frequently display a normal, rather than transformed, phenotype. This suggests that the normal cells harbor factors with tumor-suppressive activity. In addition, epidemiologic studies of the pediatric malignancy retinoblastoma strongly support the existence of recessive oncogenes. Retinoblastoma occurs in two forms. The inherited form occurs early in life, with tumors that are frequently bilateral and multifocal. The sporadic form occurs later in life and is unilateral. Hethcote and Knudson hypothesized that this tumor results from the loss of function of a key regulatory gene (236). In the hereditary form, a mutated allele is inherited; a tumor results when the second allele undergoes a somatic mutation. The sporadic form of the disease occurs as a result of two independent somatic events occurring in the same cell. Careful cytogenetic evaluation of retinoblastoma tumors revealed gross chromosomal abnormalities at 13q14. Molecular analysis of this area led to the identification and characterization of the retinoblastoma gene. Subsequently, other tumor-suppressor genes have been identified and shown to have dramatic effects on cellular proliferation. Mutational inactivation of these genes leads to deregulation of cell growth.

Mutation of the tumor-suppressor gene p53 is the most common genetic alteration in human cancer. Mutation of this gene, which frequently leads to overexpression of the p53 protein, is associated with a large number of human malignancies, including tumors of the female genital tract. In advanced-stage ovarian carcinoma, for example, p53 mutations occur in about 50% of cases. Multiple other tumor-suppressor genes have been proposed by the identification of other nonrandom allelic losses occurring within certain tumors.

Multistage Carcinogenesis Model

Careful analysis of human epithelial cancers has provided substantial evidence for the general model of multistage carcinogenesis. For instance, the study of colorectal carcinoma has identified a series of histologic and molecular correlates in the progression from normal epithelium to hyperplasia, adenoma, and, ultimately, carcinoma. Some of the molecular events in this sequence are now known and include inactivation of the *APC* and p53 tumor-suppressor genes and activation of the *ras* protooncogene (237). In other human cancers, such as lung cancer, activated *ras* genes, p53 mutations, and 3p deletions are frequently found, whereas p53 mutations, overexpression of EGF receptors, and gene amplifications of *c-myc* and *neu* are common genetic alterations in breast cancer (238,239).

Although our knowledge about the molecular biology of gynecologic malignancies has been steadily expanding, much remains unclear. Current research is directed at defining which molecular events are critical to tumor development and when these events occur. These efforts have allowed the construction

FIGURE 3.9. Multistage model for the development of cervical carcinoma. The transition from normal to dysplastic to malignant cervical epithelium is shown in association with known risk factors, such as HPV infection, tobacco use, and growth-factor stimulation. Molecular mechanisms accompanying these changes include the binding of tumor-suppressor gene products by HPV oncoproteins, activation of growth-factor pathways, and genetic alterations such as *c-myc* amplification and LOH at 3p. Tumor promoters stimulate the division of initiated, partially transformed cells. Accumulation of additional oncogene/tumor-suppressor gene mutations effects full transformation and invasion of the basement membrane.

of hypothetical models of the development of gynecologic cancers, such as that for cervical carcinoma seen in Figure 3.9. The transition from normal to dysplastic to malignant cervical epithelium is shown in association with known risk factors for this process, such as HPV infection, tobacco use, and growth factor stimulation. Molecular mechanisms accompanying these histologic changes include the binding of tumor-suppressor gene products by HPV oncoproteins, activation of growth factor pathways, and genetic alterations such as *c-myc* amplification and LOH at 3p (235). Initiated cells are stimulated to divide under the influence of tumor promoters, producing clonal expansion of partially transformed cells. As more oncogene/tumor-suppressor gene mutations occur, cells become fully transformed and invade the basement membrane.

The multistage model of carcinogenesis provides multiple opportunities for intervention. Primary prevention involves risk factor modification. Smoking cessation, avoidance of unopposed estrogen, prophylactic salpingo-oophorectomy, and dietary modification are activities aimed at preventing the initiation and/or promotion of gynecologic cancers. Secondary prevention

implies intervening once the early events in tumor formation have occurred. This involves identification of the histologic stages of early carcinogenesis and treatment of the affected tissue. Traditionally, this has meant addressing preinvasive disease by surgery, topical applications, and hormonal manipulation. More recently, laser ablation and immunotherapy have been used. Identification of the molecular events occurring early in the development of gynecologic cancers may provide new, more sensitive, and more specific markers for the early detection of these tumors.

Improved understanding of the molecular basis of the multistage process of human carcinogenesis has also provided novel approaches to cancer prevention and therapy. For initiation and progression events, compounds that inhibit the activity of activated *ras* genes, antisense oligonucleotides that can reverse the transformed phenotype of HPV-associated cancer cells, and the potential to replace the lost functions of mutated tumor-suppressor genes by gene therapy exist (230). Better understanding of the role of tumor promotion in the development of epithelial cancers has provided other excellent targets for intervention. The development of growth-factor antagonists might inhibit or reverse growth-factor-induced cellular proliferation, which is critical for tumor promotion.

Another approach aimed at inhibiting tumor-promoter-induced cellular proliferation has been suggested by the work of Brown et al., who have created a dominant-negative mutant of the nuclear transcription factor c-jun (240). This mutant protein can block the activities of wild-type transcription factors in the c-jun and c-fos families and block cellular transformation by a wide range of oncogenes. Blocking transcriptional activity may be a potent method of inhibiting cellular proliferation associated with tumor promotion. A similar but more pharmacologic approach is the use of antioxidants for chemoprevention. Epidemiologic studies have found an association between decreased serum levels of the micronutrient beta-carotene and either a diagnosis of cervical dysplasia and carcinoma or a future risk of such disease (241,242). Research regarding the potential effect of beta-carotene therapy is ongoing.

Retinoids have been shown to retard the growth and differentiation of HPV-16-immortalized human cervical cells (243,244). These agents may trigger transcriptional factor pathways that either directly or indirectly interact with other proteins to redirect cellular programming. Meyskens et al. have published the results of a randomized phase III trial in which patients with moderate or severe cervical intraepithelial neoplasia (CIN) received either topical all-*trans* retinoic acid or a placebo (245). A significant increase in the complete regression rate of CIN 2 was achieved, but no significant treatment effect was seen for the CIN 3 group. More data regarding the clinical usefulness of retinoic acid are needed.

BIOCHEMISTRY OF NEOPLASTIC CELLS

Cell Structure

Malignant cells differ from normal cells by dramatic changes in their overall size and shape, as well as changes involving their intracellular components. The nuclei of malignant cells are often enlarged and irregular, containing coarse, clumped chromatin. The nucleus:cytoplasm ratio, normally in the range of 1:4 to 1:6, frequently approaches 1:1 (2). Nucleoli are often more prominent in cancerous cells than in normal cells. These differences can be quantitated and exploited as a measure of cellular transformation. For example, the technique of silver staining and counting nucleolar organizer regions (AgNORs) has been applied to cervical dysplasia and ovarian tumors. Wistuba et al.

demonstrated an increasing number of AgNORs with increasing severity of cervical dysplasia (246). In another study involving 24 mucinous and 28 serous epithelial ovarian tumors, a higher number of AgNORs were found in invasive carcinomas than in borderline or benign tumors. The differences were not significant for mucinous tumors, but a significant difference was demonstrated for the invasive serous versus noninvasive serous neoplasms (72).

Cellular fibrils appear to have important structural and functional roles in both normal and neoplastic cells. As presented in the description of the transformed cell, disorganization of actin microfilaments is thought to underlie some of the morphologic changes and random orientation manifested by these cells (246). Experimental evidence suggests that increased actin organization is associated with *in vitro* growth suppression (247). The distribution of intermediate filaments, such as desmin, vimentin, and the keratins, varies among different types of tumors. Monoclonal antibodies that recognize these filaments can aid in the diagnosis of poorly differentiated neoplasms. In addition to their traditionally ascribed functions, such as maintenance of cell structure and assistance with cell movement, intermediate filaments have been shown to play a role in cell division and nuclear function. They are demonstrated substrates for protein kinases involved with regulation of cellular proliferation, such as p34^{cdc-2} and C-kinase. Phosphorylation of intermediate filaments is associated with their depolymerization during mitosis (248,249). Also, data suggest that lamin B, a component of the nuclear laminin complex, may be involved with the organization of chromatin during DNA replication (250).

Significant alterations in the structure and function of the cell membrane accompany malignant transformation. Modification of membrane glycoproteins, glycolipids, and cell surface adhesive properties are associated with the ability to invade and metastasize. An increased degree of branching in the glycan chains of glycoproteins has been noted as well as abnormal fucosylation and sialylation of membrane carbohydrate moieties (251,252). In some cases, new gangliosides or other novel structures are produced. These aberrantly glycosylated membrane components are recognized by monoclonal antibodies as tumor-associated carbohydrate antigens.

Tumor Metabolism

The process of malignant transformation produces profound changes in cellular metabolism. Tumor cells demonstrate a higher rate of both glycolysis and glutaminolysis, providing intermediary phosphometabolites for the biosynthesis of nucleotides, lipids, and complex carbohydrates. Alterations in the concentrations and activities of certain isoenzymes, such as the greatly increased activity of pyruvate kinase type M2, underlie these changes. Phosphometabolite levels are also higher secondary to lowered levels of their degradative enzymes (253–255). Other metabolic aberrations described in tumor cells include alterations in cholesterol biosynthesis and intramitochondrial aldehyde catabolism (255).

One consequence of altered tumor metabolism is the higher level of fucoproteins seen in the sera of cancer patients as compared to healthy individuals. Elevated serum levels of α -1,3 fucosyltransferase and fucosylated forms of α ₁-antitrypsin and haptoglobin have been detected in patients with ovarian cancer, and these levels appeared to correlate with disease status (256). Another secondary effect of the abnormal metabolism of cancer cells is its effect on the host metabolism. When cancer strips its host of nutrients, the host metabolism adapts by processes such as increasing gluconeogenesis. Eventually, anorexia and depletion of energy stores are manifested in the clinical condition known as cachexia.

Tumor-Associated Antigens, Oncofetal Proteins, Hormones, and Enzymes

Tumor cells may produce substances unique to the tissue cell of origin, such as prostate-specific antigen and human chorionic gonadotropin (2). Other substances that are secreted by tumors are infrequently or never elaborated by their normal cellular counterparts. These include ectopic hormones responsible for the paraneoplastic syndromes, tumor-associated antigens such as CA-125, and oncofetal antigens such as α -fetoprotein (2). Oncofetal antigens, although absent from normal adult tissues, can be found in developmental precursor cells. Many of these tumor products are particularly useful as tumor markers that can assist with cancer diagnosis and surveillance. In addition, cancer cells frequently demonstrate an imbalance between the activities of proteolytic enzymes, such as plasminogen activator, metalloproteinases, and cathepsins, and their inhibitors. These deregulated enzyme activities are thought to play a role in the processes of tumor invasion and metastasis (257).

Protein Processing and Degradation

For proteins to serve their roles in cellular function, they require proper structure and carefully regulated levels that reflect a steady-state balance between synthesis, folding, and degradation. Recent discoveries have shown that protein folding, which is required for proper protein function, is mediated through a group of proteins called chaperones. Heat shock protein 90 (Hsp-90) is a typical chaperone that binds to a large number of client proteins and assists in their appropriate folding (258). Once appropriately folded, these proteins are fully functional until they become denatured and then targeted for degradation. Proteins are degraded in part by ubiquitination and targeting to the proteasome. Ubiquitination is accomplished by a family of ubiquitin ligases whose substrate specificity depends upon protein sequence and phosphorylation status. The proteasome is a complex of proteins including proteases that degrades a wide range of proteins. This complex process accounts for the tissue-specific and cell-cycle regulation of expression of many critical proteins.

The ubiquitination/proteasome process has received a great deal of attention in relation to its contribution to cancer development. Mutations and alterations in the phosphorylation state have been shown to change ubiquitination status and turnover of critical proteins including those involved in the cell cycle. Based in part upon these observations, the proteasome has been targeted for the development of novel small molecule inhibitors. It is hypothesized that these inhibitors would potentially be effective chemotherapeutic agents (258).

Signal Transduction Pathways

Neoplasia may be viewed fundamentally as a disorder of cell proliferation in both space and time. Central to the orderly occurrence of normal cell proliferation is the response to environmental cues. Growth factors, originally defined as peptides or proteins extractable from living tissues that promote cell proliferation in artificial (e.g., cell and organ cultures) systems, have come to be viewed as the means by which these signals are conveyed. In this way, neoplasia can also be viewed as a disorder of cellular communication.

“Signal transduction” refers to the biochemical mechanisms by which small molecules alter the state or activities of the intracellular milieu. Two broad mechanisms for signal transduction have emerged. The first involves the covalent

modification in intracellular constituents consequent to the action, with the “signal” lasting as long as the modification is present. A common covalent modification is phosphorylation accomplished by protein kinases, enzymes that transfer the gamma phosphate of ATP to substrate molecules whose function is altered because of the attached phosphate. Two types of protein kinases of greatest importance in the regulation of cell growth are those that phosphorylate proteins on tyrosine residues and those that phosphorylate proteins on serine or threonine residues (16). Protein phosphatases function in an opposing manner to protein kinases, providing a regulatory mechanism for the previously described signaling cascades.

The second general mechanism for signal transduction is found in the generation of “second messenger” molecules produced consequent to the action of a growth factor, acting upon intracellular receptor sites to effect functional changes, usually by allosteric mechanisms. The second messengers whose role in growth control is most clearly defined include, but are not limited to, calcium, cyclic AMP (cAMP), and phospholipid metabolites. This section gives a broad overview of the growth-regulating pathways modified by growth factors employing these effector mechanisms.

Ras Pathway

Nowhere in signal transduction research has more progress been achieved than in characterizing the downstream pathways from *ras*. Multiple protein kinases have been identified and their mode of interaction characterized (259). The view of growth-factor-induced cellular activation that emerges from this train of recent investigation is represented in Figure 3.3, where input from either receptor-associated or nonreceptor-associated TKs is reflected in increased generation of activated *ras* bound to guanosine 5'-triphosphate (GTP). Three *ras* protooncogenes have been identified: the H-*ras* gene (homologous to the oncogene of the Harvey murine sarcoma virus), the K-*ras* gene (homologous oncogene of the Kirsten murine sarcoma virus), and the N-*ras* gene (which does not have a retroviral homologue and was first isolated from a neuroblastoma cell line) (260). The *ras* oncogenes encode four 21-kd proteins called p21^{ras} that are localized to the inner surface of the cell membrane (260). Ras proteins are members of the family of GTPases. Ras functions as a molecular switch that cycles between an inactive guanosine 5'-diphosphate (GDP)-bound form and an active GTP-bound state. Ras, synthesized as a biologically inactive cytosolic propeptide, is localized to the inner surface of cell membranes only after it has undergone a series of posttranslational modifications, the first and most critical of which is farnesylation, which adds a farnesyl isoprenoid group to Ras and is catalyzed by farnesyltransferase (260). Activated *ras* in turn associates with *raf* and increases the catalytic activity of the latter protein, which propagates the signal to microtubule-associated protein (MAP) kinase (261).

The *c-raf* protooncogene was originally defined as the cellular homologue of the transforming oncogene *v-raf*. However, accumulating evidence from genetic approaches, summarized by Van Aelst et al., indicates that *raf* functions downstream of *ras*. Specifically, activated *raf* abrogates the need for *ras* to transform cells. Mutations of *raf* can block *ras* transformation. Growth-factor agonists that activate *ras* have hyperphosphorylated *raf*. Most importantly, a family of serine threonine kinases, the MAP kinases, were themselves activated by MAP kinase kinases (MAPKK), which are substrates for *raf* (262). These genetic results led to a concerted effort to identify a biochemical association between *ras* or *ras*-associated molecules and *raf*. Indeed, several groups using recombinant-expressed protein or fusion proteins produced in yeast have clearly demonstrated a noncovalent association between *ras* and *raf* proteins (262,263). This association has been confirmed by precipitation

of *raf* using *ras* affinity reagents (264). However, although it is clear that inactive *raf* is brought to the cell membrane by GTP-*ras*, the precise mechanism by which *ras* activates *raf* still remains unknown. Activated *raf* in turn phosphorylates MAPKK (MEK), which activates MAP kinases (261).

One question regarding *ras* signaling is how a single protein can mediate such diverse biologic effects as apoptosis, proliferation, and differentiation. In the GTP-bound state, *ras* can activate several downstream effector pathways. These effector pathways include *raf*, GTP-binding proteins Rac and Rho, PI3K, and MEKK. Some of these *ras* effectors may play a role in the development of gynecologic cancer (265). For instance, Noey2 was originally described as a down-regulated *ras* effector in ovarian cancer (266). This protein mediates growth inhibition and may function as a tumor-suppressor gene. The *ras* effectors ERK and PI3K have been implicated in the growth control of ovarian cancer cell lines (267).

Although activated *ras* proteins are usually associated with driving growth and transformation, they may also induce senescence, apoptosis, and terminal differentiation. Ras association domain in the tumor suppressor, RASSF1, which binds *ras* in a GTP-dependent manner, is an example. Moreover, activated *ras* enhances and dominant negative *ras* inhibits the cell death induced by transient transfection of RASSF1. This cell death appears to be apoptotic in nature. Hypermethylation of the RASSF1A promoter region is common in 45% of adenocarcinomas of the uterine cervix and 40% of ovarian tumors, and is rare in squamous carcinoma of the uterine cervix (268,269). Thus, the RASSF1 tumor suppressor may serve as a novel *ras* effector that mediates the apoptotic effects of oncogenic *ras*.

Consequently, *ras*-like genes may also be important for the development of gynecologic cancers. Ras is mutationally activated in 30% of all cancers, with pancreas (90%), colon (50%), thyroid (50%), lung (30%), and melanoma (25%) having the highest prevalence (270). The mutant *ras* genes in human cancers encode mutated proteins that harbor single amino-acid substitutions primarily at residues G12 or Q61. The *K-ras* gene is mutationally activated in only 5% of invasive epithelial ovarian cancers (271). In borderline ovarian malignancies, however, *K-ras* is mutationally activated in 22% of serous and 46% of mucinous borderline ovarian tumors (272). The precise role for these effectors is not yet clear, but presumably they will serve important functions in a variety of biologic processes.

Growth Factor Receptor–Associated Tyrosine Kinases

The importance of tyrosine kinases as mediators of carcinogenic stimuli was discovered due to the identification of their capture by acutely transforming RNA tumor viruses. Characterization of the structure of these captured genes identified them as kinases, while examination of the mass of phosphorylated amino acids in virally transformed cells demonstrated an increase in tyrosine phosphate, normally a minor phospho-amino acid constituent. Antisera specific for the transforming proteins precipitated proteins that have the ability to phosphorylate themselves and, in some cases, the precipitating antibody. Characterization of the proteins demonstrated the presence of phosphorylated tyrosine moieties. Subsequently, it was demonstrated that receptors for certain growth factors also possessed kinase activity for tyrosine. Truncated or mutated versions of the receptors had oncogenic potential in certain instances. Conceptually, this links tyrosine kinase activity to the action of growth-regulatory substances.

As outlined in detail by Cadena and Gill, receptor–tyrosine kinases have at least four structural domains: (a) an extracellular domain that binds ligand; (b) a transmembrane helix domain that links the external portion with the rest of the molecule; (c) an intracellular catalytic domain that contains the core ATP

binding and phosphoryl transfer elements; and (d) regulatory domains that regulate the endogenous activity of the kinases by allosteric or intrachain “pseudosubstrate”-like mechanisms or mediate association of the receptor–tyrosine kinase with either substrates or regulatory molecules involved in the propagation of signals (273). Receptor-associated tyrosine kinases are divided into groups according to the structure of their extracellular domains, including the presence of a variable number of immunoglobulin-like domains, the number of cysteine-rich motifs, leucine-rich regions, cadherin domains, fibronectin type III repeats, discoid I-like domains, and epidermal growth factor (EGF)-like domains. These various structures result in at least 14 different families of receptor-associated tyrosine kinases.

In addition to causing dimerization and autophosphorylation of the receptor, activation of growth-factor-receptor tyrosine kinases results in phosphorylation of key substrate molecules thought to be important in propagating the growth-promoting stimulus. Both of these reactions create tyrosine phosphates, which can then form complexes with Src homology region 2 (SH2) domains. SH2 domains are approximately 100 amino acid regulatory motifs originally defined by similarity to a portion of pp60^{c-src}. Importantly, SH2 domains are found in a number of signaling molecules, including phospholipase-C-gamma, phosphatidylinositol 3'-kinase (PI 3'K), the GTPase activator for ras proteins, protein phosphatase-1C, and many nonreceptor-tyrosine kinases, including pp60^{c-src}. This important family of “adapter” molecules, represented prototypically by grb2, contains small molecules devoid of catalytic functions that consist of two SH2 domains centered around the SH3 domain and are capable of mediating protein–protein interactions. Through their SH2 domains, these adapter molecules function to physically associate proteins phosphorylated on tyrosine.

The important result of growth-factor-receptor–kinase activation is the assembly of multimeric complexes through SH2 domains of molecules with distinct signaling capabilities. Phospholipase-C-gamma (PLC-gamma) hydrolyzes membrane phosphatidylinositol bisphosphate (PIP₂), producing inositol triphosphate and increases in intracellular diacylglycerol (DAG). Inositol triphosphate interacts with the cell membrane and releases calcium. The increased DAG and calcium maximally activates protein kinase C (PKC). PI 3'K phosphorylates phosphatidylinositols at the 3' position, creating new substrates for PLC-gamma. In addition, a substrate for PI 3'K is protein kinase B (AKT), which has been demonstrated to be important in suppressing apoptosis. Finally, ras GTP hydrolysis is stimulated by ras GAP (GTPase-activating protein).

In this way, a large signaling complex is rapidly assembled around activated receptors, from which a variety of signal transduction cascades emanate. The multiple components activated through ligand binding exemplifies the profound effect that growth factors have on target cells, because each signaling pathway activated can initiate or amplify multiple functional responses. Additionally, many growth factor ligands induce receptor heterodimerization with multiple receptors and signaling pathways, providing a mechanism that generates a large number of different cellular responses from a limited number of receptors (274). Once activated, growth factor receptors are rapidly internalized by the endocytotic pathway and degraded by lysosomes (274). Ligand binding can also act as a signal for ubiquitinylation and subsequent proteasome degradation. Thus, ligand binding not only activates a myriad of signaling pathways, but also causes complementary down-regulation of cell surface receptors and attenuation of signaling transduction cascades.

In addition to the associations described above with receptor tyrosine–protein kinases, the adapter protein grb2 can form complexes with the mammalian homolog of the son of sevenless (Sos) protein originally described in the sevenless *Drosophila* mutant. The importance of this observation is that the Sos protein has GDP-exchange activity for mammalian ras

proteins. Thus, receptor–tyrosine kinase activation can both accelerate ras protein activation (through exchange of GDP for GTP) as well as lead to ras inactivation (through GAP). These findings provide a biochemical basis for the original observations that neoplastic transformation by receptor–tyrosine or nonreceptor–tyrosine kinases could be blocked by genetic maneuvers that inhibited ras function.

Nonreceptor-Associated Tyrosine Kinases

Tyrosine kinases (TKs) are enzymes that transfer the γ -phosphate groups from ATP to the hydroxyl group of tyrosine residues (275). They can be characterized as either nonreceptor type or, more commonly, transmembrane receptor type. The nonreceptor TKs are found in the cytoplasm, lack a transmembrane segment, and generally function downstream of the transmembrane receptor tyrosine kinases (RTKs). The prototype for oncogenic, nonreceptor TKs is pp60^{c-src}, the cellular homologue of the transforming oncogene of Rous sarcoma virus, pp60^{v-src}. It is representative of at least eight families of molecules with distinct domain structures. In addition to the Src family, these include the Abl, Fes/Fps, focal adhesion (FAK), c-Src kinase (CSK), Janus kinase (JAK), spleen tyrosine kinase (syk), and interleukin-2–inducible kinase (ITK) families. These kinases can have either relatively ubiquitous expression (e.g., abl, src) or tissue-restricted distribution (e.g., fyn, lyn). Although they are anatomically distinct from RTKs, they have functional similarities in that the kinase-specific activity of the nonreceptor-tyrosine kinases increases following ligand stimulation of cells in which they are found. For example, thrombin activation of platelets and platelet-derived growth factor (PDGF) activation of fibroblasts results in increased pp60^{c-src} activity, while activation of T lymphocytes through the CD4 or CD8 determinants activates pp56^{c-lck}, a pp60^{c-src} family member (276).

Another example of a nonreceptor TK with clinical relevance is Abl. The Philadelphia (Ph) chromosome found in some forms of leukemia is a result of a chromosomal translocation that juxtaposes the *c-abl* nonreceptor TK gene on chromosome 9 with a breakpoint cluster region (*bcr*) gene on chromosome 22 (275). The resulting fusion protein Bcr-Abl, is a constitutively activated form of Abl TK that drives uncontrolled growth of Ph cells. Normally, Abl can translocate into the nucleus, where it has a role in DNA-damage-induced apoptosis. However, truncated fusion protein Bcr-Abl is retained in the cytoplasm in association with the cytoskeleton, where its lack of proapoptotic activity contributes to its oncogenic properties (275).

The consequences of the activation of the nonreceptor TKs include the phosphorylation of many of the same substrates described above for the receptor-linked TKs. In particular, the activation of *ras* through grb2/Sos underscores that activation can proceed through input from a number of different sources and points to the importance of the molecules downstream of *ras* as representing a “final common pathway” of cellular activation.

Epidermal Growth Factor and Receptor

Epidermal growth factor (EGF) is so named because of growth-promoting activity originally recognized by its promotion of the normal formation of facial structures in neonatal mice. It is now recognized as the prototype for a family of growth factors widely distributed in a number of anatomic sites, including EGF, transforming growth factor- β (TGF- β), amphiregulin, neu differentiation factor, and neu/*erbB2* ligand growth factor (277,278). The growth factors share several structural motifs and bind to receptors that possess intrinsic tyrosine kinase activity. These receptors include the classic EGF receptor (EGFR, also known as *c-erbB1*), which also binds to TGF- β , and the related receptor *c-erbB2* (also known as p185*neu*), originally defined by its similar structure but distinct pattern of amplification and expression in tumors (279).

The clinical significance of EGFR protein expression in the development and progression of human ovarian carcinoma was studied in seven ovarian cystadenomas, six mucinous LMP tumors, and 25 invasive adenocarcinomas by immunohistochemistry. EGF and EGFR expression were found to be significantly higher in mucinous cystadenocarcinomas than in mucinous cystadenomas or mucinous LMP tumors (280). In a series of 226 patients with early-stage epithelial ovarian carcinomas, EGFR status was a significant independent prognostic factor with regard to disease-free survival (DFS). A prognostic model based on the presence of grade 3, p53-positive, and EGFR-positive disease found the poorest DFS for patients with all three clinical factors (281).

As outlined by Bast et al., autocrine stimulation by TGF- β and overexpression of *c-erbB2* appear to be of clear importance in ovarian carcinoma, where the level of *c-erbB2* expression appears to correlate adversely with prognosis in some series (282–284). The conflicting results regarding *c-erbB2* protein expression and survival in the literature could be explained by discrepancies between *c-erbB2* protein overexpression and the frequency of *c-erbB2* gene amplification.

Since the advent of tissue microarray (TMA) technology, researchers are able to evaluate large numbers of specimens by FISH analysis. For example, FISH analysis of 79 FIGO stage I and II epithelial ovarian cancers found a 6.7% rate of *c-erbB2* amplification. No clinical correlation of survival was attempted in this study due to the limited number of informative cases in the sample set (285). FISH analysis of 103 advanced stage ovarian cancer specimens found *c-erbB2* amplification rates of 10.7% and 33.3%, depending on the fluorescence ratio cutoff (286). No correlation between *c-erbB2* protein expression by immunohistochemistry and *c-erbB2* amplification by FISH analysis was seen. In addition, no correlation between *c-erbB2* amplification and DFS was seen (286).

Another comprehensive FISH analysis of 173 invasive ovarian cancers of all stages revealed good correlation between FISH analysis and immunohistochemistry, but no correlation between *c-erbB2* amplification and histological type, stage, grade, or prognosis (287). In this study, 79% of the invasive epithelial ovarian cancer specimens analyzed was of serous histology. The treatment period spanned from 1985 to 2002, including a variety of adjuvant chemotherapy regimens. Although the authors concluded that *c-erbB2* amplification did not correlate with FIGO stage, the percentages of early- and advanced-stage cancers analyzed were not provided. The inclusion of borderline or germ cell tumors also was not clarified (287).

Thus, the strong correlation between *c-erbB2* immunostaining and amplification seen in breast carcinoma might not be present in ovarian carcinoma. In addition, the expression of *c-erbB2* and potential relation to tumor cell growth have been outlined in endometrial and cervical carcinomas (65). Although receptors for EGF have been proposed as targets for antibodies that create a negative growth regulatory signal, initial trials have been disappointing (288–289).

Insulin-Like Growth Factors

Insulin-like growth factors (IGFs) have metabolic effects and an amino acid sequence analogous to insulin. IGF-I and IGF-II have been described. The IGF-1 receptor (IGF-1R) belongs to a family that includes the insulin receptor (IR) and IGF-2R (290). IGF-1R is expressed on the cell surface membrane as preformed dimers. Upon binding of IGF-I or IGF-II, IGF-1R undergoes autophosphorylation and conformational change (290). Signaling then depends on phosphorylation of intracellular substrates, leading to activation of the MAPK and PI3K/Akt pathways. IGF-1R signaling can be regulated on several levels, including receptor expression, ligand production, and ligand binding to proteins. Transcription of the IGF-1R gene is up-regulated by growth factors including PDGF, EGFR,

hormones, and oncogenes. Transcription of IGF-1R is down-regulated by the tumor suppressor genes *Wt1* and p53. Production of IGFs occurs primarily in the liver and is regulated by growth hormone. Only 2% of IGFs circulate in their free form, while the vast majority are bound to a series of six IGF binding proteins (IGF-BPs) (290,291).

Expression of IGF-1R is observed in most solid tumors examined to date, while overexpression of IGF-II has been demonstrated in cancer cells (292). High circulating levels of IGF-1 in serum have been associated with increased risk of breast, prostate, and colon cancer (291,292). Recent studies have implicated these receptors and their cognate growth factors in the promotion of ovarian carcinoma (293). Relative expression of IGF-II was measured in 109 epithelial ovarian cancers and eight normal ovarian surface epithelial samples using quantitative real-time polymerase chain reaction. Expression of the IGF-II gene was more than 300-fold higher in ovarian cancers compared with normal ovarian surface epithelium samples (294). High IGF-II expression was associated with advanced-stage disease at diagnosis, high-grade cancers, and suboptimal surgical cytoreduction. In multivariate analysis, relative IGF-2 expression was an independent predictor of poor survival. As such, IGF-II is a molecular marker and might be a potential therapeutic target for the most aggressive epithelial ovarian cancers (294).

IGF-II, IGF binding protein 3 (IGFBP-3), and estrogen-receptor- α expressions were evaluated in 215 patients with primary epithelial ovarian cancer. Survival analysis was done to examine the associations of IGF-II with disease progression. IGF-II expression was found to be higher in tumors with poor prognosis, including tumors with advanced stage, poor differentiation, serous histology, and large residual lesions. This study found evidence that IGF-II expression is associated with disease progression, suggesting that IGF-II and IGF signaling are potential targets for ovarian cancer treatment (295).

Platelet-Derived Growth Factor

The platelet-derived growth factor (PDGF) is of historic significance owing to its structural and functional homology to the *v-sis* viral oncogene. PDGFs are a growth factor family, each member of which contains one of four different polypeptide chains: PDGF-A, PDGF-B, PDGF-C, or PDGF-D (296). Each chain is encoded by an individual gene located on chromosomes 7, 22, 4, and 11, respectively. The polypeptide chains are linked with an amino acid disulfide bond forming homo- or heterodimers, of which five have so far been described: PDGF-AA, PDGF-AB, PDGF-BB, PDGF-CC, and PDGF-DD. These factors exert their cellular effects through PDGF- α and PDGF- β protein tyrosine kinase receptors. The platelet-derived growth factor receptor (PDGFR) system, located primarily on mesenchymal cells, transduces signals for cell survival, growth, and chemotaxis. As reviewed in detail by Fantl et al., the PDGFR is a receptor-linked tyrosine kinase with distinctive features, including an extracellular domain with five regions with homology to immunoglobulins and an intracellular domain that interrupts the kinase region and is thought to serve as a “dock” for presentation of phosphotyrosines to molecules that can bind to phosphotyrosine through SH2 domains (298). PDGFR- α can be activated by PDGF-AA, PDGF-AB, PDGF-BB, and PDGF-CC, while PDGF-BB and PDGF-DD bind and activate PDGF- β . Ligand binding induces receptor dimerization, activation, and autophosphorylation of the tyrosine kinase domain. This in turn recruits SH2-domain-containing signal transduction proteins and activates signaling enzymes including Src, PI3K. This precipitates a complex network of downstream signaling events, which have yet to be fully characterized. Activation of the receptors ultimately promotes cell migration, proliferation, and survival (299).

Ovarian and choriocarcinoma cells have been reported to express PDGF and PDGF receptors (299,300). A number of ovarian and cervical carcinomas express either c-kit and/or steel ligand, and have receptors for M-CSF (301,302). High levels of PDGF and PDGFR- α have been reported in advanced epithelial ovarian cancer, while overexpression of PDGFR- α has been shown to be associated with a reduced overall survival (299). Tissue arrays containing 84 epithelial ovarian tumors were studied by immunohistochemistry with antibodies specific for c-kit, PDGFR- α , and PDGFR- β (298). PDGFR- α was expressed in the largest percentage of ovarian tumors (58%), whereas 29% expressed PDGFR- β . No mutations were detected in six ovarian tumors with elevated immunoreactivity for each of the RTKs (c-kit, PDGFR- α , and PDGFR- β). This study demonstrates that PDGFR- α , PDGFR- β , and c-kit are expressed in a high percentage of epithelial ovarian cancers, suggesting that tyrosine kinase inhibitors may be useful in the treatment of these tumors (298).

In a mouse model of human ovarian cancer, the tyrosine kinase inhibitor SU6668 exhibited antitumor effects, both as a single agent and with paclitaxel (296,303). Reduction in tumor growth, ascites production, and metastatic spread were observed. Improvement in overall survival has also been demonstrated in mouse models of peritoneally disseminated ovarian cancer after treatment with SU6668 (303). Although the functional importance of these receptors has not been established, their presence raises the possibility that gynecologic neoplasms will depend, at some point in their pathogenesis, on the action of members of this growth-factor-receptor family. The initial clinical data in ovarian cancer, however, has been disappointing. A phase-II study of patients with relapsed ovarian cancer expressing c-KIT (CD117) or PDGFR was conducted with imatinib mesylate (304). Patients were treated daily with 400 mg of imatinib mesylate orally. Of the 19 evaluable patients, 2 (11%) had tumors expressing c-Kit, while 17 (89%) had tumors expressing PDGFR. There were no objective responders. Thirteen patients (68%) had increasing disease or symptomatic deterioration, and six (32%) went off protocol during the first month due to adverse events.

Vascular Endothelial Growth Factor and Other Angiogenic Factors

Angiogenesis, the formation of new blood vessels, is a process required by many biologic processes including the development of cancer (305). Maturation is usually incomplete in neoplastic growth. Endothelial cells of immature blood vessels require growth signals for survival to avoid apoptosis. Autocrine and paracrine loops exist between the tumor cells and stromal and/or endothelial cells (306). Autocrine stimulation by the tumor cell consists of growth factors such as vascular endothelial growth factor (VEGF), fibroblast growth factor (FGF), and PDGF, all of which stimulate the host cells in a paracrine fashion, to trigger the neovasculature that will irrigate the tumor cells. The VEGF family of glycoproteins consists of six related growth factors, VEGF-A (known as VEGF) through VEGF-E, as well as placental growth factor (PlGF)-1 and -2 (307). The VEGF gene, located on the short arm of chromosome 6, is composed of eight exons and is differentially spliced to yield four mature isoforms (308). VEGF mediates angiogenic signals to the vascular endothelium through high affinity receptor tyrosine kinases (RTKs) that are thought to activate the MAPK pathway. The VEGF family members bind their related receptors. The receptors identified so far include VEGFR-1, VEGFR-2, VEGFR-3, and the neuropilins (NP-1 and NP-2). These receptors are transmembrane tyrosine kinases that, upon ligand binding, activate a cascade of downstream proteins. These downstream pathways include PI3 kinase/AKT, ERK-1/2, and Raf-MEK-ERK pathways (308).

Although many stimulators and inhibitors of angiogenesis have been identified, the trigger that causes a dormant tumor to transform into a proangiogenic tumor remains elusive. Expression of VEGF in ovarian carcinomas was evaluated by immunohistochemistry and revealed focal or diffuse strong immunostaining in 48% to 51% of carcinomas (309). Significant associations between the VEGF expression and FIGO stage and histologic grade were observed (309,310). The survival of patients with high VEGF expression was significantly worse than that of patients with low or no VEGF expression. Multivariate analysis revealed that disease stage and VEGF expression were significant independent prognostic indicators of overall survival.

The family of FGFs comprises several members distinguished originally by binding to heparin and elution at a spectrum of pH, thus allowing their characterization as basic or acidic FGFs (311). These entities have been proposed to mediate not only the direct promotion of tumor cell growth but also the stimulation of stroma formation and blood vessel growth to sustain tumors beyond the microscopic stage. Additional angiogenic factors include platelet-derived endothelial growth factor and vascular permeability factor. Basic FGF and its receptor are expressed in human ovarian carcinomas (312). Ovarian and endometrial neoplasms have recently been demonstrated to secrete both PDGF and VEGF (313,314).

Bevacizumab (BEV) is a humanized monoclonal antibody against vascular endothelial growth factor. In a phase-II trial, 32 patients not participating in an ongoing clinical trial were treated with BEV (15 mg/kg every 3 weeks IV) (315). All patients had failed multiple prior cytotoxic chemotherapies prior to BEV. A median of six cycles (range 1 to 20) with 196 total doses of BEV was administered. A 16% response rate was seen with 62.5% of patients demonstrating stable disease. Median overall survival (OS) was 6.9 months, with median progression-free survival (PFS) of 5.5 months. BEV was generally well tolerated after multiple prior cytotoxic regimens and resulted in significant clinical benefit among women with recurrent ovarian cancer (315).

Transforming Growth Factor- β

TGF- β was originally recognized as a mediator of natural killer cell transformation. TGF- β binds directly to a receptor that is a constitutively active transmembrane serine/threonine kinase (316). Ligand binding of TGF- β results in heterodimerization with both TGF- β receptors, T β R1 and T β R2, and the ensuing phosphorylation of T β R1 (317). Phosphorylated T β R1 phosphorylates a SMAD protein that forms a heterodimer with SMAD4, travels into the nucleus, binds to DNA, and (with other factors) initiates transcription. T β R1 can also interact with a subunit of farnesyl transferase, which is involved in the farnesylation of the ras gene product. Also, H-ras has been shown to up-regulate expression of T β R1 and down-regulate expression of T β R2 (317). The importance of TGF- β to gynecologic neoplasia extends in part from the recognition that müllerian inhibitor substance (MIS), important in the embryogenesis of the normal genitourinary tract, is a member of the TGF- β family (318). TGF- β itself is recognized as a negative growth regulator of a variety of cell types, including ovarian tumor cells (252).

Ovarian cancer is resistant to the antiproliferative effects of TGF- β ; however, the mechanism of this resistance remains unclear. Investigators used oligonucleotide arrays to profile 37 undissected, 68 microdissected advanced-stage, and 14 microdissected early-stage papillary serous cancers to identify TGF- β signaling pathways involved in ovarian cancer (319). A total of seven genes involved in TGF- β signaling were identified that had altered expression >1.5-fold in the ovarian cancer specimens, compared with normal ovarian surface epithelium. Genes that inhibit TGF- β signaling (DACH1, BMP7, and EVI1)

were up-regulated in advanced-stage ovarian cancers while, conversely, genes that enhance TGF- β signaling (PCAF, TFE3, TGFBR2, and SMAD4) were down-regulated compared with the normal samples (319). These results suggest that altered expression of these genes is responsible for disrupted TGF- β signaling in ovarian cancer, potentially making them useful as novel therapeutic targets for ovarian cancer.

Tumor Necrosis Factor, TNF-Related Apoptosis-Inducing Ligand, and Interleukin-1

The tumor necrosis factor (TNF) superfamily consists of proteins involved in proliferation, differentiation, and apoptosis (320). Members of this superfamily such as TNF- α , Fas ligand (FasL), and TNF-related apoptosis-inducing ligand (TRAIL) have been shown to directly induce apoptosis. The cytokines bind TNF-family receptors that contain a conserved cytosolic structure known as the death domain; this is a protein interaction module that allows the TNF receptors to communicate with adapter proteins, which in turn bind to specific caspases (in humans, caspase-8 and caspase-10), thereby triggering apoptosis. TRAIL specifically induces apoptosis of transformed cells through the action of death domain receptors DR-4 and DR-5. It also directly induces apoptosis through an extrinsic pathway, which involves the activation of caspases. Unlike TNF and FasL, TRAIL appears to have a unique selectivity for triggering apoptosis in tumor cells while leaving normal tissues intact (320). Activation of caspase-8 by TRAIL can lead to a mitochondrial-independent signal that activates caspases downstream of caspase-8 and a mitochondrial-dependent caspase activation following caspase-8 activation and BID cleavage. It has been proposed that TNF and interleukin-1 (IL-1), cytokines originally defined as hematopoietic growth factors, operate via yet another distinct signaling mechanism. This involves the hydrolysis of membrane sphingomyelin, with the resulting ceramide acting as a second messenger to activate a ceramide-dependent protein kinase (321). Recent evidence has been accumulating that IL-1 can directly inhibit the growth of ovarian carcinoma cells and is expressed by this cell type and endometrial carcinoma cells in culture (322,323). IL-1 has also been found to regulate the secretion of collagenase, which is important in mediating invasiveness in choriocarcinoma cells (324). TNF can act as an autocrine and paracrine growth factor for ovarian carcinoma cells (325,326).

Calcium-Mobilizing Growth Factors

The importance of the G-protein-linked calcium-mobilizing growth factors and their receptors to the growth of gynecologic neoplasms has been less completely characterized than the entities described above. However, it has recently been demonstrated that the peptide bombesin can modulate sensitivity of ovarian carcinoma cells to TNF and platinum, perhaps by modulating calcium levels (327). In addition, pharmacologic treatments that seek to interfere with the increase in calcium in response to growth factors of this class are under clinical evaluation in patients with gynecologic neoplasms (328).

MAP Kinases

MAP kinase was originally defined as a distinctive protein whose phosphorylation on both tyrosine and threonine residues increased shortly after addition of growth factors to cells. It is now appreciated that there are multiple different MAP kinases and isoforms (329,330). Each family of MAP kinases has unique (although overlapping) downstream substrates and upstream activators (MAPKKs). MAP kinase families include the extracellular-signal-regulated kinase (ERK), c-Jun N-terminal kinase (JNK), and p38 families. The ERKs are phosphorylated and activated by MEK 1,2, while the JNKs are activated

by JNKK1 (SAPKK1), and the p38s are activated by MKK 3 and 6. These MAPKKs are in turn activated by specific MAPKKKs. Thus, raf signals through MEK 1,2 to the ERK family members, whereas JNK and p38 receive their activation signals from other upstream kinases. These kinase cascades allow for rapid transduction and amplification of signals from the cell membrane. Recent work has demonstrated that activation of one MAPK pathway can suppress the activity of the others (331). Thus, although these are primarily vertical pathways, there is ample lateral cross talk between them, providing integration of multiple unique cell membrane signals.

As reviewed by Garrington and Johnson, MAP kinases in turn phosphorylate a diverse series of substrates, including cytoplasmic phospholipase A₂, cytoskeletal components, protein synthesis machinery, and, perhaps most importantly, transcription factors (332). The substrate specificities of different MAP kinase families, although overlapping, are unique (333). Thus, a unique combination of proteins is activated by each MAP kinase. It is proposed that activation of transcription of new genes in response to growth-factor action extends in part from these actions of MAP kinases. Included among the transcription factors affected are those that govern the synthesis of cyclins, which allow entry into the cell cycle (334,335).

The role of the MAPK pathway in ovarian cancer has been investigated. Activation of MAPK family members was detected following stimulation of ovarian cancer cells with transforming growth factor, as well as through epidermal growth factor receptor activation (336). Treatment of ovarian carcinoma cell lines *in vitro* with paclitaxel or cisplatin resulted in measurable changes in MAPK levels, with resulting effects toward proliferation or apoptosis (337). In another analysis, ERK expression was associated with clinical parameters related to better outcome, such as lower volume of residual disease (336). Moreover, it correlated significantly with improved survival. Thus, there is evidence of a beneficial prognostic role for ERK in human ovarian cancer patients.

Phosphatidylinositol 3'-Kinase

Phosphatidylinositol 3'-kinase (PI3K) is a lipid kinase that appears to play an important role in mediating a wide variety of signals involved in diverse processes including proliferation, apoptosis, and vesicular trafficking (338). PI3K is a heterodimeric protein that is activated by a wide variety of receptor-TKs such as the insulin, PDGF, and EGF receptors. It has been well established that phosphorylation of a tyrosine residue on the receptor will serve as a docking site for a component of PI3K (p85) that in turn recruits the catalytic subunit of PI3K (p110). Alternatively, PI3K can be activated through a *ras*-dependent mechanism. The PI3K/AKT pathway has been implicated as a major determinant of oncogenic transformation in ovarian cancer. Amplification of PI3K renders ovarian cancer cells resistant to the effects of paclitaxel (339). This process can subsequently be reversed by inhibitors of PI3K. PI3K inhibitors decrease cell proliferation, increase sensitivity to paclitaxel, increase apoptosis, and decrease vascularization *in vivo* (339). PI3K is up-regulated in 30% to 45% of ovarian cancers (340,341). Only 2.3% of serous carcinomas had PI3K mutations compared with 20.0% of endometrioid and clear cell cancers. In contrast, PI3K gene amplification (>sevenfold) was common among all histologic subtypes (24.5%) and was inversely associated with the presence of mutations. Overall, PI3K mutation or gene amplification was detected in 30.5% of all ovarian cancers. Intriguingly, multiple other components of the PI3K signaling cascade, including AKT1, AKT2, P70S6 kinase, TCL1, and GSK3 α , are located at sites of copy number abnormalities in ovarian cancer, providing further evidence that this pathway is potentially important in the development of ovarian cancer (339).

As mentioned above, PI3K has been widely recognized as being able to phosphorylate phosphatidylinositols at the 3' position, which in turn activates protein kinase C (PKC). However, it is appreciated that there are other substrates of PI3K including p70, S6K, and, most importantly, PKB/AKT. AKT is a protein kinase that has been demonstrated to mediate multiple biologic processes. Of particular importance, PI3K has been identified as amplified in breast and ovarian cancers. Increased PI3K activity has been detected in a large subset of ovarian cancers, while inhibition of this pathway leads to inhibition of cellular proliferation (342).

AKT

AKT, a member of the protein kinase B family, represents a subfamily of the serine/threonine protein kinases, and the primary mediator of the effects of PI3K (338). Three members of this family, AKT1, AKT2, and AKT3, have been identified. A broad spectrum of substrates is phosphorylated by AKT, including transcription factors (Creb, Forkhead), proteins critical for apoptosis (caspase-9, BAD, IKK), and cell-cycle proteins (p21, p27) and other kinases (GSK-3). These substrates in turn activate multiple other pathways, including cross talk with the MAPK pathway. The downstream effects of AKT activation include suppression of apoptosis, induction of cell-cycle progression, and induced resistance to cytotoxic drugs. Given these effects, it is not surprising to note evidence linking AKT to the development of cancer. AKT has been found to be activated and amplified in ovarian cancer (343). It has also been shown to play a major role in drug resistance in a variety of human malignancies. Approximately 36% of primary ovarian tumors show elevated AKT2 activity (340,344). The majority of these tumors were of high grade and late stage, implicating the kinase in tumor progression. AKT3 has been shown to be highly expressed in 21% of primary ovarian tumors (340). Strikingly, purified AKT3 exhibited up to tenfold higher specific activity than AKT1. Consistent with this finding, AKT3 levels in a range of ovarian cancer cell lines correlated with total AKT activity and proliferation rates, implicating AKT3 as a key mediator of ovarian oncogenesis. Specific silencing of AKT3 using short hairpin RNA markedly inhibited proliferation of the two cell lines with the highest AKT3 expression and total AKT activity by slowing G(2)-M phase transition (340). These findings are consistent with AKT3 playing a key role in the genesis of at least one subset of ovarian cancers.

Protein Kinase C

PKC was originally described as a calcium (hence the C) and phospholipid-dependent kinase distinct from the cAMP-dependent protein kinase A. It is now recognized that the term *protein kinase C* can refer to at least eight distinct molecular isoforms that, in some cases, may actually be independent of calcium, but are related to other members of the family because of structural similarities.

The importance of PKC in tumorigenesis was suggested by the finding that PKC isoforms are receptors for the tumor-promoting phorbol esters, one of the first demonstrations of a discrete molecular effector of a carcinogenetic stimulus (345). The addition of growth factors was recognized to increase the enzymatic activity of diacylglycerols, which are normal activators of PKC that can be produced by phospholipase-C. Thus, tyrosine kinase-linked growth factors could be shown to phosphorylate and activate the phospholipase-C-gamma isoform, whereas calcium-linked growth factors (see discussion of G-protein and calcium-related signals below) activate phospholipase-C-gamma. PKC, once activated, can directly influence the activity of the MAP kinase pathway by phosphorylating raf (346). Additional pathways leading to activation of transcription from PKC-sensitive promoter elements exist.

Cyclin-Dependent Kinases

The ultimate consequence of growth factor action is the entry of quiescent cells into the cell cycle. The molecular events responsible for this process are currently being elucidated. Classic biochemical experiments showed that, at the onset of mitosis, there was an increase in protein kinase activity directed at histones. It was hypothesized that altered phosphorylation of nuclear proteins allows or promotes the morphologically apparent changes in chromosomal condensation. It was therefore of great interest when a protein with histone H1-kinase activity was found to complement a yeast mutant defective in cell-cycle progression. The responsible protein, p34^{cdc-2}, was found to be a serine/threonine kinase whose activity was cyclically regulated by the appearance during the normal yeast cell cycle of a family of molecules called cyclins, with the active H1-kinase enzyme consisting of a complex of cyclin and an appropriately phosphorylated p34^{cdc2} catalytic subunit (347–351).

Subsequently, through the use of homology cloning and complementation of function in yeast, it became apparent that progression through G₁ is also regulated by a family of analogous molecules now collectively referred to as cyclin-dependent kinases (cdk). There are at least nine cdk (cdk1 through cdk9) and 15 cyclins (cyclin A through cyclin T) (352). Cdk4 and cdk6, along with their D-type cyclins, are responsible for progression through G₁ phase. Cdk2 and cyclin E complex are responsible for progression from G₁ to S phase. Cdk2 and cyclin A are responsible for progression through S phase, while cdk1 and cyclin B are required for mitosis. These complexes in turn are inhibited by a combination of small proteins called cdk inhibitors (CKIs this is the same acronym as used earlier). The INK4 (inhibitor of cdk4) family consists of p16^{ink4a}, p15^{ink4b}, p18^{ink4c}, and p19^{ink4d} and specifically inhibits cyclin D-associated kinases. The protein kinase inhibitor family of p21^{waf1}, p27^{Kip1}, and p57^{Kip2} inhibits the cyclin E/cdk2 and cyclin A/cdk2 complexes. Loss of expression of CKIs confers a poor prognosis in a variety of cancers (352). Of great current interest is how growth factors regulate the enzymatic cascade that is directly responsible for entry into the cell cycle. Of fundamental importance is the observation that the tumor-suppressor gene product of the retinoblastoma-related locus (pRb) is a substrate for cdk2 and that phosphorylation of Rb correlates with entry into the S phase (353,354).

It is now well documented that cyclin D-cdk4/6 and cyclin E-cdk2 complexes phosphorylate Rb, causing it to release the transcription factor E2F. E2F in turn regulates the expression of S-phase genes, which are required for DNA replication. Thus, the G₁-S-phase transition is critically dependent on sufficient cdk activity and, as expected, is a frequent target for alteration in cancer cells. For instance, recent analysis has demonstrated that cyclin E is frequently amplified and overexpressed in ovarian cancer (355). Genetic abnormalities such as these may provide important enzymatic targets for novel therapeutic agents.

G-Protein and Calcium-Related Signals

Second-messenger control of intracellular events was first demonstrated convincingly in the case of cAMP and glycolysis in liver treated with α -adrenergic agonists. Paramount to establishing the mechanism of this process was the observation that guanine nucleotides were necessary for the efficient generation of cAMP. This led to the purification of proteins that, in the GTP-bound state, stimulated adenylate cyclase, and thus were called G-proteins (356). G-protein-coupled receptors (GPCR), the prototype of which is the adrenergic receptor, are structurally very distinct in comparison to receptor-linked tyrosine kinases. The GPCR superfamily, now with over 200 members, has an external ligand-binding portion,

seven transmembrane segments, and a carboxyl-terminal tail. These serpentine receptors couple to G-proteins, which are now understood to interact not only with adenylate cyclase, but also with certain phospholipases including phospholipase-C- β (325). The membrane lipid phosphatidylinositol-4,5-bisphosphate then is hydrolyzed to yield the soluble metabolite inositol 1,4,5-tris-phosphate, which releases calcium from internal stores as well as diacylglycerol, described above as the endogenous regulator of PKC (Fig. 3.3) (357).

Recent work has demonstrated that a subfamily of GPCRs that bind lysophospholipids appear to play a role in the development of ovarian cancer (358). These receptors include PSP24 and the EDG receptors. These receptors do not bind all lysophospholipids, but are activated by lysophosphatidic acid (LPA) and sphingosine-1-phosphate (325,359,360). The combination of multiple receptor family members, different ligands, and the available intracellular G-proteins produces a wide range of biologic effects including proliferation, invasion, and cellular survival.

Protein Phosphatases

Protein phosphatases are a relatively newly described group of proteins that function in an opposing manner to protein kinases, providing important regulatory mechanisms to the above-described signal cascades. In fact, it has been proposed that phosphatases play as critical a role in cellular functions, such as proliferation, differentiation, and apoptosis, as protein kinases (361,362).

Protein phosphatases are divided into groups by different criteria, but the most commonly used is that of substrate specificity: protein tyrosine phosphatases (PTPs), protein serine/threonine phosphatases (PSPs), and dual-specificity phosphatases (DSPs). PTPs are further classified according to whether they contain a transmembrane (TM) domain or not. TM-domain-containing PTPs called receptor PTPs (RPTPs) have extracellular domains and a catalytic domain in their intracellular portion. Many RPTPs (such as CD45, LAR, and PTP- β) possess structural features that suggest a role in cellular adhesion (363). Indeed, studies have revealed that several RPTPs are important regulators of neuronal adhesion (364).

Non-TM PTPs are also important regulators of tyrosine phosphorylation. Some appear to associate with tyrosine kinases through the SH2 domains found within their structures (SHP-1, SHP-2). SHP-1 and SHP-2 play critical roles in regulating tyrosine kinase signals within hematopoietic cells (349,365). *PTEN* is a tyrosine phosphatase that has been demonstrated to have an inhibitory effect on cellular proliferation (366). This inhibitory activity has been traced to a negative regulation of PI3K and AKT activity (367,368). Whether this is a direct effect of *PTEN*'s ability to dephosphorylate phosphotyrosine residues or its additional activity as a lipid phosphatase remains unclear. However, mutations in *PTEN* have been identified in a wide variety of tumors as well as in the germ line of patients with Cowden's syndrome (369). Based upon these observations, it is widely concluded that *PTEN* is a tumor-suppressor gene. Recent work has identified mutations within this gene in endometrial cancers and endometrioid ovarian cancers (370,371). In a wider number of ovarian cancers, *PTEN* activity is suppressed, leading to an over-activity of the PI3K pathway.

PSPs comprise a group of protein phosphatases containing three subunits: regulatory, variable, and catalytic (372). Previously, four major families had been identified (PP1, PP2A, PP2B, and PP2C), although a fifth family has recently been added. Multiple members exist within each family with some evidence for substrate specificity differences between families. Type 2A PSPs have selective substrate specificity for PKC phosphorylated proteins and the ribosomal S6 protein. Type 2A PSPs are of particular interest because they have been found to

associate with complexes formed by DNA tumor virus proteins and cellular proteins. The presence of PP2A in these complexes suggests it may play a role in the alteration of cellular proliferation mediated by DNA tumor viruses (373,374).

Dual-specificity phosphatases are frequently grouped with PTPs owing to their ability to dephosphorylate phosphotyrosine moieties. However, they are also able to use phosphoserine and phosphothreonine as substrates. DSPs such as MKP-1 and Cdi1 localize to the nucleus, where they have been shown to dephosphorylate MAP kinases (375). Thus, this represents an important family of proteins that may serve to regulate the incoming proliferative signals from various MAP kinase cascades. For instance, MKP-1/CL100 has been found to be differentially expressed between normal and malignant ovarian epithelium (376). Reexpression of this gene in ovarian cancer cells decreases the malignant phenotype.

Wnt/ β -Catenin Pathway

The Wnt/ β -catenin pathway is an important signal transduction pathway frequently disrupted in cancer cells (377). In the absence of Wnt signaling, β -catenin expression is controlled by the formation of a degradation complex that includes GSK3B, APC, and Axin (378). This complex produces ubiquitination of β -catenin and its subsequent degradation by the proteasome. When the Wnt ligand binds to its receptor Frizzled, the degradation complex is destabilized, resulting in higher levels of nonphosphorylated β -catenin. High levels of β -catenin translocate to the nucleus, where it acts as a cofactor for TCF/LEF transcription factor.

This pathway has been studied extensively in human cancers (377). Mutations in this pathway are very common in colorectal cancers. Germ-line mutations within the APC gene form the molecular basis for familial adenomatous polyposis (FAP). Somatic mutations of APC (and to a lesser extent β -catenin) are common in sporadic colorectal cancers. Activating mutations of the Wnt pathway are found in a wide variety of other cancers, including gynecologic cancers. This is especially true for the endometrioid histologic subtype of ovarian and endometrial cancers.

The expression of β -catenin in uterine serous carcinoma (USC) and endometrioid endometrial carcinoma (EEC) was investigated in tissue microarrays created from 20 cases of grade 3 EEC and 73 cases of USC (379). β -catenin was present in both tumor types. Expression of β -catenin was also examined by immunohistochemistry in 253 ovarian carcinomas (380). Membrane-associated staining of β -catenin was detected in nearly all cases with no correlation to clinical parameters. Most of the samples (84%) also had cytoplasmic localization, while only 13% had nuclear β -catenin localization. Nuclear β -catenin was almost exclusively present in endometrioid carcinomas. Fifty-three percent of all endometrioid tumors were positive for nuclear β -catenin expression. Better prognostic outcome was found for patients with nuclear β -catenin localization compared to the cases without it. Although the study showed no correlation between β -catenin expression, FIGO stage, and genomic instability, as determined by DNA ploidy status in ovarian carcinoma, nuclear β -catenin expression again was strongly associated with the endometrioid histologic subtype (380).

RNA Interference

Small RNAs. The most familiar role for RNA is as a relatively passive intermediary in the translation of information from genes into proteins, but other functions for this versatile molecule have been emerging (381). Although the first hints about silencing were seen decades ago, the real breakthrough in mechanistic understanding came in 1998. A landmark paper by Fire et al. showed that the trigger for gene silencing is

double-stranded RNA (dsRNA) (382). RNA interference (RNAi) was identified as a potent and highly specific gene-silencing phenomenon that is initiated or triggered by dsRNA (383). Since then, other components of the RNAi machinery have been identified at a startling rate, although the picture is still incomplete. RNAi was first observed in plants in the guise of a mysterious immune response to viral pathogens. Based on their origin or function, three types of naturally occurring small RNA have been described. The first is endogenous or artificial micro RNAs (miRNAs), which are expressed from Pol II promoters as primary miRNA transcripts subsequently processed into mature miRNAs in a regulated multistep process. The second is exogenous, short, synthetic, double-stranded, small interfering RNAs (siRNAs), while the third is endogenous siRNAs (381,384).

Micro RNAs. miRNAs are a subset of small (typically 21 to 23 nucleotides) noncoding RNAs evolutionarily conserved in many organisms including yeast, fruit flies, humans, and plants (384). miRNAs have important roles in many functions including development, proliferation, hematopoiesis, and apoptosis (383). Unlike siRNAs, miRNAs usually do not cleave the messenger RNA (mRNA) of a target gene, but instead suppress mRNA translation (384,385). RNA Pol II transcribes miRNA genes in the cell nucleus and gives rise to a large primary miRNA (Fig. 3.10). These initial primary miRNAs are then processed by RNase III, Drasha, to form pre-miRNAs in the nucleus. The pre-miRNAs are exported into the cytoplasm by the transporter exportin 5 and undergo processing by another RNase III, Dicer, to produce a miRNA duplex (384). The RNA duplex is unwound by helicase. The

FIGURE 3.10. (See color plate section.) This figure depicts distinct roles for dsRNA in a network of interacting silencing pathways. In some cases dsRNA functions as the initial stimulus (or trigger), for example, when foreign dsRNA (blue) is introduced experimentally. In other cases transcription can produce dsRNA (red) by read through from adjacent transcripts. miRNA genes often cluster on the chromosome and are transcribed by RNA Pol II to form pri-miRNAs in the nucleus. The primary miRNAs then undergo processing by RNase III, Drasha, and are exported to the cytoplasm by exportin 5. Another RNase III, Dicer, further processes the small RNA products of the Dicer, pre-miRNA or pre-siRNA, to generate a ~22nt mi/siRNA:mi/siRNA* duplex, where mi/siRNA* is complementary to mi/siRNA. Helicase can divide the duplex into two separate ones. Whereas *mi/*siRNA is degraded, mature mi/siRNA can enter the RNA-induced silencing complex (RISC). The RISC complex blocks protein synthesis by imperfectly binding to the 3'UTR of the mRNA (upper right), causing inhibition of translation; the other one is to endonucleolytically cleave the target mRNA by perfect or nearly perfect base pairing (lower right).

mature miRNA enters the miRNA-induced silencing complex, which then blocks protein synthesis by binding to the 3' untranslated region (UTR) of the mRNA.

miRNAs can influence the signaling pathway by repressing several secreted signaling proteins (384). For example, the 3'UTR of ras genes contains multiple *let-7* complementary sites allowing *let-7* to regulate ras expression. Conversely, miRNA expression can be regulated by protooncogenes. c-Myc directly binds to the locus of six miRNAs and stimulates their expression (384).

Small-Interfering RNAs. Small-interfering RNAs (siRNAs) are similar to their cousin miRNAs. The initial processing of dsRNA in the nucleus by Dicer is similar. The small RNA products of the Dicer-mediated dsRNA processing reaction guide distinct protein complexes to their targets, including the RNA-induced silencing complex, which is implicated in mRNA destruction and translational repression, and the RNA-induced transcriptional silencing complex, which is implicated in chromatin silencing (381). The single-stranded siRNA in the RNA-induced silencing complex then guides sequence-specific degradation of complementary or near-complementary target mRNA. In summary, these small interfering siRNAs trigger gene silencing by binding to their target RNA sequences and cleaving them.

Endogenous siRNAs. In addition to the endogenous miRNAs and exogenous siRNAs, endogenous siRNAs have been discovered in various organisms and fall into at least four classes: trans-acting siRNAs (tasiRNAs), repeat-associated siRNAs (rasiRNAs), small-scan RNAs (scnRNAs), and Piwi-interacting RNAs (piRNAs) (383). tasiRNAs are small (approximately 21 nucleotides) RNAs that have been reported in plants that are encoded in intergenic regions that correspond to both the sense and antisense strands (386). In *Arabidopsis thaliana*, tasiRNAs require components of the miRNA machinery and cleave their target mRNAs in transcription. It has been postulated that rasiRNAs that match sense and antisense sequences could be involved in transcriptional gene silencing in *Schizosaccharomyces pombe* and *A. thaliana* (387). scnRNAs are approximately 28-nucleotide RNAs that have been found in *Tetrahymena thermophila* and are thought to be involved in scanning DNA sequences in order to induce genome rearrangement (388). piRNAs are possibly important in mammalian gametogenesis (389). Whereas miRNA and siRNA range between 21 and 26 nucleotides, piRNAs are larger (between 26 and 31 nucleotides) and lack 20 and/or 30 OH termini (390). They tend to cluster and are diversely distributed among exonic, intronic, intergenic, and repeat sequences in the mouse genome, suggesting their potentially diverse roles in regulating gene expression. A fraction of piRNAs are associated with polysomes. Interestingly, piRNAs associate with MIWI, a murine PIWI Argonaute protein expressed exclusively in spermatogenic cells and required for initiating the spermiogenic program (389). As a result these piRNAs can control gene expression involved in sperm development.

RNAi Clinical Potential. The rationale for RNAi-based therapeutic agents is that new siRNAs could be designed to treat diseases by lowering the concentrations of disease-causing gene products. However, the development of such siRNA-based therapies faces two major challenges: the identification of chemically stable and effective siRNA sequences, and the efficient delivery of these sequences to tissue-specific targets *in vivo* with siRNA amounts that are not too toxic to humans (383). Recent advances in understanding the rules for chemically modifying siRNA sequences without compromising gene-silencing efficiencies have allowed the design and synthesis of therapeutically effective siRNA molecules that can silence target genes *in vivo* (383). Based on this rapid progress in understanding the structure and function of siRNAs and

their applications in disease models, it is likely that RNAi-based therapeutics will become a reality in the near future.

As our knowledge about tumor biology and the molecular mechanisms underlying the process of carcinogenesis continues to expand, so too will the potential for intervention. In this respect, basic science and clinical research will continue to complement each other in increasingly important ways.

CHAPTER 4 ■ TUMOR INVASION, ANGIOGENESIS, AND METASTASIS: BIOLOGY AND CLINICAL APPLICATION

CHRISTINA M. ANNUNZIATA, NILOFER S. AZAD,
EBONY R. HOSKINS, AND ELISE C. KOHN

Genetic instability is at the heart of malignant transformation. This is manifest in part by the activation of signaling events triggering malignant cells to stimulate their local microenvironment, invade locally, and then metastasize to distant sites (Fig. 4.1). Invasive and metastatic disease is responsible for much of the morbidity and mortality associated with cancer. The search for factors affecting this process began as far back as 1889 when Sir James Paget noted that women who died of breast cancer tended to have a higher frequency of metastases to bone and ovaries. He further commented that the process was not random and, even more importantly, represented a relationship between the “seed,” tumor cells of a given type, and “soil,” the microenvironment providing the growth advantage to the cells (1). Scientists have turned much attention toward dissecting the sequence of events that comprises these key steps in the disease process and translating that understanding to development of targeted therapeutics (2). Signals in the cancers that stimulate and maintain the invasive and angiogenic phenotype can also drive survival. Recognition of the regulation and roles of angiogenesis, invasion, and tumor survival in the dissemination of gynecologic cancers has and will continue to lead to improved patient care and outcome.

CLINICAL IMPLICATIONS OF INVASION, ANGIOGENESIS, AND METASTASIS

Invasion

Survival, recurrence, and response to treatment strongly correlate with tumor invasion that leads to nodal and distant metastases (3). Epithelial ovarian tumors of low malignant potential (LMP/borderline) are characterized by their lack of penetration into the ovarian stroma (4). These tumors rarely metastasize, recur late, and have an overall survival at 5 years in excess of 95% (4). The importance of invasion depth is reflected in the International Federation of Gynecology and Obstetrics (FIGO) staging systems for both cervical and endometrial cancer (5). The stage and frequency of cervical cancer metastasis increases as the depth of invasion exceeds 5 mm (6,7). Extent of invasion significantly contributed to a model predicting disease-free survival in multivariate analyses of early cervical cancer and other cancers (8). Clinical outcome in endometrial cancer is also affected by depth of invasion. As myometrial invasion proceeds

beyond the depth of 50%, the risks of nodal metastases and treatment failure escalate (9). In addition to FIGO stage and tumor type, depth of invasion has independent prognostic value in endometrial cancer (10). Invasion has been used as a discriminating clinical feature in the application of therapeutic modalities, especially for local therapies such as radiation and intraperitoneal chemotherapy. Invasion is thus an important behavior contributing to the clinical outcome of gynecologic malignancies.

Angiogenesis

Angiogenesis is the process of forming new blood vessels from a preexisting vascular network. Its role in cancer was first detailed by Folkman (11,12) and Liotta (13) in the 1970s. Angiogenesis is now considered to be an invasive process itself, and is prognostically important in tumor survival and progression. Several points in the process of angiogenesis have been successfully targeted in cancer therapy (11).

Endothelial cells from tumor samples can be identified and quantified by immunohistochemistry analysis of angiogenic markers such as von Willebrand's factor, factor VIII, CD31, or CD34 (14). Microvessel density has been correlated with disease relapse in cervical cancer (15), ovarian cancer (16,17), and endometrial cancer (18). High microvessel counts occurred in cervical cancer patients of all stages who developed early disease recurrence (19). Increased microvessel number in endometrial carcinomas has been associated with recurrent disease, progression-free survival, and overall survival (18,20). The extent of angiogenesis correlated with progression-free survival and overall survival in ovarian cancers. CD34 was the most useful discriminator of microvessels in advanced-stage ovarian cancers (21); counts and stage of disease were associated with overall survival and disease-free survival, respectively.

The expression of vascular endothelial growth factor (VEGF), a potent angiogenesis stimulator, can complement microvessel density (MVD) in the clinical assessment of angiogenesis. VEGF correlated with poor outcome in early-stage and LMP ovarian tumors; a statistically significantly worse median disease-free survival was found in patients with VEGF-positive tumors (22). Raspollini et al. (16) demonstrated that increased MVD and higher expression of VEGF were independent predictors of disease survival in serous ovarian cancer. Thus, neoangiogenesis is a consistent clinical predictor of poor progression-free survival in gynecologic malignancies.

FIGURE 4.1. Paradigm of cancer progression. The average age at diagnosis of cervical intraepithelial neoplasia III and/or carcinoma *in situ* (CIS) is approximately 42 years. Progression from CIS to invasive carcinoma occurs over 8 to 10 years. The majority of patients with invasive cervical cancer die within 10 to 15 years of their diagnosis. In comparison, a precursor or early detectable lesion for invasive ovarian cancer has not yet been found. Low malignant potential tumors are diagnosed between the fourth and fifth decade. Invasive ovarian cancer is diagnosed approximately 15 years later, with the majority of patients diagnosed dying of the disease within 5 years.

Metastasis

Both autocrine and paracrine signaling by growth factors and cytokines activate programs for invasion and angiogenesis in the progression toward metastasis. Once activated, these events set the stage for dissemination. Activation and modulation of the local microenvironment induces further permissive events supporting tumor metastasis.

Metastatic activity and pattern of spread is important in the diagnosis, prognosis, and treatment of all malignancies. Patterns of spread vary between and within tumors and follow the biology and location of the primary tumor. Consider distinct patterns of spread of gynecologic cancers. Cervical and endometrial cancers tend to follow the general adenocarcinoma pattern of early local extension with nodal involvement predicted by locally invasive behavior, followed by distant dissemination (23,24). The presence of nodal metastases is a poor prognostic sign for gynecologic malignancies, a manifestation of invasion that results in upstaging and high risk of relapse. A study of fallopian tube cancer revealed a 76-month median survival in patients without lymph node metastases. This was in contrast to a 33-month median survival in patients with documented nodal disease (25).

Unlike other invasive adenocarcinomas, however, epithelial ovarian tumors disseminate broadly within the abdominal cavity

prior to nodal and hematogenous dissemination (26–28). This occurs from tumor cell shedding, followed by adhesion to the serosal and peritoneal surfaces and migration of the malignant epithelium. Common sites of early extension are bowel and bladder serosal surfaces and the abdominal and pelvic peritoneum. Surface shedding, a nurturing milieu within the ascites, and the supportive local microenvironment of the serosa and peritoneum can result in extensive microscopic tumor burden. The microscopic and insidious nature of the surface extension of ovarian cancer limits the success of complete surgical resection. Disease can be found on the abdominal peritoneum of the diaphragm in patients before microscopic nodal involvement (FIGO stage IIIA vs. IIIC). This is in sharp contrast to other gynecologic malignancies; Matsumoto et al. compared the process of lymphatic invasion of ovarian, cervical, and endometrial cancers (29) and showed that cervical and endometrial cancers tended to involve pelvic nodes earlier in the metastatic process than ovarian malignancies.

BIOLOGY OF INVASION

Invasion is the active translocation of a cell across tissue boundaries and through host cellular and extracellular matrix barriers (Figure 4.2). It is tightly regulated in the physiologic settings of wound healing, embryogenesis, and trophoblast implantation.

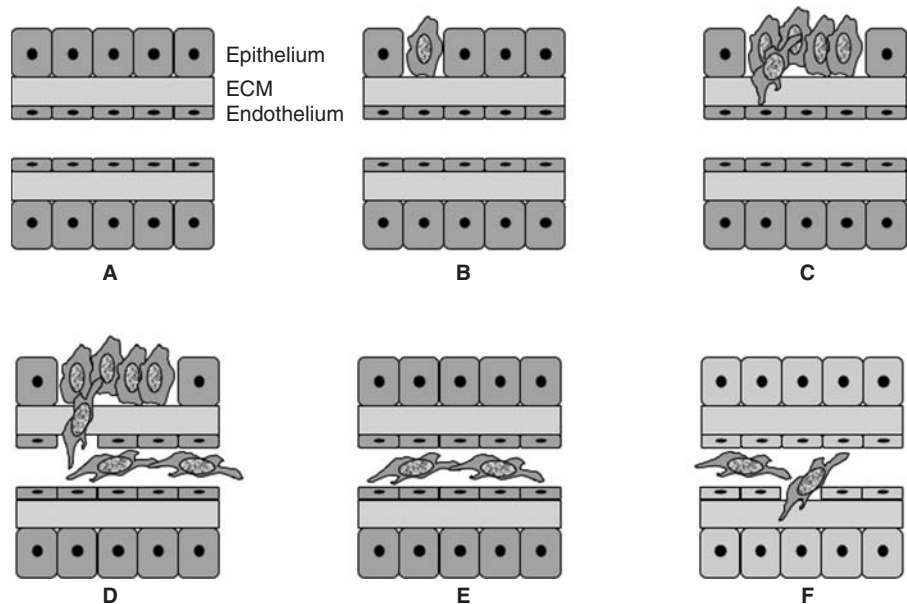

FIGURE 4.2. Schema of invasion and metastasis. (A) Normal epithelium, extracellular matrix (ECM), and endothelium. (B) Early transformation and carcinoma *in situ*. (C) Stromal invasion requiring proteolysis and ECM degradation. (D) Intravasation requiring further proteolysis. (E) Migration. (F) Extravasation into distant sites.

The components and events of physiological invasion and malignant invasion are similar. Invasion requires cellular adhesion and proteolysis, coupled with activation of migration and survival pathways (30). Quantity, activation, and regulation are what set the two forms of invasion apart. These checkpoints are disrupted or altered in the setting of malignancy.

Adhesion

Both cell-cell and cell-stroma interactions are involved in physiologic and malignant invasion. Connections through cell adhesion molecules, integrins, and cadherins stabilize tissue integrity and provide survival and activation signals (31). Loss of these connections is associated with increased metastatic potential (32,33). Cell polarity and organization during spreading and migration are regulated by cell interaction with extracellular matrix (ECM) proteins through the integrin family, and with other cells through the transmembrane glycoproteins, cadherins. Activation of these cell surface receptors passes signals from the microenvironment to the intracellular environment, thereby affecting cellular behavior. Differential expression and activation of adhesion molecules has been described as differentiating normal from malignant cells (32).

Cadherins

Cadherins are transmembrane glycoproteins that mediate cell-cell interactions in a fashion dependent upon extracellular calcium. The intracellular domain of the cadherins form complexes with the catenin family of cytoplasmic proteins (34). Cadherin-catenin complexes are linked to the cytoskeleton through direct interactions between α -catenin and α -actinin (35). Interaction with the ECM thus transmits signals intracellularly via cadherin/catenin complexes, thereby affecting both structural morphology and functional differentiation.

E-cadherin is the most extensively studied member of the family. E-cadherin functions as a metastasis-suppressor molecule in several types of carcinomas (36). Loss of E-cadherin expression is associated with an invasive phenotype. A transgenic mouse model of pancreatic islet cell carcinoma demonstrated that loss of E-cadherin was associated with early invasion and metastasis (37). The role of E-cadherin is less defined in ovarian cancer, based on its variable patterns of expression. In contrast to other normal epithelial cells, normal ovarian surface epithelium (OSE) rarely expresses E-cadherin (38,39), whereas activated metaplastic OSE cells and primary ovarian cancers often express this protein. E-cadherin protein expression is then lost as tumors become more poorly differentiated or increase their metastatic potential (37). E-cadherin expression becomes scant or absent in metastases, consistent with its description as a metastatic suppressor (36,40–42). Exogenous expression of E-cadherin in OSE cells induced expression of markers associated with preneoplastic and metaplastic OSE (43). Hence, alterations associated with control of E-cadherin could facilitate invasion in malignancy.

Integrins

The integrins are transmembrane glycoproteins composed of noncovalently linked α - and β -subunit heterodimers. Integrins serve both as cell adhesion molecules and as signaling molecules regulating apoptosis, proliferation, invasion, metastasis, angiogenesis, and survival. A variety of extracellular matrix proteins interact as ligands, including collagens, laminin, tenascin, fibronectin, vitronectin, von Willebrand's factor, and thrombospondin (44). Matrix engagement is an important stimulus of invasive behavior, signaling through integrins to activate focal adhesion kinase (FAK), phosphatidylinositol 3'-kinase (PI3K) and the AKT/protein kinase B pathway.

Feedback interdependence between these proteins was demonstrated experimentally when overexpression of AKT2 in ovarian cancer led to up-regulation of β 1 integrins and resulted in increased invasion and metastasis (45).

Integrins also exhibit the capability of serving as mechanoreceptors, allowing for the translation of mechanical external signals into biochemical messages such as during collagen matrix contraction (46). The α v β 3 integrin plays a fundamental role in angiogenesis, invasion, and survival. Its activation initiates a calcium-dependent signaling pathway, leading to an increase in cell motility and survival signals. This integrin is expressed on epithelial, endothelial, and uterine smooth muscle cells, as well as leukocytes. α v β 3 integrin is expressed minimally in normal or resting blood vessels and is up-regulated both on activated vascular endothelium and tumor epithelium, suggesting a role in tumor proliferation as well as angiogenesis (47–51). There is elevated expression of α v β 3 in cervical cancers (52) and ovarian cancers (53), that shows an increasing gradient of expression as cells progress from LMP tumors to invasive epithelial cancers (54). Cross talk may occur between the α v β 3 integrin and the tyrosine kinase domains of angiogenic growth factor receptors, amplifying downstream activation of survival and proliferation cascade (55,56). Agents directed against integrins have been tested in a variety of models, with clinical results still forthcoming. Examples of these agents can be found in Table 4.1.

Proteolysis

Local proteolysis occurs in both the tumor and stromal compartments. The process of intravasation and extravasation depends upon the ability to secrete proteolytic enzymes required to degrade the barriers within the extracellular matrix. Overexpression of such enzymes occurs in almost all cells within the tumor-host microenvironment (30). Degradation of the basement membrane is affected by net proteolytic activity that is determined by the balance of activated proteolytic enzymes and their inhibitors. A positive correlation with tumor aggressiveness has been shown for a variety of degradative enzymes, including heparanases and seryl-, thiol-, and metal-dependent enzymes (57–59). Proteolytic behavior may therefore be a logical molecular target to interrupt the invasive and metastatic process in malignancy.

Matrix Metalloproteases

Matrix metalloproteases (MMPs) are a family of neutral metalloenzymes secreted as latent proenzymes. They require cleavage of the amino-terminal domain, and their activity depends on the presence of Zn^{2+} and/or Ca^{2+} (60). There are five subclasses grouped according to substrate specificity: interstitial collagenases, gelatinases, stromelysins, membrane-type MMPs, and elastases. Increased MMP activity has been detected in and shown to correlate with invasive and metastatic potential in a wide range of cancers, including gynecologic, lung, prostate, breast, and pancreatic cancers (30,61–63). Epithelial ovarian carcinoma cells derived from primary ovarian tumors, metastatic lesions, or ascites overexpressed MMP-2 (gelatinase A) and MMP-9 (gelatinase B) (64). Increased MMP-2 expression was observed in cervixes with high-grade cervical intraepithelial neoplasia (CIN) and invasive cervical carcinoma when compared to normal and low-grade CIN cervixes (65). Expression of MMP-13 (collagenase-3) is abundant in vulvar carcinomas metastatic to lymph nodes. MMP-13 was associated with tumor-cell expression of MTI-MMP and stromal-cell expression of MMP-2 (66). Therefore, MMPs may serve as useful markers for detection of disease and/or as targets for therapeutic intervention to prevent tumor progression.

The activity of MMPs is regulated by a family of five proteins known as the tissue inhibitors of metalloproteases (TIMPs).

TABLE 4.1**MOLECULAR THERAPEUTICS OF INVASION, ANGIOGENESIS, AND METASTASIS**

Target	Drug
AKT	Perifosine PX-316 A-443654
c-Kit	Imatinib
Epidermal growth factor receptor (EGFR1)	Cetuximab Panitumumab Matuzumab Gefitinib Erlotinib Lapatinib Vandetanib Canertinib Leflunomide
Heparanase	PI-88
ERBB2 (HER2/neu)	Trastuzumab Lapatinib Canertinib
Integrins	Volociximab Cilengitide Vitaxin Endostatin Angiostatin
Matrix metal oproteases (MMPs)	Marimastat COL-3 BAY 12-9566 MMI 270 ABT-518
mTOR/FRAP	Temsirolimus Rapamycin RAD001
p53	ONYX-015
PI3K	PX-866
Platelet-derived growth factor receptor (PDGFR)	Imatinib Sunitinib Leflunomide
Protein kinase C-a (PKC-a)	Bryostatin-1 UCN 01
Raf-kinase	Sorafenib ISIS 5132 ISIS 2503
Ras	Tipifarnib Lonafarnib L-778123
Vascular endothelial growth factor (VEGF)	Bevacizumab VEGF trap
Vascular endothelial growth factor receptor-1/2 (VEGFR-1/2)	Sorafenib Vandetanib Sunitinib
Angiogenesis (unknown targets)	Thalidomide Lenalidomide IL-12

In concert with MT1-MMP, TIMP-2 can regulate activation of MMP-2, whereas it can also directly inhibit MMP-2 function (67). The balance between levels of activated MMPs and free TIMPs determines the balance between matrix degradation and matrix formation. Altering this equilibrium affects the progression of the invasive phenotype. Immunohistochemistry of MMP-2 and TIMP-2 in endometrial tumors showed that the quantity of MMP-2 increased with histologic grade, while TIMP-2 decreased (68). This pattern of MMP and TIMP expression correlated clinically, serving as indicator of local and distant metastasis. Similar data for MMPs and their inhibitors were found in ovarian cancer (69).

TIMPs have independent activities as well. TIMP-2 inhibits basic fibroblast growth factor-induced stimulation of endothelial-cell proliferation independent of its ability to inhibit MMP activity (70). TIMP-1 and TIMP-2 have been shown to inhibit tumor-induced angiogenesis in experimental systems (71) and to have antiapoptotic activity in lymphomas (72). Such information has led to development of novel agents affecting the expression or activity of MMPs and TIMPs. Multiple synthetic inhibitors of MMPs have been studied in preclinical and clinical trials (73,74) demonstrating a variety of antineoplastic effects that have not translated successfully to the clinic. Clinical response to the MMP inhibitor class has been disappointing either from lack of activity and/or unexpected toxicity. A new generation of inhibitors has been developed and is reaching clinical testing (see Table 4.1 for examples) (75).

Serine Proteases

Plasminogen activators (PAs) are serine-specific proteases that convert inactive plasminogen to active plasmin, a trypsin-like enzyme that degrades a variety of proteins, including fibrin, fibronectin, type IV collagen, vitronectin, and laminin. Plasminogen activator exists in two forms: tissue-type plasminogen activator (tPA), the primary plasminogen activator in plasma, and urokinase plasminogen activator (uPA). uPA is involved primarily in cell-mediated proteolysis during macrophage invasion, wound healing, embryogenesis, and metastasis (76). Production of uPA in ovarian carcinoma cells is reported as 17- to 38-fold higher than that found in normal ovarian epithelial cells (77,78). The role of uPA in ovarian cancer has been shown in preclinical models. Its production is stimulated by multiple ovarian-cancer-derived growth factors, such as lysophosphatidic acid (79). Approaches to molecular targeting of uPA and its related family of regulatory molecules are undergoing preclinical evaluation. New inhibitory agents directed to uPA include bikunin and soybean kunitz inhibitor, which block messenger RNA (mRNA) and protein expression of uPA, and down-regulate uPA through Src-dependent signaling pathways, respectively (80–82).

Cellular Events Promoting Invasion

ras Family

The ras family of oncoproteins is a group of integral modulators of signal transduction pathways and its members are potent inducers of mitogenesis and invasion (83). K-ras mutations have been found in 50% of mucinous ovarian cancers and 40% of LMP tumors, but are generally uncommon in serous ovarian cancers (84). Approximately 10% to 30% of endometrial cancers show K-ras mutations (85,86). H-ras mutations have been associated with the progression of papillomavirus-induced lesions in the uterine cervix (87). Mutated or overexpressed, ras functions in invasion and angiogenesis in multiple ways.

Several ras family members have been shown to regulate angiogenesis. Colorectal carcinoma cell lines constitutively expressing K-ras- and H-ras-mutant cell lines had increased VEGF expression (88). H-ras induction of VEGF expression was mediated by TGF- β and basic fibroblast growth factor (bFGF), both of which are potent proangiogenic growth factors produced in tumor autocrine and paracrine loops (89). Therapeutics inhibiting farnesyltransferase (FTase) proteins such as RAS can decrease VEGF expression *in vitro* and *in vivo* (90), suggesting that farnesyltransferase inhibitors (FTIs) may have a multifunctional role in cancer treatment (Table 4.1). FTIs are an evolving family of agents under investigation.

BIOLOGY OF ANGIOGENESIS

New Vessel Formation

Blood Vessels

Angiogenesis is a rate-limiting step in the growth of tumors and in the development of metastases (91,92). Tumor growth is limited by nutrient requirements and waste removal, and metastasis depends on tumor cells' access to the vasculature for dissemination (92–95). Net tumor volume represents a balance between cellular proliferation and cell death. Lack of angiogenesis limits growth, creating a balance between proliferation and death rates (Fig. 4.3) (93). A tumor mass larger than 0.125 mm² exceeds its capacity to acquire nutrients by simple diffusion. Further expansion of the tumor mass requires new blood vessel formation (11).

The formation of tumor neovasculature consists of multiple, interdependent steps similar to the process of invasion (96). Activation of endothelial cells by stimuli such as injury or inflammation, and tumor secretion of proangiogenic cytokines and growth factors, induces expression of a pro-invasive phenotype in the endothelial cells. This is manifest by local degradation of the capillary basement membrane, followed by endothelial-cell invasion into the surrounding stroma and

migration of endothelial cells in the direction of the angiogenic stimulus. Proliferation of endothelial cells occurs at the leading edge of the migrating column, and the endothelial cells begin to organize into three-dimensional structures to form new capillary tubes (3,97). The switch of endothelial cells from quiescent to activated is regulated by angiostimulatory and angiostatic signals (91). These include cytokines, fibrin, and integrins (98–101). These different angioregulatory processes have been targeted for therapeutic inhibition in cancer and inflammatory diseases. The results of these efforts are promising, as some cancers are highly responsive to antiangiogenic therapy. Investigators are characterizing a number of new molecular pathways that may be involved in the process of angiogenesis. Examples of these pathways include the ephrin (102), notch (103), hedgehog (104), sprouty (105), roundabouts (106), and slits pathways (106). These may prove to be novel sites for molecular targeting (Table 4.1 and Fig. 4.3).

Lymphangiogenesis

Tumors frequently metastasize to lymph nodes. The lymphatic system is composed of ducts ending in lymphatic capillaries analogous to the blood circulatory system. Lymphangiogenesis is the process of forming new lymphatic vessels. It is similarly a dynamic system and undergoes remodeling. A tumor, therefore, may prompt formation of its own lymphatic drainage by secreting factors stimulating lymphangiogenesis (107). The cytokines and receptors for lymphangiogenesis, described in the next section, are analogous to, yet distinct from, those involved in new blood vessel formation. Our understanding of this process is in its infancy, but the identification of lymphatic-specific markers has provided initial structural insights (108).

Angio-Immunology (Vascular Leukocytes)

An alternative model of neovascularization proposes that tumor-infiltrating leukocytes can be stimulated to differentiate into endothelial cell precursors (109). Typically, leukocytes express CD45 but not VE-cadherin, while endothelial cells have VE-cadherin but not CD45 (110). A distinct population of cells was isolated from primary cases of stage III ovarian cancer

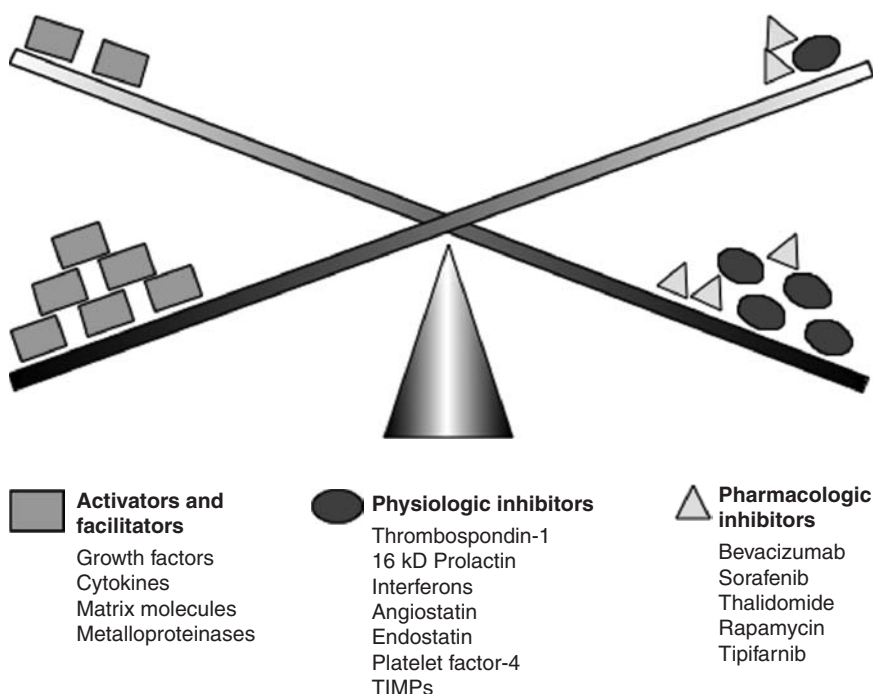

FIGURE 4.3. Schematic representation of angiogenesis. Vascular homeostasis represents a balance between physiologic activators and inhibitors of vessel formation. This balance is disrupted in cancer. Pharmacologic agents have been targeted at various elements of the angiogenic cascade in attempts to shift the balance away from an environment favorable to cancer.

based on their expression of these two markers: those that expressed markers of both leukocytes (CD45) and endothelial cells (VE-cadherin) (110). Such cells also expressed vascular endothelial growth factor receptor-2 (VEGFR2) and formed vessel-like structures when stimulated *in vitro* with VEGF (110). New blood vessels, therefore, may be derived from two distinct yet interrelated pathways, each under the influence of VEGF. The proposed vascular leukocytes may provide additional targets for therapeutic intervention based on their unique pattern of cell surface markers.

Growth Factors Promoting Angiogenesis

Vascular Endothelial Growth Factor

VEGF, described initially as vascular permeability factor, was purified from ovarian cancer xenograft ascites (98,111). Five isoforms of VEGF have been identified (A through E). VEGF-A, -B, and -E stimulate angiogenesis by binding VEGFR1 (VEGF-A and -B) or VEGFR2 (VEGF-A and -E); isoforms -C and -D signal through VEGFR3 to stimulate lymphangiogenesis (108). VEGFs are mitogens for vascular endothelial cells, induce capillary tube formation, cause increased vascular permeability and protein extravasation, stimulate endothelial-cell migration, and promote endothelial-cell survival (112). They have critical roles in normal gynecologic function, including endometrial cycling, ovarian follicle maturation, and corpus luteum formation and regression (113). VEGF-A also functions in gynecologic pathologies, including endometriosis (114) and polycystic ovarian disease (115). VEGFs are products of known tumor-growth-factor signaling cascades, such as the lysophosphatidic acid (LPA), NF- κ B, and PI3K pathways in ovarian cancer (116–118). Expression is up-regulated in a variety of tumors, including most gynecologic malignancies, and correlates with poor outcome (119,120). Tumor cells, stromal support cells, and endothelial cells express VEGFs, indicating that they are paracrine mediators of angiogenesis in cancer. Both primary and metastatic ovarian carcinoma cells can coexpress VEGFs and VEGF receptors 1 (Flt) and 2 (KDR), thus providing autocrine stimulation (121). This was the first example of localization of VEGFR2 expression in nonendothelial cells.

A strong correlation exists between the degree of vascularization of a tumor and VEGF expression (122). Circulating VEGF concentrations may be influenced by numerous factors including hormones, cytokines, and hypoxia that affect the expression of VEGF protein and mRNA (123–125). Plasma and urine concentrations of VEGF increase during tumor progression. In a study of advanced epithelial ovarian carcinomas, patients with tumors expressing higher levels of VEGF had shorter survival (126) and concordant results were found with serum levels of VEGF (120). This growth factor accumulates in malignant ascites and contributes to increasing the ascites burden through its effects on vascular permeability (127,128). The role of VEGF in malignant ascites of ovarian cancer has been exploited therapeutically in several studies, which noted decreases in ascites volume after treatment with bevacizumab, the anti-VEGF monoclonal antibody (129–132). Thus, VEGF is a prognostic factor and molecular target for gynecologic malignancies.

Epidermal Growth Factor

Epidermal growth factor (EGF) is a potent mitogen and chemoattractant for many tumor types, stromal cells, and endothelial cells (133). It is a prototype for successful targeting of growth-factor pathways in the era of molecularly targeted therapeutics. EGF expression has been correlated with malignant invasion and angiogenesis in a variety of tumors (133–136). This is a pathway subject to positive feedback,

since tumors that produce and secrete EGF can up-regulate expression of EGF receptor (EGFR) in the local vasculature. This phenomenon was associated with an antivascular and antitumor response to EGFR inhibition (137). This may be an important site of intervention, but can also lead to a mechanism for escape from single molecular targeted therapies, for example, by tumor production of bFGF when VEGF is down-regulated (138,139).

The EGFR pathway may be important in gynecologic cancers. Ovarian cancer patients with circulating EGF concentrations below 1 ng/mL had significantly better survival than those with higher EGF concentrations (140). Increased expression of EGF receptors ErBB1/HER1(EGFR) and ErBB2/HER2/neu was associated with increased metastasis and reduced survival in ovarian carcinoma (140–142). Concurrent expression of EGF-related proteins such as EGFR and cripto ligand correlated with stage of serous and clear cell ovarian cancers at surgery (143).

EGFR antagonists have putative antiangiogenic activity. ERBB2 (HER2/neu) is expressed at a lower level in gynecologic malignancies as compared to breast cancer, but is nonetheless a poor prognostic factor (141). Overexpression of ERBB2 in cultured cells has been shown to overcome therapeutic inhibition of EGFR kinase owing to shifting the balance from EGFR homodimers to ERBB2 heterodimers that retain signaling capacity (144). Laboratory investigation and clinical targeting of this class of agents is complicated by the potential of members of the EGFR (HER) family of receptors to heterodimerize. Gefitinib is an oral EGFR inhibitor that was studied in phase 2 trials in ovarian cancer, but was ineffective in achieving objective responses or stabilization of disease (145,146). Thus, it may be important to evaluate the expression of the family of receptors and/or to identify expression of the family of ligands to optimize therapeutic intervention of this pathway. Optimal intervention may require combinations of inhibitors that target multiple family members or multiple approaches to inhibition such as simultaneous inhibition of both ligand binding and kinase signaling.

Platelet-Derived Growth Factor

Platelet-derived growth factor (PDGF) expression has been demonstrated in epithelial ovarian carcinomas but not borderline ovarian tumors (147). PDGF is a dimeric protein composed of two closely related A- and B-chain polypeptides encoded by independent genes (148). The dimer is a multifunctional cytokine that acts in an autocrine and paracrine fashion in ovarian cancer and angiogenesis. Three isoforms of PDGF (AA, AB, and BB) bind to two distinct receptors, PDGFR β and - α (149). PDGF and its receptors promote tumor angiogenesis (123,150,151). PDGF stimulates migration of endothelial cells by increasing transcription and secretion of VEGF by PDGFR β -expressing endothelial cells; activation of PI3K is important for this response (123). Similarly, PDGF-BB induced VEGF expression in vascular smooth muscle cells and support cells through activation of the PI3K-AKT pathway (152). In addition, PDGF-mediated secretion of VEGF protected endothelial cells *in vitro* from apoptosis caused by serum starvation, indicating an indirect role of PDGF in supporting tumor angiogenesis through activation of survival pathways (152). There is a greater expression of PDGF and PDGFR β and - α genes in ovarian cancer than in normal epithelial ovarian cells and borderline tumors (149,153). PDGF and PDGFR β were detected by immunohistochemistry in 73% and 36% of malignant tumor samples, respectively, but no staining occurred in normal ovarian surface epithelial (OSE) cells or benign tumors (149). Furthermore, those patients without detectable PDGFR β had a 76% chance of survival at 40 months, equivalent to that of patients with early-stage ovarian cancer. Stromal expression of PDGFR β

supports its role in angiogenesis (31,149). Imatinib is an oral inhibitor of PDGFR in addition to bcr-abl and c-KIT, and has been approved for treatment of chronic myelogenous leukemia and gastrointestinal stromal tumors (154). Preclinical studies demonstrating that imatinib inhibited the PDGFR kinase led to the hypothesis that it could have antiangiogenic activity and potentially direct anticancer activity (155). This hypothesis was not borne out in phase 2 trials, which showed no clinical benefit of single-agent imatinib in ovarian cancer (156,157).

Intracellular Signals Promoting Angiogenesis

p53

p53 regulates multiple cellular functions including gene transcription, DNA synthesis and repair, apoptosis, angiogenesis, invasion, and metastasis (158,159). p53 is mutated in over half of all human cancers (160), including ovarian (161,162), endometrial (163), and cervical cancers (164). p53 has been linked to angiogenesis through several intermediates. Loss of wild-type p53 can down-regulate thrombospondin-1, an ECM protein and potent inhibitor of angiogenesis. Higher levels of thrombospondin-1 expression were demonstrated in fibroblasts with wild-type p53, whereas loss of p53 was associated with a decrease in thrombospondin-1 (165). An inverse relationship between thrombospondin-1 expression and angiogenic activity was also found. The migration of endothelial cells and cancer cell lines grown in media from wild-type p53 fibroblasts was abrogated by antibody against thrombospondin-1. Thus, one mechanism of p53-mediated angiogenesis is its regulation of thrombospondin-1.

VEGF is downstream of p53 regulation through several mechanisms. First, hypoxia induces VEGF expression via multiple intermediates, such as hypoxia-inducible factor-1 α (HIF-1 α) and *src* (166–168). Hypoxia-induced *src*-mediated overexpression of VEGF may be augmented by mutant p53 (167). Cell lines containing mutant p53 expressed 80% less VEGF than those with wild-type p53. Overexpression of *src* increased VEGF in cells with p53 mutations, but wild-type p53 had a dominant effect, causing a net decrease in VEGF expression (167). Secondly, coexpression of MDM-2 with p53 correlates with increased VEGF expression in angiosarcomas (169). Eighty percent of the angiosarcomas showed elevated expression of both MDM-2 and p53 and had increased VEGF expression. Mutant p53 also has been shown to act through the protein kinase C pathway to increase VEGF expression (170,171). Thus, several mechanisms for p53-regulated VEGF expression exist, suggesting a key role for p53 in the modulation of angiogenesis.

Biology of Metastasis

Intravasation occurs first in the progression toward metastasis. The tumor cell must migrate toward and adhere to the stromal side of the vascular basement membrane, degrade the matrix at that local site, migrate through the damaged basement membrane, and interpolate between endothelial cells in order to enter the vasculature (Fig. 4.2). Circulating tumor cells cannot complete the process of metastatic dissemination without reversing the process, extravasating at a favorable secondary site. That, coupled with stimulation of local angiogenesis and tumor cell proliferation, leads to a metastatic focus. All these events are programmed into the cell. However, the metastatic cascade is a very inefficient process. Although millions of tumor cells are shed into the circulation system daily, less than 0.01% of the shed cells successfully lead to metastases (172). Such heterogeneity in metastatic competence implies that

not all patients with circulating tumor cells will develop detectable metastatic disease. Thus, insight into these biological mechanisms may lead to new and better therapeutic targets and interventions.

Migration

Neoplastic cells migrate from the primary tumor mass and successfully traverse tissue barriers to induce metastasis to a site distant from the primary tumor (Fig. 4.1). This may involve simple cell locomotion from the primary into the interstitial stroma and subsequent shedding as seen in early ovarian cancer spread. Alternatively, it may require penetration and proteolysis of tissue obstacles, as occurs in active invasion. Furthermore, tumor cells have to survive the stage of vascular transport and arrest in the capillary bed of distant organs to engage in a second round of invasion and extravasation, whereby neoplastic cells exit from the vessel lumen into the surrounding stromal tissue (173). This key step in the cascade of events composing the invasive process of angiogenesis and metastasis is endothelial-cell and tumor-cell migration.

Chemokines and Growth Factors Promoting Metastasis

In order to achieve locomotion, cancer cells must initiate and maintain a complicated dynamic consisting of coordinated pseudopodal extension and attachment coupled with cell translocation and detachment. Tumor cells respond to a number of stimuli including host-derived motility and growth factors, extracellular matrix components, and tumor-secreted autocrine factors. Examples of these include the insulin-like growth factors (IGF-I, IGF-II), hepatocyte growth factor (HGF, also known as scatter factor) (174), fibroblast growth factors (FGFs), and PDGFs (175). ECM proteins or fragments may also stimulate chemotaxis (176–178). Some of these ECM fragments, such as endostatin and angiostatin, can have inhibitory activity (179,180). Thus, the dynamic process of migration is the balance of positive and negative regulatory influences in the local environment. This process stops in physiologic migration when sufficient events have occurred. Regulation of migration is aberrant in malignancy, allowing for progression of the metastatic phenotype. Advancements in our understanding of autocrine and paracrine stimulation of migration have uncovered new molecular targets for therapeutic interruption.

Autotaxin

The concept and role of autocrine growth factors is a longstanding and well-accepted biologic event. Some growth factors support motility and survival. Autotaxin (ATX) is a potent motility-stimulating glycoprotein that acts on both the tumor and the extracellular environment (181,182). ATX has been shown to stimulate tumor-cell migration, endothelial-cell migration and tube formation, and angiogenesis (183). ATX is linked to the production of lysophosphatidic acid (LPA) in the cellular microenvironment, cleaving lysophosphatidylcholine (LPC) to release LPA. It is thus an important component of the LPA regulatory pathway and a novel extracellular molecular target.

Lysophosphatidic Acid

LPA is a lipid that was initially characterized as a factor propagating ovarian cancer cells in ascites (184,185). It has been proposed as both a biomarker for diagnosis and a potential target for therapy of ovarian cancer (186). LPA is known to induce tumor and endothelial cell proliferation, migration,

and survival through its stimulation of the PI3K pathway in ovarian cancer (185,187). Interestingly, one study with ovarian cancer cells *in vitro* showed that LPA-induced migration could be inhibited by alendronate, a commercially available bisphosphonate (188). The receptor for LPA is a G-protein-coupled receptor; since G-protein-coupled receptors are the most successfully druggable targets (189), agents inhibiting the LPA receptor are in development (190).

Intracellular Signals Promoting Metastasis

Anoikis, or homelessness, is defined as apoptosis that occurs from loss of adhesion-linked survival signals (191). Malignant cells surviving in effusions or ascites have developed mechanisms to overcome anoikis. Ovarian cancer cells must develop such survival mechanisms early in their progression since malignant ascites and effusions occur before parenchymal metastases, in contrast to most other solid tumors. A molecular pattern of this process has been detected in ovarian cancer cells harvested from malignant effusions (192). Anoikis can be overcome by constitutive activation of the survival signals through genomic, transcriptional, and protein activation events that no longer depend on the “home” extracellular environment. These signals allow metastasis to occur. Malignant tumors consist of phenotypically heterogeneous populations that differ in their capacity to invade surrounding tissue, induce angiogenesis, and travel to distant sites (92,95,193). As with cellular transformation, loss of function and gain of function events have been demonstrated in the regulation of metastatic suppression and promotion.

PIK3CA

PIK3CA encodes the p110 α catalytic subunit of PI3K. It has been implicated in ovarian carcinogenesis and may act synergistically with RAS-mediated pathways to increase cell motility and metastasis (194). The PI3K p110 catalytic subunit shows increased gene copy number that results in increased transcription and translation of *PIK3CA* in ovarian cancer cell lines and patient samples, and that signal is transmitted through overactivation of the PI3K p85 regulatory subunit. This in turn activates the AKT pro-survival pathway and provides protection from anoikis in the absence of integrin engagement (46,194–196). Further, PI3K has lipid kinase activity wherein it phosphorylates phosphatidylinositol 4,5-phosphate (PIP2) to generate PIP3, a regulatory molecule for several other pathways involved in adhesion and motility such as phospholipase C- δ (PLC- δ), which is involved in the detachment process required for motility (197).

PTEN

PTEN (phosphate and tensin homolog) has been identified as a tumor- and metastasis-suppressor gene. Loss-of-function mutations of *PTEN* that result in the loss of the catalytic domain have been found in multiple human tumors including endometrial and ovarian cancers (196,198,199). It encodes a tyrosine and lipid phosphatase (200) that inhibits cell migration, spreading, and focal adhesion, in part by dephosphorylating focal adhesion kinase (FAK). A significant decrease in integrin-mediated cell spreading and focal adhesion formation *in vitro* was associated with a 60% decrease in tyrosine phosphorylation of FAK in *PTEN*-overexpressing cells (201). Cell invasion, migration, and growth were down-regulated by expressing *PTEN* in an ovarian cancer cell line, confirming

the metastatic suppressor phenotype (201). *PTEN* is also important as a regulator of survival pathways. Loss of *PTEN* function leaves PI3K and AKT in their activated states, driving the pro-invasive, pro-angiogenic, and pro-survival pathways. Thus, *PTEN* activity is a critical step in metastasis regulation.

NOVEL TECHNOLOGIES TO STUDY MOLECULAR MECHANISMS OF METASTASIS

Advances in technology are yielding new genes and new directions for studying the molecular mechanism of invasion, angiogenesis, and metastasis. To date, this information has been gained through examination of cultured cells and through animal models. Analysis from metastatic cell populations as they exist in their native environment may provide new insight into additional genes, proteins, and signal transduction pathways critical to oncogenic events. Several technologies have been developed that may aid in the direct evaluation of cancer cells.

Microdissection

Laser capture microdissection has provided more control in microdissection and markedly advanced our ability to evaluate events ongoing in human gynecologic and other tumors (202). Captured cells isolated from the appropriately fixed tissues can be used for genomic, expression, and protein studies. In one instance of the use of microdissected ovarian cancer cells from fixed tissues, a 50% loss of heterozygosity at chromosomal locus 8p21 was identified. This high rate of allelic loss, suggesting the presence of a tumor-suppressor gene at that locus, was missed by prior studies in which hand microdissection or no cell selection was performed and has led to further studies to identify the putative suppressor gene (203). Advances in the field of microdissection use immunohistochemistry guidance for identification of target cells (204) and have led to more precise interrogation of ovarian tumor vasculature (205).

High-Throughput cDNA Screening

The use of frozen or ethanol-fixed tissues is optimal for gene expression studies, and these products have been applied to investigative and high-throughput screening techniques. cDNA libraries from microdissected tissues have the advantage of representing the genes expressed from a specific cell population and can be compared to local stroma to discern differential gene regulation in the microenvironment. A novel growth factor, granulin-epithelin precursor (GEP), was identified as a possible ovarian cancer invasion gene from differential analysis of cDNA libraries from microdissected ovarian tumor epithelium (206–208). This finding would have been missed using nonmicrodissected cells since this gene is expressed ubiquitously in stromal cells. Microdissected samples can be adapted to high-throughput gene expression profiling by microarray analysis (209).

Proteomic Technology

New proteomic technologies applied to gynecologic cancer tumors and serum samples can identify proteins and protein pathways involved in the development and progression of these cancers. High-throughput approaches for global unbiased

searches can uncover protein family associations or signatures (210). Application of surface-enhanced or matrix-associated mass spectrometry with higher order bioinformatics and mass sequencing is now being used to generate large volumes of information related to the malignant process. This will advance development of databases of proteomic information from which target validation and therapeutic application can proceed in a directed fashion.

We recently completed clinical trials applying tissue proteomics to evaluate effects of targeted agents (145). The clinical trials assessed the targeted activity of the EGFR-inhibitor gefitinib and the c-kit/PDGFR inhibitor imatinib in patients with recurrent ovarian cancer. Percutaneous 16- to 18-gauge core needle tumor biopsies were obtained prior to beginning therapy and after 4 weeks of treatment. Tumor and stromal cells were separated using laser capture microdissection and analyzed separately by tissue lysate arrays (TLA). Arrayed samples were analyzed for the levels of EGFR and its activated (phosphorylated) forms, as well as downstream signaling molecules AKT and extracellular-signal-regulated kinase (ERK), and their activated forms. No clinical benefit was seen with either agent, but the TLAs confirmed the targeted activity of each drug. TLA results from both trials suggested that target inhibition was present but that the blocked signal was not essential for tumor growth, the level of inhibition was insufficient to completely prevent receptor signaling, and/or the receptor function was unrelated to the malignancy at this advanced and recurrent state of disease. Statistics did show, however, a relationship for signaling parameter and clinical toxicity by grade and by trend of toxicity. Increasing EGFR, AKT, p-ERK, and p-EGFR moieties in tumor after treatment were statistically significantly associated with increasing overall toxicity ($p \leq 0.05$), gastrointestinal toxicity ($p < 0.05$), and skin toxicity ($p = 0.029$) (157). This illustrates the strength of the tissue lysate array. These clinical trials demonstrated the ability to incorporate invasive sample collection and detailed biochemical analysis to confirm target modulation and to correlate the biochemical proteomic events with clinical and toxicity events.

CLINICAL APPLICATION: THERAPY DIRECTED AGAINST INVASION, ANGIOGENESIS, AND METASTASIS

Molecular Targeted Agents: Monoclonal Antibodies

Bevacizumab is a recombinant humanized version of the murine antihuman VEGF monoclonal antibody. The VEGF-neutralizing antibody inhibits VEGF-induced signaling, resulting in reduced angiogenesis and tumor growth. It has been FDA-approved based on prolonging survival when given in combination with chemotherapy in metastatic colon cancer, and has activity in breast and lung cancer as well (211,212). As a single agent, bevacizumab has been shown to prolong progression-free survival compared to placebo in a phase 2 trial in renal cell cancer (213). Moreover, a phase 2 study (GOG 170D) of bevacizumab in ovarian cancer demonstrated a 17% response rate with an added 40% of patients having stable disease in women treated with two or fewer prior therapies (214). The addition of bevacizumab to front-line chemotherapy and to maintenance therapy in epithelial ovarian cancer is now being evaluated in a large phase 3 trial (GOG 218). Recent results from the GOG phase II trial of bevacizumab in cervical cancer are promising. NB not published yet.

Cetuximab is a recombinant chimeric antibody to EGFR1 that is presently approved for treatment of metastatic colon cancer and unresectable head and neck cancer, with activity in breast and non-small-cell lung cancer as well. As monotherapy, cetuximab produced a 9% response rate in irinotecan refractory colon cancer (215) and showed responses in head and neck cancer (216). Cetuximab has also been effective as a radiation sensitizer, prolonging survival (49 vs. 29 months) in unresectable head and neck cancer treated with concomitant radiation (217). It is being evaluated in advanced cervical cancer in combination with cisplatin (GOG 76DD) and with radiation (GOG 9918). Panitumumab is a second-generation human antibody to the extracellular domain of EGFR1 and has been approved as last-line therapy in metastatic colon cancer (218,219). Preclinical and early-phase clinical work is pending for multiple other monoclonal antibodies that target pro-angiogenic receptors and pathways.

ERBB2 (HER2/neu) is expressed in less than 10% of epithelial ovarian cancer (EOC) and approximately 18% of uterine papillary serous carcinoma (220,221). Trastuzumab is a monoclonal antibody to ERBB2 and prolongs survival significantly in ERBB2 positive breast cancer in both the adjuvant and metastatic settings (222,223). A phase 2 trial of trastuzumab in recurrent ovarian cancer (GOG-160) showed only a 7.3% response rate in 41 patients with ERBB2 overexpression (2+ or 3+ by immunohistochemistry) (224). It is presently under study in a phase 2 trial in advanced endometrial cancer.

Molecular Targeted Agents: Kinase Inhibitors

In addition to direct targeting of VEGF with bevacizumab, a number of small-molecule inhibitors of the VEGF receptors have been developed and have reached clinical trials. VEGFR2 is the most commonly targeted. Preclinical data have shown this approach to be active in reducing endothelial-cell proliferation, migration, and vascular development, and xenograft models have confirmed activity in a number of solid tumors (225).

Sorafenib is an oral Raf and VEGFR2 kinase inhibitor that has been approved for treatment of metastatic renal cell cancer (226); it is presently being studied in a GOG phase 2 study in ovarian cancer (GOG-170F). Gefitinib, an oral EGFR inhibitor, was studied in phase 2 trials in ovarian cancer but did not produce objective responses or stabilization of disease (145,146). Imatinib, an oral inhibitor of bcr-abl, c-KIT, and PDGFR, has been approved for treatment of chronic myelogenous leukemia and gastrointestinal stromal tumors; it had no activity in phase 2 trials of relapsed/refractory ovarian and endometrial cancer (154,156,157). Lapatinib is an oral EGFR and ERBB2 inhibitor that has activity in breast cancer (227,228) and is being studied in a phase 2 trial in ovarian cancer, among other malignancies. Sunitinib, a VEGFR and PDGFR inhibitor, is approved for treatment of metastatic renal cell cancer (229), while erlotinib, another EGFR inhibitor, is approved as a single agent for treatment of metastatic lung cancer (230) and in combination with gemcitabine for pancreatic cancer (231). Vandetanib, a dual EGFR and VEGFR inhibitor, has been shown in preclinical work to have activity in EOC (232) and is currently in a phase 2 trial for recurrent ovarian cancer. Numerous other small molecules targeting these pathways are presently under development.

Combination Therapy

Further refinement of targeted therapy is focused on the hypothesis that inhibiting angiogenesis signals in combination with each other or with chemotherapy may be more effective

FIGURE 4.4. Example of combined targeted therapy against angiogenesis. Bevacizumab blocks VEGF from binding to its receptor, VEGFR2. Sorafenib inhibits downstream signaling from the receptor by blocking its tyrosine kinase activity, as well as that of other signal transduction molecules such as Raf.

than when used as single agents. In an attempt to target the VEGF pathway in vertical series, bevacizumab was combined with sorafenib, as Raf-kinase is a downstream effector of VEGFR2 (Fig. 4.4). A phase 1 trial of sorafenib and bevacizumab in combination has demonstrated a partial response rate of 47% (7 out of 15 patients) in heavily pretreated EOC (233). A phase 2 trial of bevacizumab combined with sorafenib for ovarian cancer is accruing at the National Cancer Institute as of this writing. Many other ongoing phase 2 clinical trials are testing targeted agents combined with chemotherapy in gynecologic malignancies (234). Trials are widely varied and range from paclitaxel and carboplatin in combination with an EGFR tyrosine kinase inhibitor or an anti-EGFR monoclonal antibody, to proteasome inhibitor with irinotecan.

CONCLUSIONS

Continued scientific, epidemiologic, and clinical advances are critically needed until successful, reproducible, and accurate early detection of gynecologic tumors becomes routine. Understanding the biology, regulation, and implications of the process of invasion and angiogenesis will continue to drive new biomarker and therapeutic target identification and intervention. Similarity between dysregulated invasion of angiogenesis and unregulated motility of metastasis allows the potential for duality of intervention. The tumor's interaction with its microenvironment becomes the focus for scientific dissection and therapeutic application (31). Here, the process of autocrine and paracrine regulation, signal pathway activation, and cell-cell conversation are critical. The use of the newer and high-throughput technologies to identify collections of biologic targets rather than one gene or protein at a time can make the process more streamlined and provide a broader view of the interaction of events. Together, improved understanding, study of events in the patient populations, and cooperative and collaborative progress will allow us to overcome invasion and metastasis, the major causes of morbidity and mortality associated with gynecologic cancers.

CHAPTER 5 ■ ONCOGENES AND TUMOR SUPPRESSOR GENES

JEFF BOYD, JOHN I. RISINGER, AND ANDREW BERCHUCK

HISTORICAL PERSPECTIVE

Discoveries over the past three decades have brought us to a new frontier in cancer research that is founded upon the identification and understanding of the basic cellular processes that become disrupted during cancer development. Historically, numerous empirical models have been proposed to explain the etiology of cancers. Attention has focused on viruses, environmental agents, chemical carcinogens, and congenital predisposition. We now know that all of these factors may contribute to carcinogenesis by disrupting genes whose products are involved in regulating cell proliferation, senescence, death, and the ability to invade and survive in ectopic locations. Most cancers are believed to arise from a single progenitor cell that has sustained mutations in several of these critical genes (1).

The genetic basis of human cancer development was implied by the work of some of the earliest cell biologists and is now considered among the most robust of biologic paradigms. In the mid-19th century, the great German pathologist Rudolph Virchow recognized that metastatic cancer cells resemble those of the corresponding primary tumor, and in the course of developing his cell theory, postulated that all cells of a cancer may arise from a single progenitor (2). Thus, the neoplastic phenotype is heritable from one tumor cell generation to the next, prompting the famous aphorism widely attributed to him, “*omnis cellulae cellula*” (every cell from a cell). In the early 1900s, Theodor Boveri extended this concept to the cytogenetic level, suggesting that gains and losses of specific chromosomes might lead to abnormal cell division and other aspects of the cancer phenotype. In his remarkable landmark treatise, *Zur Frage der Entstehung Maligner Tumoren (On the Origin of Malignant Tumors)*, Boveri initiated the age of cancer genetics, presaging the existence of tumor-suppressor genes, oncogenes, cell cycle checkpoints, multistep tumor progression, cancer predisposition through tumor-suppressor genes, the clonal origin of tumors, and other aspects of the neoplastic phenotype (3).

It required another half century, however, for Boveri's predictions to begin to be realized, with the discovery by Nowell and Hungerford in 1960 of a specific chromosomal translocation (the Philadelphia chromosome), which is characteristic of chronic myeloid leukemia (4). Nowell later provided a detailed and modernized version of the earlier notion of Virchow and Boveri that tumors are monoclonal with his theory on the clonal evolution of tumor cell populations (5). At this time in the mid-1970s, the stage was now set for the discovery by Bishop and Varmus that genetic sequences homologous to the transforming gene (*v-src*) of an avian cancer retrovirus exist in the host chicken genome (6), and indeed in the genomes of vertebrates including humans (7). This was the

first direct evidence for the existence of cellular “oncogenes,” which laid the groundwork for the field of cancer molecular genetics, and was a discovery of sufficient magnitude to warrant awarding of the Nobel Prize to Bishop and Varmus in 1989.

This brief history of cancer genetics comes full circle with discoveries in 1973 that the Philadelphia chromosome represents a reciprocal translocation involving chromosomes 9 and 22 (8), in 1983 that this translocation results in the constitutive activation of the cellular oncogene *c-abl* (9), and in 2001 that a specific inhibitor of the ABL tyrosine kinase (Gleevec) is associated with extraordinary efficacy in the treatment of a subset of patients with leukemias harboring the Philadelphia chromosome (10). Although this “bench to bedside” success story is so far the exception rather than the rule, the molecular genetic basis of cancer has been defined in sufficient detail to allow an unprecedented optimism that we will eventually attain a thorough understanding of the molecular etiology of cancer. Although the number of genes that may be mutated and contribute to the development of the various cancer types is large, perhaps in the hundreds, the problem is clearly not intractable. Recent successes in elucidating the sequence of the human genome and in using comprehensive gene expression profiles to classify human malignancies in clinically relevant contexts contribute to this optimism. As our understanding of the molecular pathogenesis of cancer evolves, it is reasonable to assume that this knowledge will facilitate the development of new approaches to prevention, early diagnosis, and treatment.

GENETIC PARADIGM OF TUMORIGENESIS

All cancers are genetic in origin in the sense that the driving force of tumor development is genetic mutation. A given tumor may arise through the accumulation of acquired (somatic) mutations or through the inheritance of a mutation(s) through the germ line followed by the acquisition of additional somatic mutations. These two genetic scenarios distinguish what are colloquially referred to as “sporadic” and “hereditary” cancers, respectively (Fig. 5.1).

Although alterations in gene expression also contribute to the malignant phenotype, the sequential mutation of cancer-related genes leading to outgrowth of a clonal population of cells is the major determinant of whether a cancer develops as well as the time required for its development and progression. The data supporting this multistep genetic paradigm are extensive (11,12), but perhaps the most compelling evidence is that the age-specific incidence rates for most epithelial tumors increase at roughly the fourth to eighth power of elapsed time, suggesting that a series of four to eight genetic alterations are

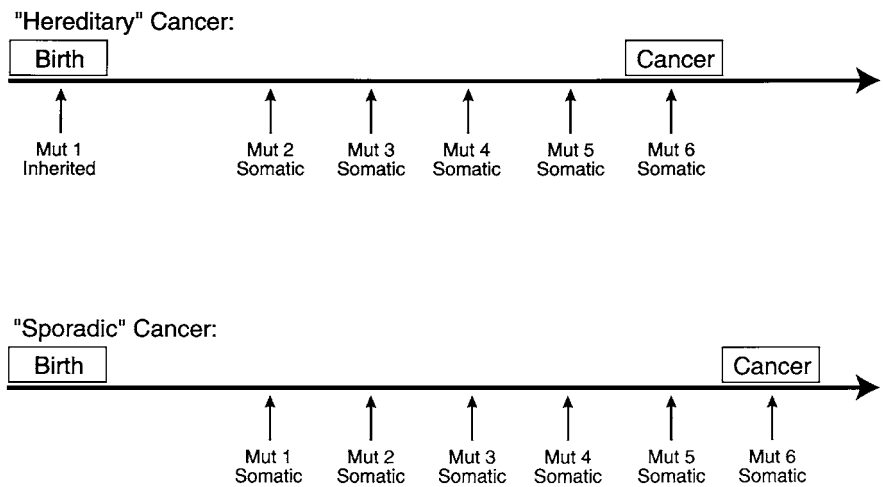

FIGURE 5.1. All cancers are genetic. "Hereditary" cancers differ from "sporadic" cancers by virtue of association with a predisposing mutation inherited through the germ line. In contrast, all of the mutations associated with sporadic tumorigenesis are acquired somatically.

rate limiting for cancer development (12). Additionally, it would seem rather self-evident that the well-characterized histopathologic progression of several common tumor types, for example, through hyperplasia, dysplasia, carcinoma *in situ*, and invasive carcinoma, reflects this multistep, multi-genic model at the morphologic level.

Genetic alterations in cancer cells occur in two major families of genes: oncogenes and tumor-suppressor genes. Proteins encoded by oncogenes may generally be viewed as stimulatory and those encoded by tumor-suppressor genes as inhibitory to the neoplastic phenotype. Gain-of-function mutations resulting in the activation of "protooncogenes" to oncogenes and loss-of-function mutations resulting in the inactivation of tumor-suppressor genes both are requisite for cancer development. Protooncogene mutations are nearly always somatic, presumably because such cellular dominant mutations in the germ line are incompatible with normal development. Two known exceptions involve the *RET* and *MET* protooncogenes, mutations of which may be inherited through the germ line, predisposing to multiple endocrine neoplasia type II (13) and papillary renal carcinoma (14), respectively. Tumor-suppressor gene mutations may be inherited or acquired somatically, and nearly all hereditary cancer syndromes for which predisposing genes have been identified are linked to mutant tumor-suppressor genes. Genes encoding proteins involved in various pathways of DNA repair have been proposed to represent a third class of genes involved in cancer development (15), but, as will be discussed below, these genes possess many of the features of tumor-suppressor genes and are considered as such in this chapter.

A human cancer represents the endpoint of a long and complex process involving multiple cellular changes in genotype and phenotype. Human solid tumors generally are monoclonal, with every cell in a given cancer having arisen from a single progenitor cell. This does imply that all cells of a tumor are genetically identical, as the genetic instability characteristic of most malignancies results in substantial genetic heterogeneity as clonal evolution occurs (16). Clonal evolution, or clonal expansion (Fig. 5.2), is the process through which a cell and its offspring sustain and accumulate multiple mutations with the stepwise selection of variant sublines (5,17). A long-term goal of studying the molecular genetics of a particular tumor type is to catalogue the specific genes that are affected by mutations and the relative order in which they are affected and, ultimately, to use this molecular genetic blueprint to improve methods of diagnosis, prognostication, and treatment. This task will undoubtedly prove to be difficult, however, because of the aforementioned genetic instability characteristic of cancers. There are multiple types of such instability that are

operative at both the chromosomal and molecular levels (18). Distinguishing the genetic mutations that are simply the by-product of genetic instability from those that are critical to the neoplastic phenotype or, indeed, responsible for increasing genetic instability of one form or another is among the most formidable challenges to be faced in human cancer research.

The greatest progress in this context perhaps has been achieved for colorectal carcinoma, and a rudimentary model has been proposed that applies molecular detail to the general paradigm of multistep tumorigenesis and clonal evolution. In addition, most colon cancers are affected by one of two distinct types of genetic instability (18), and specific molecular alterations have been shown to occur at discrete histologic stages of neoplastic progression in the colon: for example, mutation of the *APC* tumor-suppressor gene at a very early stage of hyperproliferation, mutation of the *KRAS* oncogene in the transition of early to intermediate adenoma, and mutation of the *TP53* tumor-suppressor gene in the transition of late adenoma to carcinoma (19). Several features of colorectal

FIGURE 5.2. Model of clonal evolution in neoplasia. Following the initiating mutation in a normal cell, stepwise genetic mutations and selective pressures result in a cancer consisting of a clonal population of cells all derived from the original progenitor cell. Each critical mutation in the evolving tumor may be viewed as having provided a selective advantage leading to clonal expansion.

cancers facilitate this type of characterization, including the well-defined histopathologic progression of normal colonic epithelium to cancer and the accessibility of the various premalignant lesions for molecular analyses, as well as the occurrence of some of these genetic mutations in large fractions of colorectal tumors. This type of model is more difficult to apply to other cancer types, however, as premalignant precursor lesions for many solid tumor types (e.g., ovarian carcinoma) are not readily detectable, and few genetic alterations have been described that occur in major fractions of other cancer types.

TUMOR-SUPPRESSOR GENES

The protein products of tumor-suppressor genes normally function to inhibit various aspects of the neoplastic phenotype, such as cell proliferation, and are inactivated through loss-of-function mutations. Tumor-suppressor genes (having formerly been referred to variously as “recessive oncogenes” or “antioncogenes”) are, by definition, recessive at the cellular level insofar as inactivation of both alleles (the copies present on both chromosomes) must occur for a phenotypic effect on tumorigenesis to be manifest. This is in contrast to the concept of mendelian recessivity, which refers to the necessity of germline transmission of two mutant alleles for a phenotype to be manifest. Most tumor-suppressor genes responsible for hereditary cancer syndromes are dominant at the mendelian level, which means that inheritance of a single mutant allele is sufficient to confer a high probability of developing the phenotype (cancer in this case); cellular recessivity must then occur through somatic inactivation of the second allele, and mechanisms through which this may occur are discussed below.

Several lines of evidence led to the discovery of tumor-suppressor genes. In addition to Boveri’s predictions, a statistical analysis of carcinogen-induced mouse papillomas in 1942 led to the conclusion that a cellular recessive gene must be involved in carcinogenesis (20). Nearly 30 years later, Harris et al. demonstrated that somatic cell hybrids created from tumor cells and normal cells invariably expressed a nonmalignant phenotype, again implicating a cellular recessive class of cancer genes (21). Application of this notion of a recessive cancer gene was first applied to cancer predisposition by Knudson, who in 1971 published a statistical analysis of pediatric retinoblastoma and concluded that inactivation of both alleles of a single gene, one through the germ line and one somatically, was necessary for tumor development (22). This concept became widely known as the “two-hit hypothesis” (a term not coined by Knudson), and is now inextricably linked to the more general concept of cellular recessivity of tumor-suppressor genes, the first of which to be discovered was the gene responsible for retinoblastoma, *RB1* (23).

This two-hit model for pediatric retinoblastoma is frequently misunderstood and misapplied, especially in the context of hereditary cancers generally, having become synonymous with the notion that inactivation of both alleles of a single gene is necessary *and* sufficient for tumorigenesis. It is important to recognize that this theory estimates only the number of events that are rate limiting for hereditary pediatric cancer development (22,24). As implied by Figure 5.1, most adult solid tumors, hereditary and sporadic, are likely to require mutations in multiple genes, most of which may occur at a relatively high frequency approaching zero-order kinetics, thus not appearing in the type of kinetic analysis performed by Knudson. This is especially true in cases where the inherited mutation affects a tumor-suppressor gene involved in DNA repair, with the result being increased genetic instability of one form or another.

The location and type of inactivating mutations in tumor-suppressor genes vary among genes and cancer types (Fig. 5.3). In some cases, most notably *TP53*, missense mutations occur

that change a single amino acid in the encoded protein (25). More often, however, mutations in tumor-suppressor genes alter the base sequence such that the encoded protein product is truncated owing to generation of a premature stop codon. Truncated protein products may result from several types of mutational events. Included in this category are nonsense mutations in which a single base substitution changes the sequence from a specific amino acid to a stop codon (e.g., AAG to TAG). In addition, microdeletions or insertions of one or several nucleotides that disrupt the reading frame of the DNA (frameshifts) also lead to the generation of stop codons downstream in the gene. Less commonly, large genomic deletions are known sometimes to include portions of tumor-suppressor genes. Any of these types of mutations in one allele, whether germ line or somatic, is then “revealed” following somatic inactivation of the homologous wild-type allele, as discussed earlier. In theory, the same spectrum of mutational events could contribute to inactivation of the second allele, but what is typically observed in tumors is homozygosity or hemizyosity for the first mutation, indicating “loss” of the wild-type allele. As originally demonstrated for the retinoblastoma gene, loss of the second allele may occur through mitotic nondisjunction or recombination mechanisms or large deletions (Fig. 5.3) (26). This so-called “loss of heterozygosity” (LOH) has become recognized as the hallmark of tumor-suppressor gene inactivation. Table 5.1 lists some of the most well-characterized tumor-suppressor genes and the cancer syndromes and sporadic cancers with which they are associated.

Although some tumor-suppressor gene products reside outside the nucleus, many are nuclear proteins that prevent proliferation by arresting molecular pathways directly involved in cell cycle progression. The retinoblastoma gene (*RB1*) is a prototypical tumor-suppressor gene that encodes a nuclear protein involved in G_1 cell cycle arrest (27). Mutations in *RB1* have been noted primarily in retinoblastomas and sarcomas, but also occasionally in other types of cancers. In G_1 , phosphorylated RB protein binds to the E2F transcription factor and prevents it from activating transcription of other genes involved in cell cycle progression (Fig. 5.4).

When RB is dephosphorylated, E2F is released and stimulates entry into the DNA synthetic (S) phase of the cell cycle. The phosphorylation of RB is regulated by a complex series of events that involves cyclins and cyclin-dependent kinases (CDKs). Cyclin-CDK complexes implicated in G_1 progression include cyclin D-CDK4/6, cyclin E-CDK2, and cyclin A-CDK2. Conversely, G_1 progression is restrained by CDK inhibitors such as p21, p16, and p27 (28, 29). CDK inhibitors are classified as tumor-suppressor genes because of their ability to inhibit G_1 progression, and inactivation of CDK inhibitors, particularly the gene encoding p16 (*CDKN2A*), is a frequent event in human cancers (30). In contrast to the classic “two-hit” model of tumor-suppressor inactivation in which there is a mutation in one allele and deletion of the other, loss of p16 function usually involves deletion of both alleles or silencing of gene transcription due to promoter methylation. After DNA synthesis occurs in S phase, other classes of cyclins and genes such as *CHK1* and *CHK2* are involved in regulating progression from G_2 to mitosis (M phase). Germ-line mutations in the *CHK2* (*CHEK2*) gene have been implicated in Li-Fraumeni syndrome (30) and breast cancer predisposition (31).

Several tumor-suppressor genes involved in hereditary predisposition to cancer have been shown to function in the recognition and/or repair of various forms of DNA damage. The mutational inactivation of DNA repair genes contributes to tumorigenesis indirectly by promoting one or another type of genetic instability, which leads to the mutation of additional cancer-related genes. This unique mechanism of tumor suppression has led some to suggest that the DNA repair genes should represent a third cancer gene family. In all cases

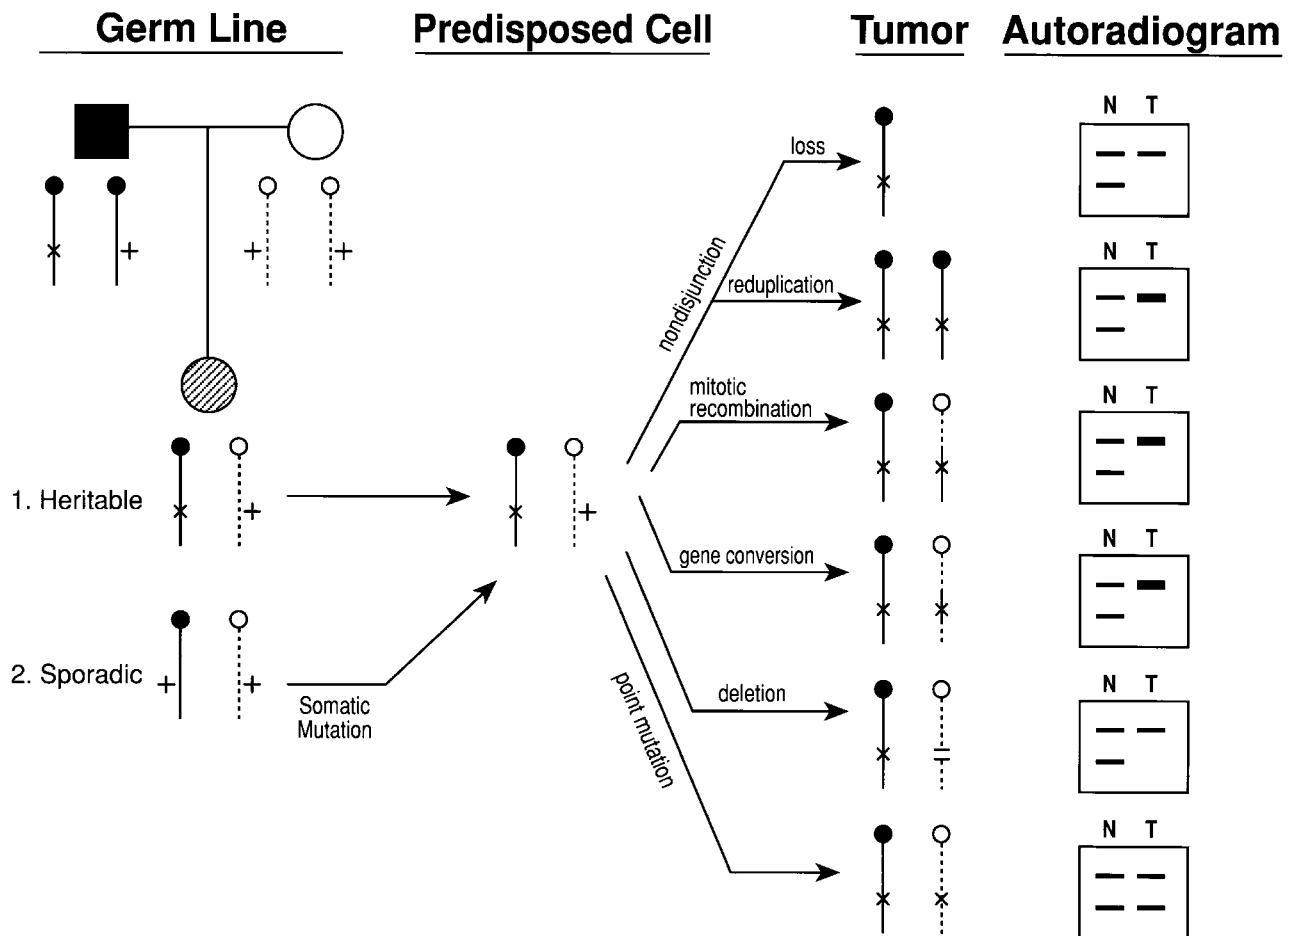

FIGURE 5.3. Model for loss of tumor-suppressor gene function and recessivity at the cellular level. In hereditary tumorigenesis, one mutant allele is inherited from either parent, in which case the “predisposed cell” is, in effect, every cell in the body. In sporadic tumorigenesis, one allele is mutated somatically, in which case there is one predisposed cell in, for example, the ovarian surface epithelium. Loss of inactivation of the remaining wild-type allele may occur through any number of somatic chromosomal mechanisms, most commonly through nondisjunction or recombination. This so-called loss of heterozygosity is manifest through Southern blotting or PCR-based procedures that allow visualization of loss of one or another polymorphic allele at or near the tumor-suppressor locus, in tumor (T) DNA compared to non-tumor (N) DNA from the same individual.

described to date, however, the genetic mechanism appears to involve a cellular recessive mechanism involving loss of function, which is consistent with the tumor-suppressor categorization. Perhaps more appropriate is the classification scheme proposed by Kinzler and Vogelstein in which tumor-suppressor genes are subdivided into the categories of “gatekeepers” and “caretakers” (15). The former category includes those genes that function directly to inhibit cell proliferation or promote cell death (e.g., *RBI*, *TP53*, and *APC*), whereas the latter category consists of those genes that function to maintain genomic integrity (e.g., the mismatch repair genes involved in HNPCC, the nucleotide excision repair genes involved in xeroderma pigmentosum, the *ATM* gene, and the *BRCA1* and *BRCA2* genes). It should be noted that some of these genes do not readily adhere to this distinction; *BRCA1* and *BRCA2*, for example, may function as both gatekeepers and caretakers.

Although numerous tumor-suppressor genes are mutated in various human cancers, only a limited number have been shown to play a significant role in gynecologic malignancies. Somatic mutations of *TP53* are observed at variable frequencies in gynecologic sarcomas and in ovarian and endometrial carcinomas, whereas viral inactivation of the p53 protein is a

central mechanism in cervical tumorigenesis. Germ-line mutations in DNA mismatch repair genes, primarily *MSH2* or *MLH1*, lead to endometrial and ovarian carcinomas in association with the Lynch syndrome, also known as hereditary nonpolyposis colorectal cancer (HNPCC) syndrome, whereas epigenetic silencing of *MLH1* is associated with some cases of sporadic endometrial carcinoma. Most cases of hereditary ovarian carcinoma are associated with inherited mutation of *BRCA1* or *BRCA2*, whereas somatic mutations in these genes are occasionally observed in sporadic ovarian carcinomas. Finally, the *PTEN* gene is somatically mutated in many endometrial carcinomas. The role of these tumor suppressors in specific cancer types will be discussed in greater detail in a later section of this chapter following a discussion of the molecular function of these genes.

TP53

The *TP53* tumor-suppressor gene is the most frequently inactivated gene described thus far in both human cancers in general as well as specifically in gynecologic cancers. Originally

TABLE 5.1

REPRESENTATIVE EXAMPLES OF TUMOR-SUPPRESSOR GENES MUTATED IN HUMAN CANCERS

Gene	Chromosomal location	Function	Hereditary cancers	Sporadic cancers
<i>RB1</i>	13q14	Cell cycle regulator	Retinoblastoma, osteosarcoma	Retinoblastoma, sarcomas, and others
<i>WT1</i>	11p13	Transcription factor	Wilms tumor	Wilms tumor
<i>TP53</i>	17p13	Transcription factor; regulator of cell cycle, apoptosis	Li-Fraumeni syndrome	Many
<i>APC</i>	5q21-q22	Signal transduction	Familial adenomatous polyposis	Colorectal, gastric
<i>VHL</i>	3p26-p25	Transcriptional elongation	von Hippel-Lindau syndrome	Renal
<i>MSH2, MLH1, PMS2, MSH6</i>	2p21, 3p21, 7p22, 2p21	DNA mismatch repair	Hereditary nonpolyposis colorectal cancer	Colorectal, endometrial
<i>BRCA1</i>	17q12-21	DNA repair; transcription factor	Breast, ovary	Ovary (rare)
<i>BRCA2</i>	13q12	DNA repair; transcription factor	Breast, ovary	Ovary (rare)
<i>NF1</i>	17q11	Negative regulator of RAS	Neurofibromatosis	None
<i>DPC4</i>	18q21	TGF- β signaling	None	Pancreatic
<i>CDKN2A (p16)</i>	9p21	Negative regulator of cyclin D	Melanoma	Many
<i>PTEN (MMAC1)</i>	10q24	Phosphatase	Cowden's syndrome	Many

identified through the physical interaction of its protein product with the SV40 large T antigen (32,33), *TP53* has been an intensely studied gene over the last 30 years. The gene was first classified as a cellular oncogene because of its apparent dominant transforming potential when transfected into rodent cells; subsequent studies confirmed, however, that the original cDNA clones used in the original studies all contained inactivating mutations, and that wild-type p53 is actually a tumor

suppressor (34). Subsequently, several convergent lines of research provided unequivocal evidence that *TP53* functions as a tumor-suppressor gene. Overexpression of exogenous wild-type p53 dramatically inhibits the growth of human colorectal carcinoma and osteosarcoma cell lines with endogenous p53 mutations (35,36), and loss of heterozygosity at chromosome 17p, seen frequently in a variety of human tumors, correlates with mutational inactivation of p53 in

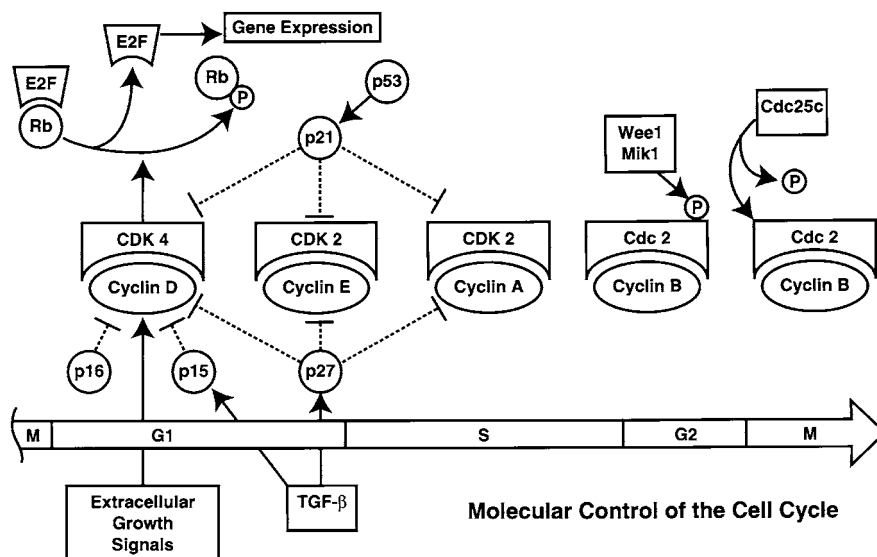

FIGURE 5.4. Molecular control of cell-cycle progression. A linear version of the various stages of the cell cycle is shown with the various cyclin/cyclin-dependent kinase complexes corresponding to the stages that they control.

FIGURE 5.5. Inactivation of the p53 gene. **A:** Normal p53 protein binds to transcriptional regulatory elements in DNA. **B:** p53 missense mutations encode proteins that no longer bind to DNA and the mutant protein complexes with and inactivates any remaining normal p53 in the nucleus. **C:** p53 mutations that encode truncated protein products result in proteins that no longer bind to DNA, and these mutations usually are accompanied by deletion of the wild-type p53 allele.

human colorectal carcinomas (37). Mutant p53 protein inactivates wild-type p53 protein by formation of inactive oligomeric complexes, reconciling the earlier observations of cellular transformation by the expression of exogenous mutant p53 constructs.

The most common class of mutation observed in *TP53* is the single nucleotide substitution that results in a missense alteration (change in one amino acid) (Fig. 5.5). Mutations that lead to truncated protein products are less common and include nonsense alterations, which directly encode premature stop codons, and frameshift mutations, which consist of small deletions or insertions. The vast majority (greater than 80%) of missense mutations occur within highly conserved regions in the middle third of p53 encoded by exons 5 through 8 (38). Structural studies reveal that these regions are involved in a physical interaction between the p53 protein and DNA (39), consistent with the known role of p53 as a transcription factor. Disruption of the ability of p53 to interact with DNA appears to be a critical mechanism of p53 inactivation. Because p53 missense mutants are relatively resistant to degradation within the cell, mutant proteins accumulate within the nucleus, leading to apparent “overexpression,” which can be detected immunohistochemically. As a result, immunostaining of p53 has been used as a rapid method of screening cancers for *TP53* mutations. However, positive immunostaining usually is not observed in cancers with protein truncating (nonsense and frameshift) mutations, so immunohistochemical analysis is relatively imprecise when used as a surrogate for mutational analysis (40).

The mechanism through which the p53 protein functions as a central element in the suppression of tumorigenesis has now been revealed in great molecular detail (41–43). The *TP53* gene encodes a 53-kD nuclear phosphoprotein that exists at low levels in all normal cells. Functioning as a homotetrameric complex, p53 binds to DNA in a sequence-specific fashion to regulate gene transcription, and oncogenic forms of p53 inhibit this transcriptional activation. Expression of p53 can be down-regulated when appropriate by the *MDM2* gene product, which targets it for degradation. Conversely, under other circumstances, p14^{ARF}, a negative regulator of *MDM2*, can increase expression of p53, leading to cell cycle arrest. It has become abundantly clear that the primary function of p53 is to activate the expression of genes involved in a DNA damage response pathway(s). Cell cycle arrest at the G₁-S checkpoint prior to DNA replication and at the G₂-M checkpoint

prior to mitosis facilitates DNA damage repair and prevents mutations and aneuploidy, respectively. Additionally, the induction of apoptosis (programmed cell death) may be considered to be a fail-safe mechanism in cases where irreparable DNA damage has occurred. The accumulation of p53 in response to DNA damage leads to an enhanced transcriptional activation of genes involved in apoptosis, such as *BAX*, *FAS*, and *BCL2*, as well as genes involved in cell cycle arrest, such as *CDKN1A* (encoding p21), which encodes a potent inhibitor of most CDKs. The molecular pathway linking DNA damage to p53 protein accumulation is still obscure. The carboxyl-terminal of p53 can bind nonspecifically to the ends of DNA molecules to catalyze renaturation and strand transfer, and can also bind to extrahelical regions of DNA affected by insertion or deletion mismatches. Double-strand breaks in DNA are especially efficient in causing p53 accumulation, probably through reduced ubiquitin-mediated proteolysis.

By activating transcription of these other genes, p53 induces cell cycle arrest in late G₁ phase or may induce apoptosis in response to DNA damage. Cells expressing mutant p53 do not pause in G₁ or undergo apoptosis, but continue directly into S phase before DNA repair is complete. *TP53* has therefore been referred to as the “guardian of the genome,” as it prevents entry into S phase until the genome has been cleared of potentially carcinogenic mutations. As many chemotherapeutic drugs and radiation exert their cytotoxic effects through the induction of DNA damage and apoptosis, loss of p53 function may decrease sensitivity to these agents, enhancing the emergence of resistant populations of cancer cells. Indeed, p53 and p21 are also essential in maintaining the G₂-M checkpoint following γ irradiation (44). Although *TP53* mutation provides cells with a selective growth advantage, it also imposes a substantial cell cycle checkpoint deficit that permits cells to undergo DNA replication and mitosis in the presence of DNA damage. Theoretically, such checkpoint defects might be exploited to treat human cancers with abnormalities of p53 function (45).

DNA Mismatch Repair Genes

HNPCC syndrome is an autosomal dominant cancer-predisposition syndrome described in detail in Chapter 2. In addition to colorectal cancers, HNPCC family members are at an

increased risk for cancers of the endometrium, ovary, gastrointestinal sites, and upper urologic tract (46). This syndrome is believed to account for essentially all cases of hereditary endometrial carcinoma and up to 5% of cases of hereditary ovarian carcinoma. The estimated lifetime risk for endometrial cancer in female HNPCC gene carriers is 40% to 60%, corresponding to a relative risk of 13 to 20, whereas that of ovarian cancer is 6% to 20%, corresponding to a relative risk of 4 to 8 (47–52). Cloning and characterization of the genes responsible has provided substantial insight into the molecular etiology of HNPCC-associated malignancies, as well as that of some sporadic gynecologic cancers.

Clues to the genetic basis of HNPCC first emerged in 1993 with several independent observations of somatic hypermutability of a class of DNA repetitive elements, known as “microsatellites,” in sporadic and familial colorectal tumors (53–55). This observation was accompanied by reports of the genetic linkage of HNPCC kindreds to two loci: one on chromosome 2p (56) and another on chromosome 3p (57). Identification and cloning of the responsible genes at these loci, *MSH2* on chromosome 2 (58,59) and *MLH1* on chromosome 3 (60,61), quickly followed, together with the realization that these genes encoded human orthologs of yeast DNA mismatch repair proteins. Thus, the microsatellite instability phenotype previously observed in colorectal and other cancer types associated with the HNPCC syndrome could be explained by loss of function of these DNA mismatch repair (MMR) genes. In HNPCC, one of these genes is inherited in a mutant form through the germ line followed by somatic loss of the wild-type allele, whereas in sporadic colorectal, endometrial, and gastric carcinomas affected by microsatellite instability, somatic silencing of *MLH1* through promoter hypermethylation appears to be the primary pathogenic mechanism (62).

Although most HNPCC kindreds appear to be linked to either *MSH2* or *MLH1*, a small fraction are linked to a third MMR gene, *MSH6*. There is some evidence that this gene may account for a substantial number of atypical or low-penetrance HNPCC kindreds, as well as those affected by a disproportionately high number of gynecologic cancers (63–66). A recent report indicates that about 2% of all newly diagnosed endometrial cancers have germ-line defects in *MSH6* and that most of these cases are not known to be associated with classic HNPCC syndrome criteria (67). Early evidence suggested that the MMR genes *PMS1* and *PMS2* may also play a role in HNPCC (68), but these observations were not widely confirmed, and a recent report involving investigators originally linking these genes to HNPCC kindreds indicates that these genes are less likely to be involved in the syndrome (69).

The genetic instability phenotype associated with defective MMR genes is most readily observed through somatic length alterations in simple repeat sequences, for example, (CA)*n*, located throughout the genome and known as “microsatellites.” Replication errors in these repeat sequences are probably common, and their inefficient repair results in the “microsatellite instability” phenotype. Since the discovery of mutant MMR genes and the corresponding microsatellite instability, a large number of studies have documented microsatellite instability in many sporadic tumor types, including those not associated with the HNPCC syndrome. Although mutations of the MMR genes have been readily identified in many HNPCC kindreds, somatic MMR gene mutations in sporadic tumors with the microsatellite instability phenotype are not commonly detected. It appears to be likely that hypermethylation of the *MLH1* promoter, resulting in down-regulation of its expression, is the causative mechanism in most sporadic colorectal, gastric, and endometrial carcinomas with microsatellite instability (70–72).

It is not clear how microsatellite instability contributes to tumorigenesis in the endometrium, ovary, or other organs affected by the HNPCC syndrome. Microsatellites exist throughout

the genome in predominantly noncoding regions of DNA. Simple repeat sequences are known to occur in the coding regions of genes, however, and their somatic mutation may result in loss of function for genes critical to the regulation of proliferation, invasion, or metastasis. Examples include genes encoding the transforming growth factor- β (TGF- β) receptor type II, the regulator of apoptosis BAX, and the insulin-like growth factor II receptor, all of which contain homopolymeric microsatellite repeats (e.g., A₈) that are mutated in some cancers with microsatellite instability (73). Frequently overlooked is the fact that the DNA mismatch repair system also functions in the repair of single nucleotide mismatches, so that defective mismatch repair would also lead to point mutations. Although the assay for this type of DNA damage is less straightforward than that for microsatellite instability, these single base-pair substitution mutations may play a more important role in tumorigenesis than microsatellite mutations.

BRCA1 and BRCA2

Approximately 10% of all epithelial ovarian carcinomas are associated with an autosomal dominant genetic predisposition. The great majority of these cases is attributable to the *BRCA1* or *BRCA2* tumor-suppressor genes and arises in the context of the hereditary breast and ovarian cancer syndrome, with a small fraction occurring in the HNPCC syndrome. (Clinical genetics aspects of this topic are discussed in Chapter 2.) Following the original reports of genetic linkage of early-onset breast cancer families (74) and some breast and ovarian cancer families (75) to the *BRCA1* locus on chromosome 17q, the *BRCA1* gene was cloned and characterized in 1994 (76). Shortly thereafter, the *BRCA2* locus on chromosome 13q was defined (77), and the gene was identified in 1995 (78). It is now clear that 60% to 90% of breast and ovarian cancer families are linked to *BRCA1*, with most of the remainder being linked to *BRCA2*, especially those with cases of male breast cancer.

The *BRCA1* and *BRCA2* genes share remarkable similarities in both structure and function, and will be discussed together. Both genes are unusually large, *BRCA1* consisting of 22 coding exons and a 7.8-kb mRNA transcript, and *BRCA2* consisting of 26 coding exons and a transcript exceeding 10 kb. Both genes contain a very large 11th exon that encodes nearly half of the transcript, a start codon located in exon 2, and a high A/T to G/C content. Mutations occur throughout both genes, with no evidence of hotspots or clustering. Over 80% of detected mutations are nonsense or frameshift alterations that are predicted to lead to a truncated protein product, with the remainder representing missense and other miscellaneous “variants of uncertain significance” (79). Somatic LOH at the *BRCA* loci in breast and ovarian cancers invariably affects the wild-type allele, which is consistent with their function as classic tumor-suppressor genes (80,81). In the search for genotype/phenotype correlations in the *BRCA* genes, it has become clear that no strong association is likely to exist for *BRCA1*, but that *BRCA2* contains an “ovarian cancer cluster region” (OCCR) in exon 11; the ratio of ovarian to breast cancers is significantly higher in families segregating a *BRCA2* OCCR mutation (82) for reasons that remain obscure.

Prior to discovery of the *BRCA* genes, it was well documented that LOH affecting the relevant regions of chromosomes 17q and 13q was common in sporadic breast and ovarian cancers, and thus it came as a surprise that somatic mutations in *BRCA1* and *BRCA2* are virtually nonexistent in sporadic breast cancers and rare in sporadic ovarian cancers. Gene silencing of *BRCA1* through promoter hypermethylation appears to play a role in the pathogenesis of a small fraction of sporadic ovarian cancers (83,84), whereas methylation

of *BRCA2* has not been reported. Attempts to explain this paradox have centered on the argument that inactivation of *BRCA* genes early in development (i.e., through the germ line) may be important for tumorigenesis, but not somatic inactivation in adult tissues. Recently, several lines of evidence suggest that inactivation of the *BRCA* pathway may play an important role in ovarian tumorigenesis through mechanisms other than inactivation of the *BRCA* genes themselves. Microarray-based gene expression profiling experiments indicate that rather than clustering as a third group, sporadic ovarian cancers all cluster as either *BRCA1*-like or *BRCA2*-like, implying the existence of a *BRCA*-deficient gene expression fingerprint in all ovarian cancers (85). Additionally, the novel EMSY protein was recently identified as a suppressor of *BRCA2* activity, and the *EMSY* gene is amplified in 17% of ovarian cancers, providing a genetic mechanism for inactivation of *BRCA2* in some sporadic cancers (86).

Over the past 10 years, a large body of data has been generated with respect to *BRCA* function, which appears to be related for the two genes, but a coherent picture of precisely how these proteins function to suppress tumorigenicity remains elusive. Generally, there is substantial evidence for a role of *BRCA1* and *BRCA2* in cellular processes related to the prevention of genomic instability, including DNA damage recognition and repair, transcriptional regulation, and control of cell cycle checkpoints (87,88). A seminal research finding in this area was that *BRCA1* colocalizes *in vivo* and physically associates *in vitro* with the RAD51 protein, known to function in the repair of double-strand DNA breaks, implying a role for *BRCA1* in the control of recombination and genomic integrity (89). Other early work on the role of *Brca2* in mouse development indicated that loss of the protein confers radiation hypersensitivity and also that *Brca2* physically interacts with Rad51 in repair of double-strand DNA breaks (90). Remarkably, *BRCA1* and *BRCA2* proteins appear to be involved in the same biochemical pathway, mediated by RAD51, regulating genomic integrity.

Data derived from the study of embryonic cells and tissues from mice rendered nullizygous for *Brca1* or *Brca2* provide strong evidence for the role of these proteins in the response to DNA damage. An embryonic lethal phenotype is observed in mice with a homozygous null mutation in *Brca1* (91) or *Brca2* (90,92), suggesting their requirement for embryonic cellular proliferation prior to gastrulation. Partial rescue of this developmental lethality is achieved by simultaneous knockout of the *TP53* gene (93,94), implying that the accumulation of DNA damage in *Brca* knockout mice leads to the arrest of cell division by p53, and that their concomitant knockout allows additional cell division to take place before eventual lethality. In cells from these *Brca*-deficient animals, gross chromosomal rearrangements are evident, and considerable data suggest that this chromosomal instability results from the inappropriate repair of DNA double-strand breaks during the S and G₂ phases of the cell cycle. Specifically, homology-directed repair of double-strand breaks, an error-free pathway, is defective in *Brca1*-deficient mouse cells (95–97) and in *BRCA2*-deficient human and mouse cells (98–100). The error-prone pathway of nonhomologous end joining remains intact in *Brca*-deficient cells, however, and the attempted repair of spontaneous and induced double-strand breaks because of inappropriate routing through this mechanism probably contributes to chromosomal instability observed in *Brca*-deficient cells. The precise roles of *BRCA* proteins in homology-directed repair remain to be determined, but evidence suggests that *BRCA1* performs the general function of linking DNA damage sensing or signaling to effector components of the cellular response to DNA damage (88), whereas *BRCA2* physically interacts with and controls the RAD51 recombinase (101), a catalytic activity essential for homologous recombination.

In contrast to *BRCA2*, there are considerable data linking the *BRCA1* protein to other functions possibly involved in tumor suppression, especially the transcriptional regulation of gene expression. Fragments of *BRCA1* are capable of transcriptional transactivation *in vitro* (102,103), and *BRCA1* is a component of the RNA polymerase II holoenzyme (104) through its interaction with RNA helicase A (105). In response to DNA damage, *BRCA1* functions as a p53-independent transactivator of the CDK inhibitor p21 (106,107). Ectopic expression of *BRCA1* results in the p53-independent induction of GADD45 expression (108), as well as the selective coactivation of p53-dependent transcription (109), one target of which appears to be the gene encoding the G₂/M checkpoint control protein 14–3-3σ (110). Microarray-based expression profiling experiments indicate that the selective expression of *BRCA1* in mouse and human cells leads to alterations in expression of numerous additional genes involved in cell cycle control and DNA repair (108,110,111).

BRCA1 is a large protein that, in addition to its role in the DNA damage and transcriptional pathways mentioned above, has been found to associate with a variety of other cellular components. Of these proteins BARD1 (*BRCA1* associated ring domain 1) appears to enhance some other cellular functions of *BRCA1* not associated with DNA interaction. Through its interaction with BARD1, *BRCA1* has been identified as an E3 ubiquitin ligase (112,113). E3 ubiquitin ligases function by attaching the ubiquitin monomer to specific target proteins, making them subject to degradation. Ubiquitin-directed degradation is a key process in regulating the levels of proteins post-transcriptionally. Defects in this process have been implicated in carcinogenesis previously. Specifically, the Von Hippel Lindau (*VHL*) tumor suppressor is a well known E3 ubiquitin ligase. *VHL* predominantly targets the hypoxia inducible factor (HIF1A) transcription factor for degradation in normoxic conditions. Loss of *VHL* leads to increased HIF1 and its subsequent transcription targets that are involved in cell survival, blood vessel development, and mitogenesis. The *VHL* mutation ultimately promotes kidney and other cancers. The role of *BRCA1*'s E3 ubiquitin ligase activity and cancer formation is much less clear. Specifically, the protein(s) targeted by *BRCA1* for ubiquitination are largely unknown (114). Recently, however, estrogen receptor alpha (ER) was found to be a specific target of *BRCA1*-mediated ubiquitination (115). The implications of this finding are not yet clarified, but may in part explain the tissue specificity of tumor formation in *BRCA1*-defective kindreds. It is conceptually difficult to understand how a protein involved in DNA repair that is expressed in a wide variety of tissues could protect only breast and ovary cells from tumor formation. However, it is more tractable to understand how an enzyme that acts on a variety of targets, some of which are tissue specific, could. Indeed the role of the *ER/BRCA1* genes in promoter transactivation has been suggested as a factor in determining the tumor spectrum of *BRCA1* mutation carriers. Tissue specific modulation of ER levels by *BRCA1* could effect diverse transcriptional targets, and the importance of ER has been demonstrated in the murine *BRCA* knockout mouse (116). Interestingly, most *BRCA1* mutant breast cancers are ER negative, which is counterintuitive if *BRCA1* normally functions to target the receptor for degradation. The significance of these recent findings remains intriguing, and the role of *BRCA* ubiquitination in carcinogenesis of the breast and ovary remains unclear.

Thus, the emerging model of *BRCA* function implies a dual role for the *BRCA*-deficient state in the initiation of tumorigenesis as well as targeted cancer therapy. In *BRCA*-deficient cells, the defective maintenance of genomic integrity may accelerate cancer initiation and progression, yet also render the resultant cancer more susceptible to therapeutic agents whose cytotoxic potential is mediated through the induction of the specific type of DNA damage that *BRCA* normally

functions to repair. A number of commonly used cancer therapies are believed to cause DNA interstrand cross links, a lesion that appears to be repaired through creation of an intermediate double-strand break followed by homologous recombination. Prototypical agents from this mechanistic category include cisplatin, mitomycin C, and γ radiation (117). That BRCA-deficient cancers may respond favorably to this class of DNA-damaging agents is suggested by studies in which modulation of *BRCA1* expression in various isogenic cell clones is shown to affect sensitivity to cisplatin (118–120), mitomycin C (97), and γ radiation (121–124). This mechanism likely represents the underlying biologic basis for improved outcome in BRCA-linked hereditary ovarian cancer patients compared to matched sporadic cases (125–127). Further, this suggests a rational basis for trials investigating the efficacy of platinum-based chemotherapy in breast cancer patients with germ-line BRCA mutations.

PTEN

A novel tumor-suppressor gene responsible for the very rare, autosomal dominant hereditary cancer syndrome Cowden's syndrome was cloned and characterized in 1997 (128,129). Cowden's syndrome, also known as multiple hamartoma syndrome, is characterized by benign hamartomas of multiple organs, including skin, intestine, breast, and thyroid. In addition to benign lesions, breast cancers develop in 30% to 50% of affected women and thyroid cancers occur in 10% of affected individuals. Bannayan-Zonana syndrome, a closely related condition, was also subsequently found to be caused by mutations in the same gene (130). Named *PTEN*, this gene was originally noted to encode a likely tyrosine phosphatase with additional significant homologies to the cytoskeletal proteins tensin and auxilin. Early studies aimed at uncovering *PTEN* function indicated that its phosphatase activity may function to suppress tumorigenesis by negatively regulating cell interactions with the extracellular matrix, specifically the inhibition of integrin-mediated cell spreading and cell migration through dephosphorylation of focal adhesion kinase (FAK) (131). Additionally, expression of *PTEN* selectively inhibits activation of the extracellular signal-regulated kinase (ERK) mitogen-activated protein kinase (MAPK) pathway (132). Other cellular targets for the phosphatase activity of *PTEN* include elements of the phosphoinositide 3-kinase/AKT pathway (133). Specifically, the *PTEN* gene functions as a lipid phosphatase negatively regulating the lipid second messenger phosphatidylinositol 3, 4, 5,-triphosphate (134). Because constitutive activation of either PI3-kinase or AKT is known to induce cellular transformation, an increase in the activity of this pathway caused by mutations in *PTEN* provided additional support for its complex role in tumor suppression. It is now well established that *PTEN*'s lipid phosphatase activity, acting through the PI3K/AKT and MAPK pathways, plays a critical role in the regulation of growth arrest, apoptosis, and other important cellular functions (135).

Although endometrial carcinoma has been suggested to represent a component tumor of Cowden's syndrome according to revised diagnostic criteria (136), germ-line mutations in *PTEN* are not associated with a significant proportion of unselected endometrial carcinomas. Remarkably, however, sporadic endometrial carcinomas frequently exhibit loss of heterozygosity in a region of chromosome 10q that includes the *PTEN* gene (137,138). Mutation analyses of *PTEN* in endometrial carcinomas indicate that this gene is somatically inactivated in 30% to 50% of all such tumors (139-141), representing the most frequent molecular genetic alteration in endometrial cancers yet defined. Inactivation of *PTEN* may represent an early event in a subset of endometrial cancers, as

mutations are detected at a significant frequency in premalignant endometrial hyperplasia specimens (142). Interestingly, *PTEN* mutations are also seen in a fraction of ovarian carcinomas of endometrioid histology (143), but not in those of serous or other histologic subtypes (141–144). More recent findings on the role of *PTEN* in specific gynecologic cancers are discussed later in this chapter.

ONCOGENES

It has been convincingly demonstrated that alterations in genes whose products normally act to stimulate cell proliferation or other aspects of the neoplastic phenotype (oncogenes) can cause malignant transformation (Fig. 5.6) (145,146). Oncogenes can be activated via several mechanisms. In solid tumors, the most common mechanism of oncogene activation appears to be gene amplification with resultant overexpression of the corresponding protein. Instead of two copies of one of these genes, there may be many copies. The *ERBB2* (*HER2/neu*) oncogene is activated in this fashion. Some oncogenes may become resistant to inactivation when affected by specific point mutations in regulatory domains, resulting in constitutive signaling. The *RAS* family of oncogenes is prototypical in this regard. Finally, oncogenes may be translocated from one chromosomal location to another and then come under the influence of promoter sequences that cause overexpression of the gene. This mechanism frequently occurs in leukemias and lymphomas (e.g., the Philadelphia chromosome), but appears to be less common in solid tumors.

In addition to gene amplification and other mechanisms mentioned above, expression of some genes can be increased due to loss of imprinted transcriptional control. Loss of imprinting (LOI) remains poorly understood in carcinogenesis. A small subset of genes in the genome is expressed solely from either the maternal or paternal inherited copy. During the carcinogenic process the maintenance of allele-specific silencing is often lost, resulting in increased expression. For example, the mitogenic peptide insulin-like growth factor 2 (*IGF2*) is commonly up-regulated in a variety of cancers where it functions to promote cell division by signaling through the insulin receptor and the *IGF1* receptor. Loss of imprinting of this

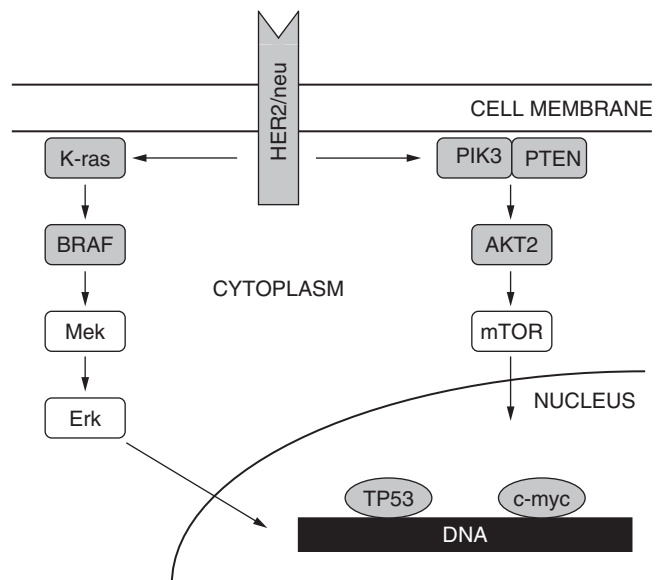

FIGURE 5.6. Cellular localization of representative oncogenes and tumor-suppressor genes that are altered in gynecologic cancers.

growth factor is common in some cancers, including some ovarian malignancies, and increases the susceptibility of tumor formation (147). However, the up-regulation of IGF2 is more common in cancers than the frequency of LOI, indicating that LOI alone is not responsible for all observed IGF2 increases. The increased levels of IGF2 are likely due to LOI in some cases and other epigenetic events in most cases at this complex genomic locus (148,149). Thus, LOI is just one of several epigenetic mechanisms that can dysregulate the expression of genes with oncogenic potential.

In various model systems and *in vitro*, many genes that are involved in normal pathways of cell proliferation, signal transduction, and transcriptional regulation can elicit neoplastic transformation when altered to overactive forms via amplification, mutation, translocation, or simple overexpression. On this basis, a large number of genes have been classified as "oncogenic." However, the actual spectrum of such genes that have been shown to be altered mutationally in human cancers (the formal criterion for classification as an oncogene) is much more limited. Presently, it appears that inactivation of tumor-suppressor genes is significantly more common than activation of oncogenes. With the advent of large gene-sequencing efforts directed at identifying activating mutations in protein kinases, it is likely that the number of genes satisfying the classic oncogene definition will increase. This may reflect the fact that mutations are more apt to disrupt the function of a gene than to create a product that is hyperactive. Alternatively, it is possible that the involvement of tumor-suppressor genes in malignant transformation has been more easily identifiable because of their association with hereditary cancer syndromes. In this section, the various classes of oncogenes are summarized, with particular attention being paid to those that are altered in gynecologic cancers.

Peptide Growth Factors and Their Receptors

Peptide growth factors in the extracellular space can stimulate a cascade of molecular events that leads to proliferation by binding to cell membrane receptors. Unlike endocrine hormones, which are secreted into the bloodstream to act in distant target organs, peptide growth factors usually act in the local environment. The concept that autocrine growth stimulation might be a key strategy by which cancer cell proliferation becomes autonomous has received considerable attention. In this model, it is postulated that cancers secrete stimulatory growth factors that then interact with receptors on the same cell. Although production of growth factors may play a role in enhancing proliferation associated with malignant transformation, they are also involved in development, stromal-epithelial communication, tissue regeneration, and wound healing. Thus, it remains unclear whether autocrine growth stimulation actually is a critical event in cancer development.

Cell membrane receptors that bind peptide growth factors are composed of an extracellular ligand-binding domain, a membrane-spanning region, and a cytoplasmic tyrosine kinase domain (150). More than a dozen receptor tyrosine kinases have been identified thus far that bind peptide growth factors. Binding of a growth factor to the extracellular domain results in aggregation and conformational shifts in the receptor and activation of the inner tyrosine kinase. This kinase phosphorylates tyrosine residues on both the growth factor receptor (autophosphorylation) and targets in the cell interior, leading to activation of secondary signals. For example, phosphorylation of phospholipase C leads to breakdown of cell membrane phospholipids and generation of diacylglycerol and inositol-triphosphate (IP₃), both of which play a role in propagation of the mitogenic signal.

Epidermal Growth Factor Receptor Family

The role of the epidermal growth factor (EGF) receptor family of transmembrane receptors and their ligands in growth regulation and transformation has been a prominent focus in cancer research over the past three decades (151). The salient findings are summarized in this section. EGF is a peptide growth factor of 53 amino acids that maintains its secondary structure by virtue of disulfide bonds between cysteine residues. At least 10 other peptide growth factors, including TGF- α , also interact with and activate the EGF receptor(s) (152). TGF- α was so named because of its ability to act in concert with TGF- β to transform some types of cells in culture. EGF, TGF- α , and other EGF receptor ligands are produced as proforms that are inserted into the cell membrane. The membrane-anchored growth factor can interact with receptors on adjacent cells, a phenomenon known as juxtacrine growth regulation. Alternatively, the active peptide then can be cleaved and released into the extracellular space. The free peptide may interact with receptors on the same (autocrine) or nearby (paracrine) cells to stimulate growth.

The EGF family of receptors has been extensively characterized from both a genetic and biochemical standpoint. Similar to other growth factor receptors, the EGF family members are composed of an extracellular ligand-binding domain, a hydrophobic membrane-spanning region, and an intracellular tyrosine kinase domain (153,154). A truncated form of the EGF receptor that lacks the outer ligand-binding domain is the viral oncogene (*v-erbB*) responsible for avian erythroblastosis. The *v-erbB* gene encodes a receptor that is constantly activated and sending growth stimulatory signals to the nucleus. The EGF receptor is ubiquitously expressed in both epithelial and stromal cells and plays a role in growth stimulation of most cell types.

The EGF receptor has been shown to be massively amplified in the A431 human vulvar squamous cell carcinoma cell line, and these cells have been widely used as a model for studying the biochemical functions of the EGF receptor. In some head and neck and lung cancers, the EGF receptor also appears to be significantly amplified, and amplification may be associated with virulent behavior. In these cancers, the EGF receptor can be targeted therapeutically with monoclonal antibodies (155). In normal squamous epithelium, expression of EGF receptor is high in the basal proliferative layer and decreases as cells migrate toward the surface and differentiate. Although levels of EGF receptor vary between different primary squamous cancers of the lower genital tract in women, gene amplification rarely occurs, and EGF receptor levels do not appear to correlate closely with clinical behavior of these cancers (156). Similarly, EGF receptor is expressed in normal ovarian epithelium and endometrium, and although the level of expression varies between cancers, this is not a strong predictor of clinical behavior.

In some human cancers, such as non-small-cell lung cancer, specific inhibitors of the EGF receptor, such as gefitinib (Iressa) or erlotinib (Tarceva), have recently been proven to be effective in their treatment, and multiple clinical trials are now under way to test the efficacy of these agents alone or in combination with traditional chemotherapeutic agents (157). Efficacy of these inhibitors is largely predictable based on whether the cancer has specific mutations within the EGF receptor. Patients with certain mutations that constitutively activate the receptor tend to preferentially respond to anti-EGFR treatment. About half of these mutations are an in-frame deletion of amino acids 747-750; most of the other mutants occur at amino acid 858 (158). The occurrence of tumors with a strong dependence on one oncogene has led to the so-called oncogene addiction theory (159). Many genetic and epigenetic alterations

may have occurred in these cancers, yet they are vulnerable to a single targeted treatment directed to a dependence on a particular oncogene. It is theorized that the anti-EGFR therapy causes an “oncogenic shock,” leading to high levels of apoptosis and significant clinical response when pro-growth stimulations are replaced by apoptotic signals. Unfortunately, many of these cancers will recover from this treatment by acquiring drug resistance.

As mentioned, the EGF receptor family of receptors is also often referred to as the *ERBB* family because the first member identified was the *v-erbB* oncogene. The second member of the family (*ERBB2*) initially was called *neu* because it was found to be the transforming gene responsible for the generation of neuroblastomas in rats treated with a chemical carcinogen. It subsequently was discovered that the *neu* gene encoded a 185-kD transmembrane receptor that is highly homologous with the EGF receptor (160). This human EGF receptor-like molecule was named both HER2/*neu* and *erbB2* by investigators working in the field. The transforming activity of *neu* in the animal model was due to the presence of a mutation in the transmembrane portion of the molecule that results in constitutive activation of the inner tyrosine kinase domain. Biochemical studies of HER2/*neu* (formally designated *ERBB2*) have shown that activation of this receptor is not driven by ligand binding, but rather is dependent on activation of other members of the *ERBB* family (161). Two members of the *ERBB* receptor family are nonautonomous and require dimerization with other family members for function. Specifically, *ERBB2* lacks ligand-binding capability, while *ERBB3* lacks the kinase activity. These two receptors develop potency of growth factor signal transmission via heterodimerization. Whereas *ERBB2* and *ERBB3* require heterodimerization for function, *ERBB1* (EGFR) and *ERBB4* can function autonomously or as heterodimers. *ERBB2* is the preferential partner for *ERBB3* and *ERBB4*. Recent attempts to characterize the complex signaling via these receptors and their ligands at systems biology level imply that *ERBB2* functions as the system amplifier (152).

In contrast to EGF receptor, which normally is expressed in both stromal and epithelial cells, *ERBB2* is expressed primarily in epithelial cells. As originally shown for breast and ovarian cancers (162), the expression of *ERBB2* is increased in several human cancer types as a result of gene amplification. In addition, artificial overexpression of this gene in some cell types in culture leads to acquisition of a malignant phenotype. In human cancers, *ERBB2* may also be overexpressed owing to alterations in regulation of transcription in the absence of gene amplification. Regardless of the underlying mechanism, it has been shown that overexpression correlates strongly with aggressive features in breast, ovarian, and endometrial cancers.

As noted above, activation of the *ERBB3* and *ERBB4* transmembrane receptors is requisite for *ERBB2* kinase activity. At least four families of ligands, collectively called neuregulins (e.g., heregulin, *neu* differentiating factor), bind to *ERBB3* and *ERBB4* (161). Interestingly, there is considerable promiscuity between *ERBB* ligands and receptors. For example, amphiregulin can activate both the EGF receptor (*ERBB1*) and *ERBB3*. And one of the more recently described ligands (epiregulin) can activate heterodimers of any of the *ERBB* family members; these heterodimers are more potent growth stimulators than homodimers of any individual *ERBB* receptor. Finally, although their molecular signaling mechanisms have not yet been fully elucidated, the *ERBB* family of receptors has also been exploited as therapeutic targets. Success has been achieved with the anti-*ERBB2* monoclonal antibody trastuzumab (Herceptin), which is approved for treatment of *ERBB2*-positive metastatic breast cancer. In combination with chemotherapy, trastuzumab provides significant clinical benefit in terms of increased response rate and extended survival compared with chemotherapy alone in patients with *ERBB2*-positive advanced breast cancer.

Trastuzumab also has therapeutic activity as monotherapy in the front-line management of *ERBB2*-overexpressed or *ERBB2*-amplified metastatic breast cancer. Given its proven efficacy in the metastatic setting, the combination and sequential use of trastuzumab with adjuvant and neoadjuvant chemotherapy are the focus of several ongoing clinical studies (163). In ovarian cancers with *ERBB2* amplification and/or overexpression, however, trastuzumab has been proven to be disappointing in terms of efficacy compared to that observed in breast cancer (164).

Extranuclear Signal Transduction

Following interaction of peptide growth factors and their receptors, secondary molecular signals are generated to transmit the mitogenic stimulus toward the nucleus. This function is served by a multitude of complex and overlapping signal transduction pathways that occur in the inner cell membrane and cytoplasm. Many of these signals involve phosphorylation of proteins by enzymes known as kinases. Cellular processes other than growth are also regulated by kinases, but one family of kinases appears to have evolved specifically for the purpose of transmitting growth stimulatory signals. These tyrosine kinases transfer a phosphate group from ATP to tyrosine residues of target proteins. Some kinases that phosphorylate proteins on serine and/or threonine residues (e.g., protein kinase C, AKT2) also are involved in stimulating proliferation. The activity of kinases is regulated by phosphatases, which act in opposition to the kinases by removing phosphates from the target proteins. Although several families of intracellular kinases have been identified that can elicit transformation when activated *in vitro* (e.g., SRC), structural alterations in these molecules appear to play a role in the development of human cancers only rarely. Recently, sequencing of kinase genes in common human cancers identified a low frequency of mutations (165). The frequency of these alterations and their significance will need to be validated in future studies; however, it appears clear that widespread mutation of specific kinases is not common. Rather, cancer is typified by a low frequency of mutations in multiple kinases.

RAS

G-proteins represent another class of molecules involved in transmission of growth stimulatory signals from the cell membrane to the nucleus (166). The RAS family of G-proteins functions as a relay switch that is positioned downstream of cell surface receptor tyrosine kinases and upstream of a cytoplasmic cascade of kinases that include the mitogen-activated protein (MAP) kinases (167,168). Activated MAP kinases in turn regulate the activities of nuclear transcription factors. RAS proteins are 21-kD molecules that localize to the inner aspect of the cell membrane. They have intrinsic GTPase activity that catalyzes the exchange of guanosine 5'-triphosphate (GTP) for guanosine 5'-diphosphate (GDP). In their active GTP-bound form, G-proteins interact with MAP kinases. Conversely, hydrolysis of GTP to GDP, which is stimulated by GTPase-activating proteins (GAPs), leads to inactivation of G-proteins.

It is estimated that point mutations in RAS genes are present in about one third of cancers (11). Mutations in this family of G-proteins (*KRAS*, *HRAS*, and *NRAS*) are among the most frequently observed genetic alterations in human cancers (e.g., gastrointestinal and endometrial cancers). In human cancers and in a wide range of chemically induced rodent tumors, activating mutations in RAS are observed at codon 12, 13, or 61 (169). The encoded amino acids at these three locations appear to play a critical structural role in the active site of ras, such that missense mutations at one of these codons destroy

the ability of RAS to convert GTP to GDP. The end result of such an activating mutation is accumulation of GTP-RAS protein that chronically transmits its growth stimulatory signal. In human epithelial malignancies, the most frequently observed mutation is that of *KRAS* codon 12; such is the case for gynecologic cancers, as is discussed later in this chapter.

To be biologically active, RAS must move from the cytoplasm to the inner plasma membrane. A posttranslational modification, specifically addition of a farnesyl group to the C-terminal cysteine, is requisite for membrane localization. Farnesylation of RAS is catalyzed by the enzyme farnesyltransferase. Recently, several compounds have been developed that can inhibit farnesylation. Preclinical studies indicate that these molecules can suppress transformation and tumor growth *in vitro* and in animal models with little toxicity to normal cells (170).

Nuclear Factors

If proliferation is to occur in response to signals generated in the cytoplasm, these events must lead to activation of nuclear factors responsible for DNA replication and cell division. Expression of several genes that encode nuclear proteins increases dramatically within minutes of treatment of normal cells with peptide growth factors. Once induced, the products of these genes (e.g., FOS, JUN, MYC) bind to specific DNA regulatory elements and induce transcription of genes involved in DNA synthesis and cell division. When inappropriately amplified and/or overexpressed, however, these transcription factors can act as oncogenes.

Among the nuclear transcription factors involved in stimulating proliferation, amplification and/or overexpression of members of the *MYC* family has most often been implicated in the development of human cancers (161). *MYC* proteins are key regulators of mammalian cell proliferation, and treatment of cells with *MYC* antisense oligonucleotides inhibits proliferation. It has been shown that *MYC* acts as part of a heterodimeric complex with the protein *MAX* to initiate transcription of other genes involved in cell cycle progression (171). Ironically, in some instances in which *MYC* expression is low, its inappropriate reexpression can elicit apoptosis (172).

The T-cell–like transcription factor 4, *TCF4/LEF1*, and the *TCF3* (now known as *TCF7L1* and *TCF7L2*) transcription factors are implicated in carcinogenesis. These factors are thought to be the chief effectors of constitutive alteration of the Wnt signal transduction pathway. As discussed elsewhere in this chapter, inactivating mutation of the *APC* tumor suppressor, activating mutation of *CTNNB1*, or multiple epigenetic inactivation events in secreted Frizzled receptors all lead to increases of β -catenin (173). β -catenin associates with the *TCF4* factor and activates or represses gene transcription from certain promoters. The exact targets of transcription remain poorly known in most cancer types. However, the *c-myc* gene contains canonical *TCF/Lef* binding sites within its promoter and may be one key target gene. Whether alterations in this pathway are relevant in the transformation of gynecologic cancers largely remains to be elucidated.

GYNECOLOGIC MALIGNANCIES

Considerable evidence has accumulated to suggest that the clinical heterogeneity of gynecologic cancers with respect to behavior (borderline vs. invasive), histologic type, stage, and outcome is attributable, to a great extent, to differences in underlying molecular alterations between cancers. The spectrum of oncogene and tumor-suppressor gene defects clearly varies both between cancer types and within a given type of cancer. A comprehensive understanding of the molecular

pathogenesis of gynecologic cancers has not yet been achieved, but new genomic technologies that allow global assessment of molecular alterations are accelerating the pace of discovery. Elucidation of the molecular pathology of gynecologic cancers promises not only to illuminate their origins, but also to facilitate the development of new approaches to diagnosis, treatment, and prevention.

Although expression of many genes and molecular pathways is dysregulated in gynecologic cancers, most of these are secondary changes that contribute to evolution of the malignant phenotype. The main focus of this chapter is on the primary mutational alterations in oncogenes and tumor-suppressor genes that lead to the initial development of gynecologic cancers.

ENDOMETRIAL CANCER

Epidemiologic and clinical studies of endometrial cancer have suggested that there are two distinct types of endometrial cancer (174). Type I cases are associated with unopposed estrogen stimulation and often develop in a background of endometrial hyperplasia. These cancers are characterized by well-differentiated, endometrioid histology, early stage, and favorable outcome. In contrast, type II cancers are poorly differentiated and/or nonendometrioid and are more virulent. They often present at an advanced stage and survival is relatively poor. In practice, not all cases can be neatly characterized as either type I or II lesions, and endometrial cancers can also be viewed as a spectrum with respect to etiology and clinical behavior. However, as the genetic events involved in the development of endometrial cancer have been elucidated, it has been found that specific alterations often, but not always, are seen primarily in either type I or II cases (Table 5.2, Fig. 5.7).

The molecular basis for the relationship between unopposed estrogenic stimulation of the endometrium and endometrial cancer remains uncertain. It has long been thought that estrogens contribute to the development of endometrial cancer by virtue of their mitogenic effect on the endometrium. A higher rate of proliferation in response to estrogens may lead to an increased frequency of spontaneous mutations. In addition, when genetic damage occurs, regardless of the cause, the presence of estrogens may facilitate clonal expansion. It has also been postulated that estrogens may act as “complete carcinogens” that both promote proliferation and act as initiating agents due to free-radical generation and production of carcinogenic metabolites. In contrast, progestins oppose the action of estrogens both by down-regulating estrogen receptor levels and by decreasing proliferation and increasing apoptosis.

The initial evidence of genetic alterations in endometrial cancers came from cytogenetic studies that revealed changes in the number of copies of specific chromosomes as well as deletions and translocations (175). Subsequently, comparative genomic hybridization (CGH) studies have demonstrated specific areas of chromosomal loss and gain in both endometrial cancers and atypical hyperplasias (176,177). The most common sites of chromosomal gain are 1q, 8q, 10p, and 10q (178–180). Chromosomal losses also are frequently observed both using CGH and in loss of heterozygosity studies (181). A correlation has been noted between higher numbers of chromosomal alterations on CGH and more virulent clinical features (182). The overall number of chromosomal alterations detected using CGH is lower in endometrial cancers relative to other cancer types.

Ploidy analysis simply measures total nuclear DNA content. About 80% of endometrial cancers have a normal diploid DNA content as measured by ploidy analysis. Aneuploidy occurs in 20% and is associated with advanced stage, poor grade, nonendometrioid histology, and poor survival (183).

TABLE 5.2

GENETIC ALTERATIONS IN SPORADIC ENDOMETRIAL CARCINOMAS

	Class	Mechanism	Approximate frequency	Type I/II ^a
<i>Hereditary</i>				
<i>MSH2, MLH1, PMS1, PMS2, MSH6</i>	DNA repair	Mutation	5%	I
<i>Sporadic</i>				
Oncogenes				
HER2/neu	Tyrosine kinase	Amplification/overexpression	10%	II
K-ras	G-protein	Mutation	10%–30%	I/II
β -catenin	Transcription factor	Mutation	10%	I
c-myc	Transcription factor	Amplification/overexpression	20%–30%	?
FGFR2	Tyrosine kinase	Mutation	10%	I
PI3KCA	Tyrosine kinase	Amplification	20%–30%	I/II
Tumor-suppressor genes				
TP53	Transcription factor	Mutation/overexpression	20%	II
PTEN	Phosphatase	Mutation/deletion	40%	I
MLH1	Mismatch repair	Promoter methylation	10%–20%	I
CDC4	Cell cycle	Mutation/deletion	15%	II

^aType I = well-differentiated, endometrioid, estrogen-associated cancers; Type II = poorly differentiated, nonendometrioid cancers.

The frequency of aneuploidy is relatively low in endometrial cancers relative to ovarian cancers (80%). The differences in frequency of aneuploidy between endometrial and ovarian cancers correlate well with the disparate outcomes of these two diseases.

More recently, microarrays that measure the expression of all the genes in a cancer have been used to identify patterns that distinguish between normal and malignant endometrium and between various histologic types of endometrial cancer (181,184,185). This approach has the potential to complement studies of the individual oncogenes and tumor-suppressor genes reviewed below and to enhance understanding of the biology of endometrial cancer.

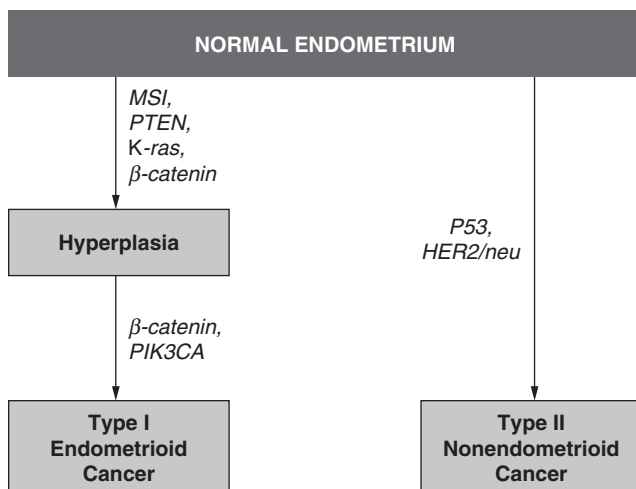

FIGURE 5.7. Molecular pathogenesis of type I and type II endometrial cancers.

Tumor-Suppressor Genes

TP53

Inactivation of the *TP53* tumor-suppressor gene is among the most frequent genetic events in endometrial cancers (186). The mechanisms of *TP53* inactivation were discussed in detail earlier in this chapter. Overexpression of mutant TPTP53 protein occurs in about 20% of endometrial adenocarcinomas and is associated with several known prognostic factors, including advanced stage, poor grade, and nonendometrioid histology (Fig. 5.8) (183,187). Overexpression occurs in about

FIGURE 5.8. Overexpression of p53. About 50% of ovarian cancers and 20% of endometrial cancers have missense mutations in the p53 tumor-suppressor gene that result in protein products that are resistant to degradation. As is demonstrated in this endometrial cancer these mutant p53 proteins overaccumulate in the nucleus of the cell and can be visualized using immunohistochemistry.

FIGURE 5.9. Mutation of the p53 gene. Endometrial cancer T861 has a missense mutation in codon 248 of the p53 gene that changes the sequence from CGG to TGG and results in the substitution of tryptophan for arginine. On the left is the normal wild-type (WT) sequence.

10% of stage III and 40% of stage III/IV cancers (187). Numerous studies have confirmed the strong association between *TP53* overexpression and other poor prognostic factors and decreased survival (188–194). In some of these studies, *TP53* overexpression has been associated with worse survival even after controlling for stage (195,196). This suggests that loss of *TP53* tumor-suppressor function confers a particularly virulent phenotype. Although little is known regarding molecular alterations in uterine sarcomas, overexpression of mutant *TP53* occurs in a majority of mixed mesodermal sarcomas of the uterus (74%) and in some leiomyosarcomas (197,198).

Endometrial cancers that overexpress *TP53* protein usually harbor missense mutations in exons 5 through 8 of the gene that result in amino acid substitutions in the protein (Fig. 5.9) (187,199,200). Most of these mutations lead to loss of DNA-binding activity. Because *TP53* mutations rarely, if ever, occur in endometrial hyperplasias (201), this may represent a late event in the development of endometrioid endometrial cancers. Alternatively, acquisition of a *TP53* mutation may typically lead to development of a virulent, poorly differentiated type II endometrioid cancer or serous cancer that does not arise in endometrial hyperplasia. In this regard, in one study of uterine serous carcinoma and its putative precursor (endometrial intraepithelial carcinoma), *TP53* overexpression was observed in 90% and 78% of cases, respectively (202).

PTEN

The *PTEN* gene on chromosome 10q encodes a phosphatase that functions as a tumor suppressor by opposing the activity of PI3 kinase, which is a lipid kinase involved in generating the second messenger PIP3 that in turn contributes to activation of downstream targets such as Akt (203). Mutations in the *PTEN* tumor-suppressor gene occur in about half of endometrial cancers (139–141), and this represents the most frequent genetic alteration described thus far in these cancers. Most of these mutations are deletions, insertions, and nonsense mutations that lead to truncated protein products, whereas only about 15% are missense mutations that change

a single amino acid in the critical phosphatase domain. Loss of *PTEN* tumor-suppressor function generally also involves deletion of the second non-mutated copy of the gene.

Mutations in the *PTEN* gene are associated with endometrioid histology, early stage, and favorable clinical behavior (204). Well-differentiated, noninvasive cases have the highest frequency of mutations. In addition, *PTEN* mutations have been observed in 20% of endometrial hyperplasias, suggesting that this is an early event in the development of some type I endometrial cancers (205). It has been reported that loss of *PTEN* protein may occur in normal-appearing endometrial glands even before the emergence of hyperplasia, suggesting that this may be a critical initiating event in endometrial carcinogenesis (206,207).

Synchronous endometrioid cancers are sometimes encountered in the endometrium and ovary that are indistinguishable microscopically. In some of these cases, identical *PTEN* mutations have been identified, suggesting that the ovarian tumor represents a metastasis from the endometrium (208). In other cases, the *PTEN* mutation seen in the endometrial cancer was not found in the ovarian tumor, suggesting that these represent two distinct primary cancers. *PTEN* mutations have also been observed in about 20% of endometrioid ovarian cancers that arise in the absence of endometrial cancers (143).

DNA Mismatch Repair Genes

As noted in Chapter 2, about 3% to 5% of endometrial cancers occur in women with a strong hereditary predisposition due to germ-line mutations in DNA repair genes in the context of the HNPCC syndrome. Endometrial cancer is the second most common malignancy observed in women with HNPCC. Cancers that arise in these individuals are characterized by mutations in multiple microsatellite repeat sequences throughout the genome. Microsatellite instability also occurs in about 20% of sporadic endometrial cancers (209,210). Endometrial cancers that exhibit microsatellite instability tend to be type I cancers. Because microsatellite instability has been noted in some sporadic endometrial cancers in women who do not carry germ-line DNA repair gene mutations that cause HNPCC syndrome (209), several groups have attempted to identify acquired somatic mutations in these genes. DNA repair gene mutations have been identified in only a minority of endometrial cancers with microsatellite instability (70,211). Loss of mismatch repair in these cases appears to be most often due to silencing of the *MLH1* gene by way of promoter methylation (212,213). Methylation of the *MLH1* promoter has also been noted in endometrial hyperplasias (210,214) and normal endometrium adjacent to cancers, suggesting that this is an early event in the development of some of these cancers (215). It is thought that global changes in methylation that result in decreased expression of a number of tumor-suppressor and DNA repair genes may be a characteristic of some endometrial cancers, particularly type I cases (216,217). Loss of DNA mismatch repair may accelerate the process of malignant transformation by facilitating accumulation of mutations in microsatellite sequences present in genes involved in malignant transformation such as *PTEN*, *BAX*, *TGF β R2*, and *CASP5* (218). Loss of mismatch repair function is clearly associated with favorable survival in colon cancers, but this has not been a consistent finding in endometrial cancer (219–222).

Other Genes

The *Par-4* gene on chromosome 12q21 encodes a putative tumor-suppressor gene that acts as a proapoptotic factor. Loss of expression of this gene has been demonstrated in some human cancers, and mice in which Par-4 has been inactivated

develop endometrial cancer. *Par-4* expression is lower in secretory than in proliferative endometrium. Reduced expression occurs in about 40% of endometrial cancers and may be attributable to methylation of the promoter region of the gene (223). Expression of *Par-4* was correlated with ER expression and microsatellite instability (MSI), but not with mutations in *PTEN*, *K-ras*, or β -*catenin*.

The *Cables* gene on chromosome 18q11–12 is a putative tumor suppressor involved in regulating phosphorylation of cyclin-dependent kinase 2 in a manner that restrains cell cycle progression. *Cables* mutant mice develop endometrial hyperplasia at an early age, and exposure to low levels of estrogen causes endometrial cancer (224). *Cables* expression is up-regulated by estrogen and decreases following progesterin treatment. Loss of *Cables* expression also occurs in human endometrial hyperplasias and cancers.

Finally, mutations in the *CDC4* gene, which is involved in regulating cyclin E expression during cell cycle progression, have been noted in 16% of endometrial cancers (225). Mutations were accompanied by loss of the wild-type allele and were more common in cancers with poor prognostic factors such as high-grade and lymph-node metastases. It is postulated that *CDC4* may act as a tumor suppressor by restraining the activity of cyclin E in promoting progression from G₁ to S phase. An additional study failed to reproduce this finding. This study evaluated 73 endometrial cancers for h*CDC4* mutation and was able to detect only a single case with a variant of uncertain significance (226). The frequency and significance of h*CDC4* alterations in endometrial cancer are uncertain.

Oncogenes

HER2/neu/ERBB2

Alterations in oncogenes have been demonstrated in endometrial cancers, but these occur less frequently than inactivation of tumor-suppressor genes (Table 5.2). Increased expression of the *HER2/neu* receptor tyrosine kinase has been noted in about 10% of endometrial cancers (192,227–229) and is associated with advanced stage and poor outcome. In some studies, multivariate analysis revealed that high expression was an independent variable associated with poor survival (228,230). Serous endometrial cancers most frequently overexpress *HER2/neu* (231). In one study of 27 serous endometrial cancers, overexpression was seen in 70% of African American cases compared to 24% of Caucasian cases, and it was suggested that this may have contributed to an observed racial disparity in outcome (232). The levels of *HER2/neu* overexpression in endometrial cancers are much less striking than in breast cancers, but there have been isolated reports that Herceptin (anti-*HER2/neu* antibody) treatment is of therapeutic benefit in some endometrial cancers (233).

K-ras and *BRAF*

The *RAS* family of genes encodes cell-membrane-associated GTPases that frequently undergo point mutations in codons 12, 13, or 61 in many human cancers. These mutations produce constitutively activated oncogenic molecules. Initially, these codons of the *K-ras*, *H-ras*, and *N-ras* genes were examined in 11 immortalized endometrial cancer cell lines (234). Mutations in codon 12 of *K-ras* were seen in four cell lines, whereas three had mutations in codon 61 of *H-ras*. Subsequent studies of primary endometrial adenocarcinomas have confirmed that codon 12 of *K-ras* is mutated in about 10% of American cases and 20% of Japanese cases (235–242). These mutations

occur more often, but not exclusively, in type I endometrial cancers. *K-ras* mutations have also been identified in some endometrial hyperplasias (236,242,243), which suggests that this may be a relatively early event in the development of some type I cancers.

The *BRAF* gene product acts downstream of *K-ras*, and also is frequently mutated in several types of cancers. Most reports have suggested that *BRAF* mutations are not a feature of endometrial hyperplasias or cancers (244,245). However, one paper from Japan found *BRAF* mutations in 21% of endometrial cancers and 11% of hyperplasias (246). These alterations were not found at locations proven to constitutively activate the *BRAF* protein. Furthermore, many were found in tumors with mismatch repair deficiency, suggesting that they may be passenger alterations. Evaluation of these “mutants” requires further study. It is also possible that these disparate findings may be due to differences between American and Japanese endometrial cancers, as has been noted with *K-ras* mutation frequency between these populations.

PI3KCA

As noted above, the *PTEN* tumor-suppressor gene, which normally acts to restrain PI3K activity, is frequently inactivated in type I endometrial cancers. Conversely, the *PI3KCA* gene is oncogenically activated in some cases. The catalytic subunit of *PI3K* (*PI3KCA*) is located on chromosome 3q26.3 and activating mutations in this gene have been described in several types of cancers. In an initial study, *PI3KCA* mutations were seen in 36% of endometrial cancers, and 24% of cases had mutations in both *PTEN* and *PI3KCA* (247). This suggested that there is an additive effect of two mutations in the same pathway. In a subsequent study, 39% of endometrial cancers and 7% of atypical endometrial hyperplasias were found to harbor mutations in *PI3KCA* (248). This study also implied that *PI3KCA* mutation occurred at the time of tumor invasion and could serve as a marker for invasion. As in the initial study, a high fraction of cases had mutations in both *PTEN* and *PI3KCA*. These and other studies confirm that PI3KCA activating mutations are common in endometrial cancers.

β -*catenin*

Alterations in a molecular pathway involving *E-cadherin*, *APC*, and β -*catenin*, the product of the *CTNNB1* gene, have been noted in some endometrial cancers. *E-cadherin* is a transmembrane glycoprotein involved in cell-cell adhesion, and its decreased expression in cancer cells is associated with increased invasiveness and metastatic potential. *E-cadherin* mutations occur only rarely in endometrial cancers (249), but cadherin expression may also be down-regulated in the absence of mutations (250,251). The cytoplasmic tail of *E-cadherin* exists as a macromolecular complex with the β -*catenin* and *APC* gene products, which link it to the cytoskeleton. It appears that a critical function of the *APC* tumor-suppressor gene is to regulate phosphorylation of serine and threonine residues (codons 33, 37, 41, 45) in exon 3 of β -*catenin*, which results in degradation of β -*catenin*. Mutational inactivation of *APC* allows accumulation of β -*catenin*, which translocates to the nucleus and acts as a transcription factor to induce expression of cyclin D1 and perhaps other genes involved in cell cycle progression (251). Germ-line *APC* mutations are responsible for the adenomatous polyposis coli syndrome, and somatic mutations are common in sporadic colon cancers, but *APC* mutations have not been described in endometrial cancers. The *APC* gene may be inactivated in some endometrial cancers owing to promoter methylation (252). In addition, it has been shown that missense mutations in exon 3 of β -*catenin* lead to the same end result—namely, abrogation of the ability of *APC* to induce β -*catenin*

degradation, which results in abnormal transcriptional activity. In view of this, the β -catenin gene is considered an oncogene (253).

β -catenin can function as an oncogene in some endometrial cancers and is a key regulatory protein involved in canonical Wnt signaling. Disruptions in Wnt signaling have been implicated in numerous cancer types (254). In addition to the defects present in the gene itself, which lead to constitutive activity, epigenetic silencing of other negative regulators of this pathway has been observed. The complexities of Wnt signaling remain poorly understood; however, it appears that these additional defects in the pathway are related to an increased signaling cascade in the absence of key proteins that normally dampen the Wnt signal. Mutations in exon 3 of β -catenin have been observed in several types of cancers, including hepatocellular, prostatic, and endometrial cancers. Mutation of β -catenin occurs in about 10% to 15% of endometrial cancers, but abnormal accumulation of β -catenin protein occurs in about one third of cases, suggesting that mechanisms other than mutation might be involved in some cases (255,256). Mutation of β -catenin tends to be associated with type I endometrial cancers, and mutations have been noted in some endometrial hyperplasias (257).

FGFR2

Efforts designed to sequence kinase genes in human cancers identified mutations of fibroblast growth factor receptors (FGFRs) in some common epithelial cancers including ovarian cancer (258). The *FGFR2* gene encodes one of a family of tyrosine kinase growth factor receptors that receive signals from a large family of ligands. Recently, one study evaluated the *FGFR2* gene for activating mutations in a series of endometrial cancers (259). The study was initiated after the unbiased sequencing approach identified mutations in two endometrial cancer cell lines and one endometrial stromal sarcoma cell line. *FGFR2* mutations were subsequently identified in about 10% of endometrioid cancers. Mutations were found almost exclusively in cancers with endometrioid histology. There was no association with clinical outcome. Further studies will be needed to evaluate the significance of the identified mutations and other mechanisms of increased FGF signaling in endometrial cancer as well as any potential clinical utility by drug targeting of the receptor.

c-myc

Among nuclear transcription factors involved in stimulating proliferation, amplification of members of the *myc* family has most often been implicated in the development of human cancers. It has been shown that *c-myc* is expressed in normal endometrium (260) with higher expression in the proliferative phase. Several studies have suggested that *myc* may be amplified in a fraction of endometrial cancers (261–263).

OVARIAN CANCER

About 10% of ovarian cancers arise in women who carry germ-line mutations in cancer susceptibility genes—predominantly *BRCA1* or *BRCA2*, which are involved in repair of double-stranded DNA breakage. The vast majority of ovarian cancers is sporadic and arises due to accumulation of genetic alterations. The etiology of the molecular alterations involved in malignant transformation of the ovarian epithelium remains uncertain, and with the possible exception of talc, exogenous carcinogens have not been strongly implicated.

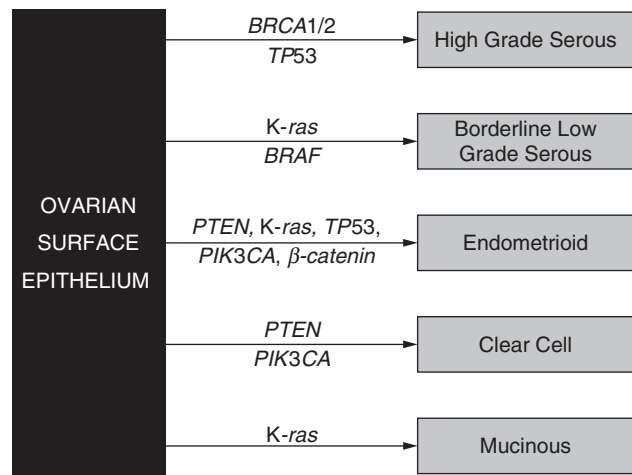

FIGURE 5.10. Molecular pathogenesis of different histological types of ovarian cancer.

Some mutations may arise spontaneously due to increased epithelial proliferation required to repair ovulatory defects. Oxidative stress and free-radical formation due to inflammation and repair at the ovulatory site may also contribute to accumulation of damage in cancer-causing genes.

Regardless of the mechanisms involved in causing genetic alterations, reproductive events that decrease lifetime ovulatory cycles (e.g., pregnancy and birth control pills) are strongly protective against ovarian cancer (264). The protective effect of these factors is greater in magnitude than one would predict based on the extent that ovulation is interrupted. Five years of oral contraceptive use provides a 50% risk reduction while only decreasing total years of ovulation by less than 20%. There is evidence to suggest that the progestagenic milieu of pregnancy and the pill might also protect against ovarian cancer by increasing apoptosis of ovarian epithelial cells, thereby cleansing the ovary of cells that have acquired genetic damage (265). The action of other reproductive hormones such as estrogens, androgens, and gonadotropins also may contribute to the development of ovarian cancers.

Epithelial ovarian cancers are heterogeneous with respect to behavior (borderline vs. invasive), histologic type (serous, mucinous, endometrioid, clear cell), stage, and outcome. These clinical and pathologic differences are reflected in diverse patterns of underlying genetic alterations (Fig 5.10). As our understanding of the molecular pathogenesis of ovarian cancer continues to mature, it is likely that the various disease subsets will increasingly be thought of as distinct entities that are defined by characteristic patterns of underlying epidemiologic risk factors, clinical features, and molecular signatures.

Global Genomic Changes

Invasive epithelial ovarian carcinoma is generally a monoclonal disease that develops as a clonal expansion of a single transformed cell in the ovary (266). There is evidence that some serous borderline tumors (229) as well as cancers that arise in the peritoneum of patients with *BRCA1* mutations may be polyclonal, however (267). Most ovarian cancers are characterized by a high degree of genetic damage that is manifest at the genomic and molecular levels. Gains and losses of various segments of the genome have been demonstrated using comparative genomic hybridization (CGH) (268). Likewise, loss of heterozygosity (LOH), indicative of deletion of specific

genetic loci, also has been demonstrated to occur at a high frequency on many chromosomal arms (269). It is unclear whether the wide range of genetic alterations in ovarian cancers reflects the need to alter several genes in the process of malignant transformation or is the result of generalized genomic instability.

Both CGH and LOH studies have shown that advanced-stage, poorly differentiated cancers have a higher number of genetic changes than early-stage, low-grade cases (270–272). This finding could be interpreted as reflective of the fact that the number of genetic changes accumulates with progression from an early to an advanced cancer. Alternatively, advanced stage cancers may be intrinsically more virulent even at their early stages by virtue of their specific mutations and/or increased genomic instability. If this latter theory is correct, then early- and advanced-stage ovarian cancers could be thought of as different diseases rather than as steps in a progressive pathway. This could have significant implications for early diagnosis, treatment, and prevention of ovarian cancer.

It is estimated that the human genome contains about 25,000 genes. Recently, microarray chips that contain sequences complementary to the messenger RNAs of thousands of genes have been created that allow global assessment of gene expression. It is likely that levels of gene expression ascertained using microarrays are reflective of all the mechanisms that can affect expression, including amplification, deletion, and mutation, as well as changes in promoter methylation. Expression arrays have proven useful in predicting clinical phenotypes of various types of cancers. Several groups have applied expression array technology to the analysis of ovarian cancers. Many of these studies have compared gene expression between normal ovarian

epithelial cells and ovarian cancers. Numerous genes have been identified that appear to be up- or down-regulated in the process of malignant transformation (273–275). In addition, microarrays have demonstrated patterns of gene expression that distinguish between invasive and borderline cases (276), histologic types (277), and early- and advanced-stage cases (275,278) and that predict survival (279,280). Although most of the changes in gene expression observed using microarrays are not reflective of oncogene or tumor-suppressor gene mutations, it has been shown that complex expression signatures reflective of specific oncogene alterations can be reliably ascertained (281).

Tumor-Suppressor Genes

TP53

Alteration of the *TP53* tumor-suppressor gene is the most frequent genetic event described thus far in ovarian cancers (Table 5.3) (40,282–287). The frequency of overexpression of mutant *TP53* is significantly higher in advanced-stage (40% to 60%) relative to early-stage cases (20%), but differences in frequencies of histologic types likely account for this difference. In this regard, about two thirds of early-stage serous ovarian cancers were found to have *TP53* mutations compared to only 21% of nonserous cases (288). The higher frequency of *TP53* alterations in advanced-stage cases may indicate that this is a “late event” in ovarian carcinogenesis. Alternatively, it is possible that loss of *TP53* confers an aggressive phenotype associated with more rapid progression. There

TABLE 5.3

GENETIC ALTERATIONS IN EPITHELIAL OVARIAN CANCERS

	Class	Mechanism	Approximate frequency	Comments
<i>Hereditary</i>				
<i>BRCA1</i>	Double-stranded DNA repair	Mutation/deletion	6%	Breast/ovarian syndrome
<i>BRCA2</i>	Double-stranded DNA repair	Mutation/deletion	3%	Breast/ovarian syndrome
<i>MSH2/MLH1</i>	DNA mismatch repair	Mutation/deletion	1%	HNPCC syndrome
<i>Sporadic Oncogenes</i>				
<i>HER2/neu</i>	Tyrosine kinase	Amplification/overexpression	5%–10%	Gene amplification rare
<i>K-ras</i>	G-protein	Mutation	20%–30%	Mostly serous borderline
<i>BRAF</i>	Serine/threonine kinase	Mutation	10%–20%	Serous borderline only
<i>AKT2</i>	Serine/threonine kinase	Amplification	5%–10%	
<i>PI3KCA</i>	Tyrosine kinase	Amplification	5%–10%	
<i>c-myc</i>	Transcription factor	Amplification/overexpression	20%–30%	
<i>β-catenin</i>	Transcription factor	Mutation	30%	Endometrioid only Type I
<i>Tumor-suppressor genes</i>				
<i>TP53</i>	Transcription factor	Mutation/deletion	50%–70%	Most common in invasive
<i>p16</i>	CDK inhibitor	Deletion, promoter methylation	15%	
<i>p21, p27</i>	CDK inhibitor	Promoter methylation	10%–40%	
<i>BRCA1</i>	Double-stranded DNA repair	Promoter methylation	10%	
CCNE (cyclin E)	Cyclin-dependent kinase	Overexpression	40%	

CDK, cyclin-dependent kinase; HNPCC, hereditary nonpolyposis colorectal cancer.

is a suggestion that overexpression of mutant TP53 protein may be associated with slightly worse survival in advanced-stage ovarian cancers (282–284,286,287,289–291). Finally, although there is a high concordance between TP53 missense mutations in exons 5 through 8 and protein overexpression, about 20% of advanced ovarian cancers contain mutations that result in truncated protein products, which usually are not overexpressed (40,291). Some of these mutations may lie outside of exons 5 through 8. Overall, about 70% of advanced ovarian cancers have either missense or truncation mutations in the TP53 gene. Most TP53 missense mutations are transitions rather than transversions (292,293), which suggests that these mutations occur spontaneously, rather than due to exogenous carcinogens.

It has been postulated that loss of functional TP53 might confer a chemoresistant phenotype because of its role in chemotherapy-induced apoptosis. In this regard, several studies have examined the correlation between chemosensitivity and TP53 mutation in ovarian cancers *in vitro* (294–299). Some have suggested a relationship between TP53 mutation and loss of chemosensitivity, but in other equally valid studies such a relationship has not been observed. It is likely that the status of the TP53 gene is just one of a multitude of factors that determines chemosensitivity.

Overexpression of TP53 is rare in stage I serous borderline tumors, but occurs in as many as 20% of advanced-stage borderline cases (300,301). In a study of advanced serous borderline tumors, TP53 overexpression was associated with a sixfold higher risk of death (301). In some cases, invasive serous cancers may arise following an earlier diagnosis of borderline tumor. It has been shown that TP53 mutational status was not concordant between the original borderline tumor and the subsequent invasive cancer (302). This suggests that the invasive cancer either arises independently or as a clonal outgrowth within the original tumor.

Rb Gene

Although mutations in the *Rb* tumor-suppressor gene are not a common feature of ovarian cancers, evidence suggests that inactivation of *Rb* greatly enhances tumor formation in ovarian cells with p53 mutations (303). In a mouse model in which these genes were inactivated in the ovarian epithelium, few cancers developed in response to loss of either p53 or *Rb* alone. When both genes were inactivated, epithelial ovarian cancers with serous features developed in almost all cases. Given that *Rb* mutations are rare in ovarian cancers, it is possible that inactivation of one of a number of genes in the *Rb* pathway can initiate transformation cooperatively with TP53. Inactivation of *Rb* itself may not be requisite. This mouse model of ovarian cancer has the potential to add greatly to our understanding of epithelial ovarian carcinogenesis. A notable feature of this model is the development of dysplastic premalignant epithelium. Although ovarian dysplasia has long been thought to represent the precursor of serous ovarian cancers (304) and is an appealing target for early detection and prevention (305), the inaccessibility of the ovaries has presented a significant obstacle to studying its natural history. The ability to track the development of preinvasive and invasive lesions in this new mouse model presents the opportunity to develop chemoprevention approaches in a setting that appears similar to human ovarian carcinogenesis.

Cyclin-Dependent Kinase Inhibitors

The cyclin-dependent kinase (CDK) inhibitors act as tumor suppressors by virtue of their inhibition of cell cycle progression from G₁ to S phase. Expression of several CDK inhibitors

appears to be decreased in some ovarian cancers. The *CDKN2A* (p16) gene undergoes homozygous deletions in about 15% of ovarian cancers (306). There is evidence to suggest that p16 (307), *CDKN2B* (p15) (308), and some other tumor-suppressor genes such as *BRCA1* (83,84,309) may be inactivated via transcriptional silencing due to promoter methylation rather than mutation and/or deletion. Likewise, decreased expression of the CDK inhibitor *CDKN1A* (p21) has been noted in a significant fraction of ovarian cancers despite the absence of inactivating mutations (310,311), and in some studies has been associated with poor survival (312). Loss of *CDKN1B* (p27) also may occur and correlates with poor survival in some studies (313–316). It has been suggested that aberrant expression of p27 in the cytoplasm may be most associated with poor outcome (317).

Other Genes

The TGF- β pathway is believed to play an important role in suppression of proliferation and malignant transformation. Normal ovarian epithelial cells are inhibited by the growth inhibitory peptide TGF- β , whereas some ovarian cancers are unresponsive (318,319). There is some evidence that mutations may occur in cell surface TGF- β receptors or in the *Smad* family of genes that are involved in downstream signaling (320), but in other studies these signaling pathways have been found to be intact (319).

A number of other genes involved in inhibiting proliferation that are not inactivated by mutation and/or deletion may be silenced due to methylation of their promoters. Examples include the *ARHI* gene on chromosome 1p31 and the *ARLTS1* gene on 13q14 (321,322).

Oncogenes

HER2/neu

Normal and malignant ovarian epithelial cells produce and respond to various peptide growth factors such as epidermal growth factor (323), insulin-like growth factors (324), platelet-derived growth factor (325), and fibroblast growth factors (326–328). Production of these growth-accelerating peptides appears to be increased during carcinogenesis. These growth factors interact with membrane-spanning tyrosine kinase receptors. The only one of these receptor tyrosine kinases convincingly shown to be activated in some ovarian cancers is HER2/neu.

About 30% of breast cancers express increased levels of HER2/neu (162), often as a result of gene amplification. Overexpression of HER2/neu in breast cancer has been associated with poor survival. Expression of HER2/neu is increased in a fraction of ovarian cancers (Fig. 5.11) and overexpression has been associated with poor survival in some studies (162,329), but ovarian cancers that exhibit HER2/neu overexpression rarely have high-level gene amplification. Monoclonal antibodies that bind to HER2/neu can decrease growth of ovarian cancer cell lines that overexpress this receptor (330). Anti-HER2/neu antibody therapy (Herceptin) has demonstrated efficacy in the treatment of breast cancer and is often administered in concert with paclitaxel (331). In a Gynecologic Oncology Group (GOG) study, only 11% of ovarian cancers exhibited significant HER2/neu overexpression (332). The response rate to single-agent Herceptin therapy was disappointingly low (7.3%), but perhaps some benefit may be found in the future using combination regimens that also include taxanes or other cytotoxics.

FIGURE 5.11. Overexpression of HER2/neu in ovarian cancer. **A:** Serous ovarian cancer. **B:** Immunostaining for HER2/neu demonstrates intense cell membrane staining indicative of overexpression.

K-ras and *BRAF*

Activating mutations in codons 12 and 13 of the *K-ras* gene are rare in invasive serous ovarian cancers (333–335). Some types of cancers that lack *K-ras* mutations have activating mutations in codon 599 of the downstream *BRAF* gene, but this is not the case in serous ovarian cancers. In contrast, *K-ras* mutations are common in borderline serous ovarian tumors, occurring in about 25% to 50% of cases (336,337). In addition, mutations in *BRAF* occur in about 20% of serous borderline cases lacking *K-ras* mutations (338). Mutations in *K-ras* and *BRAF* have also been noted in cystadenoma epithelium adjacent to serous borderline tumors, suggesting that this is an early event in their development (339). *K-ras* mutations have been noted in about 50% of mucinous ovarian cancers, but *BRAF* mutations have not been found (340). These findings highlight the distinct differences in the molecular pathology between various histologic types and between borderline tumors and invasive ovarian cancers.

PI3KCA and *AKT2*

Similar to endometrial cancers, activation of the *PI3KCA* and *AKT2* oncogenes occurs in some ovarian cancers. The region of chromosome 3p26 that includes the phosphatidylinositol 3-kinase (*PI3KCA*) is amplified in some ovarian cancers (341).

In addition, activating mutations in *PI3KCA* occur in about 10% of ovarian cancers, and are much more common in endometrioid and clear cell cancers (20%) compared to serous cancers (2%) (342). Likewise, the *AKT2* serine/threonine kinase that is downstream of *PI3KCA* also has been shown to be amplified and overexpressed in some ovarian cancers (343). *PI3KCA* and *AKT2* kinase activity is opposed by the *PTEN* phosphatase, and this tumor-suppressor gene also is inactivated in about 20% of endometrioid ovarian cancers (344).

β-catenin

As noted previously, mutations in the *β-catenin* gene are a feature of some endometrial cancers. Similarly, *β-catenin* mutations are present in about 30% of endometrioid ovarian cancers (345), but not other histologic types. This provides further evidence of the molecular heterogeneity of the various histologic types of ovarian cancer. In some endometrioid ovarian cancers with abnormal nuclear accumulation of β -catenin that lack mutations, the *APC*, *AXIN1*, or *AXIN2* genes that regulate β -catenin activity were found to be mutated (345). This suggests that alterations in this wnt signaling pathway are a feature of endometrioid ovarian cancers. Mouse models in which the wnt and the *PIK3/PTEN* pathways are inactivated in the ovarian epithelium lead to the development of endometrioid cancer and endometriosis (346,347).

c-myc

Increased activity of nuclear transcription factors also may enhance malignant transformation. In this regard, amplification of the *c-myc* oncogene has been reported to occur in some ovarian cancers. Several studies have suggested that the *c-myc* gene is amplified in about 30% of cases, although high-level amplification is rare (348–350). Despite these reports of gene amplification, evidence of *c-myc* protein overexpression has been less convincing.

CCNE (Cyclin E)

Cell cycle progression factors may also exert an oncogenic effect when overactive. In this regard, some ovarian cancers have been reported to show increased expression of cyclin E, which is involved in cell cycle progression from G₁ to S phase. In a study of advanced-stage suboptimally debulked ovarian cancers treated on GOG protocols, high cyclin E expression was associated with a 6-month decrease in median survival (351). In some, but not all, cases, amplification of the cyclin E gene was found to be the underlying cause of overexpression. In a large study using a tissue microarray, cyclin E overexpression has been shown to be associated with serous/clear cell histology, advanced stage, and poor outcome (352).

Other Genes

Global genomic approaches such as CGH have also suggested the presence of amplified genes in other chromosomal regions in some ovarian cancers. An amplicon on chromosome 11q13 results in amplification of *Cyclin D1* and/or the *BRCA2* interacting protein *EMSY* in some cases (353). Likewise, the *Notch3* gene on chromosome 19p13, the *Aurora-A* kinase on 20q13, and *eIF-5A2* on 3q26 also may be targets for amplification (354–356).

Large-scale sequencing of 518 protein kinases was performed on a panel of human cancers, including 25 ovarian cancers (258). Although the analysis did not detect a gene or genes with high prevalence of mutation, several genes were mutated infrequently in ovarian cancers including *CDKL2*, *CDKL5*, *STK36*, and *TRRAP*. The investigators performed more sequencing on additional ovarian cancers and did not find widespread alteration in these genes. Interestingly, this

screen identified a single *FGFR2* mutation in 25 ovarian cancers. There were only two endometrioid histology ovarian cancers among the 25 sequenced. Given the high similarity of mutation and histologic appearance of endometrioid ovarian cancer and endometrioid endometrial cancer, it seems possible that a low frequency of *FGFR2* mutations will be found in endometrioid ovarian cancers.

Ovarian cancer ascites also contain lipid factors such as lysophosphatidic acid (LPA) that stimulate proliferation and invasiveness of ovarian cancer cells (357). The edg-2 G-protein-coupled receptors act as functional receptors for LPA. It also has been shown that LPA induces the *Groα* gene that acts to stimulate proliferation (358). The finding that neutralization of LPA activity decreases growth and increases apoptosis of ovarian cancers suggests that manipulation of this pathway may be therapeutically beneficial (359).

CERVICAL CANCER

Cervical cancer is the most common gynecologic malignancy worldwide and accounts for over 400,000 cases annually. Molecular and epidemiologic studies have demonstrated that sexually transmitted human papillomavirus (HPV) infections play a role in almost all cervical dysplasias and cancers (360). HPV infection is also involved in the development of dysplasias and cancers of the vagina and vulva. The peak incidence of HPV infection is in the 20s and 30s and the incidence of cervical cancer increases from the 20s to a plateau between age 40 and 50. Although HPV plays a major role in the development of most cervical cancers, only a small minority of women who are infected develop invasive cervical cancer. This suggests that other genetic alterations and/or environmental factors also are involved in cervical carcinogenesis. For example, individuals who are immunosuppressed, either due to HIV infection (361) or immunosuppressive drugs, are more likely to develop dysplasia and invasive cervical cancer following HPV infection.

Cervical screening programs in developed nations dramatically reduced both the incidence of invasive cervical cancer and disease-related mortality in the 20th century. The recent development of vaccines against oncogenic HPV subtypes promises to further decrease the incidence of cervical dysplasia and cancer. Although cervical cancer mortality is now low in the United States and Western Europe, it remains among the leading causes of cancer deaths in women in underdeveloped nations. Complete eradication of cervical cancer through screening and prevention strategies that are based on an understanding of HPV biology may be within reach in the 21st century.

Human Papillomavirus Infection

There are over 80 HPV subtypes, but not all infect the lower genital tract. HPV-16 and -18 are the most common types associated with cervical cancer, and are found in over 80% of cases. Types 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 68, 73, and 82 should be considered high-risk types, and types 26, 53, and 66 should be considered probably carcinogenic (360). Low-risk types that may cause dysplasias or condyloma in the lower genital tract, but rarely cause cancers, include types 6, 11, 40, 42, 43, 44, 54, 61, 70, 72, and 81. The advent of HPV typing now allows assessment of whether patients carry high-risk or low-risk HPV types and this has proven to be clinically useful in the management of patients with low-grade Pap smear abnormalities.

The HPV DNA sequence consists of 7,800 nucleotides divided into “early” and “late” open reading frames (ORFs). Early ORFs are within the first 4,200 nucleotides of the

genome and encode proteins (E1–E8) important in viral replication and cellular transformation. Late ORFs (L1 and L2) are found within the latter half of the sequence and encode structural proteins of the virion. In oncogenic subtypes like HPV-16 and -18, transformation may be accompanied by integration of episomal HPV DNA into the host genome. Opening of the episomal viral genome usually occurs in the E1/E2 region, resulting in a linear fragment for insertion. The location of the opening may be significant since E2 acts as a repressor of the E6/E7 promoter, and disruption of E2 can lead to unregulated expression of the E6/E7 transforming genes. HPV-16 DNA may be found in its episomal form in some cervical cancers, however, and unregulated E6/E7 transcription may occur independent of viral DNA integration into the cellular genome.

Examination of the biological effects of HPV-encoded proteins has shed light on the mechanisms of HPV-associated transformation. Expression of the E4 transcript results in the production of intermediate filaments that colocalize with cytokeratins. E4 proteins of oncogenic subtypes disrupt the cytoplasmic cyokeratin matrix, whereas those of nononcogenic strains do not. It has been suggested that this may facilitate the release of HPV particles in oncogenic subtypes such as HPV-16. The E5 oncogene encodes a 44 amino acid protein that usually forms dimers within the cellular membrane. The transforming properties of E5 appear to involve potentiation of membrane-bound epidermal growth factor receptors or platelet-derived growth factor receptors. HPV E2 proteins are thought to cause a mitotic block that leads to genomic instability.

The E6 and E7 oncoproteins are the main transforming genes of oncogenic strains of HPV (Fig. 5.12) (362). Transfection of these genes *in vitro* results in immortalization and transformation of some cell lines. The HPV E7 protein acts primarily by binding to and inactivating the retinoblastoma (Rb) tumor-suppressor gene product. E7 contains two domains, one of which mediates binding to Rb while the other serves as a substrate for casein kinase II (CKII) phosphorylation. Variations in oncogenic potential between HPV subtypes may be related to differences in the binding efficacy of E7 to Rb. High-risk HPV types contain E7 oncoproteins that bind Rb with more affinity than E7 from low-risk types. The transforming activity of E7 may be increased by CKII mutation, implying a role for this binding site in the development of HPV-mediated neoplasias. The E6 proteins of oncogenic HPV subtypes bind to and inactivate the *TP53* tumor-suppressor gene product (363,364). There is also a correlation between oncogenicity of various HPV strains and the ability of their E6 oncoproteins to inactivate *TP53*. Inactivation of Rb and *TP53* by E6/E7

FIGURE 5.12. Role of p53 and Rb genes in cervical carcinogenesis. The HPV-16/18 E6 and E7 proteins inactivate the p53 and Rb genes, respectively.

circumvents the need for mutational inactivation of these key growth regulatory genes. HPV-negative cervical cancers are uncommon, but have been reported to exhibit overexpression of mutant *TP53* protein (365). This suggests that inactivation of the *TP53* tumor-suppressor gene either by HPV E6 or by mutation is a requisite event in cervical carcinogenesis. In some studies, the levels of E6 and E7 in invasive cervical cancers have been found to predict outcome, whereas HPV viral load does not (366).

Genomic Changes

Comparative genomic hybridization techniques have been used to identify chromosomal loci that are either increased or decreased in copy number in cervical cancers. A strikingly consistent finding of various studies is the high frequency of gains on chromosome 3q in both squamous cell cancers (367–370) and adenocarcinomas (371). Other chromosomes that exhibit frequent gains include 1q and 11q. The most common areas of chromosomal loss include chromosomes 3p and 2q. For the most part, with the exception of the *FHIT* gene on chromosome 3p, it has not been proven that these genomic gains and losses result in the recruitment of specific oncogenes and tumor-suppressor genes in the process of malignant transformation. It is conceivable that these chromosomal alterations may be frequent sequelae of infection with oncogenic HPVs while playing no significant role in the pathogenesis of cervical cancers. Abnormalities seen in invasive cancers using comparative genomic hybridization also have been identified in high-grade dysplasias, however, suggesting that these are early events in cervical carcinogenesis (368,369,372).

Oncogenes and Tumor-Suppressor Genes

Only a small fraction of HPV-infected women develop cervical cancer. This suggests that additional genetic alterations are requisite for progression to high-grade dysplasia and cancer, but little is known regarding these events. Allele loss suggestive of involvement of tumor-suppressor genes has been noted at loci on chromosomes 3p, 11p, and others, but alterations in specific genes remain elusive. Interestingly, the cyclin-dependent kinase inhibitor p16 is strikingly up-regulated in almost all cervical dysplasias and cancers (373). Clinical trials are ongoing to determine whether this will represent a useful adjunct to improve the positive predictive value of high-risk HPV testing for detection of cervical dysplasia.

The role of several oncogenes has been examined in cervical carcinomas. Although the epidermal growth factor receptor gene is amplified and overexpressed in some squamous cell cancers that arise in the aerodigestive tract, this is not observed in cervical cancers (374). Mutant *ras* genes are capable of cooperating with HPV in transforming cells *in vitro*. There is some evidence that mutations in either *K-ras* or *H-ras* may play a role in a subset of cervical cancers (365,375–378). Alterations in *ras* genes have not been seen in cervical intraepithelial neoplasia, suggesting that mutation of *ras* is a late event in the pathogenesis of some cervical cancers. In contrast, *c-myc* amplification and overexpression may be an early event in the development of some cervical cancers (379). Overexpression of *c-myc* has been demonstrated in one third of early invasive carcinomas and some CIN 3 lesions, but not in normal cervical epithelium or lower grade dysplasia. It has been reported that overexpression of *c-myc* gene may be due to amplification of the gene (4- to 20-fold) in some cases. In some studies, amplification correlated with poor prognosis in early-stage cases (380). Other studies have not confirmed the finding of amplification of *c-myc* in cervical cancers, however. Integration of the HPV genome near *c-myc* on chromosome 8q may lead to

increased expression due to enhanced transcription of the gene rather than amplification. Further studies are needed to clarify the role of *ras* genes, *c-myc*, and other oncogenes in cervical carcinogenesis.

The fragile histidine triad (*FHIT*) gene localized within human chromosomal band 3p14.2 is frequently deleted in many different cancers, including cervical cancer (381–383). Decreased expression of this putative tumor-suppressor gene is an early event in some cervical cancers (383,384). In one study, *FHIT* protein expression was markedly reduced or absent in 71% of invasive cancers, 52% of high-grade squamous intraepithelial lesions (HSILs) associated with invasive cancer, and 21% of HSILs without associated invasive cancer (383). In addition, reduced expression is associated with poor prognosis in advanced cervical cancers (385).

As is the case in endometrial and ovarian cancers, it is thought that gene silencing due to promoter hypermethylation also may play a role in cervical carcinogenesis (386,387). In this regard, the *RASSF1A* gene is located on chromosome 3p21.3 in an area that is frequently the site of deletions in cervical cancer. The function of this gene is not completely understood, but is thought to be involved in *ras*-mediated signal transduction pathways. Although mutations in *RASSF1A* do not occur in cervical cancers, inactivation of the gene due to promoter methylation occurs in a fraction of cases, particularly adenocarcinomas (388,389).

Molecular analyses can readily be performed using cell pellets obtained from liquid-based Pap smears. This promises to facilitate future investigation of the role of promoter methylation and other alterations in the molecular pathogenesis of cervical cancer (390,391).

GESTATIONAL TROPHOBLASTIC DISEASE

The genetic alterations that underlie gestational trophoblastic disease have been elucidated to a great extent. The most prominent feature of these tumors is an imbalance of parental chromosomes. In the case of partial moles this involves an extra haploid copy of one set of paternal chromosomes, while complete moles generally are characterized by two complete haploid sets of paternal chromosomes and an absence of maternal chromosomes. Although the risk of repeat molar pregnancy is only about 1%, women who have had two molar pregnancies have about a 25% risk of developing another mole. Although this suggests a hereditary defect that affects gametogenesis, this remains speculative. Thus far there is no convincing evidence that damage to specific tumor-suppressor genes or oncogenes contributes to the development of gestational trophoblastic disease.

CHAPTER 6 ■ IMMUNOTHERAPY OF GYNECOLOGIC MALIGNANCIES

PAUL J. SABBATINI, DAVID Z. CHANG, CHAITANYA R. DIVGI,
PHILIP O. LIVINGSTON, AND ALAN N. HOUGHTON

The natural clinical history of ovarian cancer makes it ideally suited for the evaluation of immune-based strategies. Although the majority of patients are diagnosed with advanced disease, 70% are in a complete clinical remission following initial cytoreductive surgery and platinum and taxane-based primary chemotherapy (1). However, data from second-look surgical assessments show that more than 60% of patients actually have persistent disease, which is supported by the fact that only 30% of optimally debulked stage III patients will remain disease-free with a median progression-free interval of approximately 24 months (2). Despite the high relapse rate, many patients return to a complete or partial clinical remission following additional chemotherapy. With this chronic course of relapse and response, the median survival of optimally debulked patients exceeded 60 months in a study evaluating intraperitoneal (IP) therapy as part of primary treatment (3). Neither higher doses and protracted schedules nor non-cross-resistant consolidation chemotherapy has provided additional benefit. These ovarian cancer patients with minimal disease burdens are therefore appropriate candidates for the evaluation of immune-based strategies, which typically have excellent side effect profiles.

With regard to other gynecologic malignancies, the outcome of both early-stage and locally advanced cervical cancer has been improved with the addition of chemotherapy to radiation therapy, yet for those patients who relapse, survival in the metastatic setting is short (4,5). The bulk of immune strategies being evaluated in patients with cervical cancer target human papillomavirus, and this important subject is covered separately in chapters 19 and 22 (6,7). The treatment of patients with metastatic recurrent endometrial cancer is also characterized by limited chemotherapy responses of short duration (8). There is a need in each of these gynecologic cancers for more effective therapy, especially in the adjuvant setting, when the target is circulating cancer cells and micrometastases or peritoneal implants. A variety of approaches utilizing the specificity and potency of the immune system are under evaluation including cytokines or other immunologic modulators, monoclonal antibodies, and vaccines.

CANCER IMMUNOLOGY: OVERVIEW

The immune system evolved to fight foreign invaders such as bacteria, viruses, and parasites. However, strong evidence suggests that the immune system also plays a crucial role in controlling or even rejecting incipient cancers. Mice that have major defects in immunologic molecules develop cancer more

frequently, including carcinomas, supporting the hypothesis that the immune system detects and destroys incipient cancers, the theory of *immune surveillance of cancer*. This theory has been modified to propose that the immune system not only destroys incipient cancers, but that cancer cells are able to escape this early immunity through changes in gene expression, leading to outgrowth of tumors with the capacity to escape recognition by the immune system. The process of tumor cells escaping from immunity is termed *immune editing*.

Innate Immunity

The immune system is broadly divided into two arms. *Innate immunity* is present at birth and does not require adaptation to react against microorganisms or tumors. Examples of cells that are part of innate immunity include natural killer (NK) cells, macrophages, and dendritic cells. NK cells are lymphocytes that are programmed to recognize and destroy tissues that have been altered or stressed, e.g., by viruses or by malignant transformation. Macrophages play many roles in immunity and inflammation, including production of a multitude of soluble secreted proinflammatory proteins, which are growth factors for other cells of the immune system, for neovasculature, and for cancer cells. These growth factors include *cytokines* and *chemokines*, and they support the growth, movement, and survival of immune and inflammatory cells. Macrophages play important roles in tissue remodeling during wound healing, mediating inflammatory responses, sampling molecules from the environment through internalization, and presenting antigens to stimulate T cells. Macrophages can also play a counterproductive role through production of molecules that promote tumor growth and angiogenesis (e.g., vascular endothelial growth factor [VEGF] and basic fibroblast growth factor [FGF]). Macrophages can also inhibit immune responses through production of cytokines and other molecules that down-regulate immunity, such as prostaglandins E₂, arginase I, and transforming growth factor- β . Thus, the role of macrophages in tumors is complex. Dendritic cells have some properties that are similar to macrophages, including production of cytokines and sampling of molecules from the environment. Most importantly, dendritic cells are a primary link between the innate immune system and the adaptive or acquired immune system through presentation of antigens to initiate T-cell activation. For this reason, dendritic cells are professional antigen-presenting cells.

Adaptive Immunity

Adaptive immunity is characterized by adaptation to antigens, e.g., antigens of infectious pathogens (or potentially by cancer).

This arm of the immune system is not mature or activated at birth, but rather adapts through maturation in response to antigens of pathogens. It is characterized by receptors encoded by the immunoglobulin (Ig) gene family. These receptors have the capacity to rearrange, creating enormous diversity ($>10^{11-12}$ different receptors). This provides a system to generate enormous specificity that recognizes and responds to a wide range of antigens that have not previously been encountered.

The two major cell types of acquired immunity are *T lymphocytes* (T cells) and *B lymphocytes* (B cells). T cells have the capacity to recognize antigens sequestered in different compartments within cells, for instance, antigens generated in the cytoplasm or nucleus by viral infections. T cells recognize antigens as short peptides, 8 to 16 amino acids in length. These peptides must be complexed with and presented by specialized antigen-presenting molecules, the major histocompatibility complex (MHC) molecules, to T-cell receptors. In humans, MHC molecules are the human leukocyte antigens (HLAs) expressed on virtually every cell in the body. On the other hand, B cells produce secreted *antibodies* that can recognize soluble and cell surface molecules. Both T cells and B cells initially develop with a limited range of receptors for immune recognition. However, in response to antigen (e.g., from a virus or cancer cell) presented by a professional antigen-presenting cell, T cells or B cells that have receptors with the best “fit” to the antigen itself (for B cells) or antigen/MHC complex (for T cells) are stimulated to proliferate and this subpopulation is quickly expanded.

Humoral Immunity

B cells recognize antigens usually in their natural configuration (9). An individual host has a repertoire of B cells that are capable of generating antibodies against the full range of pathogens encountered in the environment. To do this, the total population of B lymphocytes expresses a diverse repertoire of immunoglobulins. Each B cell expresses immunoglobulin against a single antigenic determinant, with the immunoglobulin expressed at the cell surface of the B cell where it acts as a specific receptor to transduce signals in response to that antigen. Once activated, the B cell is to create an individual monoclonal antibody (mAb). The diversity of specificities in different B cells is generated by rearrangements of the immunoglobulin genes, and new antibody specificities continue to be generated in response to new antigens. During development, B cells with high avidity immunoglobulins against ubiquitous self-antigens are eliminated. This elimination of B cells reactive with autoantigens is not absolute, however, as a broad array of antibodies against autoantigens is found in the blood of humans. Peripheral blood B cells consist of naïve and relatively short-lived B cells, long-lived memory B cells resulting from maturation in response to antigenic stimulation, and a small population of B cells expressing germ-line immunoglobulins that have not undergone rearrangement (which are found in the CD5+ B-cell population) (10).

B cells are very mobile, and after development in the bone marrow they migrate through the peripheral blood to B-cell-rich areas in lymphoid organs, e.g., the follicles of lymph nodes, spleen, and gastrointestinal tract. Many B cells continue recirculating in the blood. If cognate antigen is encountered in lymphoid organs, the B lymphocyte migrates to the T-cell-rich areas where appropriate T-cell help can be provided to promote increased antibody diversity and increased affinity through immunoglobulin gene rearrangements. This T-cell help does not have to be induced by the same antigen. Chemical conjugation of the antibody-recognized antigen to highly immunogenic bacterial or xenogeneic proteins or, alternatively, expression of the antigen in bacterial or viral vectors, are widely used approaches to ensure adequate

T-cell help in vaccines. The result of T-cell help is generation of plasma cells, the most mature form of B cell with the highest capacity for antibody production. In addition, T-cell help promotes formation of germinal centers in lymphoid organs where hypermutation in immunoglobulin genes and class and subclass switching occur to generate antibodies with higher affinities for antigen. Class switching refers to changes in antibody class during an immune response, with the IgM class of antibodies appearing first, generally followed by antibodies of the IgG class (different subclasses of IgG antibodies have different blood half-lives and different capacities for effector functions, such as fixation of complement or binding to Fc receptors). The consequence is plasma cells secreting increasingly higher affinity IgG antibodies as the immune response matures over time. In addition, some B cells that generally recognize non-protein antigens, e.g., carbohydrate or glycolipid antigens, can be stimulated to proliferate in the absence of T-cell help. Class switching, affinity maturation, and memory B cells do not occur “without cell help;” rather, low-affinity IgM antibodies of shorter duration result.

The immunoglobulin variable region (called the Fv region) determines antibody specificity and is located in the Fab domain of immunoglobulins. This region mediates effective binding to antigens. However, the constant region (Fc), where antibody class and subclass are determined, is equally critical. Binding of antibody to antigen results in a conformational change in the Fc portion, leading to activation of several effector mechanisms, including complement activation (discussed below). IgM antibodies are synthesized early in the response, but if T-cell help is available, antibody responses mature through immunoglobulin gene rearrangements into the higher affinity IgG classes, which are capable of improved binding to antigen as well as receptors on the bone marrow-derived cells for the Fc domain, expanding potential effector functions. The responses to most non-protein antigens are IgM class and generally do not mature to IgG responses. The IgM pentamer structure is specialized to increase avidity of binding to multimeric antigens and to efficiently activate one type of effector function: complement. Activation of complement, which includes blood components with different enzymatic properties, results in opsonization (coating of pathogens by complement components), recognition by complement receptors on macrophages, monocytes, neutrophils, and dendritic cells, with subsequent activation of these cells leading to phagocytosis and/or killing. In addition, complement can form a membrane attack complex, which creates holes in membranes of target pathogens and cancer cells, producing complement-dependent cytotoxicity (CDC). IgG antibodies are synthesized following immunoglobulin gene rearrangements, with switches in Fc domains, as the B cell matures in response to T-cell help. IgG antibodies usually have higher affinity, and can be found in the extracellular space as well as in the blood. IgG1 and IgG3 antibodies in humans are especially effective at activating complement and also at sensitization of pathogens for killing by NK cells, macrophages, and other cells with complement receptors and immunoglobulin Fc receptors.

Opsonization for ingestion and destruction by phagocytes can occur through complement activation, but also occurs directly as a consequence of engagement of Fc receptors on phagocytic cells. Antibodies complexed to antigen bind to Fc receptors, which can lead to activation signals through activating Fc receptors (e.g., FcRIII), but activation can be countered by IgG binding to the inhibitory Fc receptor, FcRIIB. Fc receptors, which are bound effectively by IgG1 and IgG3 subclasses of human antibodies, are expressed on monocytes, macrophages, NK cells, neutrophils, mast cells, and other cells. Cross-linking of Fc receptors leads to activation of the cells, in some cases leading to antibody-dependent cell-mediated

cytotoxicity (ADCC) of tumor cells through production of cytotoxic molecules, e.g., perforin and granzymes by NK cells and reactive molecular species by macrophages. Monoclonal antibodies are commonly used for cancer therapy. Antitumor effects can be in part mediated by antibody binding to critical molecules on the surface of tumor cells, for example by inhibiting tumor cell attachment or growth receptors. However, generally interactions of antibody with cell antigen are not very effective unless Fc receptor-mediated effector mechanisms are also activated.

Cellular Immunity

T lymphocytes recognize processed (digested) molecules that complex with MHC molecules within antigen-presenting cells. The antigen/MHC molecules are then trafficked to the cell surface for recognition by T-cell receptors, which are encoded by genes of the immunoglobulin family. Similar to generation of antibodies, great diversity of T-cell receptors is generated by rearrangements of these immunoglobulin family genes. Each monoclonal T-cell receptor must bind to its cognate antigen/MHC complex presented on the surface of antigen-presenting cells. Signaling from the T-cell receptor following engagement of antigen/MHC complex is insufficient to activate the T cell. Additional signals are required (co-stimulatory signals or “signal 2”). The most important co-stimulatory signal in T cells comes from the T-cell surface molecule CD28, which engages B7 molecules (CD80 and CD86) on antigen-presenting cells. Engagement of T-cell receptor by antigen/MHC in conjunction with CD28 engagement of B7 is sufficient to activate naïve T cells. Interestingly, within several days following T-cell activation, a second molecule, CTLA-4, appears on the T-cell surface to provide a brake to the T-cell response. CTLA-4 also binds B7 molecules, but with much higher affinity, therefore displacing CD28 activation signals. CTLA-4 signaling leads to down-regulation of the T-cell response. A variety of other co-stimulatory molecules are up-regulated on the surface of activated T cells, including OX40 and 4-1BB, which promote survival of T cells and help generate long-lived T-cell memory responses. Once T cells are activated by professional antigen-presenting cells (primarily dendritic cells), they gain a variety of effector functions, including the production of cytokines and cytotoxic molecules, which lead to death of target cells. Recently, a cell type combining properties of NK cells and T cells, called NKT cells, has been characterized. NKT cells can rapidly produce cytokines and also cytotoxic effector molecules in response to cognate antigen, and remarkably recognize lipid antigens presented by MHC-related molecules on antigen-presenting cells.

Antigen-Presenting Cells

Dendritic cells, the prototype professional antigen-presenting cells, sit at the crossroads of innate immunity and acquired immunity. These are phagocytic cells that sit on epidermal surfaces, including skin and mucosal membranes, constantly sampling their environment to search for infectious organisms. Although dendritic cells continuously ingest molecules from their environment, uptake of antigen is insufficient to activate dendritic cells. Rather, dendritic cells have a set of receptors, most notably the toll-like receptors (TLRs), which can recognize lipid-containing molecules and CpG-rich DNA and poly-U RNA sequences produced specifically by microbial organisms. Engagement of TLR signals for activation of the dendritic cell, with increased expression of MHC and B7 molecules, and movement of cells with captured antigen to draining lymph nodes. It is in draining lymph nodes that dendritic

cells activate appropriate T cells that recognize that particular antigen presented by MHC molecules. Subsequently, activated T cells can then travel from the draining lymph node to distant sites of infection or tumor to carry out the effector functions. One of the central problems for cancer immunology is that dendritic cells may ingest and process cancer antigens, but without activation through TLRs or other receptors, the dendritic cells remain incapable of activating T cells (because of insufficient expression of co-stimulatory molecules, such as B7) and do not move to draining lymph nodes. In fact, insufficiently activated dendritic cells presenting antigens can induce anergy, a form of immune tolerance where T cells become paralyzed and incapable of responding to cognate antigens. This is one of the mechanisms used to maintain immune tolerance to self to prevent autoimmunity, but also presents a major hurdle for cancer immunity. Cancer cells do not have any readily apparent mechanism to activate dendritic cells, although several self molecules, including heat shock protein, hyaluronate, and uric acid crystals, have been suggested to activate dendritic cells.

Helper and Regulatory T Cells

Several types of T cells are activated by dendritic cells, and which type is influenced by whether antigens are presented by MHC class I or MHC class II molecules on antigen-presenting cells. MHC class I molecules complexed with antigen stimulate CD8+ T cells that are cytotoxic and kill target cells (infected cells or tumor cells). Antigens presented by class II MHC molecules stimulate CD4+ helper T cells. Helper T cells produce chemokines and cytokines to help recruit and orchestrate other components of the immune system. Helper T cells come in several “flavors,” and different cytokines in the milieu determine what type of T cell is generated. Each type of helper T cell mediates different types of immune responses with different characteristics. Th1 T cells produce interferon (IFN)- γ to activate cytotoxic T cells and macrophages for *cellular immune responses*. On the other hand, Th2 helper T cells produce interleukin (IL)-4 and other cytokines that favor antibody responses, or *humoral immunity*. The newly discovered Th17 CD4+ T cell produces IL-17 to mediate inflammatory autoimmune diseases, such as arthritis, colitis, and encephalitis, and may play a role in cancer pathogenesis, either by promoting cancer progression or by destroying tumors. Another type of CD4+ T cell restricted by MHC II presentation negatively regulates immune responses. These are regulatory T cells, or Tregs. Tregs recognize self antigens, are dependent on IL-2, and produce inhibitory molecules such as IL-10 and transforming growth factor- β . Th1 cellular immunity may be particularly effective at attacking tumors in tissues, while humoral immunity may be better at controlling circulating metastatic tumor cells. Infiltration of ovarian cancers and other cancers by Treg cells is associated with a poorer prognosis (11–13).

Cancer Immunity and Immunotherapy

The notion that both the innate and acquired immune arms of the immune system can recognize and reject cancer had been controversial over the last hundred years. Careful studies over the past 3 decades have shown that the immune system can recognize and destroy cancers, usually involving interactions between multiple arms of the immune system. For instance, simple recognition by T cells, antibodies, or NK cells is usually not sufficient to reject cancers. Cytotoxic T cells and NK cells produce soluble and cell surface molecules that induce death

of target tumor cells. Helper T cells can produce cytokines and chemokines that not only recruit cytotoxic T cells or B cells to make antibodies, but also inflammatory cells which mediate tissue destruction. Antibodies can activate NK cells, macrophages, or other cells that have receptors for the antibodies' Fc domain, leading to activation of the recruited cells, a mechanism implicated in the antitumor effects of monoclonal antibody therapies. Antibodies can also activate complement proteins in the blood that can directly kill tumor cells and activate inflammatory cells at the tumor site.

Thus, based on solid evidence that the immune system can recognize antigens on tumor cells and that immunity is sufficient to destroy tumors, strategies are being developed for *immunotherapy*. These approaches can be broadly divided into three groups. First, *immune modulation* uses nonspecific approaches to treat cancer. Examples include cytokines such as IL-2, IL-12, interferons, BCG (*Bacillus Calmette-Guérin*, an attenuated *Mycobacterium* strain used successfully for treatment of early recurrent bladder cancer), and other microbial products. This approach tends to rely on components from the innate immune arm. *Passive therapy* refers to the transfer of specific components from the acquired immune system to the host with cancer. The best examples are monoclonal antibodies directed against antigens expressed on the surface of cancer cells. Rituximab against the CD20 antigen expressed by normal B cells is an effective part of the armamentarium for treatment of B-cell lymphomas, and trastuzumab (Herceptin) has been approved for treatment of breast cancer in combination with chemotherapy. Although the antitumor effects of trastuzumab in part probably involve inhibition of signaling by the HER2 tyrosine kinase oncogene, evidence strongly supports a major role for immune activation of Fc receptor-positive cells by both rituximab and trastuzumab (14).

A second example of passive immunotherapy is adoptive cellular therapy, where cells from the blood or bone marrow donor are purified, cultured, and/or manipulated outside the body and reinfused into the same patient (autologous) or a different patient (allogeneic). Cellular therapy has particularly focused on T cells and more recently on NK cells. Recent strategies have used genetic approaches to transduce T cells with receptors against tumor antigens (using either cloned T-cell receptors or antibody Fv regions to determine antigen specificity linked to intracellular signaling domains). In addition, genetic approaches are exploring transduction of T cells with genes encoding co-stimulatory molecules such as CD28 or 4-1BB.

Finally, active immunization refers to vaccines that trigger the patient to make her own immune response. Both passive and active immunotherapy must be directed against specific antigens on cancer cells.

Immunotherapy is already a routine part of cancer treatment (e.g., interferons, IL-2, BCG, monoclonal antibodies, and adoptive cellular therapy as part of allogeneic bone marrow transplantation). Potential difficulties remain in developing new immunotherapies, including insufficient activation of dendritic cells by cancer cells, inhibition of responses by Treg cells, and both intrinsic and extrinsic mechanisms that down-regulate T-cell responses, e.g., signaling through CTLA-4. These checkpoints all participate to dampen immune responses against cancer. On the other hand, identification of these checkpoints is leading to development of strategies with the potential of overcoming these barriers. Vaccines need to incorporate immune adjuvants that can sufficiently activate dendritic cells, often using microbial products. Therapeutic strategies to target Tregs are being assessed preclinically and clinically, including chemotherapy and new drugs targeting the CD25 molecule expressed by Tregs. Blockade of CTLA-4 by monoclonal antibodies has led to responses in patients

with ovarian cancer, melanoma, and other cancers. Passive therapy with monoclonal antibodies or with adoptive cellular treatments may be able to bypass some of these checkpoints.

Five groups of antigens have been defined on cancer cells that are recognized by the immune system: (a) Differentiation antigens, expressed by cancer cells and their normal cell counterparts; for instance, antigens expressed by ovarian carcinomas and normal ovarian epithelium are differentiation antigens. (b) Germ cell antigens, expressed by germ cells, particularly sperm, and silenced in normal adult somatic tissues, but re-expressed by certain tumors, commonly called cancer-testis antigens. (c) Genetic mutations and other alterations, such as translocations. (d) Over-expressed antigens, such as Her2 or the alpha isoform of the folate receptor. (e) Viral antigens, such as antigens encoded by oncogenic human papillomavirus.

In summary, cancer immunology has begun to create a firm scientific footing over the last few decades. In particular, identification of molecules on cancer cells that are recognized by the immune system provides new strategies for passive immunotherapy and vaccination. A number of clinical trials are in various stages of development to explore these strategies.

IMMUNOMODULATION AND CYTOKINE THERAPY

Cytokines play important roles in immune modulation. Many cytokines, including IL-2, IL-3, IL-4, IL-6, IL-10, IL-12, tumor necrosis factor- α (TNF- α), macrophage colony-stimulating factor, and IFNs, have been studied for their roles in tumor treatment. Some of these cytokines (IL-2 and IFN- α) have been approved by the U.S. Food and Drug Administration (FDA) specifically for the treatment of melanoma and renal-cell carcinoma.

Gynecologic cancers, particularly ovarian cancer, provide a unique environment for cytokine therapy in that the peritoneal cavity is a rich milieu for the elaboration of cytokines (15). The bulk of ovarian cancer occurs in the peritoneal cavity, making the regional administration of biologic therapy theoretically attractive. Distinct patterns of cytokine expression have been observed between the tumor and peritoneal compartments. Some of these cytokines may be counter-regulatory components of T-lymphocyte networks that have the potential to either augment or inhibit host antitumor responses (16). The successful outcome of cytokine treatment in ovarian cancer may be the result of a number of mechanisms. Whereas some cytokines may inhibit tumor cell growth, down-regulating the production of growth and survival factors, other cytokines may stimulate adaptive immunity or modulate angiogenesis. It is also possible that an individual cytokine has more than one role (17). The major cytokines that have been tested in gynecologic cancers are IFN- α , IL-2, and IL-12.

Interferons

Cytokine therapy in gynecologic cancers has been studied most extensively with IFN- α . There has been no head-to-head comparison between IFN- α and IFN- γ ; nonetheless, they appear to have similar antitumor efficacy in ovarian cancer (18–20), and most studies have focused on IFN- α . Although the exact mode of action of IFN in patients with ovarian cancer is unknown, several mechanisms have been proposed: (a) stimulation of NK cells and macrophages, both of which are known to have antitumor properties (21); (b) anti-angiogenic effects; and (c) inhibition of expression of dysregulated

oncogenes (such as *HER2/neu*) and thereby improving the responsiveness of cisplatin-resistant cells (22).

Initial trials with IFN evaluated administration of systemic IFN- α to patients with advanced ovarian cancer. The objective response rate was generally low at about 10% in a Gynecologic Oncology Group (GOG) study, where patients with measurable disease in whom higher priority treatment methods had failed were treated with IFN intramuscularly (23). The role of IFN- α as a maintenance treatment after initial surgical resection and chemotherapy was also evaluated by a randomized phase 3 study and was recently reported to be negative (24). The systemic IFN- α was also associated with frequent dose-limiting toxicity, including fatigue and flu-like symptoms, and moderate toxicity, such as leukopenia and thrombocytopenia. Because of the poor response rate and frequent toxicity of systemic administration, further studies were focused on IP administration of IFN- α . Multiple clinical trials with IP IFN therapy were carried out in women with persistent ovarian cancer (21,25–33). The surgically documented response rates from these studies ranged from 30% to 50%. An important finding was that the response rate was inversely correlated with tumor bulk and was not observed in patients with tumors >5 mm. For example, in a study where an overall response rate was 44%, patients with minimal residual disease (defined as <5 mm) had a response rate of 71%, whereas none of the four patients whose tumors were ≥ 5 mm responded (25). Systemic IFN toxicity developed following peritoneal absorption, and the maximal tolerable dose (MTD) was defined as 50 MU IP once per week (15). A randomized, placebo-controlled GOG phase 3 trial attempted to address the value of IP recombinant IFN- α as an adjuvant therapy in stage III ovarian patients with no evidence of disease at second-look surgery. Unfortunately, the study was prematurely terminated owing to slow accrual secondary to a decline of frequency of second-look surgery nationwide.

Some *in vitro* studies had suggested that IFN (both IFN- α and IFN- γ) could increase the sensitivity of cytotoxic drugs, such as cisplatin and doxorubicin, in cancer cells (19,34). It was found that IFN produced no significant change in the uptake of cisplatin. Studies indicated that the mechanism of IFN-induced sensitization in human ovarian cancer cell lines is multifactorial. Several phase 1 studies have been carried out to define the optimal dosing schedule of IP IFN- α in combination with cis-platinum-based chemotherapy (30,35,36). The MTDs were generally 20 to 30 MU/m² of IFN- α with 60 to 75 mg/m² cis-platinum. The most common toxicities were myelosuppression, flu-like symptoms, abdominal pain, and fatigue. In general, the combination of IP IFN- α with cis-platinum was less tolerated than IFN- α alone. Several phase 2 studies have evaluated the efficacy of this combination with response rates in the range of 20% to 50% (28,30,37). IP carboplatin with or without IFN- α was also evaluated in a randomized trial in 111 patients with advanced ovarian cancer and minimal residual disease who had previously had platinum-based front-line chemotherapy (38,39,40). Median survival was 22 and 29 months in the carboplatin arm and in the carboplatin plus IFN- α arm, respectively ($p = 0.9$). The IP IFN- α did not add benefit to the results achievable with IP carboplatin alone, while the toxicity and the costs of the combination were consistently higher. Based on data suggesting that cyclosporine A could potentiate the cytotoxic activity of platinum, a phase 2 trial was conducted with subcutaneous injection of IFN- α added to a continuous infusion of cyclosporine A combined with carboplatin in patients with recurrent ovarian cancer. Thirty patients with both platinum-sensitive and -resistant disease were included. Only three partial responses were seen, and toxicities included myelosuppression, nausea, vomiting, and headache. Insufficient clinical resistance reversal was observed to warrant further

investigation of this combination (39). Taking together all of these studies, there is no evidence to date showing that those combinations of IP IFN- α with cytotoxic chemotherapy provide any benefit over single agents. A more recent study with IP IFN- α chemotherapy in ovarian cancer patients with minimal residual disease reported a total complete remission rate of 49% (40). This somewhat higher response rate remains to be confirmed by prospective controlled trials.

The combination of IFN- γ with chemotherapy has also been evaluated. A randomized phase 3 trial evaluating cyclophosphamide and cisplatin for first-line therapy in 148 patients of a planned 200 with or without IFN- γ demonstrated a progression-free survival advantage of 17 versus 48 months ($p = 0.031$) in favor of the IFN- γ -containing arm. Accrual was halted early when taxane and platinum-based combination therapy became standard and power in the study was compromised. No statistically significant survival benefit was seen (41). A follow-up phase 1/2 study combining IFN- γ with the newer standard chemotherapy paclitaxel and carboplatin showed that the combination was safe and had a response rate of 71% as first-line treatment for ovarian cancer (42). Randomized trial results will be required to determine if a benefit exists for the addition of IFN- γ to standard therapy.

In cervical cancer, monotherapy with IFN- α had minimal activity (43,44). In a multi-institutional, prospective phase-2 clinical trial by the Eastern Cooperative Oncology Group (ECOG) evaluating the activity of IFN- α 2b in women with metastatic or locally recurrent cervical cancer, only 10% achieved a clinical response. Further studies had been focused on the combination of IFN- α and retinoids because of observed synergistic antiproliferative, differentiating, and anti-angiogenic activities in some human hematologic and solid-tumor systems (45,46,47,48). The proposed mechanisms include (a) the additive activation of transcription of a retinoic reporter gene (45); (b) the induction of higher levels of IFN- α -stimulated genes than the levels induced by either agent alone (46); (c) the up-regulation of HLA class I and intracellular adhesion molecule-1 (ICAM-1) molecules, inducing an additive effect on the expression of immunologically important surface antigens on human cervical cancer cells (47). An initial phase 2 study with this combination for untreated locally advanced cervical or uterine cancer patients yielded response rates of 50% to 58% (45). However, in pretreated recurrent cervical cancers, this combination appears to be less active, with response rates of 0% to 31% (49–52). Another study for patients with locally advanced cervical cancer showed a response rate of 47% with mild fever being the major toxicity (53). In addition, the combination of IFN- α with cytotoxic agents, namely, cisplatin plus 5-fluorouracil (5-FU), has also been evaluated in the treatment of cervical cancer (54). It was relatively well tolerated, as toxicity was comparable to that of cisplatin plus 5-FU alone with a major response rate of 31%. Recent studies have shown that concurrent cisplatin-based radiotherapy and chemotherapy have significantly improved survival in both early- and locally advanced-stage cervical cancer (4,5,55), and has now become the standard of care. Future studies may test whether addition of IFN- α and/or retinoic acid will provide additional benefit.

Regional therapy with IFN- α gel for vulvar intraepithelial neoplasia was also evaluated in a prospective, randomized, double-armed crossover study comparing IFN- α with and without 1% nonoxynol-9. An overall response rate of 67% was achieved, and the toxicity was lower than previously reported for topical 5-FU. These data support the hypothesis that IFN- α is an active agent in the treatment of vulvar intraepithelial neoplasia III (56). Intralesional IFN- α was also evaluated for cervical intraepithelial neoplasia (57). However, with the good surgical success rate, this approach has received less enthusiasm.

In summary, IP IFN- α is well tolerated, and while it has produced clinical responses in ovarian cancer patients with minimal residual disease, no randomized data has supported a survival benefit to date. The combination of IFN- α with standard cytotoxic agents adds toxicity without adding significant antitumor activity. The improved progression-free survival with IFN- γ in conjunction with platinum-based primary chemotherapy is intriguing, and the evaluation of IFN- γ in combination with current standard regimens in appropriately randomized and controlled trials is reasonable. Combinations of IFN and retinoic acid or chemotherapy may have clinical benefit in cervical cancer, and appropriate controlled trials could be considered.

Interleukin-2

IL-2 is a T-cell growth factor that plays a central role in the immune system. Initial studies of IL-2 in the treatment of ovarian cancer involved continuous intravenous infusion therapy for patients with minimal residual disease at second-look surgery. The toxicity was significant and about 86% required dose reduction (58). Subsequent studies had been focused on IP administration of IL-2. A phase 1-2 study (59) of IP IL-2 in patients with laparotomy-confirmed persistent or recurrent ovarian cancer after ≥ 6 courses of prior platinum-based chemotherapy had shown an overall response rate of 25.7%, with an overall 5-year survival probability of 13.9%. For the patients who responded to therapy, the median survival time had not been reached (range 27 to 90+ months) at the time of the report. This study also showed that IP IL-2 is better tolerated as a weekly infusion compared with a 7-day infusion. In the follow-up phase 2 study of outpatient weekly infusion of IP IL-2 in patients with persistent ovarian cancer after primary paclitaxel (Taxol) and platinum therapy in patients with minimal residual disease (<2 cm), 17.6% had a surgically documented response and 41% of patients had stable disease. This study suggests that IP IL-2 may have activity in persistent epithelial ovarian cancer and is well tolerated as an outpatient regimen (60). The combination of IL-2 and cytotoxic agents, for example, cisplatin, has been studied in mouse ovarian tumor models. In tumors that were minimally responsive to treatment with either of the drugs alone, combined local treatment with low doses of cisplatin and IL-2 resulted in an effective antitumor response with a complete response of 60%. Analysis of tumor-associated leukocytes showed that the combination of cisplatin and IL-2 resulted in enhanced nonspecific cytolytic activity of peritoneal leukocytes. Therefore, in the mouse model, combined local treatment with low doses of cis-platinum and IL-2 was more effective than cisplatin alone. Randomized data would be required to determine if similar efficacy exists in human ovarian cancer (61).

A disadvantage of frequent administration of high-dose IL-2 is the occurrence of dose-limiting side effects. Therefore, delivery of IL-2 from an expression plasmid has been evaluated for the treatment of ovarian cancer. IP treatment of ovarian tumors with an IL-2-expressing plasmid resulted in an increase in local IL-2 levels, a change in the cytokine profile of the tumor ascites, and a significant antitumor effect in a mouse model (62). A phase 1 trial with an IL-2 gene-modified tumor in refractory ovarian cancer patients was proposed and the result is not yet available (63).

In summary, IL-2-based therapy has been reported to be associated with long-term remissions in selected ovarian cancer patients as with other solid tumors. The treatment, however, is hindered by significant toxicity. Approaches to minimize toxicity and optimize efficacy are being tested. The combination of low doses of cis-platinum with IL-2 seems to be a promising strategy in mouse models and warrants clinical trials to assess efficacy in humans.

Interleukin-12

IL-12 is a cytokine mainly produced by activated monocytes, tissue macrophages, and B cells. It can induce IFN- γ and together with IL-2 becomes a potent activator of cytotoxic T lymphocytes and NK cells (64,65). Whereas IL-4 and IL-10 mediate the development of Th2-type immunity, IL-12 initiates the differentiation to the Th1 phenotype. In addition, IL-12 production can be negatively or positively regulated by cytokines. For example, IL-10 and IL-4 have been shown to inhibit the production of IL-12 (16,66), whereas IL-2 and IFN- α enhance its production. In addition, IL-12 has potent anti-metastatic and antitumor effects in several murine tumor models, as well as in human tumor cells *in vitro* and *in vivo* (65,67). IL-12 was better than IL-2 in enhancing the cytotoxicity against ovarian cancer cells of lymphocytes from ascites or peripheral blood from patients (68). IL-12 and IL-2 have a synergistic effect on the lymphokine-activated killer activity in peripheral blood mononuclear cells cultured in ovarian cancer ascitic fluid (69). It has been suggested that the antitumor effects of IL-12 involve enhanced IFN- γ production by antitumor T cells, their accumulation to tumor sites, and *in situ* IFN- γ production (70). In addition, IL-12 promotes IFN- γ -mediated up-regulation of adhesion molecules (vascular cell adhesion molecule [VCAM-1] and ICAM-1) on tumor-associated blood vessels, providing access for circulating lymphocytes (68). However, ascitic IL-12 has also been shown to be an independent prognostic factor for adverse outcome in ovarian cancer (71).

A phase 2 GOG clinical trial (72) evaluated intravenously administered recombinant human IL-12 in patients with recurrent or refractory ovarian cancer. The study showed that, as a single agent, IL-12 could be tolerated, and myelotoxicity and capillary leak syndrome were the major adverse events. However, the response rate was low, with no complete responders, and a partial response rate of 3.8%. IP administration of human recombinant IL-12 was also evaluated in patients with refractory ovarian and gastrointestinal malignancies after primary standard therapy (73). Among the 29 patients, two patients (one with ovarian cancer and one with mesothelioma) had no remaining disease at laparoscopy, eight patients had stable disease, and 19 had progressive disease. In this study, the dose-limiting toxicity was elevated transaminases. More frequent toxicities included fever, fatigue, abdominal pain, nausea, and catheter-related infections. Preclinical data had suggested that IL-12 may potentiate the activity of the HER2 monoclonal antibody trastuzumab. A phase 1 trial with this combination in HER2-positive malignancies in 15 patients showed no clinical evidence of increased activity with the combination with one complete response and otherwise disease stabilization as best response (74).

BASIS FOR ANTIBODY-MEDIATED THERAPY OF CANCER

Antibodies are the primary mechanism for eliminating infectious pathogens from the bloodstream. The effect of all commonly used vaccines against infectious agents is thought to be primarily a consequence of antibody induction. Antibodies are also ideally suited for elimination of circulating tumor cells and micrometastases. The importance of antibodies in mediating protection from tumor recurrence is well documented in experimental animals (75,76). Experiments involving administration of monoclonal antibody 3F8 against GD2 or induction of GD2 antibodies by vaccination after challenge with EL4 lymphoma (which expresses GD2) are two examples. Administration of 3F8 prior to intravenous tumor challenge

or as late as 4 days after tumor challenge results in complete protection of a majority of mice (76). Comparable protection from EL4 challenge was induced by immunization with a GD2-KLH conjugate vaccine. This timing may be comparable to antibody induction, or administration, in patients in the adjuvant setting after surgical resection of the primary or lymph node or peritoneal metastases, or after response to chemotherapy. In both cases, the targets may be circulating tumor cells and micrometastases.

There is also evidence in cancer patients that natural or passively administered antibodies in the adjuvant setting are associated with clinical benefit:

1. Natural antibodies (antibodies present in patient sera prior to vaccination) and vaccine-induced antibodies have been correlated with an improved prognosis. This is true for patients with paraneoplastic syndromes where high titers of antibodies against onconeural antigens expressed on particular cells in the nervous system and certain types of tumors have been associated both with debilitating autoimmune neurologic disorders and with delayed tumor progression and prolonged survival. Also patients with American Joint Commission for Cancer (AJCC) stage III melanoma and natural antibodies against GM2 ganglioside treated at two different medical centers have had an 80% to 100% 5-year survival compared to the expected 40% rate (77–79). Tumor vaccine-induced antibodies in the adjuvant setting against GM2 and several other melanoma antigens at four different medical centers, and against sialyl Tn (sTn) antigen in adenocarcinoma patients, have been correlated with prolonged disease-free interval and survival (reviewed in Ref. 80).
2. A series of monoclonal antibodies against antigens expressed at the cell surface of cancer cells has now been shown to have clinical efficacy in the advanced disease setting and has been approved by the FDA. These include rituximab, ibritumomab, and tositumomab for B-cell lymphomas; gemtuzumab for acute myelocytic leukemias; alemtuzumab for chronic lymphocytic leukemias; cetuximab for colorectal and head and neck squamous cell carcinomas; and trastuzumab for breast cancer. It is likely that all of these mAbs would be more effective if administered in the adjuvant setting. This appears to be the case for trastuzumab. Treatment of patients with advanced *HER2/neu* positive breast cancers resulted in an overall response rate of 19% to 26% and response duration of

9 to 15 months, while treatment with trastuzumab in the adjuvant setting has resulted in a 50% decrease in the recurrence rate at 1-year median follow-up and at 3 years (81).

Hence, passively administered and vaccine-induced antibodies have been shown to correlate with clinical responses or improved disease-free and overall survival in the mouse and human. Preclinical studies strongly suggest that the optimal setting for antibody therapy is the adjuvant setting. Since the great majority of gynecologic cancer patients are initially rendered free of detectable disease by surgery and/or chemotherapy after initial diagnosis, administration of mAbs or vaccines inducing antibodies may have broad applicability. There are advantages to each approach. Titers of anticancer antibodies are generally acutely higher after administration of mAbs, and mAbs can be generated against virtually any antigen. On the other hand, human antimouse and anti-idiotypic antibodies may limit the usefulness of continued administration of mAbs, and maintenance of antibody titers with vaccines is more practical and less expensive than with mAbs.

Target Antigens for Antibodies

We have screened a variety of malignancies and normal tissues with a series of 40 mAbs against 25 antigens that were potential target antigens for immunotherapy of cancer (82–84). Since recognition of antigens on living cancer cells by antibodies is largely restricted to the cancer cell surface, the focus was on cell surface antigens. Antigen expression on ovarian and endometrial cancers and several other malignancies for the seven defined antigens expressed strongly in at least three of five biopsy specimens are shown in Table 6.1 (82–86). The antigens expressed by ovarian and endometrial cancers are similar, and quite different from those expressed by melanomas, and similar to, although not the same as, those expressed by prostatic cancers. The 18 excluded antigens (including CEA and *HER2/neu*) were expressed in one or zero of five specimens. With the possible exception of GM2 (for which there are no previous reports), our results are consistent with the separate studies describing the expression of these individual ovarian cancer antigens from other centers. Our studies identify ganglioside GM2 as an antigen present on many malignancies, which is a conclusion supported by an increasing number of recent reports (87,88).

FIGURE 6.1. Glycolipid and glycoprotein antigens expressed at the cell surface of gynecologic cancers. *Symbols:* ◇ = sialic acid; □ = fucose; ○ = glucose, galactose, N-acetyl-galactosamine, or N-acetylglucosamine.

The expression of these eight antigens on normal tissues is essentially restricted to apical epithelial cells at luminal borders, a site that appears not to be accessible to the immune system. Administered mAbs to several of these antigens have induced clinical responses but have not induced autoimmunity, indicating that antigen in these locations may not be accessible to antibodies. The exception is GM2, which is also expressed in the brain, although far less than the related ganglioside GD3, where the blood-brain barrier prevents autoimmune toxicity (infusions of monoclonal antibodies against GD3 have been associated with many clinical responses and no incidents of central nervous system [CNS] toxicity). BR96 recognizes a broader specificity than Lewis-y (Le^y) (89,90), also including Lewis-X (Le^x), which explains the reactivity with polymorphonucleocytes (which express Le^x but do not express Le^y). Hemorrhagic gastritis has been reported after high doses of BR96 (against Le^y), possibly related to a broader specificity of BR96, since treatment with another mAb, 3S193, against Le^y has not been associated with these toxicities. The extensive expression of CA-125 in over 80% of serous and endometrioid ovarian cancers has been well documented since the early 1980s (91). Following the successful cloning of CA-125 and identifying it as a complex mucin, it has been termed MUC-16 (92–94). Contributing to tumor mucin specificity is the less intense glycosylation of tumor mucins than normal mucins, involving shorter carbohydrate chains. The simplified structures of these antigens in relation to the cancer cell surface lipid bilayer are shown in Figure 6.1.

There is now sufficient experience from clinical trials with vaccine-induced antibody responses against GM2, TF, sTn, MUC-1, and KSA antigens, and passive administration of

mAbs against sTn, MUC-16 (CA-125), and KSA to draw conclusions about the consequences of antigen distribution on various normal tissues. GM2 exposure on cells in the brain and GM2, sTn, TF, MUC-1, and KSA antigen expression in cells at the secretory borders of epithelial tissues induce neither immunologic tolerance nor autoimmunity once antibodies are present, suggesting that they are sequestered from the immune system. Against this background, GM2, T, Tn, sTn, Globo H, MUC-1, MUC-16 (CA-125), and KSA all appear to be good cell surface targets for active immunotherapy with vaccines that induce antibodies, or for passive immunotherapy with monoclonal antibodies.

Antibody Selection

Tumor cells have defined antigens and receptors on the cell surface that may differ from those present on normal cells. mAbs directed against these targets have potential diagnostic and therapeutic applications. The selection of the optimal antigen-antibody system for clinical development depends on a number of biologic and technical factors, including antigen density, pathways of catabolism, tumor specificity, heterogeneity of expression, effector mechanisms, and binding affinity. Antigens that have been used for immune targeting of gynecologic malignancies with mAbs for antibody development include (a) over-expressed tumor antigens (e.g., CA-125, TAG-72 [sTn], MUC-1, polymorphic epithelial mucin [PEM], folate-binding protein [FBP], and Lewis-Y); (b) over-expressed growth-factor receptors (e.g., *HER2/neu* [erbB2], epidermal

TABLE 6.2
MONOCLONAL ANTIBODIES TARGETING GYNECOLOGIC MALIGNANCIES

Targeted antigens	Antibody examples	Therapeutic considerations
Mucins CA-125 (MUC-16)	OVAREX (B43.13), OC125 ACA125 (anti-id OC125)	Ovarian cancer

CEA, carcinoembryonic antigen.

growth-factor receptor [EGFR], and vascular endothelial growth factor [VEGF]); and (c) mutated tumor-suppressor genes (e.g., p53 and *BRCA-1*). Binding of mAb to these antigens may have antitumor effect generated through these possible mechanisms: (a) antibody-mediated recruitment of human effector mechanisms *in situ*, ADCC against the tumor cells; (b) development of tumor-specific cytotoxic T lymphocytes (CTLs); (c) activation of the complement system; (d) stimulation of granulocytes cytotoxic to the cancer cells; and (e) induction of an anti-idiotypic antibody that can elicit active immunity. The available antibodies and their targeting antigens that have been tested in gynecologic malignancies are summarized in Table 6.2.

Obstacles in Antibody Therapy and Engineering Strategies

Despite decades of efforts, there are currently few non-immunogenic antibodies against cell-surface antigens that are of therapeutic significance in gynecologic cancers. The major obstacles have been (a) development of human anti-murine antibodies (HAMA) that form immune complexes with subsequent antibody administration, which results in altered patterns of catabolism and host toxicity; (b) limited immunobiologic activity of nonconjugated antibody; (c) expression of antigens (e.g., growth-factor receptors on a wide range of normal host tissue); and (d) heterogeneity of antigen expression among different histologies and patients. Various engineering strategies have been tested to overcome these obstacles.

Overcoming HAMA

Because murine mAbs are xenotypic proteins, the immunocompetent human will recognize them as foreign and generate antibody responses (HAMA) against them. Although the resultant immune complexes may potentially boost the immune response to the antigen epitope, leading to enhanced recognition by the immune system and an increased processing by dendritic and antigen-presenting cells, the more likely outcome is increased blood clearance and less effective tumor

targeting, precluding repeat administration. This has been one of the major obstacles in the application of murine mAbs to the treatment of human cancers. To minimize the effect of HAMA, various strategies have been explored, including construction of smaller antibody fragments, design of recombinant antibodies with substitution of human for murine sequences, and direct cloning of human variable regions with the desired binding specificity. Chimeric or fully humanized antibodies have been developed to reduce HAMA responses associated with the administration of murine mAbs, with the concomitant possibility of manipulating the effector function (95). The reduced immunogenicity of humanized antibodies allows their repeated administration in many cases. Initial efforts involved development of a mouse-human chimeric mAb by replacing the murine immunoglobulin heavy- and light-chain constant regions with those of the human Ig (chimerization).

A widely used procedure for the humanization of xenogeneic antibodies is based on grafting the hypervariable or complementarity-determining regions (CDRs) of a xenogeneic antibody onto the human Ig framework. With this approach, a minimally immunogenic variant of humanized anti-CC49 mAb has been developed (96). Construction of smaller molecules has also been explored to decrease HAMA. Immunoglobulins have been engineered to retain only the domains that are required for antigen binding and/or effector functions and have also been rebuilt into multivalent, high-affinity reagents to achieve the desired efficacy (97). Studies with different forms of mAbs have shown that antibody fragments of lower molecular weight can penetrate tumor faster than whole IgG molecules (98,99). A humanized CC49 single-chain (scFv) construct (hu/muCC49 scFv) has been prepared, where the murine CC49 variable light chain was entirely replaced by a homologous human light chain. Pharmacokinetic studies in mice showed rapid blood and whole-body clearance with a half-life of 6 minutes, and biodistribution studies demonstrated equivalent tumor targeting to human colon carcinoma xenografts for muCC49 and hu/muCC49 scFv (100), indicating that it has potential diagnostic and therapeutic applications for TAG72-positive tumors. mAb constructs that have a deletion of the CH₂ portion of the constant region have been created: h-ΔCH₂CC49 is a humanized CC49 with its CH₂ region deleted, with identical affinity for TAG-72 (101). The clinical characteristics of these constructs

and conjugates are being tested. Conjugates of these constructs with radionuclides, for example, ^{225}Ac , have also been made (102). A more recent technology uses immunization of transgenic mice with human immunoglobulin genes (and deleted mouse immunoglobulin genes) to generate fully human monoclonal antibodies.

Antibody Conjugates

In view of the limited efficacy of unconjugated antibody, efforts have been made to optimize the antitumor activity by conjugating with radionuclides, toxins, cytotoxic drugs, or second antibodies (Table 6.3) (15). Combinations of multiple antibodies to

TABLE 6.3

RADIONUCLIDES, TOXINS, AND CYTOTOXIC AGENTS USED AS mAb CONJUGATES

Reagents	Mechanistic considerations	Therapeutic considerations
RADIONUCLIDES		
^{125}I	Auger electron antitumor effects	Standard iodination chemistry, subject to dehalogenation.
^{131}I	$T_{1/2}$ 60 d 364 KeV γ (imaging) 606 KeV β (therapy) $T_{1/2}$ 8 d	Auger effects limited to 15 Å radius. β penetrates ~1 mm and can kill adjacent antigen-negative cells. γ associated with wider penetration and dose-limiting marrow suppression.
^{90}Y	2.27 MeV β $T_{1/2}$ 2.7 d	Requires chelation. Almost pure β penetrates ~3 mm. Free ^{90}Y localizes to bone, associated with dose-limiting marrow suppression.
^{212}Bi	High LET 6.2 MeV α $T_{1/2}$ 1 h	α penetrates only several cell diameters (~20–100 μm). Toxicity not oxygen dependent, increased energy deposition compared to β .
^{211}At	High LET 6.0 MeV α $T_{1/2}$ 7.2 h	^{212}Bi has very short $T_{1/2}$ (demanding rapid localization), requires chelation, and can be generated in laboratory. ^{211}At requires a cyclotron for generation, and can be directly conjugated.
^{186}Re	137 KeV γ (imaging) 1.1 MeV β (therapy) $T_{1/2}$ 3.7 d	Techniques available for direct conjugation or chelation. Low abundance γ suitable for imaging.
^{177}Lu	208 KeV γ (imaging) 0.5 MeV β (therapy) $T_{1/2}$ 6.7 d	Evaluated as chelate. Low abundance γ suitable for imaging.
TOXINS		
PE	Bacterial <i>Pseudomonas</i> exotoxin A. Enzymatic inactivation of protein synthesis by ADP ribosylation of elongation factor 2.	Both PE and RA require internalization and cytoplasmic translocation for protein synthesis inhibition. PE requires acid hydrolysis. No mechanisms for killing adjacent antigen-negative or non-targeted cells. Recombinant PE and RA fragments available for chemical conjugation or construction of single-chain chimeric proteins.
RA	Ricin A-chain from castor beans. N-glycosidase-mediated inactivation of 28S ribosomal RNA.	
CYTOTOXIC AGENTS		
DOX	Doxorubicin-associated free-radical formation, DNA intercalation, inhibition of topoisomerase-II	Toxicity requires internalization and acid hydrolysis to release free DOX.
Anti-CD	Effector activation via the T-cell receptor complex	Requires simultaneous presence of activated effector cells, antibody, and antigen-positive tumor. Indirect cytokine effects, recruitment of inflammatory cells, and enhancement of immunity can occur.
Anti-FcR	Effector activation via NK/LGL Fc γ RIII complex	
Biotin	Multistep amplification using biotin-streptavidin system	Permits adding second- and third-step reagents with high affinity for the primary antibody. Allows for systemic clearing with increased tumor localization and tumor-to-normal-tissue ratios.

compensate for antigen heterogeneity in ovarian carcinomas have been evaluated. The choice of conjugates and specific antibodies is influenced by features such as antigen internalization, lysosomal degradation, shedding, and heterogeneity of expression. Although internalization is a prerequisite for cellular toxicity of some drug and toxin conjugates, it may result in reduced efficacy and increased host toxicity due to intracellular catabolism (15).

Radionuclides

A variety of radionuclides have been conjugated with antibodies for imaging and treatment. The optimal radionuclide for cancer therapy is not easy to define (15). Radioconjugates with β (i.e., ^{131}I and ^{90}Y) and α (i.e., ^{211}At and ^{212}Bi) emitters have been proposed for regional therapy of peritoneal implants. Estimates of dosimetry suggest that adequate therapy (i.e., 20 Gy) could be delivered to tumors with a depth $<300\ \mu\text{g}$ using ^{211}At , $<0.1\ \text{cm}$ using ^{131}I , and $<1\ \text{cm}$ using ^{90}Y when conjugated to antibodies. Delivery of effective radiation dose is greatly influenced by the extent of tumor binding, depth of tumor penetration, catabolism, and relative distribution between tumor and normal tissues. Although internalization is usually detrimental owing to enhanced catabolism, internalization is required for maximal Auger electron chromosomal toxicity from ^{131}I owing to an extremely limited sphere of penetration (15). At the present time, β emitters are considered to be the optimal candidates for radiotherapy, as they avoid excessive systemic exposure associated with γ radiation. Conjugates with ^{131}I have been most extensively studied because of isotope availability, ease of chemical conjugation, and ability to perform γ imaging and β therapeutic studies with the same reagent. There has been an interest in finding alternatives to ^{131}I due to the nonspecific γ irradiation, bone marrow toxicity, and the tendency for rapid dehalogenation, which limits tumor retention. ^{90}Y provides 100% decay suitable for therapy over several millimeters (15), although it has no γ emission useful for imaging. Lutetium-177 (^{177}Lu) is a rare earth metal with a physical half-life of 6.7 days and β emissions that penetrate 0.2 to 0.3 mm in soft tissue. ^{177}Lu also emits two relatively low-abundance, low-energy rays (113 to 208 keV) that allow imaging with a gamma camera, but pose less radiation hazard to health care personnel compared with ^{131}I (103).

Immunotoxins, Drugs, and Cytokines

An important factor limiting the treatment of cancer is the low therapeutic index, which may be improved by targeted delivery of cytotoxic agents (Table 6.3) (15) to tumor sites. mAbs have been attractive carriers for tumor-directed therapy by increasing the intratumoral concentration of targeted agent, and to minimize toxicity by reducing systemic exposure (104). Drugs, toxins, and cytokines conjugated to mAb have been evaluated in gynecologic cancers. Immunotoxins incorporate an antibody-binding domain and a toxin joined by a chemical cross-linker, peptide, or disulfide bond. The specific targeting afforded by mAbs and the relative potency of the toxin moiety present potential therapeutic advantages. The two most studied toxins have been *Pseudomonas* exotoxin A (PE), originally isolated from bacteria, and ricin, initially extracted from castor beans (15). In general, there has been less enthusiasm for antibodies conjugated with conventional cytotoxic drugs owing to concerns about quantitative drug delivery compared to treatment with maximally tolerated doses of the drug alone (15). The major drug conjugate that has been investigated in ovarian cancer is BR96-DOX, an immunoconjugate of doxorubicin (DOX)

and an anti-Lewis-Y mAb. Studies utilizing these antibody conjugates are discussed in respective sections below and summarized in Table 6.4. Ref. (103, 105–130).

CLINICAL TRIALS WITH MONOCLONAL ANTIBODIES

Antibodies Targeting CA-125: OvaRex (mAb B43.13) and OC125 Conjugates

CA-125, a tumor-specific antigen that is found in 97% of patients with late-stage ovarian cancer, was first described by Bast et al. as an antigen that is elevated in the serum of patients with epithelial ovarian cancer (131). CA-125 has been cloned and identified as a mucin MUC-16 (89); its function is not clear. *In vitro* studies suggested that CA-125 can produce a dose-dependent increase in invasiveness in a collagen gel invasion assay (132). It has also been shown that CA-125 can be induced by IL-1 β , TNF- α , and TGF- α , whereas glucocorticoids and TGF- β can suppress the release of CA-125 from ovarian cancer cells (133). These findings may have a clinical implication on the measurement of CA-125 levels as an indicator of response to cytokine therapy (134). Two mAbs against CA-125 have been used in a series of clinical trials: mAb B43.13 (OvaRex) and OC125 (Table 6.4) (103, 105–130).

mAb B43.13 (OvaRex)

mAb B43.13, a murine anti-CA-125 mAb, was radiolabeled with $^{99\text{m}}\text{Tc}$ for detection of recurrent ovarian cancer. The therapeutic potential was serendipitously discovered when a retrospective study noted that patients who received radiolabeled mAb B43.13 for immunoscintigraphy exhibited unexpected prolonged survival times (95,135). It has been speculated that mAb B43.13 binds to circulating CA-125 antigens to form complexes that are recognized as foreign because they contain the foreign antibody. Several *in vitro* and *in vivo* studies have been carried out to explore the robustness of this finding. A series of prospective placebo-controlled and open-label studies in patients with ovarian cancer was carried out to assess therapeutic efficacy of naked mAb B43.13 or in combination with cytokines (e.g., IFN) or chemotherapy. Immunologic parameters in 100 patients with ovarian cancer who had been injected with mAb B43.13 were studied to explain the serendipitous observation of prolonged survival after such treatment (136). In addition to CA-125-specific humoral and cellular responses, IFN- γ was also found to be induced in those patients receiving the antibody. *In vitro* studies indicated that the expression of MHC I, MHC II, and ICAM-1 in ovarian tumor cells was up-regulated in response to IFN- γ . Such tumor cells were also found to be more sensitive to CA-125-specific cytotoxic T cells compared with cells that were not incubated with IFN- γ . It was further noted that the clinical outcome was attributed to the induction of an anti-idiotypic network by this antibody (135). In addition, these anti-CA-125 antibodies were able to conduct Fc-mediated tumor-cell killing (ADCC). In a multivariate analysis of clinical and immunologic profiles of 60 patients exposed to labeled mAb B43.13 compared to a contemporaneous historical cohort of 247 patients, the patients in the mAb B43.13 group were 2.7 times less likely to die from ovarian cancer than were control patients managed with chemotherapy alone ($p < 0.001$) (137). The mAb B43.13 group had a twofold higher median survival time compared with the control group. The 5-year survival rate was 40.7% in the mAb B43.13 group compared with 11.4% in the control group. Survival correlated with changes in three humoral immune parameters, including nonspecific HAMA responses,

Note: ADCC, antibody-dependent cell-mediated cytotoxicity; CR, complete response; DFS, disease free survival; DLT, dose limiting toxicity; EDTA, ethylenediamine tetraacetic acid; HACA, human anti-chimeric antibodies; HAAMA, human anti-murine antibodies; IP, intraperitoneal; IV, intravenous; MTD, maximal tolerable dose; POD, progression of disease; PR, partial response; SC, subcutaneous; SD, stable disease; TTP, time to progression.

Ab2, and anti-CA-125 antibody development. This study suggested that mAb B43.13 exerts its therapeutic effects via stimulation of specific and nonspecific immune responses.

mAb B43.13 (OvaRex) in Recurrent Disease

Ehlen et al. reported a single-center, open-label trial to assess the induction of tumor protective immunity utilizing mAb B43.13 in a cohort of 13 patients with advanced chemorefractory recurrent ovarian cancer (105). It was noted that HAMA induction occurred in 12 of 13 patients, Ab2 was found in approximately two thirds of the patients, and anti-CA-125-specific antibodies were elicited in one third of the patients. These immunologic data demonstrate that the injection of a murine antibody to CA-125 can induce CA-125-specific antibody and T-cell responses even in late-stage cancer patients with substantial tumor burden. Administration of the antibody was well tolerated without infusion-related adverse events. Notably, six patients survived at least 50 weeks and three patients experienced a prolonged period of disease stability with survival approaching 2 years. The use of mAb B43.13 in combination with second-line chemotherapy in patients with recurrent ovarian cancer has been evaluated (106–109). The treatment has been well tolerated without significant added toxicities. Immune responses in this disease setting included HAMA and Ab2, as well as T-cell responses to CA-125 and autologous tumor cells. CA-125 measured prior to dosing of the antibody was noted to decline prior to additional chemotherapy. Patients remained progression-free for prolonged periods of time. Subsequent or concurrent chemotherapy did not abrogate the induced immune responses, and T-cell responses to autologous tumor actually increased. Patients with a T-cell response to CA-125 on the autologous tumor showed a highly significant benefit in time to progression (TTP) and survival compared with non-responders ($p < 0.01$). Furthermore, the T-cell responses were MHC class I and II restricted, indicating the activation of CTLs and T helper cells. Chemotherapy did not ablate the immune response as traditionally thought. A long-term follow-up study of 49 of the 218 patients who received injections of mAb B43.13 demonstrated periods of disease stabilization and showed that the magnitude of immunologic responses to mAb B43.13 assessed by serial evaluation of HAMA levels, anti-CA-125 antibody levels, and T-cell responses appeared to correlate with the clinical impact of treatment. A significant survival benefit post-antibody treatment was observed in patients with HAMA responses $>2,000$ ng/mL ($p = 0.001$). Long-term survival was noted in 7 of these 49 patients who remained alive with disease 3 to 6 years after receiving mAb B43.13. These results suggest that treatment with mAb B43.13 can stimulate immune responses even in patients with relapsed ovarian cancer, and activity is associated with disease stabilization in some patients (138).

mAb B43.13 (OvaRex) in Consolidation

One of the first randomized, double-blind, placebo-controlled studies of mAb B43.13 for adjuvant consolidation in epithelial ovarian cancer was reported by Bookman et al. (111). In this study, 55 patients who had no clinical or radiographic evidence of disease after surgery and first-line chemotherapy, but presented elevated CA-125 levels (>35 U/mL), were randomized to receive either mAb B43.13 or placebo. Immune responses were induced at a frequency similar to that reported by other studies. However, the limitation here was that the study population relapsed rapidly, and treatment was discontinued upon clinical relapse. Nevertheless, the subpopulation of patients who had time to mount an immune response had a trend of improved survival, with a 6-month progression-free

survival of 75% for the mAb B43.13-treated group and 35% for the placebo cohort. The impact of different schedules on immune responses and clinical outcomes has been evaluated in a study of 102 patients with stage III-IV epithelial ovarian cancer treated with surgery and chemotherapy. Patients were randomized to adjuvant mAb B43.13 in three different schedules. Antibody responses specific for the constant (HAMA) and variable (Ab2) regions of mAb B43.13 were analyzed serially by enzyme-linked immunosorbent assay (ELISA) and T-cell responses by IFN- γ enzyme-linked immunosorbent spot (ELISPOT). It was noted that mAb B43.13 dosing can be increased without adversely affecting safety, and more than two doses were needed for optimal immune responses (108,109). A randomized, placebo-controlled trial with 145 patients with stage III or IV epithelial ovarian cancer (EOC) received intravenous oregovomab in their first clinical remission (109,112,113). No significant toxicity was seen. The median TTP from randomization post front-line therapy for patients receiving oregovomab versus placebo was 13.3 months versus 10.3 months ($p = 0.71$). In a subgroup of patients (≤ 2 cm residual at debulking, CA-125 ≤ 65 U/mL before third cycle, and CA-125 ≤ 35 U/mL at entry), TTP for patients receiving oregovomab versus placebo was 24 months versus 10.8 months (hazard ratio [HR] 0.543; 95% CI, 0.287 to 1.025). Using the eligibility criteria of the subgroup, the investigators have completed prospective enrollment of phase 3 Immunotherapy Pivotal ovarian Cancer Trials I and II (IMPACT) with 354 patients. Efficacy results from these studies are expected to be available when sufficient events have occurred for analysis.

mAb B43.13 (OvaRex) in First-Line Chemo-immunotherapy

The use of anti-CA-125 antibodies in chemo-immunotherapy as first-line therapy remains controversial. Traditionally, it has been thought that the combination of immunotherapy and chemotherapy was not desirable because of the immunosuppressive nature of cytotoxic agents. However, several reports have suggested that chemotherapy may selectively eliminate immunosuppressive lymphocyte populations, and thereby may beneficially alter the characteristics of an immune response (139). The study with concurrent mAb B43.13 and chemotherapy in recurrent epithelial ovarian cancer reported above also supports the idea that favorable specific immune responses could be generated despite concurrent chemotherapy (108). This observation, coupled with benign toxicity profiles and the association between antibody response and survival prolongation, suggests that concurrent chemo-immunotherapy should be evaluated as a first-line therapy for this and other vaccine approaches.

mAb B43.13 (OvaRex) with Conjugates

A drug-antibody conjugate was tested in human ovarian serous adenocarcinomas after it showed selective toxicity *in vitro* against dividing cell populations of the human ovarian cancer cell lines expressing CA-125 (140). Daunorubicin (DNR)-OC125 was made from a new analog (PIPP-DNR) of daunorubicin that chemically links the drug to monoclonal antibodies. The immunofluorescence data show that the DNR-OC125 conjugate had high affinity and specificity for proliferating malignant cells from human ovarian tumors and indicated that the OC125 monoclonal antibody can indeed serve as a cancer-targeting carrier for daunorubicin and its analogs. The clinical efficacy has not been tested.

Immunoconjugated antibodies have been tested in the treatment of ovarian cancer. A distribution and pharmacokinetics study of ^{131}I -OC125 in patients with gynecologic tumors revealed that IP versus IV administration of the radio-labeled antibody resulted in a higher uptake of antibody in the

tumor and a lower uptake of antibody in normal tissues (114). Therefore, this study suggested that for radioimmunotherapy of ovarian cancer, IP administration of radiolabeled antibodies is preferable to intravenous administration. This was also consistent with a study in nude mice with ovarian cancer xenografts (141). In a phase 1 study, 20 patients with recurrent or persistent epithelial ovarian cancer failing conventional therapies were treated with a single IP injection of ^{131}I -OC125 mAb (115). Rare acute side effects were nausea and mild diarrhea, and no dose-limiting toxicity has been observed for doses ≤ 120 mCi of ^{131}I . Only three patients had partial responses of short duration. A phase 2 study with IP radioimmunotherapy in patients with minimal residual ovarian adenocarcinoma after primary treatment with surgery and chemotherapy showed little therapeutic benefit (116). Toxicity was mainly hematologic, with grade III neutropenia and thrombocytopenia in two patients. In a retrospective study of patients with ovarian carcinoma who received 1 mg of ^{131}I -OC125 mAb one to five times after radical surgery and polychemotherapy, patients who developed high titers of Ab2 responses had a significantly higher survival rate than the ones with weak or no immunologic response to ^{131}I -OC125 mAb treatment ($p < 0.05$) (142). The diagnostic value of ^{131}I -OC125 to localize ovarian tumors was tested prospectively. Scintigraphy revealed the presence of active disease, which was confirmed by laparotomy/laparoscopy in the majority of patients considered to be in clinical remission. Therefore, the sensitivity of scintigraphy with ^{131}I -OC125 was high enough and may have diagnostic value (143). The assessment of clinical efficacy will require randomized, prospective clinical trials.

Antibodies Targeting MUC-1: HMFG1 and HMFG2

A murine immunoglobulin G1 mAb raised against human milk fat globules (HMFG1) reacts with an epitope in the protein core of polymorphic epithelial mucin (PEM) antigen (MUC-1) that is expressed by $>90\%$ of epithelial ovarian cancers and many other carcinomas. The therapeutic potential of HMFG1 has mainly been assessed in the form of conjugates with radionuclide. In one study, 24 patients with persistent epithelial ovarian cancer were treated with IP ^{131}I -labeled mAbs directed against tumor-associated antigens, including HMFG1 (117). Acute side effects were mild abdominal pain, pyrexia, diarrhea, and moderate reversible pancytopenia. Of the 16 patients with small-volume disease (<2 cm) at the time of treatment with radiolabeled antibody, 9 responded. Analysis of the data on relapse indicated that doses >140 mCi were more effective than lower doses. This study suggested that the IP administration of ≥ 140 mCi ^{131}I -labeled tumor-associated monoclonal antibodies had activity in patients with small-volume stage III ovarian cancer. In a phase 1-2 trial of IP ^{90}Y -HMFG1 in patients with ovarian cancer, the dose was limited by myelotoxicity as described by bone deposition of free ^{90}Y carcinoma (118). The intravenous use of a chelating agent, ethylenediamine tetraacetic acid (EDTA) (Ledclair), allowed the dose to be increased from 18 to 30 mCi without causing severe myelotoxicity. An additional 52 patients with epithelial ovarian cancer were treated with IP ^{90}Y -HMFG1 following conventional surgery and chemotherapy, results showed that patients with advanced ovarian cancer who receive conventional therapy and achieve a complete remission may benefit from further treatment with IP radioactive mAbs (119). Another adjuvant study with one dose of 25 mg of HMFG1 labeled with 18 mCi/m² ^{90}Y given intraperitoneally yielded a 5-year survival of 80% compared to 55% in control cases selected from the database ($p = 0.0035$). All patients developed serologic evidence of HAMA. This study was hypothesis generating and

suggested a survival benefit for patients with ovarian cancer who receive IP radioimmunotherapy in the adjuvant setting (144). To overcome the myelosuppression toxicity from bone deposition of ^{90}Y , stable chelating agents, such as the benzyl analog of diethylene triamine pentaacetic acid (DTPA), 6-p-isothiocyanatobenzyl diethylene triamine penta-acetic acid (CITCDTPA), was conjugated with ^{90}Y -HMFG1. However, anti-chelate antibody responses developed against the macrocycle benzyl-DOTA, resulting in clinical side effects with hypersensitivity syndrome (145). Despite the provocative activity suggested in the phase 2 trials with ^{90}Y -HMFG1, a large randomized, placebo-controlled study failed to show benefit. In the study by Verheijen et al., a total of 844 stage IC to IV patients were initially screened, of whom 447 patients with a negative second-look laparoscopy after primary surgery and chemotherapy were randomly assigned to receive either a single IP dose of ^{90}Y -muHMFG1 followed by observation or observation alone. The study had an 80% power to detect a 15% improvement in survival. After a median follow-up of 3.5 years, 70 patients had died in the active treatment arm compared with 61 patients in the control arm. Cox proportional hazards analysis of survival demonstrated no difference between treatment arms. It was concluded that a single IP administration of ^{90}Y -muHMFG1 given to patients having a negative second-look laparoscopy after primary therapy did not extend survival or time to relapse. Several factors have been suggested as contributing to the negative results such as inadequate dose or dosing frequency. A follow-up analysis of this study further characterized the negative result, showing that treatment was associated with improved control of intraperitoneal disease ($p < 0.05$) but a shorter time to disease recurrence in extraperitoneal sites ($p < 0.05$) (146). Nonetheless, this represents the largest randomized consolidation study to date in patients with ovarian cancer utilizing radionuclides with unfortunately disappointing results.

Antibodies Targeting Tumor-Associated Glycoprotein-72: CC49, B72.3

Human mammary and other carcinoma cells secrete and express on their cell surfaces complex, mucin-like glycoproteins that are recognized as tumor-associated antigens by a variety of mAbs. One such mAb, B72.3, was initially developed using a membrane-enriched fraction of human metastatic mammary carcinoma tissue as an immunogen (147). This mAb has been extensively studied with respect to the range of reactivity for a variety of carcinomas versus normal tissues. Tumor-associated glycoprotein-72 (TAG-72) is a tumor-associated glycoprotein recognized by mAb B72.3, which has more recently been shown to be specific for clusters of sTn (148). This high-molecular-weight mucin is expressed by the majority of common epithelial tumors. In an effort to improve the parental mAb B72.3, a series of second-generation mAbs has been developed that also recognize TAG-72 (149,150). Among the members of the initial library of antibodies produced, murine mAb CC49 was selected for further clinical studies because of its higher affinity and more rapid plasma clearance compared with mAb B72.3. mAb CC49 recognizes a different epitope than mAb B72.3 (although still sTn related) and exhibits higher reactivity to several carcinomas (151,152). The potential value of this mAb in immunotherapy has been tested for conjugates with various radionuclides in different cancers, including that of the breast (153,154), colon (155–159), and prostate (160–162). The studies in ovarian cancers are summarized below.

Animal model studies have shown considerable antitumor activity for ^{177}Lu -CC49 in TAG-72–positive human tumor xenograft models (103,163). Several phase 1 trials (121)

showed that treatment with $^{177}\text{Lu-CC49}$ was well tolerated. Side effects included mild discomfort with administration, delayed transient arthralgia, and marrow suppression. The dose-limiting toxicity was bone marrow suppression with an MTD of 45 mCi/m^2 . Antitumor effects were noted against chemotherapy-resistant ovarian cancer, even at lower dose levels, and resulted in prolonged disease-free survival of most patients with microscopic disease. The combination of IFN and paclitaxel (Taxol) with IP $^{177}\text{Lu-CC49}$ was also evaluated in persistent ovarian cancer (164). Human recombinant IFN- α was administered to increase the expression of the tumor-associated antigen TAG-72. Paclitaxel, which has radiosensitizing effects and antitumor activity against ovarian cancer, was given intraperitoneally 48 hours before radioimmunotherapy. The therapy was well tolerated with the expected reversible hematologic toxicity, and addition of IFN- α increased hematologic toxicity. The MTD was 40 mCi/m^2 $^{177}\text{Lu-CC49}$ when given with IFN- α in combination with 100 mg/m^2 paclitaxel. A different radionuclide isotope, ^{90}Y , was also evaluated with mAb CC49. Treatment of patients with persistent ovarian cancer with a combination of subcutaneous IFN- α 2b, IP paclitaxel, and IP $^{90}\text{Y-CC49}$ was associated with primarily hematologic toxicity (122). The MTD of IP $^{90}\text{Y-CC49}$ was established at 24.2 mCi/m^2 in this combined regimen. Partial responses were observed in some of the patients with measurable disease.

The CC49 mAb was also evaluated as a drug conjugate with doxorubicin in mouse models. The immunoconjugate, designated CC49-BAMME-CH-DOX, was approximately a log less potent than unconjugated doxorubicin in an *in vitro* cytotoxicity assay (165). Immunoreactivity of the antibody was fully retained. When evaluated in a nude (*nu/nu*) mouse xenograft model with the antigen-positive human colorectal tumor target, CC49-BAMME-CH-DOX and free doxorubicin had similar tumor-suppressive activities. However, the immunoconjugate was clearly less toxic, as measured by weight loss and deaths. When evaluated in an NIH:OVCAR-3 human ovarian carcinoma xenograft model, CC49-BAMME-CH-DOX was superior at prolonging survival in comparison to free doxorubicin, unmodified CC49, and a non-tumor-binding doxorubicin immunoconjugate (165). These results indicate that targeting of doxorubicin with the CC49 antibody may improve the toxicity and/or the potency of the drug depending on the tumor target being evaluated.

In summary, these phase 1-2 studies have shown that IP treatment with radiolabeled antibodies is well tolerated. Although these studies were not designed to estimate response rate or survival, they do provide evidence of antitumor activities with this approach. One advantage of administering isotopes conjugated to antibodies intraperitoneally is to ameliorate bowel complications associated with IP administration of unconjugated radioisotopes. Various forms of mAb CC49 have been engineered to improve delivery of radiation doses to tumors and minimize undesirable pharmacokinetics that lead to significant radiation exposure of normal tissues. The clinical efficacy of these different constructs will be tested.

Antibodies Targeting Folate-Binding Proteins: MOv18 and MOv19

The mAbs MOv18 and MOv19 were raised against a membrane preparation from an ovarian carcinoma surgical specimen. They reacted with a surface antigen present on the majority of non-mucinous ovarian malignant tumors tested but not with normal adult tissue (166). This antigen was subsequently identified to be folate-binding protein (FBP) (167), which is over-expressed in ovarian adenocarcinoma. The therapeutic potentials of these mAbs in ovarian cancer have been assessed in several pilot and phase 1 studies. A pilot study in 16 patients with minimal residual ovarian cancer with a single

dose of $^{131}\text{I-MOv18}$ (mean dose 14 mg) with 3,700 GBq ^{131}I showed complete response in 5 of 16 patients, and the majority of patients produced HAMA responses (123). The toxicity of radioimmunotherapy was negligible, with only mild and transient bone marrow suppression in one patient. A chimeric form of MOv18 (c-MOv18) was evaluated in several clinical trials with single or repeated injections of c-MOv18 (124,125,168). Toxicity was generally mild and transient. No human anti-chimeric antibody (HACA) response was found. Increased ADCC levels corresponding to a slight increase in CD4^+ and CD8^+ fractions were observed, whereas the CD4/CD8 ratio and the levels of CD25 remained unchanged. The radionuclide-labeled MOv18 ($^{131}\text{I-cMOv18}$) was also demonstrated to be safe with only mild myelosuppression, again without significant HACA response (126). These studies showed that immunotherapy aimed at boosting the patient's immunologic capacity has minor effects in patients with ovarian cancer who have been heavily pretreated with chemotherapy and suggested that such strategies should be evaluated in patients who are more immunocompetent.

A bispecific OC/TR mAb that cross-links the CD3 molecule on T cells with human FBP was also generated and produced some complete and partial responses in clinical trials of patients with ovarian carcinoma (169). Most patients developed HAMA, which can inhibit OC/TR mAb-mediated lysis. An antibody-cytokine conjugate was constructed as a fusion protein between IL-2 and the scFv of MOv19 (170). This small molecule combines the specificity of MOv19 with the immunostimulatory activity of IL-2. The newly designed molecule may have improved tissue penetration and distribution within the tumor and reduced immunogenicity, and it may lack the toxicity related to the systemic administration of IL-2. In a syngeneic mouse model, IL-2/MOv19 scFv specifically targeted α -folate receptor gene-transduced metastatic tumor cells without accumulating in normal tissues owing to its fast clearance from the body. Treatment with IL-2/MOv19 scFv, but not with recombinant IL-2, significantly reduced the volume of subcutaneous venographic tumors. The pharmacokinetics and biologic characteristics of IL-2/NMOV19 scFv may allow the combination of systemically administered IL-2/NMOV19 scFv and adoptive transfer of *in vitro* retargeted T lymphocytes for the treatment of ovarian cancer, thereby providing local delivery of IL-2 without toxicity.

It is worth noting that unlike other cancer-associated antigens, for example, CA-125 and TAG-72, whose expression may be enhanced by IFN, expression of MOv18 and MOv19 was not modulated by IFN- α , INF- β , or IFN- γ (125,171). Addition of IL-2 *in vitro* also did not change any immunologic parameters (125).

Antibodies Targeting the Lewis-Y Antigen: BR5, BR96, B3, 3S193

The Lewis-Y (Le^y) antigen is a type 2 blood group-related glycoprotein that is expressed by 60% to 90% of human carcinomas of epithelial cell origin, including breast, pancreas, ovary, colon, gastric, and lung cancer (83,90,172–175). A total of 75% of the analyzed ovarian cancer specimens expressed Lewis-Y (175). Because of its high frequency in tumors, high density and altered expression on the surface of tumor cells, and relatively homogeneous expression in primary and metastatic lesions, Lewis-Y has been an antigenic target for solid tumor immunotherapy (176). Several mAbs have been developed, including BR55 (177), BR64, and BR96 (178), B1 and B3 (179), and 3S193 (180). Some of these mAbs have been evaluated for their potential therapeutic use in gynecologic malignancies.

mAb B3 radiolabeled with ^{111}In demonstrated good tumor localization in patients with advanced epithelial tumors (127).

The MTD of ^{90}Y -mAb B3 was 20 mCi, with myelosuppression as the dose-limiting toxicity. An immune toxin conjugate of B3 and *Pseudomonas* exotoxin, designated LMB-1, had excellent antitumor activity in nude mice bearing Lewis-Y-positive tumors (181). In a phase 1 study of 38 patients with solid tumors who failed conventional therapy and whose tumors expressed the Lewis-Y antigen, LMB-1 produced objective antitumor activity. The MTD of LMB-1 was 75 $\mu\text{g}/\text{kg}$ given intravenously three times every other day. The major toxicity reported at this dose was vascular leak syndrome.

A drug conjugate consisting of chimeric mAb BR96 and doxorubicin, BR96-Dox has been shown to cure 94% of athymic rats with subcutaneous human lung cancer (182). BR96-Dox conjugate was generally well tolerated with mild gastrointestinal toxicities, and did not show significant clinical antitumor activity in metastatic breast cancer (183–185). Another humanized anti-Lewis-Y mAb (hu3S193) was evaluated using a radionuclide conjugate of the ^{131}I isotope alone or in combination with paclitaxel in an MCF-7 xenografted BALB/c nude mouse, which is a breast cancer model (186). It has been noted that the combination of paclitaxel and ^{131}I -hu3S193 had a synergistic effect with significant tumor inhibition in 80% of the analyzed mice. Its value in the treatment of ovarian or other gynecologic cancers has not been well studied and remains to be tested in the future.

Antibodies Targeting Carcinoembryonic Antigen: MN-14

Carcinoembryonic antigen (CEA) belongs to the class of tumor-associated antigens and has been most extensively studied in gastrointestinal cancers. The diagnostic and therapeutic value of CEA has also been evaluated in ovarian cancers. An anti-CEA mAb radiolabeled with ^{99}Tc was shown to be a promising radioimmunoimaging method for the detection of malignant ovarian tumors with excellent sensitivity and specificity (187). Complete clinical remission was observed in a patient with advanced ovarian cancer, refractory to paclitaxel therapy, treated with two cycles of ^{131}I -labeled murine MN-14 anti-CEA mAb (188). A follow-up phase 1 therapy trial with intravenously administered ^{131}I -MN-14 anti-CEA mAb in patients with epithelial ovarian cancer showed that myelosuppression was the only observed treatment-related toxicity, and dose-limiting toxicity was seen at 50 mCi/m². It seems that MN-14 anti-CEA mAb is a suitable agent for tumor targeting, and it may have a therapeutic potential in patients with chemotherapy-refractive epithelial ovarian cancer, especially those with minimal disease (129).

Antibodies Targeting MX35 Antigen

mAb MX35 is a murine IgG1 that was initially developed at Memorial Sloan-Kettering Cancer Center (189,190). It detects an antigen expressed strongly and homogeneously on approximately 90% of human epithelial ovarian cancers (130), and was subsequently identified to be a 95-kD glycoprotein (191). The exact function of this antigen is yet to be defined; however, given its strong expression in ovarian cancers but not in normal peritoneum, mAb MX35 in the form of immune radionuclide conjugate has been tested for its therapeutic potential in ovarian cancer. In one study, 25 patients with advanced ovarian cancer were entered into a clinical trial using ^{125}I - or ^{131}I -labeled MX35 in escalation doses administered by intravenous or IP injection (130). Specific localization of mAb in tumor was demonstrated by tumor:normal tissue ratios ranging from 2.3:1 to 34:1 (mean 10.18:1), demonstrating that mAb MX35 localizes well to tumor in selected patients with ovarian cancer. Another study to quantify the targeting of the mAb MX35 to micrometastatic epithelial ovarian cancer

demonstrated that mAb MX35 localizes to the micrometastatic ovarian carcinoma deposits within the peritoneal cavity (192). These two dosimetry results suggest a therapeutic potential for this antibody in patients with minimal residual disease (<5 mm).

Antibodies Targeting ERBB1 (EGF), ERBB2 (HER2/neu), and VEGF

The epidermal growth factor receptor (EGFR) has been a frequent target for cancer treatment development in the past decade. Several EGFR antibodies have been approved by the FDA for cancer treatment such as cetuximab and panitumumab for colorectal cancer. These encouraging data have prompted their evaluation in other malignancies. In ovarian cancer, the EGF tyrosine kinase inhibitor gefitinib had a minimal objective single agent response rate of 4% in unscreened patients (9% in EGF + patients). The patient with the only objective response had a mutation in the catalytic domain of EGFR, and the frequency of mutation in this study was 1/32 or 3% (193). The anti-EGFR antibody, matuzumab, was then tested in patients with recurrent, EGFR-positive ovarian or primary peritoneal cancer in a multi-institutional single-arm phase 2 trial of 75 patients, and showed no significant clinical activity as a monotherapy in this population of very heavily pretreated patients. Taken together, these data suggest that anti-EGF targeted therapy as a single agent in ovarian cancer is relatively inactive, but combination studies with chemotherapy are ongoing (178).

Original data had suggested that approximately 30% of ovarian cancer patients overexpress HER2, providing a rationale for investigation (194). Furthermore, HER2 overexpression appears inversely correlated with overall survival when considered in univariate and multivariate analysis among other usual prognostic factors (195). However, the most significant treatment experience in patients with recurrent or refractory ovarian or primary peritoneal cancer comes from the GOG study that screened 837 tumor samples for HER2 expression, and showed the required 2+/3+ expression in only 95 (11.4%) of patients (196). Forty-five patients were entered into the study with an overall response rate of 7.3% with a median progression-free interval of 2.0 months. Based on infrequent HER2 expression, and the low rate of objective responses, the clinical value of single-agent trastuzumab appears limited in these patients. It is unknown whether a clinical benefit could be seen by combining chemotherapy with trastuzumab in those patients with appropriate HER2 expression, but this benefit would be limited by the frequency of expression.

Recent intriguing results have been published from a small series evaluating HER2 overexpression in the aggressive papillary serous variant of endometrial cancer. In 10 consecutive specimens, eight patients showed 2+/3+ expression, and this series is currently being expanded (197). The need for better treatment for patients with uterine papillary serous cancer is apparent, and if this degree of overexpression is confirmed, clinical studies will be warranted.

The growth and metastasis of malignant neoplasms require the presence of an adequate blood supply, and recent data have confirmed the therapeutic potential of antivascular strategies. Bevacizumab, a humanized recombinant antibody against VEGF that prevents its binding to VEGFR, inhibits angiogenesis and tumor growth. Randomized trials have shown statistically significant improvements in progression-free and overall survival when bevacizumab is combined with chemotherapy in several solid tumors, including colorectal cancer (198), non-small-cell lung cancer (199), and breast cancer (200). In these particular tumor types, significant single-agent activity was not observed despite the improvements when used in combination. By contrast, single-agent bevacizumab did

improve progression-free survival in renal cell cancer (201). Interestingly, single-agent activity of bevacizumab has also been clearly established in recurrent ovarian cancer by two prospective trials with a response rate of 16% to 18% (202,203). A combination of bevacizumab with metronomic oral cyclophosphamide in recurrent ovarian cancer patients with up to two prior regimens showed a response rate of 28% (204). It should be noted that in the trial by Cannistra et al., a gastrointestinal perforation rate of 11.4% was seen resulting in the death of one patient. This prompted a National Cancer Institute Investigational New Drug (IND) action letter dated October 4, 2005, which alerted investigators to the risk of gastrointestinal perforation in patients with advanced ovarian cancer treated with bevacizumab. A recent analysis has combined data from all available studies in ovarian cancer, resulting in an estimated risk of gastrointestinal perforation of 5.4% (95% CI, 2.2 to 9.4), which appears to exceed the published risk in colorectal cancer of 2.4% (205,206). Randomized phase 3 trials evaluating the addition of bevacizumab to the adjuvant treatment of patients with ovarian cancer after surgical debulking are ongoing and will provide awaited estimates of clinical efficacy and toxicity when used in this patient population.

Antibodies Targeting MN/CAIX Antigens: M75

The MN antigen is a tumor-associated antigen initially identified from a cervical carcinoma cell line HeLa (207), and was later identified to be CAIX, a carbonic anhydrase (208). It was found to be expressed in cervical intraepithelial neoplasia and 90% of invasive cervical cancer but not in normal cervical tissue (207–209). Although the exact role of MN/CAIX antigen in carcinogenesis is not known, it has been suggested that it may facilitate acidification of the extracellular milieu surrounding cancer cells and in this way may promote tumor growth and spread (210). A retrospective study of 130 squamous cell cervical carcinomas demonstrated that a semiquantitative immunohistochemical analysis of CAIX expression in tumor biopsies is a significant and independent prognostic indicator of overall survival and metastasis-free survival after radiation therapy. Prospective studies have shown that MN/CAIX expression is up-regulated in hypoxic human cervical tumors and is a significant and independent poor prognostic indicator (211). Therefore, CAIX may act as an intrinsic marker of tumor hypoxia and poor outcome after radiation therapy. The level of CAIX expression may be used to aid in the selection of patients who would benefit most from hypoxia-modification therapies or bioreductive drugs. Mouse mAb M75 has been used in immunohistochemical staining in the above studies.

Summary of mAb Trials

In summary, progress has been made in the application of mAb to treatment of B-cell malignancies, breast cancer, and colorectal cancer. Bevacizumab has shown promise in ovarian cancers. Additional human or humanized antibodies against cell surface antigens that are of therapeutic significance needed to be studied in gynecologic cancers. A panel discussion of mAb in the treatment of ovarian cancers was held at the Helene Harris Memorial Trust 9th Biennial Forum on Ovarian Cancer in Stratford, England (17). It was concluded that future trials should aim to develop humanized monoclonal antibodies to surface antigens that can be internalized. More effective radionuclide conjugates and chelates should be developed. Work should be encouraged with isotopes that are primarily α or possibly β emitters. The priorities in the development of

effective mAb therapy, as summarized by the panel, are (a) development of human/humanized mAbs to surface antigens that are internalized; (b) development of more effective radionuclides, chelates; (c) definition of suitable surrogate markers; (d) development of xenotypic antibodies that can induce immunity to autologous antigens; and (e) exploration of combinations with chemotherapy.

ADOPTIVE CELLULAR THERAPY

The goal of most immunotherapeutic approaches is to generate large numbers of highly reactive specific antitumor lymphocytes. Adoptive cellular therapy seeks to overcome tolerance hurdles by selecting and activating large numbers of lymphocytes *in vitro*, and manipulating the host environment to which they are introduced for maximum effect (139). Recent provocative data correlated progression-free and overall survival in patients with epithelial ovarian cancer to the presence or absence of tumor-infiltrating T cells. The 5-year overall survival rate was 38% among ovarian cancer patients whose tumor cells contained T cells and 4.5% among patients whose tumors did not contain T cells ($p < 0.001$). This finding could represent a prognostic phenomenon, and the addition of T cells via the adoptive transfer approach or via vaccination may or may not be beneficial, but it warrants further exploration (212). The adoptive immunotherapeutic approach has resulted in striking clinical responses in melanoma patients after pretreatment with myeloablative chemotherapy (139). In the study by Dudley et al., 13 HLA-A2+ patients with metastatic melanoma received immuno-depleting chemotherapy with cyclophosphamide and fludarabine followed by the transfer of highly selected *in vitro* expanded MART-1 (melanocyte differentiation antigen) reactive T cells and high-dose IL-2. Six of 13 patients had clinical responses, and four had a mixed response. Immunohistochemical studies of tumor deposits revealed predominant infiltrates of CD8+ cells, and both MHC class I and II antigens were highly expressed. The first phase 1 study in patients with EOC using gene-modified autologous T cells with reactivity against the ovarian cancer-associated antigen α -folate receptor (FR) was reported (213). Cohort 1 received T cells with IL-2, and cohort 2 received dual specific T cells followed by allogeneic peripheral blood mononuclear cells. Five patients in cohort 1 experienced toxicity likely due to the cytokine. No reduction in tumor burden was seen in any patient. Polymerase chain reaction (PCR) analysis showed that gene-modified T cells were present in the circulation the first 2 days after transfer, but declined. An inhibitory factor developed in the serum of three of six patients tested over the period of treatment, which significantly reduced the ability of gene-modified T cells to respond against FR+ tumor cells. Future studies need to employ strategies to extend T-cell persistence. There is much interest in further exploring adoptive T-cell approaches in patients with epithelial ovarian cancer.

CANCER VACCINES DESIGNED TO AUGMENT ANTIBODY RESPONSES

Selection of KLH Conjugation Plus QS-21 for Vaccine Construction

A variety of approaches have been explored to induce the antibody responses against carbohydrate and peptide cancer antigens, including the use of autologous and allogeneic tumor cells modified in various ways, or not (reviewed in Ref. 17), different immunologic adjuvants (214–217), anti-idiotypic

TABLE 6.5**ROLE OF CONJUGATE VACCINE COMPONENTS IN ANTIBODY INDUCTION AGAINST CANCER ANTIGENS**

Antigen	Carrier (KLH)	Adjuvant (QS-21)
1) Antigen configuration mimics expression on tumor cell. Conjugation site and tertiary structure are key.	1) Highly immunogenic carrier molecule is key for optimal cytokine release and overcoming tolerance.	The mechanism of action for most adjuvants includes:
2) High density of antigen per carrier molecule optimal.	2) Sequence of cytokine release may be important, so an immunogenic carrier may be better than a cytokine, cytokine mixture, or cytokine inducer.	1) Activation of APCs 2) B-cell activation 3) T-cell activation 4) Depot effect

vaccines (218,219), chemical modification of antigens to make them more immunogenic (220–222), and conjugation to various immunogenic carrier proteins (223,224). The conclusion from these studies is that the use of a carrier protein plus an immunologic adjuvant is the optimal approach. The optimal immunologic adjuvant in each case was one of two saponins (QS-21 or GPI-0100) obtained from the bark of *Quillaja saponaria* (225,226). The optimal carrier protein was in each case KLH (227–230). Each component of this approach is absolutely required; conjugate without adjuvant, antigen plus adjuvant, antigen plus KLH not conjugated plus adjuvant, all result in greatly diminished antibody responses. The rationale for this approach is reviewed above and in Table 6.5.

Conjugate Vaccines Against Cell Surface Antigens

Based on this background, GM2-KLH plus QS-21 (termed GMK) was tested in patients. It induced eight times higher titers of IgM antibody that lasted twice as long compared to our previous GM2/BCG vaccine, and for the first time GMK induced consistent IgG antibodies as well (231). Antibodies were induced in >95% of patients vaccinated with GMK instead of <85% as seen with the GM2/BCG vaccine. Previous trials comparing high-dose IFN- α to no treatment (232) and GM2/BCG to BCG (79) resulted in comparable benefit for IFN and GM2/BCG. However, the time in follow-up needed to detect the benefit was different, which may be important to consider as future trials are designed to ensure adequate follow-up periods. The beneficial effect of IFN was evident during the initial 6 to 8 months of follow-up, whereas the effect of GMK vaccine was not clearly evident until after 2 years. Consequently, a randomized multicenter intergroup trial comparing GMK to high-dose IFN- α was conducted by ECOG in stage III and high-risk stage II melanoma patients. An assessment after 18 months median follow-up demonstrated a significantly prolonged disease-free survival for the patients receiving IFN (233), and the trial was discontinued. It remains possible that one explanation for the lack of benefit for vaccine is the low or heterogeneous expression of GM2 in most melanomas. The presence of tumor cell heterogeneity, heterogeneity of the human immune response, and the correlation

between overall antibody titer against tumor cells and antibody effector mechanisms (234) provide a rationale for favoring the evaluation of polyvalent vaccines in future studies.

A randomized adjuvant multicenter trial with a vaccine against sTn has recently been conducted by Biomira, Inc. (Edmonton, Alberta, Canada). The vaccine contained sTn disaccharide (also referred to as TAG-72) covalently linked to KLH and mixed with immunologic adjuvant Detox. Biomira conducted the trial in patients with high-risk breast cancer at multiple centers in Canada, the United States, and Europe. This trial was based on the high titer antibodies induced by this vaccine in this patient population, the correlation between expression of sTn on tumors and a more aggressive phenotype, and the correlation between antibody induction against sTn and longer disease-free and overall survival in previous studies (80). This trial did not meet its predetermined statistical endpoints of time to disease progression or survival (235), again possibly because of the low or heterogeneous expression of sTn on most breast cancers. While the study failed to reach its primary endpoint, a subgroup analysis showed prolonged survival in patients who were treated with concomitant hormonal therapy compared with patients who received a control vaccine with KLH (median survival for theratope 36.5 months and for KLH 30.7 months, $p = 0.0360$) (236,237).

The strategy to use KLH conjugate plus QS21 has been applied to the development of vaccines against gynecologic malignancies. Vaccines have been tested against seven antigens expressed by gynecologic malignancies, in a series of monovalent vaccine trials. These vaccines have induced antibodies against GM2, MUC-1, and sTn in 80% to 90% of patients, and against Globo H, TF, and Tn in 50% to 80% of patients (223,238–240). Le ν has proved less immunogenic than the other antigens with only 20% to 30% of patients receiving Le ν -KLH vaccines producing significant antibody responses (241). With each of these antigens, the antibodies induced by the antigen-KLH conjugate plus QS21 vaccines reacted by flow cytometry with tumor cells expressing these antigens. The IgG subclasses in all trials have been restricted to IgG1 and IgG3, the two subclasses known to mediate CDC and ADCC.

Preclinical models have shown that a heptavalent KLH conjugate plus QS21 vaccine induced antibody titers comparable to those induced by monovalent vaccines containing Tn, sTn, TF, MUC-1, and Globo-H. Lower titers were produced

against Lewis-Y and GM2 than when evaluated as monovalent antigens (242). Recently, a pilot study was performed to test a heptavalent vaccine in ovarian cancer patients in second or greater complete clinical remission (241). The objectives of this phase 1 study were to characterize safety and immunogenicity in preparation for an adequately powered randomized efficacy trial. Eleven patients in this study received a heptavalent vaccine subcutaneously containing GM2 (10 µg), Globo-H (10 µg), Le^y (10 µg), Tn(c) (3 µg), sTn(c) (3 µg), TF(c) (3 µg), and Tn-MUC-1 (3 µg) individually conjugated to KLH and mixed with adjuvant QS21 (100 µg). Vaccinations were administered at weeks 1, 2, 3, 7, and 15. No systemic toxicity was seen. After immunization, median IgM titers were as follows: Tn-MUC-1, 1:640 (IgG 1:80); Tn, 1:160; TF, 1:640; Globo-H, 1:40; and sTn, 1:80. Only one response was seen against Lewis-Y, two against GM2. Eight of nine patients developed responses against at least three antigens. Fluorescent-activated cell sorting (FACS) and CDC analysis showed substantially increased reactivity against MCF7 cells in seven of nine patients, with some increase seen in all patients (241).

As exemplified in the case of the GM2 and sTn vaccines discussed above, where signals suggesting activity in phase 2 trials did not translate into clinical benefit in the phase 3 setting, a randomized phase 3 trial of a multivalent-KLH construct with QS21 as the adjuvant is the next step to follow the phase 1 study. This study is planned to randomize patients in second or greater clinical remission to a multivalent-KLH construct + QS21 versus QS21. The endpoint will be an improvement in the proportion of patients remaining in remission at 12 months.

CANCER VACCINES DESIGNED TO AUGMENT T-LYMPHOCYTE RESPONSES

Options Available

There is a wide range of options for augmenting the immunogenicity of the antigenic targets for T-cell immunity (242,243, 244). For these antigens, the options include (a) the full proteins or MHC-restricted peptides modified by amino acid substitutions to increase immunogenicity; (b) genes or mini-genes for these proteins or peptides used as DNA vaccines; or (c) genes expressed in viral or bacterial vectors. Co-stimulatory molecules, cytokines, or molecules targeting antigens to particular processing compartments can be incorporated into these vaccines. DNA vaccines are especially appealing in this regard because of ease of production, versatility, and adaptability to such combinations. Most of these approaches can also be applied to expressing these antigens in antigen-presenting cells, such as dendritic cells, that are then used to vaccinate the patient. Furthermore, since many tumor-rejection antigens detected by T cells in experimental animals are individually unique (mutated), a variety of individualized vaccines are being tested. Whole-cell vaccines can be prepared from a specific patient (if accessible tumor is available) and immunogenicity may be increased by the use of an immunologic adjuvant and transduction with genes for cytokines or co-stimulatory molecules, or treatment with haptens such as dinitrophenyl (DNP). Other approaches to increasing the immunogenicity of unique and shared antigens include the use of heat shock proteins that may carry the full range of cancer peptides, anti-idiotypic vaccines, and DNA or messenger RNA vaccines that may be obtained from smaller biopsy specimens. The range of options for augmenting T-cell immunity against cancer is daunting. Clinical trials with each of these approaches

to augmenting T-cell immunity have been recently completed, are ongoing, or have been planned. There is no basis for selecting one over the other at this time.

Target Antigens to T Lymphocytes: Selecting a Strategy

Antigens shared by ovarian or endometrial cancers from different patients are KSA, MUC-16, WT1, CEA, MUC-1, HER2/neu, and cancer-testis antigens (including the MAGE family) and NY-ESO-1. None of these cancer antigens defined as targets for T cells to date is a perfect candidate for the majority of patients due to (a) over-expression on less than 50% of ovarian or endometrial cancers (HER2/neu, CEA, and the cancer-testis antigens) and (b) wide expression (though at lower levels) on normal tissues (KSA, CEA, HER2/neu, MUC-1). The highly polar extensive expression of KSA and some other antigens on cells apically at mucosal borders (lumens) in many normal epithelial tissues does not exclude them as a target for antibodies because IgG1, IgG3, and IgM antibodies are present in much lower concentrations in these lumens, or not at all, and there is little or no complement and no antibody-dependent cell-mediated cytotoxicity (ADCC) effector cells. Since antigen presentation to T cells in the context of HLA antigens is not known to have the same polar distribution, KSA would be a worrisome target for T cells. MUC-16 for ovarian cancers and human papillomavirus (HPV)-related antigens for cervical cancer are especially strong candidates at this time because of their widespread expression on the respective cancers and restricted expression on normal tissues.

Molecular analysis of endometrial carcinomas has identified a variety of proteins that may serve as target antigens for vaccine-based therapy. For example, over-expression of HER2/neu has been correlated with advanced disease and poor outcome in both adenocarcinoma and uterine papillary serous carcinoma (245,246). More recent reports have implicated alterations in the hMLH1, p16(ink4a) (p16), and *PTEN* genes as promoters of carcinogenesis, as well as over-expression of the *SART-1* gene, which encodes the SART-1 (247) tumor antigen that is recognized by HLA-A26-restricted cytotoxic T lymphocytes (32% of tested specimens) (248,249).

CLINICAL TRIALS WITH SELECTED VACCINES DESIGNED PRIMARILY TO INDUCE T-CELL RESPONSES

NY-ESO-1 Vaccine

The NY-ESO-1 antigen belongs to the cancer-testis antigen family that includes the MAGE-1 protein (first human gene product recognized by CD8⁺ T cells identified in a patient with cancer), and the GAGE and BAGE families (250,251). NY-ESO-1 has shown consistent immunogenicity, and the existence of overlapping CD8⁺ and CD4⁺ T-cell epitopes within these antigens has provided the opportunity of using one short peptide, ESO 157–170, to generate both CD4⁺ and CD 8⁺ T cells (252). Immunoscreening studies have found NY-ESO-1 expression in ovarian cancers, and interestingly the cancer-testis family antigens are represented by the MAGE series (with the exception of MAGE-10), LAGE-1, and PRAME genes, but NY-ESO-1 expression is absent in patients with cervical cancer (253,254). The represented antigens would be appropriate targets for vaccines, and studies with a

peptide vaccine targeted at NY-ESO-1 are ongoing in patients with ovarian cancer at the Memorial Sloan-Kettering and Roswell Park Cancer Centers. An existing phase 1 clinical trial immunized 12 patients with metastatic NY-ESO-1-expressing tumors (seven were NY-ESO-1 serum antibody negative and five patients were NY-ESO-1 positive at the start of the study) using intradermal administration of three HLA A2-restricted peptides. Primary peptide-specific CD8⁺ T-cell reactions were generated in four of seven NY-ESO-1 antibody-negative patients. Although there were no complete or partial clinical responses, induction of a specific CD8⁺ T-cell response to NY-ESO-1 in immunized antibody-negative patients was associated with disease stabilization and objective regression of single metastases. Stabilization of disease was observed overall in four of the seven seronegative patients who developed CD8⁺ T-cell responses by ELISPOT and delayed-type hypersensitivity (DTH) reactions after vaccination (one of the two ovarian cancer patients had decreasing ascites and stable peritoneal carcinomatosis lasting 20 weeks) (255).

Granulocyte-Macrophage Colony-Stimulating Factor–Secreting Tumor-Cell Vaccines

Granulocyte-macrophage colony-stimulating factor (GM-CSF) has a variety of properties desirable for vaccine production including enhancing immune responses by inducing the proliferation, maturation, and migration of dendritic cells and the expansion of both T- and B-cell lymphocytes (256). A recent characterization of its adjuvant response has shown the early elevation of inflammatory molecules such as IL-6, TNF- α , and monocyte chemoattractant protein-1 (MCP-1) followed later by IL-12 and IFN- δ production, among others (257). *In vitro* characterization of a GM-CSF-secreting vaccine was performed by genetically engineering UCI-107 (ovarian cancer cell line) to secrete GM-CSF by retrovirus-mediated gene transduction with the LXS_N retroviral vector containing the human GM-CSF gene and the neomycin resistance selection marker. A clone (UCI-107 GM-SF-MPS) was extensively characterized and shown to secrete high levels of GM-CSF over 6 months of study (258). In human trials, a variety of studies have shown that vaccination with irradiated tumor cells engineered to secrete GM-CSF stimulates long-lasting immunity in murine models and in patients with metastatic melanoma. A phase 1 study evaluated patients with metastatic non-small-cell lung carcinoma. A metastatic site was resected, processed to single-cell suspension, infected with a replication-defective adenoviral vector encoding GM-CSF, irradiated, cryopreserved, and then given intradermally at weekly and biweekly intervals. Vaccines were made successfully for 34 of 35 patients. Dendritic cell, macrophage, granulocyte, and lymphocyte infiltrates were elicited in 18 of 25 assessable patients. Two patients rendered disease-free by surgical removal of metastatic disease prior to trial enrollment were disease-free at 43 and 42 months; five patients had stable disease ranging from 3 to 33 months; and one patient had a mixed response (259). Additional trials in other solid tumor types, including gynecologic malignancies, are warranted.

Folate Receptor–Targeted Vaccines

Previous studies have identified the alpha isoform of the folate receptor (FR), which is a 38-kD GPI-anchored protein constitutively expressed at high levels in 90% of non-mucinous ovarian cancer and at low levels in normal tissues (247). The reason for over-expression is unknown, but one hypothesis is that over-expression provides an alternate folate-processing pathway to compensate for deletion of the tetrahydrofolate reductase gene

that is deleted frequently in cancer cells (167). FR expression has been shown in preclinical models to confer a growth advantage in FR-transfected cells, which suggests a role for the receptor in the control of cell proliferation (260). Growth regulation may be related to an inverse relationship between folate receptor expression and Cav-1, a 21- to 24-kD protein that may negatively regulate the activity of several cytoplasmic signaling proteins and tyrosine kinase inhibitors (258).

The preferential over-expression of the folate receptor in malignant tissue has prompted the investigation of this antigen in several preclinical immunization studies. Neglia et al. (261) evaluated FR alpha cDNA after ligation into the VR1012 (Vical) expression vector under transcriptional control of the cytomegalovirus promoter. Purified plasma DNA was injected into BALB/c mice three times at 14-day intervals. At 10 days after the second injection, sera (100%) showed antibody titers against syngeneic C26 cells transduced with FR alpha, but not against unmodified C26 cells. Specific cytotoxic T-lymphocyte activity against FR alpha-transduced C26 cells could be seen in splenocytes from all immunized animals. Challenge by subcutaneous injection with FR alpha-transduced C26 cells (administered 10 days after third injection) showed a statistically significant delay in tumor growth (261). Further studies by Peoples et al. showed that both immunodominant E39 (folate-binding protein [FBP], 194–202) and subdominant E41 (FBP, 246, 248–255) epitopes of human high-affinity FBP are presented by HLA-A2 in both ovarian and breast cancers (262). Tumor-associated lymphocytes stimulated with FBP peptides exhibit cytotoxicity not only against peptide-loaded targets but also against FBP-expressing epithelial tumors of different histologies. Finally, FBP peptides induced E39-specific cytotoxic T lymphocytes (CTLs) and E39- and E41-specific IFN- δ and IP-10 secretion in a proportion of healthy donors. These studies provide motivation for proceeding to clinical trials with DNA and peptide FR vaccines in ovarian cancer patients.

Dendritic-Cell Approaches

Dendritic cells (DC) are phenotypically distinct, potent antigen-presenting cells well suited for vaccine strategies (263). They are found throughout the body, particularly at the portals of entry for infectious organisms, such as in the epidermis and other epithelial surfaces. Cancers may be ineffective at attracting DCs, may attract the wrong type of DCs, or may attract immature DCs that induce tolerance. Zou et al. observed that ovarian carcinoma cells express high levels of the chemokine SDF-1 that attracts a subset of DC precursors with capacity to differentiate into plasmacytoid DCs, which are implicated in immune suppression through induction of IL-10 by T cells. Myeloid DCs, which are more effective at inducing immune responses, were not detected (264). Also, plasmacytoid DCs have been implicated in inducing a set of CD8⁺ regulatory T cells in ovarian carcinoma (265). DCs from patients with ovarian cancer can be matured *ex vivo* to activate T cells producing IFN- γ in response to autologous tumor cell lysates, but not cytotoxic T cells (266). Ovarian carcinoma cell lines can directly inhibit maturation of DCs (267). These results and many others suggest that DCs from cancer patients can be defective at fully activating T cells. Curiel et al. showed that myeloid DCs from tumor or draining lymph nodes of ovarian carcinoma expressed B7-H1, a molecule in the B7 family implicated in inhibiting immune responses (268). Blockade of B7-H1 led to marked increases in T-cell responses. Multiple animal studies have demonstrated CTL-mediated protective immunity and even regression of established tumors with the administration of antigen pulsed dendritic cells (269,270). A variety of approaches have been considered with regard to antigen type and loading techniques

to include recombinant or fusion proteins (271), peptides as tumor antigen-derived CTL epitopes (272), DC-tumor cell hybrids (273), HLA-restricted antigens (274), and autologous antigens from tumor cell lysates and apoptotic tumor cells (275,276). A number of antigen sources are possible for DC-based treatment of ovarian cancer, including germ cells/cancer testis antigens, HER2, and MUC-16 (CA-125) (92).

Both the clinical relevance and presence of the target are obviously essential when using this tumor antigen approach. For example, several studies have demonstrated the effectiveness of using *in vitro*-generated DCs loaded with HLA-A2 restricted peptide fragments from either HER2 (E75) or the HER2 intracellular domain (ICD) in terms of immune response. Brossart et al. vaccinated patients with advanced breast cancer or ovarian cancer with DCs pulsed with peptides from HER2 or MUC-1, detecting peptide-specific cytotoxic T-cell responses in T cells from peripheral blood of 5 of 10 patients (277). However, recent data from a GOG study showed that only 11.4% of 837 screened ovarian cancer tumor samples showed 2+ or 3+ over-expression of HER2. Furthermore, using the monoclonal humanized anti-HER2 antibody trastuzumab, an overall response rate of 7.3% was seen, showing that even with appropriate over-expression, minimal single-agent activity is seen (278).

Santin et al. showed that DCs loaded with lysates of autologous ovarian cancer cells from three patients were able to induce specific cytotoxic T-cell responses *in vitro*, suggesting feasibility of this approach (279). Using the autologous tumor antigen pulsed DC approach in patients with ovarian cancer (n = 8) and uterine sarcoma (n = 2), Hernando et al. harvested DCs, and pulsed them with KLH and autologous tumor cell lysate in the presence of GM-CSF (270). Significant tumor antigen-specific lymphoproliferative responses were seen in two ovarian cancer patients. Progression-free intervals of 25 to 45 weeks were seen in three patients (two with demonstrable immune responses), suggesting an effect of disease stabilization. Homma et al. treated 21 patients, including patients with ovarian cancer, with DCs fused to tumor cells using polyethylene glycol, with or without systemic treatment with IL-12 (280). They observed antibody responses against autologous tumor cells in one patient and resolution of malignant ascites in a patient with gastric carcinoma. These data combined with DCs pulsed with lysates from other solid tumors such as melanoma, renal cell carcinoma, and selected pediatric tumors showing specific T-cell immunity, and some objective responses further support evaluation of this approach in patients with gynecologic cancers (275,281,282).

Dendritic cell approaches are potent at inducing T-cell responses. A variety of variables require further study to optimize the approach including choice of DC subtype, maturational status at immunization, adjuvant cytokines, antigen loading method, and route and frequency of administration.

ANTI-IDIOTYPE VACCINES

Anti-idiotype vaccines strive to augment both antibody and T-cell responses by using antibody facsimiles of the native antigens to overcome their poor immunogenicity and availability. Tumor-associated antigens are traditionally weakly immunogenic as the large majority of them in humans are non-mutated self-antigens. One approach has been to present the desired epitope to the now tolerant host in a different molecular environment, but the problem with many tumor antigens is that they are ill-defined chemically and difficult to purify and produce (110).

The "immune network hypothesis" attempts to transform epitope structures into idiotypic determinants expressed on the surface of antibodies, and was originally proposed in the

1970s (283,284). This approach assumes that immunization with a given antigen will generate the production of antibodies against this antigen (termed Ab1). Ab1 can generate anti-idiotypic antibodies against Ab1, termed Ab2. Some of the anti-idiotypic antibodies (Ab2 β) express the internal image of the antigen recognized by the Ab1 antibody and can be used as surrogate antigens. Immunization with Ab2 β can cause the production of anti-anti-Id antibodies (termed Ab3) that recognize the corresponding original antigen identified by Ab1 (285,286). (Since Ab3 can have Ab1-like reactivity, it is also called Ab1' to distinguish it from the original Ab1.)

ACA-125 (Abagovomab)

The generation and production of the murine anti-idiotypic antibody ACA-125 (abagovomab) for clinical use has been described in detail (287). Briefly, BALB/c mice were immunized with murine monoclonal antibody OC125 (CIS; Bio International, Gif-Sur-Yvette, France) directed against the tumor-associated antigen CA-125. Splenic cells of immunized mice were fused with myeloma cells yielding an ACA-125-producing hybridoma that was adapted to serum-free medium. Large-scale production of mAb ACA-125 was performed in a hollow fiber system with yields of 10 to 15 mg of antibody per day. mAb ACA-125 was purified from culture supernatant by affinity chromatography with protein G-sepharose and the preparation was checked by SDS-PAGE analysis (PHAST-System; Pharmacia Biotech, Uppsala, Sweden) to give >95% purity. The final product for vaccination in previous phase 1-2 trials contained 2 mg of Ab2 IgG1 in sterile, pyrogen-free, polynucleotide-free, mycoplasma virus-free, and retrovirus-free phosphate-buffered saline (PBS) solution.

The anti-idiotype approach has been used in a variety of clinical studies including patients with colon cancer, melanoma, small-cell lung cancer, and neuroblastoma. Immune responses have been demonstrated, and some have suggested a benefit in those patients in whom antibody develops (288-292). Problems with interpreting such phase 2 studies have been appropriately recognized, and prospective phase 3 studies are in development in several tumor types directed toward a variety of antigens.

A two-step study with ACA-125 has been conducted in Germany in patients with ovarian cancer and reported by Wagner et al. (293). Initially, 18 patients were enrolled in the phase 1 portion, which was extended into a phase 2 study with a total of 42 patients being treated. The objective of the phase 1 portion was to confirm safety. The objectives of the phase 2 portion were to (a) further characterize the effect of ACA-125 vaccination on the Ab3 titer as a marker of a specific anti-ACA-125 immune response, and (b) to evaluate overall survival comparing those patients in whom antibody was generated with those in whom it was not. Other immunologic parameters evaluated to better characterize the humoral response included assays of Ab1 and ADCC. The cytolytic activity of immunized patients' peripheral blood lymphocytes against human ovarian cancer cells (CA-125 expressing = OAW-42 and non-expressing = SK-OV3) was also evaluated using a standard europium-release cytotoxicity assay.

Forty-two patients with advanced/recurrent epithelial ovarian carcinoma were enrolled with an average number of 2.1 prior regimens (range 1 to 5). All patients had tumors that strongly expressed CA-125 and received an intramuscular injection of 2 mg of alum-precipitated ACA-125 for four injections at 2-week intervals followed by monthly administration. A mean number of 16.6 + 10.8 vaccinations were delivered (range 2 to 46). Minimal pain at the injection site was seen but no other systemic adverse effects. Hyperimmune sera of 27 of 42 patients (64.2%)

showed an increase in HAMAs (>100 ng/mL). Ab3 responses were negative in all patients before ACA-125 administration, and 28 of 42 patients (66.7%) developed specific anti-anti-idiotypic antibodies (Ab3) during ACA-125 administration. The IgG subclass was evaluated in 10 patients: predominantly IgG1 and IgG2. No correlation could be shown between number of doses, serologic CA-125 concentration, and maximum Ab3 reactivity. The specificity of the immune responses induced after vaccination was demonstrated by a series of competition experiments showing that binding of Ab3 to the anti-idiotypic ACA-125 could be inhibited by the idiotypic mAb OC125 and the CA-125 antigen (293). Cell-mediated cytotoxicity from peripheral blood lymphocytes (PBLs) against CA-125-expressing and CA-125-non-expressing human ovarian cancer cell lines in 18 patients was evaluated with measured cell kill increasing in 9 of 18 patients from $19.6\% \pm 11.7\%$ to $52.7\% \pm 13.6\%$ at the effector:target cell ratio of 100:1 (259). Cell-mediated lysis was accompanied by the induction of Ab3 in eight of nine patients, prompting only humoral response evaluation in the remaining patients. Overall survival of all patients vaccinated with ACA-125: 14.9 ± 12.9 months; of all patients with a positive response to ACA-125: 19.9 ± 13.1 months; and of all patients with no detectable response to ACA-125: 5.3 ± 4.3 months; $p < 0.0001$.

Two additional studies have explored different doses (2.0 mg vs. 0.2 mg), routes (subcutaneous vs. intramuscular), and number of immunizations (nine vs. six) of abagovomab. A phase 1 trial with 42 patients showed that neither route ($p = 0.628$) nor dose ($p = 0.4602$) was statistically significant in terms of effect on maximum post-baseline Ab3 titer (294). Induction of Ab3 was observed in all evaluable patients. A second phase 1 study in 36 patients evaluated two subcutaneous vaccination schedules (nine vs. six injections) (295). No treatment-limiting toxicities occurred in either group and induction of Ab3 was observed in all evaluable patients. IFN- γ -expressing CA-125 specific CD8+ T cells were significantly more frequent in those receiving nine vaccinations, while there was no significant difference between CD4+ T cells in the two groups.

Therefore, vaccination with a suitable anti-idiotypic antibody may offer a way to induce immunity against undefined antigens or poorly immunogenic tumor antigen, such as CA-125. As seen in other immune approaches, phase 1/1 data show an association between the desired immune response and longer survival, but a randomized, appropriately powered trial is required to confirm benefit. Side effects have been minimal. More recently, a study in mice has suggested that injection of the ACA-125 antibody fused to IL-6 may increase the specific humoral response against CA-125, although the clinical relevance has not been studied (296).

Based on the sum of the phase 1 data, an international, multicenter, randomized phase 3 trial of abagovomab versus placebo for stage III or IV epithelial ovarian cancer patients, with an accrual goal of 870 patients, began accruing patients in 2007 under the direction of the Arbeitsgemeinschaft Gynäkologische Onkologie (AGO) group and the Cooperative Ovarian Cancer Group for Immunotherapy (COGI). Eligible patients have completed standard debulking and platinum with taxane-based chemotherapy (intravenous or intraperitoneal) and are in complete remission. The primary endpoint of this study is progression-free survival with a secondary endpoint of overall survival.

CONCLUSIONS

Most patients with cervical, endometrial, or ovarian cancer who will eventually die of disease can be initially rendered free of detectable disease by surgery, radiation therapy, and/or

chemotherapy for varying periods. This adjuvant setting where the targets are circulating tumor cells or micrometastasis is ideal for treatment with immune interventions such as cytokines administered intraperitoneally, adoptive immunotherapy with monoclonal antibodies or cellular therapy, and vaccines that induce T cells or antibodies. This is especially true for cervical and ovarian cancers where HPV-related antigens and MUC-16 (CA-125), respectively, are uniquely specific target antigens. HPV-related interventions against cervical cancer are discussed in chapter 19 by Dr. Thomas Wright. Initial studies in ovarian cancer patients using IFN or IL-2 administered IP have resulted in occasional partial or complete regressions of metastatic disease, especially of tumors less than 5 mm in diameter, but the impact on overall survival has yet to be demonstrated in randomized trials. Administration of mAbs against MUC-16, MUC-1, and sTn have resulted in occasional clinical responses and evidence of prolonged survival compared to historical controls, but results of randomized trials in ovarian cancer evaluating the benefit of these approaches are not yet available. A well-conducted randomized trial of the radionuclide ^{90}Y -HMFG1 showed no benefit, but many other conjugates using other doses and schedules remain to be tested (120). Vaccines have augmented T-cell or B-cell immunity, and these responses have been associated with stabilization of disease in some patients with advanced disease and prolongation of disease-free and overall survival compared to historical controls. Again, randomized trials confirming the benefit of vaccines remain to be accomplished but several are now ongoing. The suggestion of clinical efficacy to date in trials with IP cytokines, monoclonal antibodies, and vaccines is encouraging but not definitive. As awareness of the unique features of the peritoneal cavity, radiolabeled mAb technologies, and vaccine design for augmentation of antibodies and T cells continues to evolve, further progress is likely (128). However, over the next several years, the focus will need to be on testing the clinical impact of these immunologic interventions in appropriately controlled randomized trials in the adjuvant setting. Only in this way can a firm foundation be built on which to explore combinations of these treatments with each other and with surgery, radiation, and chemotherapy.

CHAPTER 7 ■ DEVELOPMENT AND IDENTIFICATION OF TUMOR MARKERS

ALEKSANDRA GENTRY-MAHARAJ, IAN JACOBS,
AND USHA MENON

Tumor markers are biological substances that are produced by malignant tumors and enter the circulation in detectable amounts. In the management of cancer, the most useful biochemical markers are the macromolecular tumor antigens, including enzymes, hormones, receptors, growth factors, biological response modifiers, and glycoconjugates. Global nondirected screening strategies looking at DNA, RNA, and protein levels are constantly identifying novel tumor markers that could complement those previously identified by candidate gene or antibody-based techniques.

Tumor markers are used for screening, diagnosis, monitoring therapeutic response, and detecting recurrence. An ideal tumor marker would need to have 100% sensitivity, specificity, and positive predictive value (PPV). The calculation of each of these attributes is outlined in Table 7.1. *Sensitivity* refers to the percentage of patients with tumor correctly identified as a result of a positive test, whereas *specificity* refers to the percentage of the population without tumor correctly identified as a result of a negative test. PPV refers to the percentage of patients with positive test that have tumor (true positives). In addition, it would need to be tumor-specific and produced in sufficient amounts to allow detection of minimal disease so that it quantitatively reflects the tumor burden. There are few, if any, markers that satisfy these criteria. The most limiting factor is *lack of specificity* as the majority of markers are tumor associated rather than tumor specific, and such markers are elevated in multiple cancers, in benign and physiological conditions, and in the fetal circulation. This restricts their use, with few exceptions, to monitoring therapeutic response and follow-up. This chapter focuses on those markers that are clinically relevant to female genital tract malignancies.

OVARIAN AND FALLOPIAN TUBE CANCERS

Epithelial ovarian cancers represent the majority of ovarian malignancies. A great number of markers have been investigated for use in screening, prognosis, monitoring of response, and recurrence, with CA125 being the best-known marker.

CA125

CA125 was first described by Bast et al. in 1981 as an antigenic determinant on a high-molecular-weight glycoprotein recognized by the murine monoclonal antibody OC-125 (1). It carries two major antigenic domains, classified as A, the domain binding monoclonal antibody OC-125, and B, the

domain binding monoclonal antibody M11 (2). During fetal development, CA125 is expressed by amniotic and coelomic epithelium. In the adult, the determinant is found in structures derived from the coelomic epithelium (the mesothelial cells of the pleura, pericardium, and peritoneum) and in tubal, endometrial, and endocervical epithelium. Surprisingly, CA125 is not expressed by the surface epithelium of normal fetal and adult ovaries with the exception of inclusion cysts, areas of metaplasia, and papillary excrescences (3).

Serum CA125 was originally quantified using a homologous assay based on the monoclonal antibody OC-125 alone. This assay has been replaced by a heterologous assay that uses OC-125 as the capture antibody and M11 as the detection antibody. There are a number of CA125 assays available, most of which correlate well with each other and are clinically reliable. For some samples, however, differences between methods exist, suggesting a need for parallel testing when introducing a new method (4,5).

A CA125 serum value of 35 U/mL, representing 1% of female healthy donors, is often accepted as the upper limit of normal in clinical practice (6). It should be noted that this is an arbitrary cutoff and may not be suitable for all applications of CA125. In postmenopausal women or in patients who have undergone hysterectomy, for example, CA125 levels tend to be lower than in the general population and lower cutoffs may be more suitable: levels of 20 U/mL and 26 U/mL have been suggested (7–9). Approximately 85% of patients with epithelial ovarian cancer have CA125 levels of >35 U/mL (6,10). Elevated levels of >35 U/mL are found in 50% of patients with stage I disease, but raised levels are found in over 90% of patients with advanced disease (11). CA125 levels are less frequently elevated in mucinous, clear cell, and borderline tumors compared to serous tumors (11–13). CA125 can be elevated in other malignancies (pancreas, breast, colon, and lung cancer) and in benign conditions and physiological states such as pregnancy, endometriosis, and menstruation (11). Many of these nonmalignant conditions are not found in postmenopausal women, thus improving the diagnostic accuracy of elevated CA125 in this population.

Screening

The role of CA125 in screening for ovarian cancer is still under investigation. Elevation of CA125 in apparently healthy postmenopausal women is a powerful predictor of increased risk of ovarian cancer (14,15). However, if used alone, it is not a suitable screening test as it lacks sufficient specificity (16). When combined with abnormal ovarian imaging, the risk of ovarian cancer is increased (15). A multimodal screening strategy combining CA125 with pelvic ultrasound achieves high specificity (99.9%) and PPV (26.8%) in postmenopausal

TABLE 7.1**PARAMETERS OF TUMOR MARKER ASSAYS**

Tumor marker result	True tumor status	
	Positive	Negative
Positive	a (True positives)	b (False positives)
Negative	c (False negatives)	d (True negatives)

Sensitivity = True positives/All with tumor = $a/a + c$
 Specificity = True negatives/All tumor free = $d/d + b$
 Positive predictive value (PPV) = True positives/All with positive tumor-marker result = $a/a + b$

women (17). Preliminary data has shown that this may impact on survival. In a randomized controlled trial (RCT) of ovarian cancer screening (OCS) involving 22,000 postmenopausal women, median survival of those diagnosed with ovarian cancer in the screened group (72.9 months) was significantly better than that of women in the control group (41.8 months) (18).

CA125 was initially interpreted using a fixed cutoff. Sensitivity and specificity has been improved by the development of a statistical algorithm (Risk of Ovarian Cancer [ROC] algorithm) based on the age-specific risk of the disease and the behavior of CA125 with time in women with ovarian cancer versus normal controls (19). When the ROC algorithm was applied retrospectively to serial samples from an OCS trial of postmenopausal women, the area under the curve was significantly improved in comparison to a fixed CA125 cutoff (93% vs. 84%). For a target specificity of 98%, the ROC calculation achieved a sensitivity of 86% for preclinical detection of ovarian cancer, whereas CA125 cutoff achieved a lower sensitivity of 62% (20). The performance of the ROC algorithm has been evaluated prospectively in an RCT of 13,582 postmenopausal women aged over 50. Women with normal ROC results were returned to annual screening; those with intermediate values had repeat CA125 testing, while those with elevated values underwent transvaginal ultrasound (TVS). Women with abnormal or persistently equivocal findings on TVS were referred for a gynecologic opinion. High specificity (99.8%; 95% CI, 99.7 to 99.9) and PPV (19%; 95% CI, 4.1 to 45.6) for primary invasive epithelial ovarian cancer was achieved by using the ROC algorithm strategy in the prevalence screen involving 6,532 women (21).

There is controversy as to whether a raised CA125 in asymptomatic postmenopausal women is a predictor of nongynecologic cancer. An initial nested case control study of 1,542 women with elevated (≥ 30 U/mL) and normal (< 30 U/mL) CA125 levels using data from an RCT of 22,000 postmenopausal women (18) reported that elevated serum CA125 was not a predictor of a nongynecologic malignancy on mean follow-up of 2,269 days (22). However, it was associated with significantly increased risk of death from all causes in the next 5 years (23). In contrast, data from the Norwegian OCS trial of 5,500 women showed that breast and lung cancer were overrepresented among women with elevated CA125 (24). The two reports, although discrepant in their findings, agree that elevated CA125 is a risk factor for death from malignant disease. It is probably best to rule out other malignancies such as breast, lung, and pancreas in asymptomatic postmenopausal women with rising CA125 levels with no evidence of gynecologic malignancy.

One of the limitations of CA125 is that 15% to 20% of ovarian cancers do not express the antigen. Rosen et al. explored 10 potential serum markers that could complement CA125 in 65 ovarian cancers with weak or absent CA125 tissue expression. All specimens lacking CA125 expressed human kallikrein 10 (HK10), human kallikrein 6 (HK6), osteopontin, and claudin 3. A small proportion of CA125-negative ovarian cancers expressed DF3 (95%), vascular endothelial growth factor (VEGF) (81%), MUC1 (62%), mesothelin (MES) (34%), HE4 (32%), and CA-19-9 (29%). MES and HE4 showed the greatest specificity when reactivity with normal tissues was considered. Differential expression was also found for HK10, osteopontin, DF3, and MUC1 (25). Several of these markers are currently being assessed in nested case control studies using serum samples from ovarian cancer screening trials.

There are currently two large RCTs of OCS in postmenopausal women that incorporate CA125 measurement. Both seek to address the key issue of whether OCS will impact disease mortality in the general population. The U.K. Collaborative Trial of Ovarian Cancer Screening (UKCTOCS) involves 202,638 postmenopausal women aged 50 to 74, randomized to annual screening until the end of 2011 with serum CA125 using the ROC algorithm (50,640), TVS (50,639), or no screening (101,359) (www.ukctocs.org.uk) (Menon U, Gentry-Maharaj A, Ryan A, et al. Recruitment to multicentre trials—lessons from UKCTOCS: descriptive study. *Bmj* 2008;337:a2079.) The ovarian cancer screening arm of the National Institutes of Health Prostate Lung Colorectal and Ovarian Cancer Screening trial (PLCO) has randomized 78,237 women aged 55 to 74 (26,27). A proportion of women are not eligible for the ovarian screening as they have undergone bilateral oophorectomy. A total of 28,816 women had a serum CA125 (interpreted using a cutoff) and a TVS as part of the ovarian cancer prevalence screen. Of these, 1,338 (4.7%) had abnormal TVS and 402 (1.4%) had abnormal CA125 and 29 neoplasms; 26 ovarian, 2 fallopian, and 1 primary peritoneal neoplasm were identified (9 were tumors of low malignant potential and 20 were invasive). The positive predictive value for invasive cancer was 3.7% for an abnormal CA125, 1.0% for an abnormal TVS, and 23.5% if both tests were abnormal (27). Both trials are ongoing and will report in 2012–2014.

Women at increased risk of ovarian cancer due to hereditary predisposition often seek screening. It needs to be highlighted that in this population, the current recommendation is that women consider risk-reducing bilateral salpingo-oophorectomy once they have completed their families. The sensitivity and effectiveness of screening is still not established. Studies so far have not been of sufficient size or rigor to be able to draw any definitive conclusions with regard to the effectiveness of ovarian cancer screening in the high-risk group (28). In addition, multifocal primary peritoneal cancer is probably a phenotypic variant of familial ovarian cancer, and both CA125 and ultrasound are not reliable in detecting early-stage disease (29). False positive rates for CA125 and ultrasound are also higher in this population as most women are premenopausal (30,31). Table 7.2 gives details of studies involving 1,000 or more women. A more detailed review of all studies in this area is available elsewhere (37). One of the most promising trials to report so far is the U.S.-based Cancer Genetics Network (CGN) (38). Unlike previous studies, which used annual CA125 with a fixed cutoff and TVS, this trial used the ROC algorithm to screen 2,343 high-risk women at 3 monthly intervals. Thirty-eight women underwent surgery following 6,284 screens. Five ovarian cancers were detected, two prevalent (one early, one late stage) and three incident (three early) cases resulting in a PPV of 13%. Three further occult cancers were detected at risk-reducing salpingo-oophorectomy and one woman developed an interval (late-stage) cancer (36). Currently, there are two ongoing ovarian cancer screening trials in the high-risk population: the U.K. Familial Ovarian Cancer Screening Study

TABLE 7.2

STUDIES OF OVARIAN CANCER SCREENING IN WOMEN AT HIGH RISK (ONLY THOSE WITH OVER 1,000 PARTICIPANTS ARE LISTED)

Study	No.	Inclusion criteria	Screening tests	No. of invasive detected (LMP Tumors)	Cancers in screen-negative women (months from last screen)
Karlan et al. 1999 (29)	1,261	OC diagnosis since enrollment in the Gilda Radner OC Detection Program (women with <i>BRCA1/2</i> gene mutation)	TVS, CD, and CA125	One EOC, three PP (two), one stage I	Four PP (5, 6, 15, 16 mo); one EOC (2 mo)
van Nagell et al. 2000 (32)	3,299	Women over 50 and women over 25 with documented family history of OC in at least one first- or second-degree relative	TVS, CD, and CA125	Three (one), two stage I	Two (12, 14 mo)
Taylor et al. 2003 (33)	2,500	Prospective study of symptom-free women with at least one close relative who had developed ovarian cancer	TVS and CD	Six (four), four stage I	Two PP (20–40 mo); seven EOC (9–46 mo)
Stirling et al. 2005 (34)	1,110	First-degree relative with either one OC and one BC (age <50); one OC and two BC (age >60); hMLH1, hMSH2 mutation carrier; two or more OC; individual with BC and OC; three or more individuals with BC or OC over three generations; known <i>BRCA1</i> , <i>BRCA2</i> mutation carrier	TVS and CA125	Nine (one), two stage I	Three (2, 4, 12 mo)
Jacobs et al. 2005 ^a (35) (data as presented at the meeting)	2,005	Two first-degree relatives with OC; first-degree relatives with one OC and one BC (age <50); first-degree relatives with one OC and two BC (age >60); HNPCC (first-degree relatives with one OC and three colorectal cancers—1 <50); mutation positive families (<i>BRCA1</i> , <i>BRCA2</i> , <i>MLH1</i> , <i>MSH2</i> , <i>MSH6</i> , <i>PMS1</i> , <i>PMS2</i>)	CA125 (ROCA) and TVS	Nine, five early stage, four late stage	Not reported
Skates et al. 2007 ^a (36)	2,343	First- or second-degree relative with either <i>BRCA1/2</i> mutation; two of OC or early onset BC (age = 50); Ashkenazi ethnicity and one of OC or BC	CA125 (ROCA) and TVS	Six early stage, three late stage	Not reported

Note: BC, breast cancer; CD, Color Doppler; EOC, epithelial ovarian cancer; HNPCC, hereditary nonpolyposis colorectal cancer; OC, ovarian cancer; PP, primary peritoneal cancer; ROCA, Risk of Ovarian Cancer algorithm; TVS, transvaginal ultrasound; MO, months.

^aAbstract only.

(UK FOCSS) with 3,300 of the target of 5,000 women recruited, and gynecologic Oncology Group 199 trial (39) which aims to recruit 2,332 women. Both trials are using the ROC algorithm with a screening interval of 3 to 4 months. It is likely that they will report in 2012 at the same time as the general population trials.

Differential Diagnosis of an Adnexal Mass

Serum CA125 is of value in differential diagnosis of benign and malignant adnexal masses, especially in postmenopausal women. Using an upper limit of 35 U/mL, sensitivity of 78%, specificity of 95%, and PPV of 82% was achieved for malignant

disease in women with palpable adnexal masses (40). This has since been confirmed by numerous studies (41–43). Further improvements in specificity were achieved by using a panel of markers (CA125 II, CA-72-4, CA-15-3, and lipid-associated sialic acid) and an artificial neural network approach to differentiate malignant from benign pelvic masses (44).

The most valuable clinical tool has been combining serum CA125 values with ultrasound findings and menopausal status to calculate a Risk of Malignancy Index (RMI). It yielded a sensitivity of 85% and a specificity of 97%. Patients with an elevated RMI score had, on average, a 42-fold increase in the background risk of ovarian cancer (45). The RMI has since been validated both retrospectively and prospectively in gynecologic oncology and general gynecologic units (46–55) with prospective studies reporting lower sensitivity, specificity, and PPV (46,53). Higher sensitivity can be achieved by increasing the RMI cutoff (49,52,54), using artificial neural networks or altering the RMI calculation (46,50,51).

Recently the performance of RMI values of 25 to 1,000 in combination with specialist ultrasound (US), magnetic resonance imaging (MRI), and radioimmunoscintigraphy (RS) in a prospective cohort study of 180 women with an adnexal mass referred to a teaching hospital has been assessed. In women with an RMI cutoff of ≥ 25 and $< 1,000$, addition of US and MRI provided a sensitivity of 94% and a specificity of 90%. The authors concluded that utilizing this approach in contrast to an RMI cutoff value of 250 can improve the correct referral of cancer patients to a cancer center, without change in the proportion of patients with benign disease being managed locally (55,57). It has also been suggested that the use of an RMI over 200 and the absence of an ovarian crescent sign (an ultrasound feature that depends on the fact that healthy ovarian tissue can be seen adjacent to the cyst within an ipsilateral ovary) used sequentially may improve the accuracy of ovarian cancer diagnosis (56). Despite limited value in borderline, stage I invasive, and nonepithelial ovarian cancers, the RMI is a simple, easily applicable method in the primary evaluation of patients with adnexal masses that identifies ovarian cancers more accurately than any other criterion used in diagnosis of this disease (47).

Prognosis

In ovarian malignancy, preoperative serum CA125 levels are related to tumor stage, tumor volume, and histological grade. Although initial studies did not find preoperative CA125 to be an independent prognostic factor (58–60), more recent work has confirmed it to be of value in localized/early-stage disease (61). A recent study of 118 patients with FIGO stage I epithelial ovarian cancer demonstrated that patients with stage I epithelial ovarian cancer and preoperative serum CA125 levels < 65 U/mL had a significantly longer survival compared to stage I patients with preoperative serum CA125 ≥ 65 U/mL (62). This was confirmed in a study of 600 patients from gynecologic cancer centers in Australia, the United States, and Europe with stage I epithelial ovarian cancer. On multivariate analysis, preoperative serum CA125 > 30 U/mL and age > 70 years at diagnosis were the only independent predictors for overall survival. Levels of CA125 of ≤ 30 U/mL dominated over histological cell type, substage, and grade and were able to identify a subgroup of FIGO stage I patients with a genuinely good prognosis and extremely good survival who could possibly be spared of adjuvant chemotherapy (63). Additional parameters such as cyclooxygenase-2 overexpression in combination with preoperative CA125 level of under 30 U/mL have recently been found to be independent predictors of survival in univariate and multivariate analyses (64). In advanced ovarian cancer, CA125 does not seem to be an independent prognostic factor (61).

Postoperative CA125 levels have been found to be significant prognostic factors (58) with patients with a low CA125

prognostic score composed of two CA125 values, one taken preoperatively and the other taken 1 month after surgery, having significantly better prognosis than patients with high scores (65). It should be noted that CA125 levels can be elevated in the immediate postoperative period as a result of the abdominal surgery, and therefore measurements are best postponed for at least 4 weeks (66).

During primary chemotherapy, serum CA125 half-life is an independent prognostic factor in patients with advanced epithelial ovarian cancer, for both complete remission and survival (67–69). The most commonly used cutoff is a CA125 half-life of 20 days (69–71). In patients with CA125-positive tumors, other useful prognostic indicators of survival are the serum CA125 levels prior to a third course of chemotherapy (67,72,73) and the slope of the CA125 exponential regression curve. A recent retrospective analysis of patients treated in maintenance chemotherapy trials suggests that, in women achieving a clinically defined complete response to primary chemotherapy with a baseline CA125 level of ≤ 35 U/mL, the baseline CA125 level before initiation of maintenance chemotherapy strongly predicts the risk of subsequent relapse. Patients with pre-maintenance baseline CA125 values ≤ 10 U/mL have a superior progression-free survival compared to those with higher levels in the normal CA125 range (74).

Serum CA125 continues to be of prognostic significance when ovarian cancer recurs, with patients with normal serum CA125 levels (≤ 35 U/mL) at relapse having a better prognosis than patients with elevated levels (75).

Monitoring Response to Treatment

Serum CA125 levels reflect progression or regression of disease in over 90% of ovarian cancer patients with elevated preoperative levels (6,76) (Fig. 7.1). These findings have resulted in the widespread use of serum CA125 levels to monitor the clinical course of ovarian cancer and its response to chemotherapy (77). It is to be noted that CA125 should not be used as the sole criterion to determine clinical response (78) as studies involving second-look laparotomy have confirmed that CA125 values of < 35 U/mL do not exclude active disease (79). The pattern of CA125 over time is a more useful parameter than using an arbitrary cutoff level (71,72,80,81). Precise mathematical definitions to evaluate response to treatment have been suggested, with 50% response corresponding to a 50% decrease in CA125 after two samples, confirmed by a third sample collected at least 28 days later, and a 75% response defined as a serial decrease over three samples of greater than 75% (82,83). A recent French multicenter study on the kinetics of CA125 under induction chemotherapy has again confirmed that prechemotherapy CA125, its half-life, nadir concentration, and time to nadir, all had a univariate prognostic value for disease-free and overall survival (84).

Detecting Recurrence

Among patients with elevated CA125 levels at diagnosis, serial monitoring following initial chemotherapy can lead to the early detection of recurrent disease. Median lead time prior to clinical progression of 63 to 99 days has been demonstrated between marker detection of disease progression and clinically apparent progressive disease (85,86). The value of marker lead time depends ultimately on a patient's remaining therapeutic options, and the clinical value of this approach is unclear (87).

In a study of 39 patients with elevated serum CA125 at time of diagnosis and complete clinical and radiographic response to initial treatment with normalization of serum CA125, Santillan et al. reported that a relative increase in CA125 of 100% (odds ratio [OR] = 23.7; 95% CI, 2.9 to 192.5) was significantly predictive of recurrence. From baseline CA125 nadir

FIGURE 7.1. Correlation between serum CA125 and clinical course in ovarian cancer.

levels, an absolute increase in CA125 of 5 U/mL (OR = 8.4; 95% CI, 2.2 to 32.6) and 10 U/mL (OR = 71.2; 95% CI, 4.8 to >999.9) were also significantly associated with the likelihood of concurrent disease recurrence. These data suggest that for patients in complete clinical remission, a progressive low-level increase in serum CA125 levels is strongly predictive of disease recurrence (88).

CA125 measurements together with thin-section computed tomography (CT) and careful review of the clinical history are recommended in follow-up of patients with ovarian carcinomas (89). However, a study of 58 patients with recurrent ovarian cancer revealed that 98% of recurrences were identified by physical examination and CA125, with ultrasound and CT not providing additional clinically relevant information during follow-up (90).

Combination With Other Markers

Tumour-associated trypsin inhibitor (TATI), CA-19-9, CA-72-4, and carcinoembryonic antigen (CEA) in addition to CA125 may be useful in mucinous ovarian cancer (91). Increased pre-operative sensitivity for early-stage disease has been reported by combining CA125 with CA-72-4, CA-15-3, and M-CSF (92). The majority of studies, however, report limited ability to improve diagnostic sensitivity by addition of other serum markers for patients with nonmucinous tumors (81,93–96). In clinical situations when CA125 is inconclusive or negative, Cancer-associated serum antigen (CASA) may be useful in the follow-up of patients with advanced disease (97). A more recent immunohistochemical study of CA125-negative ovarian cancers showed that all specimens expressed human kallikrein 10, human kallikrein 6, osteopontin, and claudin 3 with a smaller proportion expressing DF3 (95%), VEGF (81%), MUC1 (62%), MES (34%), HE4 (32%), and CA-19-9 (29%). From all the markers assayed, MES and HE4 exhibited greatest specificity (25). Further investigation of these markers in serum is underway.

Carcinoembryonic Antigen

Carcinoembryonic antigen (CEA) was first identified in 1965 in serum of rabbits immunized with colon carcinoma (98). It is an oncofetal antigen that is found in small amounts in the adult colon. Elevated levels are associated with colon and pancreatic cancer. CEA levels are also raised in benign diseases of the liver, gastrointestinal tract, and lung, and in smokers. In ovarian cancer, CEA is expressed by most endometrioid and Brenner tumors, and in areas of intestinal differentiation in mucinous tumors. In contrast to CA125, this marker is not expressed in normal and inflammatory conditions of the adnexa. Around 25% to 50% of ovarian cancer patients have elevated levels of CEA, and the correlation with ovarian cancer is not as well established as with the other markers (99,100).

Alpha-Fetoprotein

Alpha-fetoprotein (AFP) is an oncofetal protein produced by the fetal yolk sac, liver, and upper gastrointestinal tract. Elevated levels of AFP occur in pregnancy and benign liver disease. Serum levels are raised in most patients with liver tumors, and some patients with gastric, pancreatic, colon, and bronchogenic malignancies have elevated AFP levels (99). AFP levels were investigated in 135 patients with germ-cell tumors, and elevated levels were found in all patients with endodermal sinus tumors, 62% with immature teratomas and 12% with dysgerminoma (101). AFP also accurately predicts the presence of yolk sac elements in mixed germ-cell tumors (102). Although AFP production in epithelial ovarian cancers is extremely rare, a case of ectopic production of AFP by an ovarian endometrioid tumor has been described in the literature (103).

In women with endodermal sinus tumors, AFP is a reliable marker for monitoring therapeutic response and detecting recurrence (104,105). On univariate analysis, AFP levels of

over 1,000 ng/mL, age over 22, and histology were found to be major prognostic factors in 43 patients with ovarian and extragonadal germ-cell tumors (106).

Human Chorionic Gonadotropin

Human chorionic gonadotropin (hCG) is synthesized in pregnancy by the syncytiotrophoblast. It is a glycoprotein hormone made up of two dissimilar covalently linked subunits α and β . Production of hCG by the tumor is accompanied by varying degrees of release of the free subunits into circulation. Recent advances in our understanding of hCG/hCG- β synthesis by trophoblastic and nontrophoblastic tissues alongside an improvement in techniques measuring hCG have helped define its role in clinical practice. hCG is elevated in virtually all cases of gestational trophoblastic disease (hydatidiform mole, invasive mole, and choriocarcinoma) and serves as an ideal tumor marker. There is a close correlation between hCG levels and tumor burden, and hCG levels are used in staging and clinical management. Serum hCG can also be detected in patients with nontrophoblastic cancers. Although gynecologic cancers are prominent in this group, the sensitivity of using hCG is lower than for other markers in current use except in germ-cell tumors with a chorionic component (107).

In a retrospective analysis of 113 patients with stage IC to IV malignant ovarian germ-cell tumors, both on univariate and multivariate analyses, stage of disease and elevation of serum hCG- β and AFP were significant predictors of overall survival, whereas age at diagnosis was of no prognostic value (108). It is worth noting that this is the first study to demonstrate stage and tumor markers as prognostic parameters in patients with malignant ovarian germ-cell tumors and may help in deciding on a therapeutic regimen.

Inhibin and Related Peptides

Inhibins and activins are structurally related dimeric proteins, first isolated from ovarian follicular fluid on the basis of their ability to modulate pituitary follicle-stimulating hormone secretion. They are members of a larger group of diverse proteins, the transforming growth factor- β (TGF- β) superfamily, which are involved in cell growth and differentiation. Inhibin is a heterodimeric glycoprotein composed of a common α -subunit and one of two β -subunits, resulting in either inhibin A ($\alpha\beta_A$) or inhibin B ($\alpha\beta_B$), for which specific immunoassays are now available. The serum also contains immunoreactive forms of the alpha subunit not attached to the beta subunit, the most abundant of which is pro- α_C and pro- $\alpha_{N-\alpha_C}$. The pro- α_C assay measures these precursor forms of inhibin. The original Monash assay detected immunoreactive inhibin that included a range of inhibin-related peptides in addition to biologically active inhibin dimers.

In 1989, Lappohn et al. (109) reported elevated serum immunoreactive inhibin concentrations in women with granulosa-cell tumors. Numerous studies have since confirmed serum inhibin elevation in ovarian sex cord/stromal tumors and established its role in differential diagnosis and surveillance of these malignancies (110–112). The major molecular forms detected are bioactive dimeric inhibins A and B (113,114). Antimüllerian hormone, or müllerian inhibitory factor, is another member of the TGF- β superfamily that is being investigated as a marker for granulosa-cell tumor (113,115,116).

In epithelial ovarian cancer, the role of the inhibin peptides remains to be determined. Using the initial nonspecific Monash assay, elevated serum inhibin levels were reported in 25% to 90% of women with epithelial ovarian cancer (117–119). In 2004, an ELISA assay for total inhibin was developed (120).

Tsigkou et al. investigated the sensitivity/specificity of serum total inhibin for epithelial ovarian cancer in 89 postmenopausal women with stage II to III epithelial ovarian cancer and found that patients with serous or mucinous tumors showed the highest total inhibin levels. At 95% specificity, the total inhibin assay detected 93% of serous and 94% of mucinous tumors (121). Mucinous ovarian cancers are most likely to be associated with increased inhibin levels (111,122). In contrast, using specific assays that measure bioactive dimeric inhibin A, elevated serum levels were only found in 5% to 31% of women with epithelial ovarian cancer (116,122,123). Overall, the picture is emerging that dimeric inhibin A and B levels are not informative in epithelial ovarian cancer, and total inhibin/pro- α_C immunoreactive forms are the most commonly elevated of the inhibin-related peptides (121,123,124). Furthermore, although there is preferential secretion of precursor forms of the alpha subunit rather than dimeric inhibin A by epithelial ovarian cancer, pro- α_C is unlikely to be a useful marker if used alone (125). Combining pro- α_C with CA125 may improve the sensitivity for detection of epithelial ovarian cancer (123). More recently, when total inhibin was combined with CA125, all cases of serous and mucinous tumors were detected and the overall sensitivity for epithelial ovarian cancers was 99% at 95% specificity, respectively. On further follow-up, it became clear that an increase of total inhibin levels was associated with recurrence. These recent data suggest that total inhibin is a sensitive and specific marker of epithelial ovarian cancer in postmenopausal women and may therefore be combined with CA125 for noninvasive diagnosis of epithelial ovarian cancer. Furthermore, it may also be a useful serum marker to monitor disease-free intervals (121).

In conclusion, the data suggest that functional inhibin is secreted by most ovarian granulosa-cell tumors and may be superior to estradiol in assessing therapeutic response and predicting recurrence. For epithelial ovarian cancer, dimeric inhibin A and B levels are probably not informative. While the role of total inhibin/pro- α_C needs further investigation, most recent data suggest that total inhibin displays high sensitivity and specificity for serous and mucinous cancer, which is improved when total inhibin is combined with CA125.

Activin is a dimer of the two-beta subunits of inhibin and exists as activin A ($\beta_A \beta_A$), activin B ($\beta_B \beta_B$), and activin AB ($\beta_A \beta_B$). Serum activin A has been shown to be significantly elevated in epithelial ovarian cancer (113,125,126), with highest levels detected in undifferentiated tumors. More recently, high concentrations of activin A in the peritoneal fluid of women with serous ovarian carcinoma have been shown to be useful in distinguishing serous ovarian cancer from cystadenoma (128). Preliminary data suggest a poor correlation of activin levels and the clinical course of the disease (113). It is possible that activin A could play a role in ovarian cancer but further investigation is needed.

Estrogen/Androgen

Estrogen secretion is associated with granulosa-cell tumors. Serial estradiol levels are of significant value in monitoring these patients after surgery, in view of the difficulty in assessing the malignant potential of these tumors on histological grounds. Androgen levels are elevated in women with Sertoli-Leydig-cell tumors.

Kallikreins

The human kallikrein gene family currently consists of 15 members. There is accumulating evidence that in addition to prostate-specific antigen (PSA, hK3) and human glandular

kallikrein (hK2) (both prostate cancer biomarkers), many other members of the human kallikrein gene family are differentially regulated in breast, ovarian, and testicular cancers. Recently it has been shown that the malignant phenotype of ovarian cancer cells can be enhanced by overexpression of the human tissue kallikrein genes 4, 5, 6, and 7 (129). Potential biomarkers for ovarian cancer include kallikreins 5, 6, 7, 8, 10, 11, and 14 (130,132,133). Kallikrein 4 is up-regulated in epithelial ovarian carcinoma cells in effusions (132) and kallikrein expression may have some value in differentiating ascites resulting from ovarian cancer from other malignant and nonmalignant causes (134). Human kallikrein 8 seems to be an independent marker of favorable prognosis in ovarian cancer (135), while kallikrein 7, although not an independent prognosticator for ovarian cancer, has been found to be associated with unfavorable characteristics of the disease (136).

Mesothelin

Mesothelin is a marker that was initially identified in mesotheliomas and ovarian cancers in 1996 (137). Serum levels are higher in ovarian cancer patients when compared to women with benign ovarian tumors or from the normal population. The levels increase significantly from early to advanced stages. Elevated mesothelin levels before therapy are associated with poor overall survival both in patients with optimal debulking surgery and in those with advanced disease (138). It is possible that mesothelin may prove to be a useful tumor marker for differential diagnosis of epithelial ovarian cancer as well as for prognosis.

Prostasin

Prostasin, a serine protease secreted by the prostate gland, was identified following use of cDNA microarray technology on RNA pooled from ovarian cancer and normal human ovarian surface epithelial cell lines to detect overexpressed genes for secretory proteins that might be potential serum biomarkers (139). The initial study reported higher levels of prostasin in ovarian cancer patients compared to controls, with levels decreasing following surgery. For a fixed specificity of 94%, sensitivity for detection of ovarian cancer for CA125 was 64.9% (95% CI, 47.5 to 78.9), for prostasin 51.4% (95% CI, 34.4 to 68.1), and for the combination 92% (95% CI, 78.1 to 98.3) (139). Prostasin may have clinical potential but it needs further investigation and validation.

Osteopontin

Osteopontin is another biomarker that has been identified using gene-expression profiling techniques. The initial investigation showed osteopontin tissue expression to be weak or absent in 93% of ovarian adenocarcinomas, compared to positive expression in 81.5% in borderline tumors and 50% in omental and lymph node implants. Its expression did not correlate with histological type, grade, or clinical stage (140). In 2002, Kim et al. showed an increased expression of this marker in ovarian cancer cell lines, microdissected tissues, and plasma of epithelial ovarian cancer patients (141). Preoperative plasma osteopontin and CA125 levels were investigated in patients with ovarian cancer, benign ovarian tumor, other gynecologic cancers, and healthy women and showed significantly higher levels in patients with ovarian cancer than the other groups. Higher plasma osteopontin levels were detected in late-stage ovarian cancer patients (stage IV) and ovarian cancer patients with ascites with no correlation with histological type.

Sensitivity of preoperative plasma osteopontin in detecting ovarian cancer was 81.3%, which increased to 93.8% when combined with CA125, suggesting that preoperative osteopontin may be a useful biomarker for differential diagnosis of ovarian cancer, particularly when combined with CA125 (25,142). Osteopontin levels have been shown to correlate with the presence of ascites, bulky disease, and recurrence (143). In predicting clinical response to therapy, osteopontin is inferior to CA125. However, levels increase earlier in 90% of patients developing recurrent disease, leading the authors to suggest that it may be useful as a complementary marker in detecting recurrent ovarian cancer (144).

Cytokines

Cytokines are soluble mediator substances produced by cells that exercise a specific effect on other target cells. Their importance in tumor biology has increased since the demonstration that many cytokines are produced by cancer cells and can influence the malignant process in a positive and a negative manner (127). However, cytokines do not fulfil the classic criteria for tumor markers, as they may be elevated in a number of pathological conditions, are invariably produced by nonmalignant surrounding tissue rather than the tumor itself, and are not specific for one cell type. Despite this, their measurement in malignant conditions may provide valuable clinical information regarding prognosis and response to treatment.

Details of some of the cytokines and their roles as tumor markers in ovarian malignancy are shown in Table 7.3. The majority are at an early stage of evaluation, with conflicting reports associated with some. The most studied cytokine in the context of ovarian cancer is serum M-CSF (or CSF-1). It appears to be a marker with high specificity for ovarian malignancy with elevation being related to stage (163,167). When combined with other markers, it may have a role in ovarian cancer screening (165,167). Combination of CA125II, CA-72-4, and M-CSF significantly increased sensitivity for detecting early-stage disease compared to CA125II alone (70% vs. 45%) while maintaining 98% specificity (92). M-CSF may be highly sensitive and specific for malignant germ-cell tumors of the ovary, especially dysgerminoma (166). It has been shown that elevated serum levels are associated with poor outcome after adjusting for stage, grade, and degree of surgical clearance (59). In patients with advanced disease, low ascitic fluid M-CSF was associated with longer overall survival and was a better indicator in comparison to other prognostic factors except for zero residual disease (164). Serum M-CSF does not seem to be useful in follow-up of women with advanced disease (168).

Interleukins have also been studied in ovarian cancer. Preliminary reports demonstrated IL-6 elevation in 50% of ovarian cancers (145,146). However, the combination of IL-6 and CA125 did not improve the sensitivity of CA125 alone (146). A more recent report investigating the role of CA125, IL-6, IL-7, and IL-10 in 187 ovarian cancer patients, 45 patients with benign ovarian tumors, and 50 healthy controls found that a combination of IL-7 and CA125 could accurately predict 69% of the ovarian cancer patients, without falsely classifying patients with benign pelvic mass (152).

Cytokeratins

Cytokeratins are intermediate filaments that are part of the cytoskeleton of all epithelial cells. They are specific markers of epithelial differentiation and continue to be expressed by epithelial cells following malignant transformation. Fragments of cytokeratins, in contrast to cytokeratins themselves, are soluble in serum and can be detected and measured using monoclonal

TABLE 7.3

STUDIES REPORTED ON THE ROLE OF CYTOKINES AS TUMOR MARKERS IN OVARIAN CANCER

Cytokines	Description
Interleukin-6 (IL-6)	High levels of IL-6 in 50% of patients with primary ovarian cancer (145,146). Serum levels correlate with stage of disease (147). IL-6 sensitivity lower than that of CA125, and the combination of both assays did not increase the sensitivity of CA125 alone (146). Conflicting reports on the role of elevated IL-6 serum levels in predicting prognosis (146,148–150). It has been shown that <i>IL6-174</i> promoter polymorphism impacts serum cytokine levels through transcriptional regulation. Recent data has shown that the <i>IL6-174</i> GG genotype has a strong, independent, and favorable impact on survival for women with ovarian and peritoneal carcinoma (151).
Interleukin-7 (IL-7)	Serum levels of CA125, IL-6, IL-7, and IL-10 were determined in 187 ovarian cancer patients with complete clinicopathologic data and follow-up, 45 patients with benign ovarian tumors, and 50 healthy controls and were found to be elevated in ovarian cancer patients compared to patients with benign ovarian tumors. A combination of IL-7 and CA125 serum levels accurately predicted 69% of the ovarian cancer patients, without falsely classifying patients with benign pelvic mass. IL-7 was not an independent predictor of overall survival when clinicopathologic parameters were included (152).
Soluble interleukin-2 receptor (sIL-2R)	Elevated in numerous malignancies and in liver, renal, and autoimmune diseases. Only patients with advanced epithelial ovarian cancer had elevated preoperative serum sIL-2R alpha levels (153). Conflicting reports on the usefulness of sIL-2R as an adjunctive tool for the differential diagnosis of ovarian masses (154, 155). Limited benefit for monitoring response to chemotherapy and follow-up of patients with epithelial ovarian cancer (153,156–158).
Tumor necrosis factor (TNF)	Raised levels documented in various malignancies and several benign conditions. Significantly higher levels were reported in patients with epithelial ovarian cancer than in those with benign ovarian disease (159). A more recent study has shown that serum TNF- α levels differed between benign tumors and endometriomas ($p < 0.01$), but not between endometriomas and malignant tumors (160). No correlation has been shown between preoperative TNF values and common prognostic variables or the clinical outcome of patients (159).
Soluble receptors of TNF (sTNF-R)	Initial studies suggested that preoperative serum levels might have a potential role for detection, prognosis, and monitoring disease (159,161). The ratio of preoperative serum TNF- α receptor 1 (p55) and 2 (p75) may be of value in differential diagnosis of ovarian cancer (162).
Macrophage colony-stimulating factor (M-CSF)	Levels significantly elevated in 61% to 64% of patients with ovarian cancer compared with 6% to 7% of patients with benign ovarian tumors. Elevation related to stage of disease and independent of histologic type (163,164). Serum M-CSF, but not CA125, significantly associated with outcome following adjustment for stage, grade, and degree of surgical clearance (54). May have a role in ovarian cancer screening (163,165). Combination of CA125II, CA-72-4, and M-CSF significantly increased sensitivity for detecting early-stage disease compared to CA125II alone (70% versus 45%) while maintaining 98% specificity (92). M-CSF may be highly sensitive and specific for malignant germ-cell tumors of the ovary, especially dysgerminoma (166).

antibodies. Their role as tumor markers in various malignancies is currently being investigated.

Tissue Polypeptide-Specific Antigen

Tissue polypeptide-specific antigen (TPS) is a proliferation marker closely related to the tumor marker TPA. It is recognized by a monoclonal antibody raised against the M3 epitope on cytokeratin 18. TPS is elevated in 50% to 77% of ovarian cancers studied with a specificity of 84% to 85% (169–172). Preoperatively, serum levels of TPS and CA125 were significantly higher in patients with cancer rather than benign disease and in those with advanced compared to early-stage disease. Similarly, levels of TPS and CA125 were higher in malignant and benign tumor cysts and ascitic fluids than in corresponding sera with levels in cyst fluid from cancer patients being the highest (173). However, no correlation between TPS levels and survival have been shown (172). Its serial measurement may be of value in the follow-up of

patients (169,170). When combined with CA125, sensitivity for predicting recurrence of 81% was achieved with a specificity and PPV of 82% and 58%, respectively (171,172).

CYFRA 21-1

CYFRA 21-1 is a fragment of cytokeratin 19. The assay was first developed in 1993 by Stieber et al. (174). It was initially found to be elevated in cervical and endometrial cancers (175). It does not seem to be very useful in the differential diagnosis of adnexal masses, with most studies reporting sensitivities of 40% to 45% (176,177). It may have a role as a prognostic factor but there are conflicting reports. Elevated CYFRA 21-1 levels prior to therapy were reported to be associated with poor overall and disease-free survival in ovarian cancer (177). However, preoperative levels of CYFRA 21-1 were higher in patients with advanced disease, but Cox regression analysis failed to detect a significant association between preoperative CYFRA 21-1 values and survival. For patients with

advanced ovarian cancer, preoperative CYFRA 21-1 levels appear to be predictive of response to chemotherapy but not of survival (178). In a recent case report, elevated levels of CYFRA 21-1 together with neuron-specific enolase, estradiol, and CA125 were described in a patient with Sertoli-Leydig-cell tumor of the ovary, and it was suggested that it may be useful to further investigate the role of these tumor markers in individualized monitoring (179).

Proteomics

Proteomics is the study of the expression, structure, and function of all proteins as a function of state, time, age, and environment (180–182). It complements the genomics-based approaches and has become very popular in the past few years. While two-dimensional gel electrophoresis continues to be the cornerstone of protein separation, mass spectrometry is increasingly being used for diagnostics, tissue imaging, and biomarker discovery as it is a high-throughput technique requiring small amounts of sample (183). Surface-enhanced laser desorption ionization time-of-flight (SELDI-TOF) analysis and matrix-associated laser desorption ionization time-of-flight (MALDI-TOF) technology have the potential to identify patterns or changes in thousands of proteins in the mass range under 20 kDa. When combined with matrices that selectively absorb certain serum proteins, these approaches can globally analyze almost all small proteins in complex solutions, such as serum or plasma (184,185). Two proteomic approaches have been used: one examines the pattern of peaks on mass spectrometry, and the other uses proteomic analysis to identify a limited number of critical markers that are then assayed by more conventional methods. Both approaches are promising but require further development.

In a preliminary study, SELDI-TOF in combination with powerful computer algorithms identified a pattern of protein changes in serum with sensitivity of 100%, specificity of 95%, and PPV of 94% for both early and late ovarian cancer in a limited set of samples from 50 patients with ovarian cancer and 50 unaffected women (186). There were numerous issues with the study design (131,187–189) and the results are still to be validated. In a multicenter case-control study that followed, three potential serum biomarkers for ovarian cancer were identified: lower levels of apolipoprotein A1, lower levels of a truncated form of transthyretin, and elevated levels of a cleavage fragment of inter-alpha-trypsin inhibitor heavy chain H4 (ITIH4) (190). These findings were confirmed in an independently conducted blinded study of 42 women with ovarian cancer, 65 with benign tumors, and 76 with digestive diseases. The mean levels of five of the six forms of transthyretin were significantly lower in cases than in controls (191). The specificity of a model including transthyretin and apolipoprotein A1 alone was high (96.5%; 95% CI, 91.9 to 98.8) but sensitivity was low (52.4%; 95% CI, 36.4 to 68.0). A class prediction algorithm using all seven markers, CA125, and age maintained high specificity (94.3%) but had higher sensitivity (78.6%) (191). Proteomic analysis of plasma samples has also yielded informative protein spots that may be complementary to those identified in the serum. Using four specific protein peaks in plasma, a sensitivity of 90% to 96.3% and specificity of 100% for the studied cases and controls were reached (192). However encouraging these results are, further validation studies with due consideration to the influences of sample handling, subject characteristics, and other covariates on biomarker levels need to be undertaken. A recent report has confirmed that sample processing after venipuncture affects serum protein profile with the largest effect related to room temperature prior to sample separation. Certain proteins (transthyretin, apolipoprotein C1, and transferrin) were unaffected by handling, while others (ITIH4 and hemoglobin β) displayed significant variability (193). This further highlights the need for biomarker discovery to be carried

out on samples collected in a standardized fashion. More recent efforts have involved exploring antibodies raised to 35 of 217 protein spots obtained by proteomic profiling of ovarian cancer and normal tissue (194) and subtype-specific biomarker candidates obtained by differential protein expression of tissue specimens from clear cell and mucinous ovarian cancers (195,196). In contrast to the biomarker studies described above, where proteomic profile is assessed in differing numbers of specimens from cases and controls, another proposed approach is the creation and use of standard serum sets developed from pooled healthy donors and pooled sera from ovarian cancer cases. Preliminary data show that CA125 remains the best single marker for non-mucinous ovarian cancer, complemented by CA-15-3 or soluble mesothelin-related protein (36).

The high volume of data obtained from proteomic analyses is difficult to handle. Various algorithms are being developed to analyze the preprocessed mass-spectrometry data and identify the most informative “common” peaks, but these approaches still need fine tuning (197–199). It is critical that once the technology is standardized, large, prospective, multicenter trials are carried out to ensure validation (200).

Metabolite Profiling

Metabolites are the end products of cellular regulatory processes. Alterations in their levels can be regarded as response to genetic or environmental changes. Analysis of 66 invasive ovarian carcinomas and nine borderline ovarian tumors by gas chromatography/time-of-flight mass spectrometry (GC-TOF MS) using a novel contamination-free injector was undertaken to assess if quantitative signatures of primary metabolites can be used to characterize molecular changes in ovarian tumor tissues. A total of 291 metabolites were detected and 114 were already annotated compounds. Principal component analysis as well as additional supervised predictive models allowed a separation of 88% of the borderline tumors from the carcinomas. The data suggest that metabolomics is a promising high-throughput, automated approach in addition to functional genomics and proteomics for analyses of molecular changes in malignant tumors (201).

Other Serum Markers

Table 7.4 details other serum markers that have been assessed in isolation and as part of panels in women with ovarian cancer, both in the context of screening and differential diagnosis, as well as in assessing prognosis, monitoring response to treatment, and detecting recurrence. Table 7.5 details their current role in ovarian cancer. It is important to note that in women with ovarian cancer, no single marker or combination of markers has emerged with a clear clinical advantage over CA125, except in specific tumor subtypes such as germ-cell tumors with yolk sac and chorionic elements, and granulosa-cell tumors. The results of the proteomic and genomics studies are therefore eagerly awaited. The consensus is that these new approaches are most likely to identify novel markers or marker panels that in combination with CA125 will improve biomarker accuracy in ovarian cancer.

ENDOMETRIAL CANCERS

There are no serum markers with an established role in the clinical management of endometrial cancer. Serum CA125 is elevated in 10% to 31% of patients (265–268) with elevated

TABLE 7.4

OTHER TUMOR MARKERS FOR OVARIAN CARCINOMA THAT ARE NOT REFERRED TO IN DETAIL IN THE TEXT

Tumor marker	Description
CA-15-3	Tumor-associated antigen in human milk fat globule membrane. Most used in breast carcinoma. Elevated levels in 57% to 71% of ovarian cancer patients and 2% to 6% of patients with benign tumors (202,203). Not useful on its own (204), but in combination with CA125 increases the specificity of the CA125 assay in the differential diagnosis of adnexal masses (203). Preoperative sensitivity for early-stage disease was 45% for CA125II; 67% for CA125II and CA-72-4; 70% for CA125II, CA-72-4, and M-CSF; and 68% for CA125II, CA-72-4, M-CSF, and CA-15-3. CA-15-3 in combination with the other three markers performed second in comparison to using the other markers alone (92).
CA-72-4 or TAG-72	Defines a glycoprotein surface antigen found in colon, gastric, and ovarian cancer. Levels elevated in 67% of ovarian cancers (205) with a better sensitivity than CA125 for mucinous tumors (206,207). The specificity of CA-72-4 for ovarian malignancy was >95%, and combination with CA125 increased sensitivity without substantial change in specificity (208). Combination of CA125II, CA-72-4, and M-CSF significantly increased preoperative sensitivity for early-stage disease from 45% with CA125II alone to 70%, while maintaining 98% first-line specificity (92). The addition of serum CA-72-4 to the combination of pelvic examination, ultrasound, and serum CA125 improved discrimination between malignant and benign pelvic masses (209).
CA-19-9	Defines an antigen that is part of the Lewis blood group antigens. Elevated in gastrointestinal, lung, ovarian, and endometrial carcinoma. Most useful in pancreatic carcinoma. Mucinous ovarian cancers express the antigen more frequently (76%) than serous tumors (27%). Unlike CA125, not affected by pregnancy (210). Together with CA125, was the most useful marker in patients with borderline ovarian tumors (12). In patients with mature cystic teratomas of the ovary, elevated levels were found in 38.8%, whereas serum CA125 was elevated in 25% of the patients. Patients with an elevated serum CA-19-9 level showed significantly higher rates of bilateral tumors (51.6% versus 12.2%) than the patients with low levels (211). In a recent study of 28 stage I ovarian cancers, preoperative serum CA125 and CA-19-9 levels in stage IA patients were much lower than in patients with stage IC disease (212).
OVX1	Antigenic determinant on a high-molecular-weight mucin-like glycoprotein present in ovarian and breast cancer cells. Recognized by murine monoclonal antibody OVX1 (213). Elevated serum levels (>7.2 U/mL) reported in 5% of 184 normal individuals and in 70% of 93 epithelial ovarian cancer patients (214). OVX1 as a part of a panel of markers improved the sensitivity for discriminating malignant from benign pelvic masses (165,215). However, although the combination of serum OVX1, CA125II, and M-CSF markers had greater sensitivity than CA125 alone for all stages of ovarian cancer, only CA125 was able to distinguish invasive stage I tumors from apparently healthy women (216). A preliminary report found that serial measurement of OVX1 in combination with CA125 improved the sensitivity, specificity, and PPV of CA125 alone in primary screening for epithelial ovarian cancer (217). However, the OVX1 radioimmunoassay is highly dependent on sample handling (96) and therefore is not widely used.
CASA/OSA	Tumor-associated antigens assayed by dual epitope ELISAs using the same capture monoclonal antibody (BC2) and different second antibodies (OM-1 and BC3, respectively). Elevated levels reported in 38% to 58% of ovarian cancers (94,218) with CASA showing higher specificity (94). In addition, CASA was elevated in patients with breast, lung, prostate, and bladder cancer (218). CASA may have a role in prognosis and monitoring disease—postoperative OSA and CASA assays were superior to CA125 for detection of small-volume occult ovarian carcinoma (219); on multivariate analysis of survival rates postoperative CASA levels ranked above all prognostic factors except age (220); postoperative CASA levels supplemented the prognostic value of CA125 measurements in monitoring disease (221,222); in patients with recurrent ovarian carcinoma, elevated level of CASA before treatment was an adverse prognostic factor for survival (223); high serum levels of CASA were associated with increased risk of second-line chemoresistance (224).
Growth factors	Insulin-like growth factors (IGFs) and IGF-binding proteins (IGFBPs) have been shown to play a physiologic role in the female genital system, including the ovarian follicular system. Expression of the insulin-like growth factor binding protein-2 (<i>IGFBP-2</i>) gene is elevated in advanced epithelial ovarian cancers in comparison to normal ovarian epithelium. This is also reflected in the serum with elevated serum <i>IGFBP-2</i> levels detected in epithelial ovarian cancers compared to both normal controls and patients with benign gynecologic disease (225,226). The relationship between circulating levels of IGF-I and its major binding protein (IGFBP-3) in relation to ovarian cancer risk was investigated in a case-control study nested within the European Prospective Investigation into Cancer and Nutrition involving prediagnostic serum samples of 214 women who subsequently

Tetranectin	<p>developed ovarian cancer and 388 matched control subjects. No association was found between the circulating IGF-I or IGFBP-3 levels and the risk of ovarian cancer in the cohort. However, for women diagnosed with ovarian cancer aged 55 or younger, the relative risk was higher in the middle or top tertiles of serum IGF-I, when compared with women in the lowest tertile. In premenopausal women with ovarian cancer relative risks for ovarian cancer diagnosed before age 55 were higher for second and third tertiles. The results suggest that IGF-I circulating levels may play a role in the development of ovarian cancer in women of a pre- or perimenopausal age (227).</p> <p>A tetrameric, plasminogen-binding plasma protein first discovered in 1986. Blood levels reduced in patients with a variety of cancers. At a false-positive rate of 1%, the sensitivity for ovarian cancer stages I and II was 33% for serum tetranectin against 76% for CA125. Combining tetranectin with CA125 increases sensitivity without causing a concomitant increase in the rate of false-positive results. However, neither marker rose to levels that would allow use in the discrimination of localized cancer and benign tumors (228). Preoperative tetranectin levels correlated with survival and were a strong prognostic variable in patients with advanced ovarian cancer (61,229). Chemotherapy induced significant increases in serum tetranectin levels with a decrease in serum tetranectin during chemotherapy being highly indicative of recurrence and poor outcome (230). Hogdall et al. (231) measured serum tetranectin, CA125, and CASA prior to 63 second-look and five third-look operations for ovarian cancer. Patients with residual tumor had significantly lower levels of tetranectin and higher levels of CASA and CA125 compared with tumor-free patients. Using multivariate Cox analyses, it was found that all three markers were independent prognostic predictors of survival.</p>
Tumor-associated trypsin inhibitor (TATI)	<p>In ovarian cancer patients, a 6 kD polypeptide, TATI, can occur in elevated concentrations in both urine and serum (232). When used as a single marker, serum TATI has lower sensitivity and specificity than CA125. However, it is more sensitive than CA125 in diagnosing mucinous and poorly differentiated carcinomas (233,234). TATI may also be useful in differentiation of primary and metastatic ovarian tumors. In a recent report of 38 patients with secondary ovarian malignancies and 76 control patients with primary epithelial ovarian cancer, although the preoperative serum CA125 was not different between the two groups, patients with secondary malignancies displayed higher levels of serum TATI and CEA. The study demonstrated that tumors less than 9 cm with solid structure, absence of ascites, and elevated serum CEA and TATI levels are typical of secondary ovarian malignancies (235). Unlike CA125, TATI levels seem to correlate with tumor grade (234). It may have a prognostic role as elevated preoperative levels have been associated with a twofold increase in risk of death (60) and a 5-year cumulative survival in advanced ovarian cancer of 8% as opposed to 45% in patients with normal preoperative values (236). In patients with stage III and IV disease on multivariate analysis, TATI tissue expression along with tumor grade has been reported to be an independent prognostic factor for adverse cancer-specific and progression-free survival (237).</p>
GAT (galactosyltransferase associated with tumor)	<p>Elevated in 4.5% to 6.0% of women with endometriosis and 46% to 48% of women with ovarian cancer. GAT may be useful in discriminating ovarian malignancy from endometriosis (238,239). GAT has been shown to be a marker of ovarian cancer with a high specificity. Human serum contains certain factors that decrease the GAT level, but these factors seem to be inhibited in ovarian cancer patients so that a high GAT level persists. (240).</p>
LASA (lipid-associated sialic acid)	<p>The assay predominantly determines glycogen-bound sialic acid and has high positivity rate in leukemia, Hodgkin's disease, melanoma, sarcoma, advanced ovarian carcinoma, and oropharyngeal tumors (241). The value of determination of LASA in addition to CA125 in invasive epithelial ovarian cancer is due to lack of specificity (242,243). When used as part of a panel of serum markers, it may be useful in women with a pelvic mass (215). It was investigated as part of a panel of multiple markers (CA125, HER2/neu, urinary gonadotropin peptide, lipid-associated sialic acid, and Dianon marker 70/K) in serial samples obtained during 6 years of follow-up of 1,257 healthy women at high risk of ovarian cancer. The findings suggested that individual-specific screening rules may be developed with the potential to improve early detection of ovarian cancer (244) using these markers.</p>
VEGF (vascular endothelial growth factor)	<p>A promoter of angiogenesis, VEGF is believed to play a pivotal role in tumor growth and metastasis. In a preliminary study, serum VEGF had a sensitivity of 54% for ovarian cancer and was not useful in the differential diagnosis of adnexal mass (245). A more recent study has shown that higher serum VEGF, higher FIGO stage, and presence of residual tumor mass after primary surgery were independently associated with a shortened overall survival and that serum VEGF is an independent prognostic parameter regardless of the stage (246).</p>
IAP (immunosuppressive acid protein)	<p>Increased levels detected in 70% of patients with ovarian cancer, 25% with benign tumors, and in 4.5% of normal women. The simultaneous determination of IAP and CA125 allowed an overall sensitivity of 84% without any significant reduction of specificity (247). On multivariate analysis, there was significant association with survival (248). Since then, the performance of IAP in combination with IL-6 and M-CSF was examined in 61 serum samples of previously untreated ovarian cancer patients. Whereas a direct correlation between IL-6 and M-CSF was found, IAP serum levels failed to correlate with M-CSF and IL-6 levels (249).</p>

(continued)

TABLE 7.4**OTHER TUMOR MARKERS FOR OVARIAN CARCINOMA THAT ARE NOT REFERRED TO IN DETAIL IN THE TEXT (CONTINUED)**

Tumor marker	Description
Lysophosphatidic acid (LPA)	LPA is a bioactive phospholipid with mitogenic and growth-factor-like activities that stimulates the proliferation of cancer cells (250,251). It has been shown to increase cell proliferation, cell survival, resistance to cisplatin, and production of VEGF in ovarian cancer cells, but not in normal ovarian surface epithelial cells (252), and accounts for the ability of ascites to activate ovarian cancer cells (253). LPA levels were significantly higher in ascites from ovarian cancer patients than in malignant effusions from other cancer patients, suggesting a role for LPA-like lipids in the peritoneal spread of ovarian cancer (254). In an initial study, elevated plasma LPA levels were detected in 9 out of 10 patients with stage I ovarian cancer; all 24 patients with stage II, III, and IV ovarian cancer; and 14 patients with recurrent ovarian cancer. In contrast, raised plasma LPA levels were detected in 5 of 48 controls, 4 out of 17 women with benign disease, and in no women with breast cancer or leukemia (255). Using a new highly specific, sensitive, and reproducible assay, Bast et al. demonstrated elevated levels of LPA in more than 90% of stage I or II ovarian cancer patients, less than 50% of whom had elevated CA125 levels (256). There have, however, been no further studies validating the potential of plasma LPA as a potential biomarker for ovarian cancer.
DNA methylation	Circulating methylated DNA may represent a new generation of tumor marker (257), as changes in DNA methylation are one of the most common alterations in human neoplasia (258). Hypermethylation of tumor-derived DNA can be found in serum and plasma of cancer patients (259,260). Recently, in colorectal cancer the pattern of methylation of serum DNA has been shown to be a prognostic factor (261). In the next decade it is possible that this approach may identify novel tumor markers for ovarian cancer.
Cadherin	Cadherin expression has been explored as a potential tool to differentiate ovarian cancer from malignant mesothelioma cell effusions. However, it turned out that different cadherins are co-expressed and P-cadherin, E-cadherin, and N-cadherin are not useful for differentiation between ovarian/primary peritoneal and malignant mesothelioma cell in effusions (262).
Shed glycans	Shed glycans can be used as possible markers for ovarian cancer (263). Glycoproteins shed by cancer cells are found in the supernatant (or conditioned media) of cultured cells. They can be profiled for their oligosaccharide content using beta-elimination conditions, and any changes in glycosylation can be monitored by matrix-assisted laser desorption/ionization Fourier transform ion cyclotron resonance mass spectrometry (MALDI-FTICR-MS). As glycoproteins can be detected in the serum, oligosaccharide profiling data can be applied to ovarian cancer patients and normal sera to determine at least 15 unique serum glycan markers in ovarian cancer patients that were absent in normal individuals (264).

Note: There were initial studies in the early 1990s exploring the role of sialyl SSEA-1 antigen, TPA, and serum CA-130 in ovarian cancer but none since 1995. Hence, these markers have been omitted from the above table. CASA, Cancer-associated serum antigen; CEA, carcinoembryonic antigen; OSA, Ovarian serum antigen; PPV, positive predictive value.

levels detected in 63% to 67% of patients with advanced-stage and 10% to 19% of those with early-stage disease (269,275). Preoperative assessment of serum CA125 may be of use in predicting the presence of extra-uterine and metastatic disease and, to a lesser extent, myometrial invasion (270). It was suggested that serum CA125 may be useful in follow-up of patients with early-stage endometrial cancer but has not been shown to add to clinical examination and imaging (271). While distant metastases may raise CA125 levels, isolated recurrences in the vagina do not. Levels can be falsely elevated in the presence of severe radiation injury (266). In an analysis of 97 patients with endometrial cancer, elevations of CA125 and CA-15-3 were significantly associated with poor prognostic clinical factors. On multivariate analysis, CA-15-3 was highly significant and had a larger hazard ratio than CA125 (268).

In the 1990s, the role of a number of serum markers was explored in endometrial cancer—CYFRA 21-1 (175), urinary beta-core or UGF levels (272,273), SCC and CA-15-3 (274), CA-19-9 (267), amino-terminal propeptide of type III procollagen (275), placental protein 4 (276), CA-72-4 (277), OVX1 antigen (253), soluble interleukin-2 receptor (278), and M-CSF (265,279). However, none proved to be very useful and this is confirmed by the lack of further publications.

Recent publications indicate significantly higher levels of serum and plasma human kallikrein 6 in women with uterine serous papillary endometrial cancer compared to those with endometrioid carcinoma and controls without cancer (280), increased expression of inhibin β B in grade 3 compared to grade 2 endometrial cancer (281), and an association of matrix metalloproteinase 2 (MMP-2) expression with CA125 and clinical course in endometrial carcinoma. Expression of the MMP-2 and MMP-9 proteins was found in 88% and 70% of the primary endometrial cancers with positive MMP-2 immunostaining associated with a shortened recurrence-free and cancer-specific survival. MMP-2 negativity seemed linked to favorable prognosis. Preoperative serum levels of CA125 were higher in the patients presenting with tumors positive for MMP-2 than in those with negative immunostaining (282). However, the value of such observations still remains to be determined.

CERVICAL CANCERS

Screening for cervical cancer is based on exfoliative cytology and high-risk HPV DNA detection in cervical specimens. Currently, no serological markers are being explored.

TABLE 7.5

STATUS OF CURRENT TUMOR MARKERS IN OVARIAN CANCER

Screening	Differential diagnosis of an adnexal mass	Prognostic indicator	Monitoring response to therapy	Monitoring disease and recurrence
EPITHELIAL CANCERS				
Clinical practice				
Research	<p>CA125 is the main marker—when combined with menopausal status and ultrasound features in the risk of malignancy index (RMI), a sensitivity of 71% to 85% and specificity of 96% to 97% are achieved.</p> <p>CEA</p> <p>Inhibin pro-α C/total inhibin, kallikreins, mesothelin, prostasin, osteopontin, M-CSF, TPS, proteomic markers (profile, transthyretin, apolipoprotein A).</p> <p>CA-15-3, CA-72-4, CA-19-9, TATI, GAT, free serum DNA methylation, free glycans, IL-7, TNF-α receptors</p>	<p>CA125 levels post surgery and during chemotherapy are independent prognostic indicators. Note: Further discussion and references are in the appropriate section in the accompanying text or in Table 7.4. CASA, Cancer-associated serum antigen; CEA, carcinoembryonic antigen; CGN, Cancer Genetics Network; GAT, galactosyltransferase associated with tumor; GOG, Gynecologic Oncology Group; TATI, tumor-associated trypsin inhibitor; TPS, tumor necrosis factor; TPS, tissue polypeptide-specific antigen; VEGF, vascular endothelial growth factor.

However, a variety of serum markers have been investigated in assessing prognosis, monitoring response to treatment, and detecting recurrence.

Squamous-Cell Carcinoma Antigen

In 1977, Kato and Torigoe (283) isolated the tumor antigen TA-4 from a cervical squamous-cell carcinoma antigen (SCC). SCC is one of 14 subfractions of tumor antigen TA-4. Elevated levels of SCC are found in 57% to 70% of women with primary squamous-cell carcinoma of the cervix (284–286). The release of SCC into the circulation is independent of local tissue content, as high antigen concentrations are found in the cytosol of normal cervical squamous epithelia, but in these cases serum levels are always in the normal range (287). The antigen is not specific for cervical squamous-cell carcinoma with elevated levels found in other squamous-cell carcinomas of the head and neck, esophagus, and lung, and in adenocarcinoma of the uterus, ovary, and lung. SCC levels can also be raised in skin diseases such as psoriasis and eczema (288). SCC is probably a marker of cellular differentiation of squamous cells, as the incidence of elevated serum levels is higher in women with well-differentiated (78%) and moderately differentiated carcinoma (67%) than in those with poorly differentiated tumors (38%) (287). Its levels before treatment correlate with stage, tumor volume, lymph node status, and blood vessel invasion (289–293).

In the past, there have been conflicting reports on the prognostic significance of pretreatment SCC levels (285,289,290,292,294–296), but increasingly it seems that a combination of pre- and post-treatment values may be useful both for predicting prognosis and for estimating clinical response in women, especially in those undergoing neoadjuvant chemotherapy (296–299). On multivariate analysis of 352 patients with stage IIB to IVA squamous-cell carcinoma of the cervix managed with both external irradiation and high-dose-rate intracavitary brachytherapy, pretreatment SCC antigen level and lymph node metastases were found to have a significant independent effect on absolute survival and disease-free survival (300). Elevated post-treatment serum SCC levels have been shown to be indicators of treatment failure (295,299,301) and be associated with poor survival rates (296). In a recent study involving 211 patients treated with concurrent chemoradiotherapy, SCC levels normalized in 93% of patients at 1 month after completing treatment. In patients with complete remission who had previously elevated pretreatment SCC antigen, the values were normalized in 96% (134 out of 139) at 1 month (286). Various authors have suggested the need for further treatment in patients with elevated SCC levels at completion of treatment. Nonetheless, the evidence is preliminary and further studies are needed before any definitive conclusions can be drawn.

In serum SCC-positive patients, serial measurements correlated with clinical course of the disease in 72% of women (302). Raised SCC levels were found in 50% to 71% of patients with recurrent carcinoma, with a lead time ranging from 0 to 12 months (284,303).

Preliminary studies suggest that SCC antigen (SCCA) isoforms may provide additional clinical information when compared to total SCCA. In early-stage cervical cancer, it has been shown that 2-year disease-free survival is significantly lower in patients with high SCCA2/SCCA1 mRNA ratios (50%) compared to those with low SCCA2/SCCA1 mRNA ratios (92%) (304). More recently, Roijer et al. have developed and evaluated specific serum immunoassays for the different forms of SCC antigen (free SCCA2, total SCCA2, total SCCA1, and total SCCA). Both SCCA1 and SCCA2 levels were elevated in serum from cervical cancer patients and followed the clinical course of the disease during monitoring of treatment. Patients with recurrence or progressive disease had rising levels of

SCCA1 and SCCA2, with elevations in SCCA2 being more prominent than those in SCCA1. SCCA2 did not show improved tumor specificity as compared to SCCA1 (305). These results need to be confirmed in a larger study in order to make firm conclusions.

CYFRA 21-1

Following detection of elevated levels of CYFRA 21-1 in patients with squamous-cell carcinoma of the lung, various groups started investigating its role in cervical carcinoma. Tsai et al. detected elevated CYFRA 21-1 levels in 14% of controls, 35% of patients with stage IB to IIA squamous-cell carcinoma of the cervix, and 64% of patients with stage IIB to IV disease (306). Although CYFRA 21-1 was related to tumor stage and size in patients with cervical cancer (307) and there was a positive correlation with SCC, its sensitivity and specificity for detection of squamous-cell carcinoma of the cervix were lower than SCC (306). In cervical adenocarcinoma, it was elevated in 63% of patients (308). CYFRA 21-1 may have a role in follow-up of women with cervical cancer (309). In the study by Pras et al. (299) elevated CYFRA 21-1 levels after chemoradiation for cervical cancer indicated residual tumor in 70% of patients. Nonetheless, the evidence available so far does not justify the routine measurements of these markers.

CA125/CEA

Serum CA125 is only elevated in 13% to 21% of women with squamous-cell carcinoma (275,302). It is a better marker than SCC for cervical adenocarcinoma (275,302,310). In combination with CA-19-9, a sensitivity of 60% for cervical adenocarcinoma was reported, with the addition of CEA to this combination increasing sensitivity to 70% (311). Elevated CA125 levels have been found to contribute to prognosis (312,313) with levels falling in women who respond to chemotherapy (314). In adenosquamous cervical cancer, serum CA125, SCC, and CEA were found to be elevated in patients with progressive disease, whereas only CA125 was elevated in women with adenocarcinoma (310). Serum CEA alone is less useful in cervical cancers, with an overall sensitivity of 15% and specificity of 90%. Patients with cervical adenocarcinoma have significantly higher levels of CEA than those with squamous-cell cancers (315).

VULVAR AND VAGINAL CANCERS

Tumors of the vulva and the vagina are rare and there are relatively few studies on circulating markers in these conditions. TPS has been shown to be elevated in 80% of patients with vulvar or vaginal cancer (169), whereas SCC levels were elevated in 43% (316). Carter et al. (317) studied the urinary core fragment of the β -subunit of hCG in these cancers. Although the sensitivity of beta-core was only 38%, a highly significant difference was observed in the survival curve between those with elevated beta-core levels compared to those with normal levels. Ninety percent of patients with elevated levels died within 24 months in contrast to 32% of those with normal levels. It might also be useful in detecting recurrence, as rising urinary gonadotropin fragment (UGF) levels at an earlier clinic visit predicted recurrence in four of seven patients. These data, albeit limited, suggest that for lower genital tract malignancies, the measurement of urinary beta-core may be valuable as a prognostic indicator, allowing a more informed approach to treatment and in follow-up.

CONCLUSIONS

The potential role of serum tumor markers is hampered by the fact that these markers are neither confined to the malignant tumor cell nor limited to the malignant phenotype. Of all the markers available in gynecologic malignancies, serum hCG in gestational trophoblastic disease remains closest to the ideal tumor marker. Serum CA125 continues to be the most useful clinical marker, with an established role in diagnosis and monitoring of epithelial ovarian cancer.

Biomarkers are increasingly being used in the differential diagnosis of adnexal masses. Numerous tumor markers have been recognized as promising prognostic factors, and this will aid the development of novel treatment strategies in the future. The role of markers in monitoring therapeutic response and detecting recurrence is yet to be fully explored. In screening trials, serial serum CA125 in combination with ultrasonography is currently being investigated in ovarian cancer screening trials in the general and high-risk populations.

Promising novel biomarkers, especially for ovarian cancer, identified through proteomics and genomics are undergoing validation studies and continuing developments in these two fields, metabolomics and DNA methylation, will probably lead to further candidates that can be used either alone or in combination with existing tumor markers.

CHAPTER 8 ■ CANCER PREVENTION STRATEGIES

MARY B. DALY

INTRODUCTION

The prevention of gynecologic cancer is becoming a reality due to the recognition that cancer initiation and progression is a multistep process characterized by distinct molecular genetic events that provide opportunities to intervene in the carcinogenic process at several steps and reverse its early stages. The concept of preventing gynecologic cancer is based on an understanding of causally related risk factors, their role in carcinogenesis, and opportunities for their avoidance and/or reversal of their effect. There are three distinct models that can be applied to gynecologic cancer prevention: (a) *risk avoidance and adoption of protective practices* includes the identification of key risk factors and the development of strategies for their avoidance. Included in risk avoidance are the avoidance of exogenous and endogenous exposures (chemical, hormonal, infectious, etc.) and the avoidance of risky health behaviors. The adoption of protective practices, such as vaccination with the human papillomavirus (HPV) vaccine, a healthy diet, and exercise, may forestall early premalignant events; (b) the use of *chemopreventive agents*, both natural and synthetic, to reverse early, premalignant changes; and (c) *surgical prophylaxis* to remove either healthy at-risk organs or tissues with premalignant changes.

In addition to establishing valid interventions for cancer prevention, it is important to identify optimal target populations for their application, and to tailor the interventions to the level of risk. Interventions for use in the general population at average risk must be highly effective, safe, inexpensive, and socially acceptable. Population groups with high risks may tolerate interventions that confer more risk and higher costs. All prevention efforts are greatly enhanced by public and professional education about their use and by a health care system that values, promotes, and invests in prevention activities.

The avoidance of environmental, occupational, and lifestyle risk factors through public education and social policies has the potential to prevent a large proportion of human cancer. The epidemiological literature has provided a wealth of information about the risks associated with cancers of the cervix, uterus, and ovary, which allows us to devise risk avoidance and risk reduction strategies. This chapter focuses on the opportunities for primary prevention of these three cancers and directions for the future.

CERVIX CANCER

Risk Factors

There are approximately 14,000 new cases of cervical cancer per year in the United States, and 5,000 women die of the disease. The disease burden is not distributed equally but is

overrepresented among African American, Mexican American, American Indian, Vietnamese American, and rural poor women (1). The burden of cervical cancer is worldwide (Fig. 8.1), where 470,000 new cases are diagnosed each year, and 250,000 women die of the disease (2). Traditionally, the most significant factor associated with the risk of cervical cancer has been number of sexual partners and the early onset of sexual activity. This observation has led to the discovery that the primary cause of cervical cancer, and its precursor, intraepithelial lesions, is persistent infection with HPV, which is sexually transmitted. The HPVs are a large (over 100 types, Fig. 8.2) family of viruses that infect skin and mucosa. Of the approximately 40 HPV types that infect the genital tract, about one half are associated with anogenital warts and are considered low risk for malignancy, or non-oncogenic. The other half may give rise to a range of anogenital cancers, including cervix, vulva, and anus in women, and penis and anus in men, and are referred to as high-risk or oncogenic (3). HPV types 16 and 18 alone account for >70% (Fig. 8.3) of all cervical cancers. Similarly, HPV types 6 and 11 account for >90% of all anogenital warts. In the United States, close to 20% of girls are sexually active by age 15 years, and close to 60% are sexually active at age 18 years. As a result, the infection rate of HPV among the general population is high, peaking in the second and third decades of life when infection rates range from 27% to 46% (1). The median length of infection is 8 to 12 months and most individuals have cleared the virus by two years. A small proportion, 10% to 13%, however, develop chronic persistent HPV infection, which can lead to genital warts, cervical dysplasia, carcinoma *in situ*, and invasive cancer (Fig. 8.4). Persistence of HPV infection is likely to be related to modifying factors, including immune status, the use of oral contraceptives (OCP), and smoking. Prolonged duration of OCP use is thought to function as a promoter of HPV-related carcinogenesis, not as a facilitator of HPV infection, although the mechanisms are uncertain (4). Tobacco carcinogens have been found in cervical secretions, and it is postulated that smoking constituents may interact with HPV to induce immunologic changes leading to cervical dysplasia, or may produce genomic damage via genotoxins (5,6).

The HPVs are nonenveloped, double-stranded DNA viruses whose circular DNA encodes eight genes, six early genes, which encode nonstructural proteins (E1, E2, E3, E4, E5, and E6) responsible for viral replication and transcription, and two late genes (L1 and L2), which encode the structural components of the viral capsid. HPV can infect the basal cells of the cervical epithelium and replicate in an extrachromosomal form. In HPV-related malignancy, the virus can integrate into cellular DNA and interact with p53 and RB (retinoblastoma), which prolongs the cell cycle, inhibits apoptosis, and can result in malignant transformation (2,7). Another potential mechanism for carcinogenesis that has been observed in HPV-16-infected

FIGURE 8.1. Age-standardized rates of new cases of cervical cancer per 100,000 women, 2002.

cells is aberrant mitotic spindle pole formation resulting in genetic instability (8). The recent production of prophylactic vaccines that induce the generation of neutralizing antibodies to certain oncogenic types of HPV, therefore, represents a major breakthrough in the prevention of cervical cancer.

Prevention

Risk Reduction and/or Adoption of Healthy Practices

Cervical cancer prevention requires decreasing the risk of infection with oncogenic strains of HPV. Having few sexual partners and the use of condoms have been associated with a reduced risk for cervical cancer (9). Avoidance of those factors that enhance the persistence of HPV infection, viz. smoking and OCP use, has the potential to reduce the rate of malignant change. OCPs, however, are the most effective means of contraception, and their avoidance overall is not a wise public health strategy. Safe and effective vaccines now offer the best option for cervical cancer prevention. Early studies in animal models provided the proof of principle that neutralizing antibodies, directed to determinants on the major viral capsid protein, were generated by infection with HPV and could be detected in the serum. In the early 1990s it was found that the L1 protein, when expressed in recombinant vectors, self-assembled into

FIGURE 8.2. Human papillomavirus.

FIGURE 8.3. HPV types in cervical cancer.

virus-like particles (VLPs), which closely resemble the antigenic characteristics of the wild-type virions (10). VLPs formulated on aluminum adjuvants were shown to induce a strong virus-neutralizing antibody response in nonhuman primates (11,12), leading to their development for human populations. A series of phase 1 trials in humans tested the immunogenicity and safety of monovalent VLP-based vaccines and found that they generated levels of neutralizing antibodies that far exceeded those seen in natural infections, and were well tolerated. The predominant antibody responses are of the immunoglobulin G1 (IgG1) subclass (3). Prevention of persistent HPV-16 and HPV-18 was also demonstrated, although only short-term follow-up was available (13).

Subsequently, two vaccines have been developed for use in humans, Gardasil (Merck), a quadrivalent vaccine that includes HPV-16, -18, -6, and -11 and is formulated with aluminum adjuvant, and a bivalent vaccine Cervarix (GlaxoSmithKline), which includes HPV-16 and -18 and is formulated with a proprietary adjuvant, AS04, which contains aluminum and a bacterial lipid. Gardasil has undergone four randomized, placebo-controlled trials among a total of 20,583 women. In a U.S. multicenter proof of principle study, 2,391 young women aged 16 to 25 were assigned to a monovalent yeast-derived HPV-16L1 VLP, formulated on aluminum adjuvant, by intramuscular injection at day 0, month 2, and month 6 or placebo. The primary outcomes were persistent HPV-16 infection and HPV-16-related carcinoma *in situ* (CIN) 2 and 3. At a follow-up of 48 months, administration of the three-dose regimen of HPV-16 vaccine resulted in a 94% reduction in persistent HPV infection in those treated according to protocol. The vaccine was 100% effective in protecting against HPV-16-related CIN 2 and 3 (14).

A phase 2 dose-ranging assessment of immunogenicity and efficacy was conducted in the United States, Brazil, and Europe among 552 women aged 16 to 23 years. Women were randomized to one of three vaccine doses versus placebo given at day 1, month 2, and month 6. At close to 3 years of follow-up, vaccine efficacy for persistent HPV infection was 90% and for clinical disease (cytologic abnormalities, CIN, cervical cancer, or external genital lesions) was 100%. Vaccine efficacy was similar for each of the three doses. All women who received the vaccine developed high antibody titers by month 7 (15).

The two pivotal phase 3 trials enrolled >18,000 women and included both precancerous lesions, CIN 2, CIN 3, adenocarcinoma *in situ* (AIS), or invasive cervical cancer with documented HPV-16 or -18 in DNA from the involved tissue, vulvar and vaginal lesions, and genital warts as outcomes.

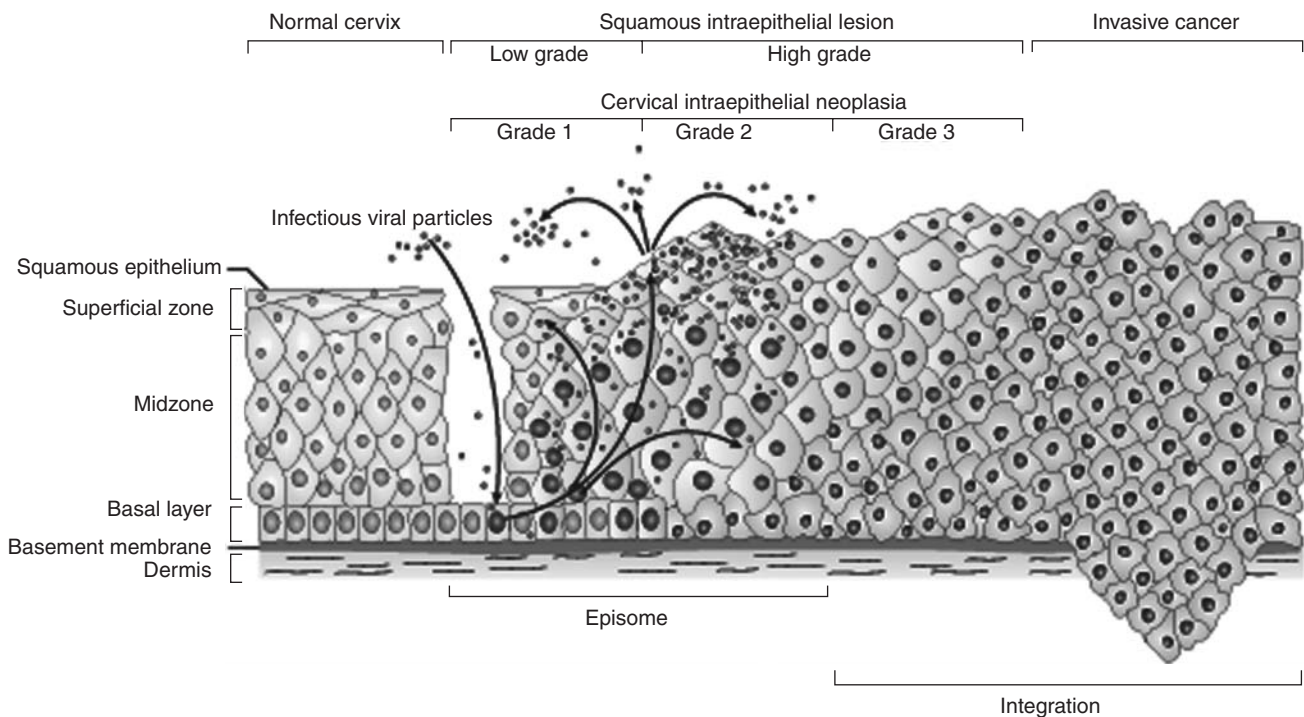

FIGURE 8.4. (See color plate section.) HPV-mediated progression to cervical cancer.

Women with evidence of previous infection with HPV, or with cytologic abnormalities, were not excluded. At 3 years, vaccine efficacy in those women treated according to protocol was 99%, with only one case of CIN 3 occurring among the vaccine recipients. In the intent to treat population, which included women with prevalent HPV-16/18 infection and women who did not complete the vaccination schedule, CIN 2/3 and AIS were reduced by 44% (16,17). The vaccine was also efficacious against high-grade vulval and vaginal lesions (18). Side effects in all of the studies were minimal and included discomfort at the injection site and occasional mild fever. Anti-HPV antibody titers remain high 5 years after administration. In June 2006, Gardasil received FDA approval for the vaccination of women aged 9 to 26, followed closely by approval for its use in children and adults aged 9 to 26 years by the European Commission.

The initial trial of Cervarix randomized 1,113 women aged 15 to 25 years to receive a bivalent HPV-16, -18 vaccine versus placebo. No cases of persistent HPV-16 or HPV-18 were seen in the women vaccinated according to protocol, whereas there were seven cases of infection in the control group. The vaccine was 95% effective against persistent infection and 93% effective against cytologic abnormalities even when including those women who did not complete the vaccine regimen. In an extended follow-up of 776 women, the vaccine continued to demonstrate 98% efficacy at close to 4 years. The bivalent vaccine also showed significant efficacy against two additional oncogenic strains, HPV-45 and -31 (13,19). A second study randomized 18,644 women to three doses of Cervarix versus hepatitis A vaccine. HPV vaccine efficacy, assessed in women who were seronegative DNA for HPV-16/18 at baseline, against CIN 2+ lesions was 90% at 14.8 months (20).

Overall, achieving close to 100% effective vaccination of a cohort of 12-year-old girls is estimated to result (Fig. 8.5) in a 76% reduction in the incidence of cervical cancer (21). Markov modeling has been used to estimate the clinical benefits

and cost-effectiveness of a population-based HPV-16/18 vaccination program. Parameters considered were the natural history of HPV and cervical cancer, age at vaccination, vaccine cost, vaccine efficacy (Fig. 8.1), waning immunity, the risk of replacement with other oncogenic strains of HPV, age at onset of screening, and screening intervals. One model that combined vaccination at age 12 with triennial cytologic screening beginning at age 25 years resulted in a cost-effectiveness ratio of less than \$60,000 per quality-adjusted life year (QALY) and a 94% reduction in a woman's lifetime risk of cervical cancer (22,23). Another model found that vaccination plus biennial cytologic screening beginning at age 24 years had the most attractive cost-effectiveness ratio (\$44,889) (24). In both models, the combination of a highly effective vaccine, a delay in the onset of cytologic screening, and a decrease in colposcopy rates result in a cost-effective use of health care resources. The Advisory Committee on Immunization Practices (ACIP) of the Centers for Disease Control and Prevention (CDC) recommends routine vaccination for HPV of girls age 11 to 12 (range, 9 to 26 years) and has added Gardasil to its Vaccines for Children program (25,26). Similarly, the American Cancer Society recommends that all girls should be vaccinated against HPV at age 11 to 12 years.

There are several questions remaining regarding the use of HPV vaccines. The duration of protection afforded by HPV vaccines is not known, although data from animal models report long-lasting protection even with low levels of circulating antibody. Evidence from recent clinical trials in humans suggests persistence of immunity beyond 4 years. The need for a booster dose is at this time unknown. Because the neutralizing antibodies generated by the current vaccines appear to be type specific, it is not clear if there is cross-reactivity with other HPV types. It is also unclear whether vaccinating an adolescent population will be socially acceptable in all cultures. Most of the randomized trials performed to date focused on young women in their late teens and early 20s, an age when sexual activity has likely already begun. Because HPV vaccines are ineffective after infection with HPV, vaccination should

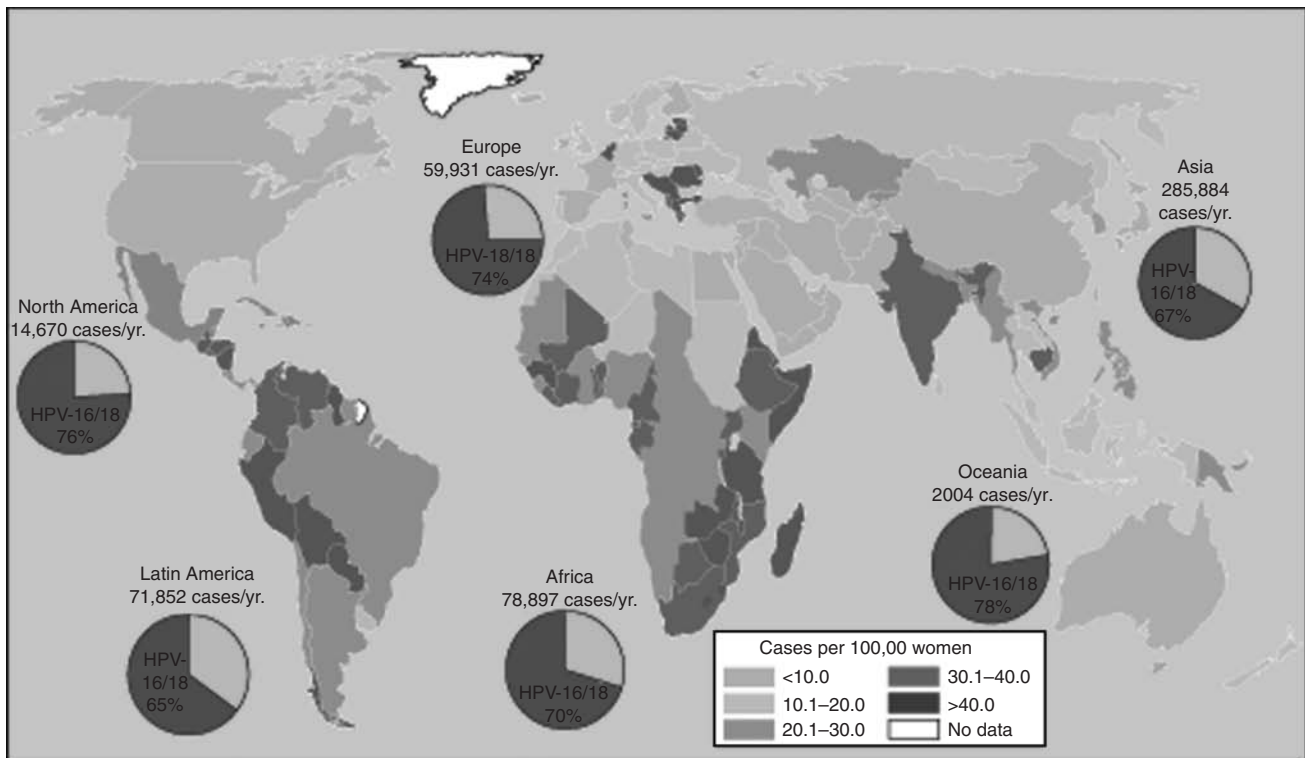

FIGURE 8.5. (See color plate section.) Impact of HPV-16/18 vaccines on incidence of cervical cancer.

occur prior to the onset of sexual activity, or at a younger age. The majority of females will become infected with HPV within 2 to 3 years of the onset of sexual activity. Depending on sociocultural variations in sexual debut, the target age for vaccination would ideally be girls aged 9 to 12. There is currently no systematic vaccination program beyond infancy and preschool in the United States. Although vaccinating older women who are uninfected with HPV is likely to induce an effective immune response, studies have shown that antibody response is higher among 10 to 15 year olds than among 16 to 23 year olds (14,27).

Another unanswered question is the added benefit of vaccinating males. Although the majority of morbidity associated with HPV is seen in females, males remain the major vector for the disease. Furthermore, both males and females would need to be vaccinated to achieve herd immunity. Information on the natural history of HPV in males is lacking, and vaccination studies to date have focused predominantly on females. A study is currently under way to evaluate the safety and effectiveness of Gardasil in males.

Among women, the impact of effective vaccination on subsequent screening practices is not known. There is concern that women who receive the HPV vaccine might be less likely to adhere to screening guidelines because they feel protected from cervical cancer. Women who have been vaccinated will, however, need to continue cytologic screening since the current vaccines do not protect against all oncogenic types, and since some women will have already been infected at the time of vaccination. It is likely, however, that the onset of screening could safely be delayed. Concerns about the impact of HPV vaccination on subsequent accuracy of cytologic screening have also been raised.

Much work remains to be done to educate the public about HPV and cervical cancer. Recent studies have shown that the majority of women are unaware of the link between HPV and cervical cancer. Awareness of HPV is increased among young

women, more educated women, and those with more access to the health care system (28,29). Public health efforts to introduce the vaccine will clearly need to be accompanied by vigorous educational programs directed at both young women and their parents to increase acceptability and the success of the HPV vaccine program. One concern that parent and other groups have expressed is the fear that vaccination against HPV may lead to a sense of invulnerability, would undermine abstinence-based messages, and may increase high-risk sexual behavior. There is no data, however, to suggest that fear of HPV is an important deterrent from sexual activity in young men or women. Several states have considered legislation to mandate HPV vaccination, although few have actually enacted such laws. All of the proposed laws have opt-out provisions for parents who object. However, they do not address the potential financial burdens imposed by the mandate. Mandating HPV vaccination would certainly boost vaccine coverage rates, but at a price of loss of parental autonomy.

These and other vaccine-related concerns will need to be addressed by primary care providers as well as public health officials. Surveys of physicians indicate a relatively high rate of acceptance of HPV vaccination, although many are reluctant to vaccinate the youngest age groups (10 to 12 years) for whom the vaccination is likely to offer the most benefit (30). Providers cite safety, durability, and affordability of the vaccine as important determinants of their acceptance, and indicated that they would be influenced by the recommendations of their professional organizations (23,31,32).

The most significant unresolved issue pertains to the application of HPV vaccines to underdeveloped nations, where the greatest burden of disease attributable to HPV is found (Fig. 8.5). The highest rates of cervical cancer occur in Africa, Central and South America, and Micronesia (1). Contributing to this burden is a lack of understanding of the dimensions of the disease, weak infrastructures and insufficient funds for population-wide vaccination programs, and a lack of the political

TABLE 8.1**CERVIX CANCER—MAJOR POINTS**

Virtually all cervix cancer is related to persistent infection with HPV. HPV infection is common, affects up to 50% of women, and peaks in the second and third decades of life. Altered immune status, smoking, and the use of OCPs affect the rate of persistent HPV infection. Rates of cervical cancer are highest in the underdeveloped countries of the world. Two HPV vaccines have shown high efficacy in eliminating persistent HPV infection and cervical lesions in previously uninfected women.

HPV, human papillomavirus; OCPs, oral contraceptives.

will to address a sexually transmitted disease. The delivery of a new vaccine to a non-pediatric population is particularly problematic in countries with limited public health resources. Yet it is precisely in these countries that the potential benefit for a widespread vaccination program is greatest. Administering the vaccine in infancy along with other basic childhood vaccines may be the best choice, even though the duration of protection is at this time unknown. Clearly, the contribution of the international community will be required to make HPV vaccination a reality in the third world.

Chemoprevention

Several promising targets for the chemoprevention of cervical cancer have been identified, including topical retinoids, carotenoids, prostaglandins, indole-3-carbinol, and immune modulators (33). In phase 1 and 2 trials topical retinoids applied directly to the cervix resulted in significant complete histologic regression of CIN 2 lesions compared to placebo (34). None of the proposed agents, however, have been subject to definitive phase 3 randomized trials.

Surgical Prophylaxis

The introduction of widespread cervical cancer screening using the Papanicolaou (Pap) smear has dramatically reduced the incidence of invasive cervical cancer through the detection of treatable, premalignant lesions, referred to as cervical intraepithelial neoplasia (CIN). Because of the high rate of spontaneous regression, management of women with CIN 1 and satisfactory colposcopy (visualization of the entire squamocolumnar junction) is repeat cytology at 6 and 12 months or DNA testing for oncogenic types of HPV at 12 months.

Alternatively, ablative (cryotherapy, electrocoagulation, or laser vaporization) or excisional (cold-knife conization or loop electrosurgical excision procedure [LEEP]) treatment may be offered. If the entire squamocolumnar junction cannot be visualized, an excisional procedure is the preferred approach. Treatment of CIN 2,3 lesions with satisfactory colposcopy involves excision or ablation of the entire transformation zone rather than just the colposcopically identified lesion (35). Cryotherapy, laser vaporization, and LEEP all appear to be effective modalities, although over time LEEP has become the procedure most widely chosen. When colposcopy is not satisfactory, a diagnostic excisional procedure is recommended. A variety of posttreatment surveillance protocols utilizing cervical cytology with or without colposcopy and HPV testing at frequent intervals have been proposed. Hysterectomy is reserved for recurrent or persistent biopsy-confirmed CIN 2,3 or for positive margins when repeat diagnostic excision is not possible (36). This approach to cervical cancer prevention based on large-scale cytologic screening programs is not feasible, however, in countries in the developing world, due to lack of infrastructure, funding, and public health education (Tables 8.1 and 8.2).

OVARIAN CANCER**Risk Factors**

Ovarian cancer is the most common cause of death from a gynecologic cancer in the United States and accounts for approximately 14,000 deaths per year. Worldwide there are 192,000 new cases per year (37). Due to a lack of effective screening tools to identify ovarian cancer at early, highly curable stages, the majority of ovarian cancers are diagnosed at

advanced stages when survival is poor. While our understanding of the biology of epithelial ovarian cancer is slowly advancing, most of our current knowledge regarding risks for ovarian cancer has emerged from the epidemiologic literature. Advancing age, reproductive factors (specifically, nulliparity), and heredity are established risk factors for the disease. The majority of ovarian cancers are diagnosed after menopause. Rates are higher in nulliparous women, while parity has been found to offer protection. The risk of ovarian cancer is increased twofold in women who are infertile, and the risk appears to be independent of fertility drug treatment (37). Although the majority of cases of ovarian cancer are sporadic, approximately 5% to 10% are thought to fit a hereditary pattern of autosomal dominant inheritance. Epidemiologic studies have estimated a two- to fourfold increase in risk among first-degree relatives of women with ovarian cancer. Recently, a number of genes have been identified that account for a large percentage of hereditary ovarian cancer and that allow more precise estimates of risk. Since the identification of *BRCA1* on chromosome 17q in 1994, and *BRCA2* on chromosome 13q in 1995, several hundred mutations in these genes have been characterized, many of which lead to premature truncation of protein transcription and, therefore, presumably defective gene products. Ovarian cancer in these families is characterized by multiple cases of ovarian and breast cancer in successive generations, earlier age of onset, and evidence of both maternal and paternal transmission (Fig. 8.6). The penetrance of *BRCA1/2*, i.e., the likelihood that a mutation will actually result in ovarian cancer, is estimated to range anywhere from 16% to 39% for *BRCA1* mutation carriers, and from 11% to 16% for *BRCA2* mutation carriers (37). Some mutations may be more specifically related to ovarian cancer risk than others. An ovarian cancer cluster region has been identified, for example, in exon 11 of *BRCA2*, which is associated with a higher rate of ovarian cancer than other mutations in the gene. The wide variation observed may also reflect the interaction of the genetic mutation with other genetic and/or environmental factors, and suggests that these genes may function as “gatekeepers” and, when lost, allow other genetic alterations to accumulate. Ovarian cancer is also included in the phenotype of the recently described mismatch repair genes associated with the hereditary nonpolyposis colon cancer (HNPCC), or Lynch syndrome, in which the lifetime risk for ovarian cancer is estimated to be approximately 12% (38) (Fig. 8.7). The identification of hereditary syndromes of ovarian cancer provides new opportunities to understand the biology of the disease and to devise novel preventive strategies.

Prevention

Risk Avoidance and/or Adoption of Protective Practices

The available evidence regarding factors that lower ovarian cancer risk has been based primarily on the results of case-control studies retrospectively comparing the reproductive, hormonal, or behavioral characteristics of ovarian cancer cases with matched controls, not on prospective randomized trials. These studies have consistently shown an inverse association of ovarian cancer with increasing parity, with the first birth conferring significantly more protection (35%) than subsequent births (15%). The protective effect of pregnancy occurs regardless of fertility history and is not age dependent (39). Pregnancy is characterized by a prolonged period of anovulation as well as high levels of circulating progesterone, which may cause terminal differentiation of premalignant cells on the surface of the ovary (40,41).

The evidence supporting a protective effect of breast-feeding against epithelial ovarian cancer risk is weak and inconsistent. Some studies suggest a 10% to 20% decrease in ovarian cancer risk associated with breast-feeding. In those studies that are positive, the impact of breast-feeding on ovarian cancer risk appears to be greatest for the first 6 months of lactation with no apparent increase in ovarian cancer protection with longer-term lactation (42,43).

Several studies have examined the association of hormone replacement therapy (HRT) with ovarian cancer risk. While the majority finds a modest increase in risk, most lack statistical significance. The strongest association is seen in endometrioid histologies, where relative risks range from 1.2 to 5.5 (44).

Several retrospective and prospective studies have examined associations between dietary factors and ovarian cancer risk. Modest levels of protection have been reported for fruits and vegetables in general, and for vitamin A and beta-carotene in particular, although findings are inconsistent (45–50). Nor is there a consistent relationship between physical activity or obesity and ovarian cancer risk (37,51,52).

Chemoprevention

The ovarian epithelium is a hormonally responsive target organ that expresses receptors for most members of the steroid hormone superfamily, including receptors for progestins, retinoids, androgens, and vitamin D. Although little is

known regarding the physiologic role of steroid hormones within the ovarian epithelium, there is mounting epidemiologic and laboratory evidence suggesting that these hormones have direct and potent biologic effects on the ovarian epithelium relevant to the prevention of ovarian cancer. Progestins, retinoids, and vitamin D have been shown to exert a broad range of common biologic effects in epithelial cells, including induction of apoptosis, up-regulation of transforming growth factor- β (TGF- β), cellular differentiation, and inhibition of proliferation. In addition to hormonal agents, there is growing evidence that nonsteroidal anti-inflammatory drugs (NSAIDs) may have ovarian cancer preventive effects (53).

To date, only OCP use has been consistently shown to be protective against ovarian cancer. OCPs were first introduced in the United States in the 1960s. Most formulations include estrogen, progesterone, or a combination of the two. In addition to suppressing ovulation, OCPs also reduce pituitary secretion of gonadotropins. In addition to these potential mechanisms, a 3-year study in primates demonstrated that the progestin component of an OCP has a potent effect on apoptotic and TGF- β signaling pathways in the ovarian epithelium, raising the possibility that progestin-mediated biologic effects may underlie the ovarian cancer protective effects of OCPs (54,55). The use of OCPs appears to decrease a woman's risk for ovarian cancer by 30% to 60%. Risk reduction is apparent with as little as 3 months of use, increases in magnitude with increased duration of use, and persists for as long as 10 years after discontinuation of use. The risk reduction applies to nulliparous as well as parous women, to all histologic subtypes, including tumors of low malignant potential, to women with a hereditary risk for ovarian cancer, is consistent across races, and is independent of age at use or menopausal status (41,56,57). Although there has never been a randomized clinical trial to demonstrate the protective effect of OCPs on ovarian cancer risk, it is often recommended empirically to women with a family history of ovarian cancer to reduce their risk.

Epidemiologic and laboratory evidence suggest a potential role for retinoids as preventive agents for ovarian cancer (58). Retinoids are natural and synthetic derivatives of vitamin A. They have great potential for cancer prevention, due to a broad range of important biologic effects on epithelial cells, including inhibition of cellular proliferation, induction of cellular differentiation, induction of apoptosis, cytostatic activity, and induction of TGF- β . *In vitro*, it has been reported that the growth of human ovarian carcinoma cell lines and normal human ovarian epithelium is inhibited by retinoids. The mechanism underlying this effect may involve induction of TGF- β and/or apoptosis in ovarian epithelial cells. The most significant evidence supporting a rationale for retinoids as chemopreventive agents for ovarian cancer is that of a recently published Italian study suggesting an ovarian cancer preventive effect from the retinoid 4-HPR. Among women randomized to receive either 4-HPR or placebo in a trial designed to evaluate 4-HPR as a chemopreventive for breast carcinoma, significantly fewer ovarian cancer cases were noted in the 4-HPR group as compared to controls (59).

Vitamin D is a fat-soluble vitamin that is essential as a positive regulator of calcium homeostasis. The vitamin D receptor and the retinoic acid receptors share strong homology and readily dimerize, making it likely that vitamin D and retinoids have common signaling pathways in the cell (60). Vitamin D has been shown to have diverse biologic effects in epithelial cells relevant to cancer prevention, including retardation of growth, induction of cellular differentiation, induction of apoptosis and up-regulation of TGF- β (61). With regard to ovarian cancer, a recent study has correlated population-based data regarding ovarian cancer mortality in large cities across the United States with geographically based long-term sunlight data reported by the National Oceanic and Atmospheric

Administration. The study demonstrated a statistically significant inverse correlation between regional sunlight exposure and ovarian mortality risk (62). Given that sunlight induces production of native vitamin D in the skin, it might confer protection against ovarian cancer via direct biologic effects on nonmalignant ovarian epithelium, for example, through induction of apoptosis and/or TGF- β in the ovarian epithelium, leading to selective removal of nonmalignant but genetically damaged epithelial cells.

Epidemiologic studies have suggested that use of NSAIDs may lower ovarian cancer risk (63). Several biologic mechanisms have been proposed to account for the chemopreventive effects of NSAIDs, including inhibition of ovulation, inhibition of COX and down-regulation of prostaglandins, enhancement of the immune response, and induction of apoptosis (41,64,65). Despite a growing body of preclinical data indicating chemopreventive effects of several agents, clinical research exploring their efficacy to reduce rates of ovarian cancer is hindered by the relatively low incidence of the disease, insufficient understanding of the preclinical course of ovarian cancer, the lack of validated preclinical biomarkers, and inadequate screening strategies.

Surgical Prophylaxis

For women with a family history of ovarian cancer, or a hereditary pattern of breast cancer, bilateral salpingo-oophorectomy (BSO) has been shown to lower the risk of subsequent epithelial ovarian cancer by 80% to 95% (66–68). There is also a 50% reduction in rates of breast cancer in women who undergo prophylactic BSO (69). Occult ovarian and fallopian tube tumors have been found at the time of BSO in 3% to 4% of *BRCA1/2* mutation carriers (70), emphasizing the need for both deliberate removal of the fallopian tubes at the time of prophylactic surgery, and of careful pathologic examination of the surgical specimen. The incidence of primary peritoneal cancer following BSO is reported to be approximately 2% to 5% (68). Because the median age of diagnosis of ovarian cancer among women with a hereditary risk is 50 years, the recommended age for prophylactic surgery is at the completion of childbearing, or at age 35 years.

In addition to the significant reduction in ovarian cancer incidence associated with BSO, several studies have found a significant decline in ovarian cancer worry and anxiety following the procedure (71–73). These potential benefits of prophylactic oophorectomy must, however, be weighed against its adverse consequences, including the short- and long-term surgical risks, the physical and psychological impact of early menopause, and the potential subsequent risks of cardiovascular disease and osteoporosis related to early estrogen/progesterone depletion. Although the use of combined estrogen/progesterone HRT has been associated with an increased risk for breast cancer among postmenopausal women in the general population, one study with short follow-up found no increased risk of breast cancer among *BRCA1/2* mutation carriers who took HRT following BSO (74). And data from the Mayo Clinic showed that there was no increase in breast cancer among women under the age of 50 years undergoing BSO (75). Women seeking information regarding prophylactic oophorectomy should be counseled about the practical short- and long-term sequelae of the surgery, the risks and benefits of postoperative HRT, and the small potential for primary peritoneal cancer (76).

Tubal ligation has been associated with lower ovarian cancer risk in both case-control and cohort studies. A strong inverse association was observed between tubal ligation and ovarian cancer risk in the Nurses Health Study, with a relative risk of 0.33 (CI, 0.16 to 0.64) after controlling for age, OCP use, and parity (77). A Danish population-based study also supports a significant association between tubal sterilization

TABLE 8.3**OVARIAN CANCER—MAJOR POINTS**

Several risk factors, including age, nulliparity, and family history, have been identified for ovarian cancer.

Germ-line mutations in the *BRCA1/2* genes and the DNA mismatch repair genes associated with Lynch syndrome significantly increase the risk of ovarian cancer.

Primary cancer of the fallopian tube is considered a component of the hereditary ovarian cancer syndromes.

OCPs confer significant protection from ovarian cancer and the level of protection is related to the duration of use.

Tubal ligation also confers a significant protection from ovarian cancer, although the physiologic mechanism is unknown.

Prophylactic bilateral salpingo-oophorectomy is the most effective method of preventing ovarian cancer in women with a hereditary pattern of ovarian cancer.

No effective method of screening for ovarian cancer has been identified.

OCPs, oral contraceptives.

and ovarian cancer (78). A case-control study among *BRCA1/2* carriers found an odds ratio of 0.39 for ovarian cancer among women with *BRCA1* mutations who had undergone tubal ligation. No effect was seen in *BRCA2* carriers (79). Proposed mechanisms include changes in local or circulating hormones, reduced access of carcinogens to the ovary, or a reduction in inflammatory processes on the ovarian surface. Although the protective effect of tubal ligation appears to be substantial, the ability to perform BSO using a laparoscopic approach would seem to make this procedure a preferable choice among women with an increased risk of ovarian cancer (Tables 8.3 and 8.4).

ENDOMETRIAL CANCER

Risk Factors

Endometrial cancer is the most common gynecologic cancer in the United States, but the least common cause of gynecologic cancer death. Close to 40,000 new cases are diagnosed each year, and there are 7,400 deaths annually (80). Worldwide, there are close to 200,000 new cases and over 50,000 deaths (81). The relatively low case fatality rate is due to early detection and treatment at early-stage disease. The majority of risk factors associated with type 1 (endometrioid) endometrial cancer, viz. increased age, nulliparity, early age at menarche, late age at menopause, obesity, the long-term use of unopposed estrogen replacement therapy, and the use of tamoxifen, are all thought to exert their effect through estrogen-induced endometrial proliferation leading to hyperplasia and malignant transformation. The increased risk associated with diabetes, hypertension, and thyroid disease suggests a role for

TABLE 8.4**OVARIAN CANCER—REMAINING QUESTIONS**

Can effective screening strategies, using biomarkers and/or imaging studies, be identified?

Are there effective chemopreventive agents that will reduce the risk of ovarian cancer?

altered growth hormone pathways in addition to the steroid hormone pathways. There are also genetic syndromes associated with endometrial cancer. Women with mutations in the DNA repair genes associated with the HNPCC or Lynch syndrome have a 40% to 60% risk of endometrial cancer (82). Endometrial cancer is also a component of Cowden syndrome (Fig. 8.8), in which it is estimated that mutations in the *PTEN* gene confer a lifetime risk for endometrial cancer of approximately 5% (83). Type 2 serous endometrial cancer is uncommon and is not related to unopposed estrogen exposure.

Prevention

Risk Avoidance and Uptake of Protective Behaviors

It has been estimated that approximately 40% of endometrial cancers are attributable to excess body weight in developed countries (84). Maintenance of ideal body weight, regular physical activity, and control of diseases associated with endometrial cancer (diabetes, hypertension, and thyroid

FIGURE 8.8. Family pedigree illustrating Cowden syndrome.

TABLE 8.5**ENDOMETRIAL CANCER—MAJOR POINTS**

The major risk factors for type 1 endometrial cancer exert their effect through estrogen stimulation of the endometrial surface epithelium. Altered growth hormone pathways may also be involved in endometrial carcinogenesis. Hereditary forms of endometrial cancer have been associated with the Lynch syndrome and with Cowden syndrome. The majority of endometrial cancers present at an early stage with abnormal uterine bleeding. Endometrial cancer screening is not recommended for the general population, although women with a hereditary risk are recommended to undergo annual endometrial biopsy. Prophylactic hysterectomy in high-risk women has been shown to protect women from subsequent endometrial cancer.

disease) are all prudent approaches to reduce disease risk. Women considering the use of tamoxifen or raloxifene for breast cancer risk reduction should carefully weigh the risk of endometrial cancer with the benefits as they make their decision.

Chemoprevention

The addition of a progestin to the estrogen component of HRT has been shown to eliminate the increased risk of endometrial cancer. Progesterone reverses the estrogen effect on the endometrium and prevents the development of hyperplasia. Women with an intact uterus who elect HRT are routinely prescribed a combined estrogen-progestin preparation. Long-term use of combination OCPs also reduces the risk of endometrial cancer by approximately 10% per year of use (40). The reduction in risk associated with OCP use is attributed to the suppression of endometrial hyperplasia by the progestin component (85).

Surgical Prophylaxis

It is thought that the majority of invasive endometrial cancers progress through a series of premalignant stages, simple hyperplasia, complex hyperplasia, simple atypical hyperplasia, and complex atypical hyperplasia, all of which may present with abnormal vaginal bleeding (86). Conservative management of these conditions involves the use of progestational agents, which results in a complete regression of atypical hyperplasia in 50% to 94% of cases. Even in complete responders, however, there is a high rate of recurrence, and definitive therapy of atypical hyperplasia is hysterectomy (33). Among women with documented germ-line mutations associated with the Lynch syndrome, a retrospective study

found that prophylactic hysterectomy conferred 100% protection from subsequent endometrial cancer (87). Because of the high success rate for endometrial cancer treatment, however, it is not clear if this protection would translate into a significant survival benefit. This study also found 100% protection from ovarian cancer, which may warrant the consideration of prophylactic total abdominal hysterectomy–bilateral salpingo-oophorectomy (TAH-BSO) in this population. Alternatively, annual endometrial biopsy starting at age 30 to 35 is recommended in women with Lynch syndrome to detect early, premalignant endometrial lesions (82) (Tables 8.5 and 8.6).

FUTURE DIRECTIONS

The prevention of gynecologic malignancies involves many disciplines and requires the collaboration of basic scientists, clinicians, behavioral scientists, and policy makers. The successful development of the HPV vaccines is a major breakthrough in the prevention of cervical cancer and will likely undergo further improvements and refinements. Advances in molecular genetics, molecular pathology, and molecular imaging will contribute to the early identification of specific markers of premalignant change associated with gynecologic malignancies. The identification of safe and effective chemopreventive agents will provide additional strategies for prevention. Accompanying this progress will be the need to address the psychosocial and cultural barriers to the adoption of preventive strategies.

CHAPTER 9 ■ CLINICAL TRIALS METHODOLOGY AND BIOSTATISTICS

MARK F. BRADY, ALAN D. HUTSON, AND DANIEL P. GAILE

Issues involved in the design, conduct, and analyses of clinical trials are presented in this chapter. Phase 1, 2, and 3 trials are presented, as well as screening trials. Since translational research objectives are often integrated into modern clinical trials, this topic is also described. Statistical jargon and mathematical notation is avoided wherever possible. Studies from the field of gynecologic oncology are used as examples in order to illustrate specific points. This chapter is an overview of these very expansive topics. Details can be found in books dedicated to the subject of clinical trials, like Piantadosi, 2005 (1), Green et al., 2003 (2), or Everett and Pickles, 1999 (3).

This chapter begins with general systems for classifying interventions and study designs. Then, some historical highlights from medical research are described. This synopsis of history is intended to provide a sense of how the concepts of clinical trials matured from an intuition-based practice of medicine to the more sophisticated evidence-based medicine used today. The procedures for designing, conducting, and analyzing clinical trials continue to mature as the demand for evidence-based medicine increases. The following sections in this chapter describe the components of a clinical trial and some essential considerations for each of these components. Since translational research objectives are incorporated into many modern clinical trials, some issues related to design and analyses of these components are also considered.

CLASSIFICATION OF INTERVENTIONS AND STUDY DESIGNS

In general, a clinical trial is any experiment involving human subjects that evaluates an intervention that attempts to reduce the impact of a specific disease in a particular population. When an intervention is applied in order to prevent the onset of a particular disease, the trial is classified as a primary prevention trial. For example, a primary prevention trial may evaluate healthy lifestyles or a vitamin supplement in a population of individuals who are considered to be at risk of a particular disease. Secondary prevention trials evaluate interventions that are applied to individuals with early stages of a disease in order to reduce their risk of progressing to more advanced stages of the disease. Tertiary intervention trials are aimed at evaluating interventions that reduce the risk of morbidity or mortality due to a particular disease.

Clinical trials that evaluate methods for detecting a disease in a preclinical state are called screening trials. Early detection

may mean diagnosing a malignancy in an early stage (e.g., the use of mammography in the detection of breast cancer) or in a premalignant state (e.g., the use of Papanicolaou smear in the detection of cervical intraepithelial neoplasia). There are typically two interventions in a screening trial. The first intervention is the screening program (e.g., annual mammograms), which involves individuals who appear to be free of the disease. However, once the disease is detected in an individual, a secondary intervention (e.g., surgery) is performed in hopes of stopping the disease from progressing to more advanced stages. Consequentially, screening trials require *both* interventions to be effective. An effective screening procedure is useless if the secondary intervention does not alter the course of the disease. On the other hand, an ineffective screening procedure would cause the secondary intervention to be applied indiscriminately.

Nonexperimental studies (or observational studies) can be classified into three broad design categories: cohort (or prospective), case-control (or retrospective), and cross-sectional. In a cohort study individuals are initially identified according to their exposure status, which can include environmental, genetic, or lifestyle factors. These individuals are then followed in order to determine who develops the disease. The aim of these studies is to assess whether the exposure is associated with the incidence of the disease under study. This design is in contrast to the case-control study, which identifies individuals on the basis of whether they have the disease and then measures and compares their exposure histories. Measuring exposure may be as simple as questioning the individuals about their personal or employment history, or it may involve a more sophisticated assessment such as analyzing the individual's blood for markers of exposure. Though the case-control study is susceptible to several methodological flaws, it has the advantage of often being less expensive, and easier and quicker to perform than a cohort study, especially when the disease is rare. The power of the case-control design is apparent from a review of the case-control studies published between 1975 and 1983 (4), which demonstrated the deleterious effects of exogenous estrogens in perimenopausal women. Finally, the goal of the cross-sectional study is to describe the prevalence of a disease and an exposure in a population during a specific period of time. These studies can often be conducted more quickly than either the cohort or case-control study, but they are frequently not used when the time between exposures and the disease onset is long, as it is for cancer.

HISTORICAL PERSPECTIVE

Clinicians make treatment recommendations daily. These recommendations arise from culling information from standardized clinical guidelines, published reports, expert opinion, or

Brian N. Bundy, PhD, contributed to prior editions of this chapter.

personal experiences. The synthesis of information from these sources into a particular recommendation for an individual patient is based on a clinician's personal judgment. But what constitutes reliable and valid information worthy of consideration? Clinicians have long recognized that properly planned and conducted clinical trials are important sources of empirical evidence for shaping clinical judgment.

The Greek physician Hippocrates in the 5th century BCE had a profound influence in freeing medicine from superstitions. He rejected the notion that the cause of an individual's disease had a divine origin. Rather, he postulated that diseases originated from natural causes that could be determined from observing environmental factors like diet, drinking water, or local weather. He also proposed the revolutionary concept that a physician could anticipate the course of a disease after carefully observing a sufficient number of cases. Despite these insights, medicine continued to frequently consist of a mixture of herbal concoctions, purging, bloodletting, and astrology.

In the Middle Ages, Avicenna (980–1037 CE) wrote *The Canon of Medicine*, a work considered to be the preeminent source of medical and pharmaceutical knowledge of its time. In his writings Avicenna proposed some rules for testing clinical interventions. First, he pointed to the need to experiment in humans since "testing a drug on a lion or horse might not prove anything about its effect on man." Also, he described the basic experiment as observing pairs of individuals with uncomplicated but similar forms of the disease. Finally, he emphasized the need for careful observation of the times of an intervention and then reporting the reproducibility of its effects (5). Despite these insights, *The Canon of Medicine* does not include any specific reports of clinical experimentation.

Early trials frequently lacked concurrent comparison groups. For example, Lady Mary Wortley-Montague in 1721 urged King George I to commute the sentences of six inmates from the Newgate prison if they agreed to participate in a smallpox inoculation trial (5). The prisoners were inoculated with smallpox matter from a patient with a naturally occurring form of the disease. Since these individuals remained free of smallpox, this was considered evidence supporting treatment by inoculation. Later, however, the results of this trial were considered less compelling, when it was discovered that some of these inmates might have been exposed to smallpox prior to the trial (6). Without a proper control group, it can be difficult to interpret the efficacy of an intervention. There are frequently many factors, both known and unknown, that influence an individual's outcome.

Subjective assessments from either the subject or the practitioner may also influence the interpretability of a trial. In the late 18th century the King of France selected Benjamin Franklin to head a royal commission to investigate the physician Franz Mesmer's claims that he could promote good health by manipulating a force he called "animal magnetism" (7). Franklin devised several ingenious experiments in which the subjects were blindfolded and not told whether or not they were receiving Mesmer's treatment. These trials led Franklin to conclude that the therapeutic effects of mesmerism were due to imagination or illusion. Several years later John Haygarth demonstrated the importance of controlling for assessment biases. At that time magnetic healing rods were commonly used to relieve pain due to chronic rheumatism (6). He treated five patients on two consecutive days once with sham wooden rods and once with genuine magnetic rods. He noted that four individuals reported pain relief and one experienced no relief, regardless of which rods were used. Franklin's and Haygarth's trials established the importance of implementing experimental procedures aimed at removing all sources of subjectivity from the assessment of treatment effects.

It had long been appreciated that there is a potential for misguided inference about the effectiveness of a treatment when the comparison involves a group with a dissimilar prognosis. The apparent benefits attributed to a new treatment might in fact be biases due to prognostic differences in patients between treatment groups. One of the earliest clinical trials to attempt to address this bias was reported in 1898 by Johannes Fibiger (8). Four hundred and eighty-four patients admitted to his clinic with diphtheria were given either standard care or diphtheria serum twice daily. In order to disassociate the mode of treatment from the individual's prognosis, the patient's treatment was to be determined by the day of clinic admission, and it alternated from day to day (9). Using this type of procedure to disassociate prognosis from treatment is only partially effective, since the practitioner or the subject knew which treatment would be applied and this knowledge may have influenced the individual's decision to participate in the study. Therefore, masking the treatment assignment so that it cannot be part of the decision to participate in the trial is important for controlling this source of selection bias.

Treatment randomization in clinical trials was performed as early as 1926 (10). However, it was not until the 1940s when Corwin Hinshaw (11), using a coin toss, and later Bradford Hill (12), using random numbers in sealed envelopes, established the methodologic importance of randomizing treatments in clinical trials. Balancing the unpredictable and spontaneous remissions exhibited by some patients with pulmonary tuberculosis motivated Amberson (10) and later Hinshaw (11). While methodological principles motivated Hill, the short supply of streptomycin after World War II provided the opportunity to use randomization as an equitable way to distribute the drug (13).

One of the first randomized clinical trials in the study of gynecologic malignancies was initiated in 1948 (14). This trial compared ovarian irradiation to standard treatment for breast cancer. Initially, shuffled sealed envelopes were used to designate treatment. However, this procedure was later changed due to administrative difficulties so that treatment depended on the woman's date of birth. This latter procedure is susceptible to the same selection bias mentioned in Fibiger's trials since the treatments were not masked.

Despite these methodological advances, the inadequate justification for selecting one medical procedure over another led one contemporary physician to express his frustration: "Early in my medical career I was appalled at the 'willy-nilly' fashion by which treatment regimens slipped in and out of popularity. How many operations that I was trained to do or medicines that I was instructed to give because of somebody's conviction they were beneficial passed into oblivion for no apparent reason, only to be replaced by others of equally dubious worth?" (15).

The first randomized clinical trial at the National Cancer Institute (NCI) was begun in 1955 (16). This trial involved 65 evaluable patients with acute leukemia from four different institutions. The trial incorporated many elements that should be part of most modern clinical trials: uniform criteria for response assessment, a randomized comparison of at least two treatment regimens, and a complete accounting of all patients entered. The published report included considerations for such issues as patient selection bias and the study's impact on the patient's welfare (17). The first NCI randomized clinical trial in solid tumors followed shortly thereafter and was organized by the Eastern Group for Solid Tumor Chemotherapy (18). By 2007, there were 12 NCI-sponsored cooperative groups conducting clinical trials, and the annual funding for these groups was \$155 million (19).

In the late 1950s most patients with gynecologic cancers were included incidentally in small trials to screen new agents

for broad-range activity. The first NCI-sponsored group to organize trials specifically for gynecologic malignancies was the Surgical Ovarian Adjuvant Group. This group was formed in the late 1950s, initiated a few trials, and then disbanded in 1964. Starting in 1963 the Surgical Endometrial Adjuvant Group was one of the earliest efforts toward a multidisciplinary group. This multidisciplinary cooperative group included gynecologic surgeons, medical oncologists, pathologists, radiation oncologists, and biostatisticians. It was from this group that the Gynecologic Oncology Group (GOG) was eventually formed in 1970 to deal with a broader range of gynecologic malignancies (20). Over the following 10 years, the field of gynecologic oncology matured. Board certification procedures for gynecologic oncologists were developed, fellowship programs were initiated in the comprehensive cancer centers, and a professional Society of Gynecologic Oncologists was organized in 1969.

COMPONENTS OF A CLINICAL TRIAL

Objectives

In clinical oncology research, where the disease is often fatal, the ultimate purpose of a research program is to develop a treatment plan that puts patients into a disease-free state, reduces the risk of cancer recurrence, and allows patients to return to their normal lifestyle within a reasonable period of time. The objectives of a particular clinical trial are often more specific and less grandiose. A clinical trial attempts to answer a precisely defined set of questions with respect to the effects of a particular treatment(s) (21). These questions (objectives) form the foundation upon which the rest of the trial is built. The study objective typically incorporates three elements: the interventions to be evaluated, the “yardstick” to be used to measure treatment benefit (see the Endpoints section), and a brief description of the target population (see the Eligibility Criteria section). These three elements (i.e., “what,” “how,” and “who”) should be stated in the most precise, clear, and concise terms possible.

The choice of experimental therapy to be evaluated in a randomized clinical trial is not always easy. Both a plethora of new therapies and the absence of innovative concepts make for difficult choices. The former is problematic since many malignancies in gynecologic oncology are relatively uncommon. Definitive clinical trials may require 4 to 5 years to accrue a sufficient number of patients even in a cooperative group setting. This time frame limits the number of new therapies that can be evaluated. The absence of new therapies is a problem since substantial increases in patient benefit are less likely to be observed in trials that merely alter doses or schedules of already acceptable therapies. An open dialogue among expert investigators remains the most effective approach for establishing the objectives of any clinical trial.

Endpoints

The endpoint of a trial is some measurable entity in the patient’s disease process that can be used to assess the effectiveness of an intervention. A study may assess more than one endpoint, but in these instances the endpoint of primary interest should be clearly specified or else the study design should carefully reflect the complexity of interpreting multiple outcomes. Endpoints can be a composite measure of multiple outcomes. For instance, some studies assessing quality of life aggregate patient-reported scores from several related items

that are all considered components of a larger concept called quality of life.

Selecting endpoints that will reflect the effectiveness of an experimental therapy is not always obvious. First, endpoints should be a valid (unbiased) measure of the treatment effect on the disease process. Endpoints that are susceptible to a systematic error that favors one treatment lead to biased treatment effects. For instance, trials assessing time to disease progression, in which the schedule for computed tomography (CT) scans is different for each treatment group, are susceptible to this assessment bias. This problem is not uncommon in studies comparing two different modalities such as chemotherapy and radiation therapy. Second, the measurement of an endpoint should be reliable and not susceptible to subjective interpretation. In some cases clinical response can be considered unreliable, since it is not uncommon for experts to disagree when interpreting the same radiograms (22). Third, endpoints that are directly relevant to the patient are preferable, although valid surrogate endpoints are considered indirectly relevant to the patient. Finally, endpoints that are not too expensive or inconvenient for the patient are preferred. It is not always possible for a single endpoint to exhibit all of these characteristics simultaneously. For example, avoiding death is extremely relevant to a patient with a lethal disease like advanced gynecologic cancer. Also, survival can be measured very reliably. However, most cancer patients will not only receive the treatments prescribed by the study, but after exhibiting signs of disease progression, they may also receive other anticancer therapies. In this case, the validity of overall survival comparisons is suspect since they not only reflect the effects of the study treatment, but also the effects of other therapies that are external to the study. For example, a meta-analysis of those trials comparing the survival of patients who were randomized to non-platinum versus platinum regimens for the treatment of advanced ovarian cancer concluded that these trials appear to have underestimated the true effect of platinum on survival. The reason is that many patients who were not randomized to the platinum regimen eventually received platinum treatment (23). For this reason, progression-free survival (PFS) may be considered a more appropriate endpoint in those trials, since it is unaffected by subsequent therapies. Survival may remain a reasonable endpoint in trials that explicitly compare a strategy of immediate treatment versus delayed treatment.

Endpoints may be classified as categorical (e.g., clinical response), continuous (e.g., serum CA125 values), or time-to-event (e.g., survival time). A time-to-event endpoint includes both time (a continuous measure) and censoring status (categorical measure). The data type influences the methods of analysis.

Measurement Errors

The susceptibility of an outcome to measurement errors is an important consideration when choosing an endpoint. Both random and systematic errors are components of measurement error. Random error refers to that part of the variation that occurs among measurements that is not predictable, and appears to be due to chance alone. For example, a serum sample could be divided into 10 aliquots and submitted to the laboratory for CA125 determinations. If the laboratory returns nearly the same value for each aliquot, then the associated random error is low and the measurement may be deemed reproducible. On the other hand, if the CA125 values vary considerably among aliquots, perhaps due to inconsistent laboratory procedures, then individual values may be considered unreliable. In this case, taking the average CA125 measurement across all 10 aliquots is expected to be a better estimate of the patient’s true CA125 value than any single measurement.

Concern for reliability is one of the reasons for incorporating several items into a quality of life questionnaire. Quality of life is a complex entity and no single question can be expected to reliably measure it. A measurement of an individual's quality of life is therefore typically composed from an individual's responses to several items that are all considered to be associated with quality of life. Indeed, one step toward demonstrating the usefulness of any quality of life instrument is to show that it provides reproducible results when assessing individuals under the same conditions (24).

Systematic error, also called bias, refers to deviations from the true values that occur in a systematic fashion. For example, suppose an investigator initiates a randomized clinical trial comparing two treatments with time to disease progression being the primary endpoint. The protocol indicates that the patient should be assessed after each cycle of therapy. However, suppose that a cycle duration is 2 weeks for one treatment group and 4 weeks for the second treatment group. Using a more intense assessment schedule for one treatment group would tend to detect failures earlier in that group. Therefore, the time to failure comparison between treatments would systematically favor the second treatment group.

When there are recognized sources of error, it is important that the study design implement procedures to avoid or minimize their effect. For example, random error in many cases can be accommodated by either increasing the number of individuals in the study, or in some cases by increasing the number of assessments performed on each individual. Systematic measurement error cannot be addressed by increasing the sample size. In fact, increasing the sample size may exacerbate the problem since small systematic errors in large comparative trials can erroneously contribute to a "significant" treatment effect. The approaches to controlling sources of systematic error tend to be procedural. For example, treatment randomization is used to control selection bias, placebos are used to control observer bias, standardized assessment procedures and schedules are used to control measurement bias, and stratified analyses are used to control biases due to confounding. For an extensive description of biases that can occur in analytic research see Sackett, 1979 (25).

Surrogate Endpoints

Surrogate endpoints do not necessarily have direct clinical relevance to the patient. Instead, surrogate endpoints are intermediate events in the etiologic pathway to other events that are directly relevant to the patient (26). The degree to which a treatment's effect on a surrogate endpoint predicts the treatment's effect on a clinically relevant endpoint is a measure of the surrogate's validity. The ideal surrogate endpoint is an observable event that is a necessary and sufficient precursor in the causal pathway to a clinically relevant event. Additionally, the treatment's ability to alter the surrogate endpoint must be directly related to its impact on the true endpoint. It is important that the validity and reliability of an endpoint be established with appropriate evidence and not presupposed (27,28). Surrogate endpoints are sometimes justified on the basis of an analysis that demonstrates a statistical correlation between the surrogate event and a true endpoint. However, while such a correlation is a necessary condition, it is not a sufficient condition to justify using a particular surrogate as an endpoint in a clinical trial. For example, CA125 levels following first-line treatment of ovarian cancer have been shown to be associated with subsequent overall survival. Those patients with normal CA125 levels at the end of treatment tend to survive longer than those who have abnormal levels. However, it has not (yet) been demonstrated that the degree to which treatments reduce CA125 levels reliably predicts their effects on clinically relevant endpoints like overall survival.

The most frequently cited reasons for incorporating surrogate endpoints into a study include reduction in study size and duration, decreased expense, and convenience.

Primary Endpoints in Gynecologic Oncology Treatment Trials

The Food and Drug Administration (FDA) recently held a conference to consider endpoints for trials involving women diagnosed with advanced ovarian cancer (29). Meta-analyses were presented which indicate that PFS can be considered a valid endpoint for trials involving women with advanced ovarian cancer. It is important to recognize that although the general validity of PFS for predicting overall survival in this patient population has been established, PFS comparisons in a particular study can be biased. One source of bias arises from using different disease assessment schedules for each treatment group either intentionally or unintentionally. Delaying assessments for one treatment group artificially increases the apparent time to progression. Survival time is generally not susceptible to this source of bias.

Progression-free interval (PFI) may be a more reasonable endpoint in trials involving patients with early or locally advanced ovarian cancer. PFI should be distinguished from PFS. The difference resides in how patients who die without any evidence of disease progression are handled in the analysis. Patients who die without evidence of progression are censored at the time of their death in a PFI analysis, but considered an uncensored event in a PFS analysis.

Response (disease status) assessed via reassessment laparotomy following treatment has been proposed for use as a study endpoint in ovarian cancer trials (30). The justification is that those patients with no pathologic evidence of disease are more likely to experience longer survival than those with evidence of disease. The principal drawback to this endpoint is that reassessment laparotomy is a very onerous procedure for the patient, and many patients refuse reassessment surgery or the surgery may become medically contraindicated. Even among highly motivated and very persuasive investigators the percentage of patients not reassessed is typically greater than 15%. These missing evaluations can significantly undermine the interpretability of the study.

To date PFS has not been formally validated for use in trials involving patients with advanced cervical, endometrial, or vulvar cancers. In the absence of a formally validated endpoint, overall survival or symptom relief are reasonable endpoints. Since relief from symptoms is susceptible to assessment bias, trials utilizing these endpoints should consider blinding the study treatments when possible.

The endpoint selection for trials involving patients with recurrent cervical cancer has been controversial. Historically, some trials have been designed with clinical response as the primary endpoint. However, in recent GOG trials involving these patients, such as GOG Protocol 179 (A Randomized Phase III Study of Cisplatin Versus Cisplatin Plus Topotecan Versus MVAC [methotrexate, vinblastine, adriablastine, and cisplatin] in Stage IVB, Recurrent, or Persistent Squamous Cell Carcinoma of the Cervix), overall survival is considered the primary endpoint. The rationale for this choice arises from the observation that treatments that have demonstrated an improvement in the frequency of response have not consistently prolonged survival (31–33). Although subsequent therapies may have distorted the cause-effect relationship, the effect is probably at best minimal since there are currently no known treatments that have consistently demonstrated an ability to influence the survival time of patients with advanced or recurrent cervical cancer (i.e., median survival: 8.5 months).

In summary, the ideal endpoint provides reasonable assurance that inference about the causal relationship between the intervention and the endpoint is valid. The ideal endpoint can be measured reliably. It is convenient and cost-effective to measure. Unfortunately, in some trials these features are not available simultaneously. If a surrogate endpoint is used then its validity should be established, not presumed.

Eligibility Criteria

The eligibility criteria serve two purposes in a clinical trial. The immediate purpose is to define those patients with a particular disease, clinical history, and personal and medical characteristics that may be considered for enrollment into the clinical trial. The subsequent purpose of eligibility criteria comes after the clinical trial is completed and the results are available. Physicians must then decide whether the trial results are applicable to their particular patient. A physician may consider the trial results to be applicable when the patient meets the eligibility criteria of the published study. Unfortunately, this principle is problematic. The necessary sampling procedure for selecting patients for the study (i.e., a random sample of all patients) is never actually applied in clinical trials. Moreover, the principle ignores the fact that extrapolation is an inherent part of medical practice.

Within the general population there is a target population that includes those patients to whom the results of the trial are intended to apply (e.g., women with advanced endometrial cancer having had no prior systemic cytotoxic therapies). While an investigator can typically specify an idealized definition for the target population, additional practical issues also frequently need to be considered. For example, there are varying opinions about whether patients diagnosed with an adenocarcinoma of the fallopian tube should be included in studies that target the treatment of patients with adenocarcinomas of the ovary. Some clinical investigators will argue for the need to study a “pure” study population and ignore the fact that their treatment decisions for patients with cancers of the fallopian tube frequently come from the results of trials involving only patients with advanced ovarian cancer. Ideally, the size of a subgroup represented in a study should be in proportion to their presence in the target population (see the Ethics section). The degree to which a study sample reflects the target population determines the generalizability or external validity of the study results. Eligibility criteria should reflect a concern for the generalizability of the trial results. When clinicians frequently resort to extrapolating the results of a trial to patient groups that were not eligible for the trial, this may be considered a serious indictment of the study’s eligibility criteria.

The ideal situation is when each patient who meets the eligibility criteria of a clinical trial is asked to participate. This is seldom possible since not all physicians who treat such patients participate in the study. Also, not all patients wish to be involved in a clinical trial. Impediments in traveling to a participating treatment center further reduce the target population. The source population is the subset of patients in the target population who have access to the study. Figure 9.1 displays common restrictions that can limit the entry of patients to a clinical trial.

Restricted access to the study may contribute a biased sample from the target population, referred to as selection bias. For example, participating investigators at university hospitals might tend to enroll disproportionately more patients with ovarian cancer who have undergone very aggressive initial debulking surgeries than their counterparts at community hospitals.

A potentially useful approach for determining the necessity of a particular eligibility criterion is to clearly identify its function. There are four distinct functions that an eligibility criterion

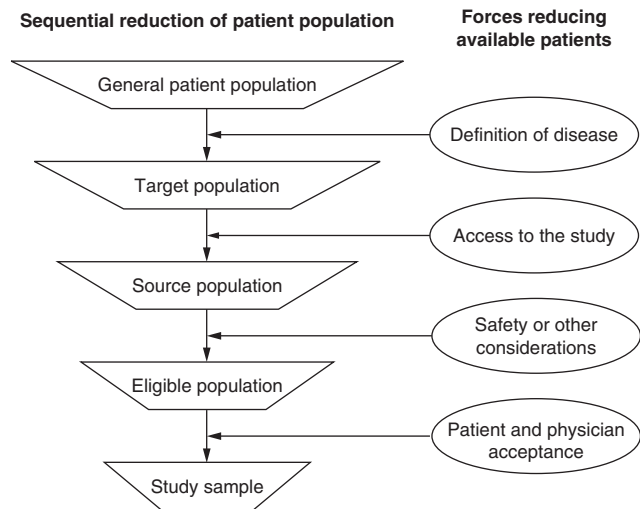

FIGURE 9.1. Sequential reduction of patient population.

may serve: benefit-morbidity equipoise (safety), homogeneity of benefit (scientific), logistic, and regulatory (34).

Criteria for benefit-morbidity equipoise or safety are frequently imposed to eliminate patients for whom the risk of adverse effects from treatment is not commensurate with the potential for benefit (see the Ethics section). This concern can manifest in two ways. First, in oncology trials there is often some concern that study treatments may be too toxic for those with compromised bone-marrow reserves or kidney function. These patients are frequently excluded from trials when the potential benefits of treatment are not consistent with the risk associated with treatment. Second, even otherwise healthy cancer patients may be eliminated from the study when the risks from treatment are considered too great. For example, chemoradiation after hysterectomy is normally considered excessive treatment for a patient with stage IA cervix cancer since even without this treatment the risk of relapse is relatively small, but the morbidity of this combined modality following hysterectomy may be substantial. Therefore, eligibility criteria that eliminate these patients may be justified.

Eligibility criteria may be warranted when there is a scientific or biologic rationale for a variation in treatment benefit across patient subgroups. There is no scientific reason to expect that the effect of treatment is entirely homogeneous across all subgroups of patients included in the study. The effect of a new therapy may be expected to have such dramatic inconsistencies across the entire spectrum of the target population that statistical power is compromised (34). One example of this type of exclusion criterion is found in GOG Protocol 152 (A Phase III Randomized Study of Cisplatin [NSC #119875] and Taxol [Paclitaxel] [NSC #125973] with Interval Secondary Cytoreduction Versus Cisplatin and Paclitaxel in Patients with Suboptimal Stage III and IV Epithelial Ovarian Carcinoma). This study was designed to assess the value of secondary cytoreductive surgery in patients with stage III ovarian cancer. All patients entered into this study were to receive three courses of cisplatin and paclitaxel. After completing this therapy they are then randomized to either three additional courses of chemotherapy or interval secondary cytoreductive surgery followed by three additional courses of chemotherapy. The eligibility criteria excluded patients with only microscopic residual disease since there is no scientific reason to expect interval debulking would be of any value to patients with no gross residual disease.

Clinical investigators frequently implement eligibility criteria in order to promote homogeneity in patient prognoses. The desire to attain a study population with homogeneous prognoses is a common reason for excessive eligibility criteria. However, the concept is both unattainable and overemphasized. This notion may arise from an investigator's attempt to duplicate the experimental method conducted in the laboratory. It is standard practice in laboratory experiments on animals to use inbred strains in an effort to control genetic variability. In large-scale clinical trials this approach seldom has merit in light of the cost to generalizability. Eligibility criteria should be as broad as possible in order to enhance generalizability. For example, GOG Protocol 165 (A Randomized Comparison of Radiation Plus Weekly Cisplatin Versus Radiation Plus PVI [Protracted Venous Infusion] 5-FU in Patients with Stage IIB, IIIB, and IVA Carcinoma of the Cervix) includes patients with no surgical sampling of the para-aortic lymph nodes. Previous GOG trials required sampling of these nodes. However, there is no evidence or sound biological justification to support the notion that the relative treatment benefit depends on the extent of surgical staging. This is not to say whether or not surgical staging is itself beneficial.

Eligibility criteria can be justified on the basis of logistic considerations. For example, a study that requires frequent clinic visits for proper evaluation or toxicity monitoring may restrict patients who are unable to arrange reliable transportation. The potential problem with such a restriction is how it is structured. A criterion requiring that the patient have a car at her disposal is probably too restrictive in a trial of women with advanced cervical cancer, since patients from this target population tend toward poorer socioeconomic status (SES) and may not have access to private transportation. Such a restriction erodes the generalizability of the trial by over sampling those with higher SES and may prolong study accrual. Moreover, complicated eligibility criteria are more likely to function ineffectively. In general, complicated eligibility restrictions should be avoided.

Eligibility criteria based on regulatory considerations include those institutional and governmental regulations that require a signed and witnessed informed consent and study approval by the local Institutional Review Board. These restrictions are required in most research settings and are not subject to the investigator's discretion.

Currently many biostatisticians believe that eligibility criteria in oncology trials tend to be too restrictive and complicated (34,35). Overly restrictive or complex eligibility criteria hamper accrual, prolong the study's duration, and delay the reporting of results. The Medical Research Council has demonstrated that it is possible to conduct trials with simple and few eligibility criteria (36). The ICON3 (International Collaborative Ovarian Neoplasms) trial compared standard carboplatin or cisplatin-adriamycin-cyclophosphamide regimen to paclitaxel plus carboplatin in women with newly diagnosed ovarian cancer. This trial had six eligibility criteria, three of which were for safety: (a) fit to receive, and no clear contraindication to, chemotherapy, (b) absence of sepsis, and (c) bilirubin less than twice the normal level for the center. This is in sharp contrast to GOG Protocol 162 (A Phase III Randomized Trial of Cisplatin [NSC #119875] with Paclitaxel [NSC #125973] Administered by Either 24-Hour Infusion or 96-Hour Infusion in Patients with Selected Stage III and Stage IV Epithelial Ovarian Cancer), which compared two different paclitaxel infusion durations in patients with advanced ovarian cancer and had 34 eligibility criteria.

PHASES OF DRUG DEVELOPMENT TRIALS

The traditional approach to identifying and evaluating new drugs has relied on sequential evidence from phase 1, 2, and 3 clinical trials. Each of these study designs stems from very distinct

study objectives. Phase 2 trials build on the evidence gathered from phase 1 trial results, and similarly phase 3 trials build on phase 2 and phase 1 trial results. The investigation of a given treatment may be halted at any phase, either due to safety and/or efficacy issues. Depending upon the underlying investigation, the time from the initiation of a phase 1 trial for a given treatment to the completion of a phase 3 trial often spans several years.

Phase 1 Trials

The purpose of a phase 1 therapeutic trial in cancer-related research is to determine an acceptable dose or schedule for a new therapy as determined by toxicity and/or pharmacokinetics. A phase 1 trial marks the first use of a new experimental agent in humans. Most phase 1 trials escalate the dose or schedule of the new agent after either a prespecified number of consecutive patients have been successfully treated or within an individual as each dose is determined to be tolerable. The usual phase 1 trial of a cytotoxic agent attempts to balance the delivery of the greatest dose intensity against an acceptable risk of dose-limiting toxicity (DLT). The conventional approach increases the dose after demonstrating that a small cohort of consecutive patients (three to six) is able to tolerate the regimen. However, once an unacceptable level of toxicity occurs (e.g., two or three patients experiencing DLT), the previously acceptable dose level is used to treat a few additional patients in order to provide additional evidence that the current dose has an acceptably low risk of DLT. If this dose is still regarded as acceptable, it becomes the dose and schedule studied in subsequent trials and it is referred to as the recommended dose level (RDL). The RDL should not be confused with the maximum tolerated dose (MTD). The MTD is a theoretical concept used to design phase 1 trials, while the RDL is an estimate of the MTD, which may or may not be close to it. Due to the limited number of patients involved in phase 1 trials, outcome measures such as response and survival are not the primary interest in these studies. When these outcomes are reported, they are considered anecdotal evidence of treatment activity. Eligibility criteria for phase 1 trials in oncology typically limit accrual to patients in whom conventional treatments have failed.

Early phase 1 trial designs were often ad hoc. Alternative strategies for estimating the MTD have recently been proposed. The primary motivation for these newer strategies is to reduce the number of patients treated at therapeutically inferior doses and to reduce the overall size of the study. One of these alternatives implements a Bayesian approach and is referred to as the continual reassessment method (CRM) (37). It has the attractive feature of determining the dose level for the next patient based on the toxicity experience from all of the previously treated patients. While the traditional approach has been criticized for treating too many patients at sub-therapeutic doses and providing unreliable estimates of the MTD, CRM has been criticized for tending to treat too many patients at doses higher than the MTD (38). Refinements to CRM have been proposed (39) and found to have good properties when compared to alternative dose-seeking strategies (40). Another family of designs termed the accelerated titration design (ATD) allows doses to be escalated within each patient and incorporates toxicity or pharmacologic information from each course of therapy into the decision of whether to further escalate or not (41). Both the modified-CRM and ATD designs can provide significant advantages over the conventional phase 1 design.

Even though the majority of phase 1 trials in cancer research follow what was described above, it should be noted that alternative phase 1 trials may arise in other settings such

as medical device trials, prevention trials, education intervention trials, behavior modification trials, and where the first phase of investigation may actually utilize healthy subjects, like studies interested in determining the utility of a new educational intervention on smoking cessation. The phase 1 trial may simply be utilized as an approach toward gaining some experience with the intervention prior to moving forward to the next phase of investigation.

Phase 2 Trials

Once a dose and schedule for a new regimen have been deemed acceptable, a reasonable next step is to seek evidence that the new regimen is worthy of further evaluation in a particular patient population. The principle goal of a phase 2 trial is to prospectively quantify the potential efficacy of the new therapy. Since a phase 2 trial treats more patients at the RDL than in a phase 1 trial, it also provides an opportunity to more reliably assess toxicities. A phase 2 trial is often referred to as a drug-screening trial because it attempts to judiciously identify active agents worthy of further study in much the same way a clinician screens a patient for further evaluation. The study should have adequate sensitivity to detect active treatments and adequate specificity for rejecting inactive treatments. A phase 2 trial may evaluate a single new regimen, or incorporate randomization to evaluate several new therapies or treatment schedules simultaneously. However, in oncology a concurrent control arm is often not included in randomized phase 2 trials since these trials are too small to draw a reliable inference about relative therapeutic efficacy of the experimental treatments.

Phase 2 trials can have a single-stage or multi-stage design. In a single-stage design, a fixed number of patients are treated with the new therapy. The goal of the single-stage design is to achieve a predetermined level of precision in estimating the endpoint. While precision is one important goal in cancer trials, there is also a concern for reducing the number of patients treated with inferior regimens. For this reason many phase 2 cancer trials use multi-stage designs. Multi-stage designs implement interim analyses of the data and apply predetermined rules to assess whether there is sufficient evidence to warrant continuing the trial. These rules, which are established prior to initiating the study, tend to terminate those trials with regimens having less than the desired activity, and tend to continue to full accrual those trials with regimens having at least a minimally acceptable level of activity. Two-stage designs, which minimize the expected sample size when the new treatment has a clinically uninteresting level of activity, have been proposed (42). These designs are often appropriate for trials involving a small number of clinics. However, phase 2 trials in the cooperative group setting demand more flexibility in specifying when the interim analysis will occur. This is due to the significant administrative and logistic overhead of coordinating the study in several clinics. Modifications to the optimal design, which do not require that the interim analyses occur after a precise number of patients are entered, are useful in the cooperative group setting (43).

Regardless of the measure of treatment efficacy, most designs treat toxicity as merely a secondary observation. This approach is not likely to be appropriate in phase 2 trials of very aggressive treatments, such as high-dose chemotherapy with bone marrow support. In these trials, stopping rules that explicitly consider both response and the cumulative incidence of certain toxicities may be more appropriate (44–46). Bayesian designs, which permit continuous monitoring of both toxicity and response, have also been proposed (47).

The procession from phase 1 to phase 3 is a typical research path for evaluating a new therapy in humans. However, this

research paradigm may not always be appropriate, and all three elements (i.e., “what,” “how,” and “who”) of a phase 2 trial (see the Objectives section) have been challenged. It may be justifiable to eliminate strict phase 2 testing of a new combination of known active agents, if the combination is known to be safe and there is no antagonism anticipated between the agents, especially if the phase 3 trial includes provisions for futility analyses (see the Data Monitoring section). Another challenge to the paradigm is directed at whether patients whose disease is no longer responsive to standard treatments represent a fair test of a promising treatment plan. If the subsequent phase 3 trial of the therapy will involve newly diagnosed patients, it is debatable whether patients with treatment-refractory disease represent the proper phase 2 study population. Finally, clinical response has been a classic measure of activity in phase 2 oncology clinical trials. However, response may be considered a surrogate endpoint and is frequently not an ideal one, especially in trials of patients with cervical cancer. Additionally, new treatments that exhibit a different mode of action from the traditional cytotoxic drugs (e.g., antiangiogenesis drugs) may render response an unsuitable endpoint. In this case, PFI and survival time may be preferable endpoints for evaluating treatment efficacy in phase 2 trials (48). There are many issues that come to bear on whether the conventional research paradigm is appropriate. A thoughtful discussion among experts should precede all clinical research endeavors.

Phase 3 Trials

The goal of a phase 3 trial is to prospectively and definitively determine the effects of a new therapy relative to a standard therapy in a well-defined patient population. Phase 3 trials are also used to determine an acceptable standard therapy when there is no prior consensus on the appropriate standard therapy. Some phase 3 trial methodologies, such as randomization and blocking, have origins in comparative laboratory experiments. However, in clinical trials the experimental unit is a human being and, consequently, there are two very important distinctions. First, each individual must be informed of the potential benefits as well as the risks and must freely consent to participate before enrollment into the study (see the Ethics section). Second, an investigator has very limited control over the patient's environment during the observation period. This latter distinction can have a profound statistical implication, which will be discussed later.

Trials With Historical Controls

The strict definition of a phase 3 trial does not necessitate concurrent controls (i.e., prospectively enrolled patients assigned the standard treatment) or randomization (i.e., random treatment allocation). However, these two features are almost synonymous with phase 3 trials today. The basic phase 3 design is what is termed a two-arm randomized parallel design, i.e., given an appropriately executed randomization, the only potential difference (from a statistical perspective) between the two experimental groups in terms of an outcome variable is the experimental factor. In contrast, the principal drawback from inferring treatment differences from a historically controlled trial is that the treatment groups may differ in a variety of characteristics that are not apparent. Differences in outcome, which are in fact due to differences in characteristics between the groups, may be erroneously attributed to the treatment. While statistical models are often used to adjust for some potential biases, adjustments are possible only for factors that have been recorded accurately and consistently from both samples. Shifts in medical practice over time, differences in the definition of the disease, eligibility criteria, follow-up

procedures, or recording methods can all contribute to a differential bias (see the Endpoints section). Unlike random error, this type of error cannot be reduced by increasing the sample size. Moreover, the undesirable consequences of moderate biases may be exacerbated with larger sample sizes. When a trial includes concurrent controls, the definition of disease and the eligibility criteria can be applied consistently to both treatment groups. Also, the standard procedures for measuring the endpoint can be uniformly applied to all patients. Inclusion of prospectively treated controls within the clinical trial requires a method of assigning the treatments to patients. Randomization and its benefits are discussed in the next section (see the Other Design Considerations section).

It is useful to distinguish phase 3 objectives as having an efficacy, equivalency, or non-inferiority design consideration. An efficacy design is characterized by the search for an intervention strategy that provides a therapeutic advantage over the current standard of care. An equivalency trial seeks to demonstrate that two interventions can be considered sufficiently similar on the basis of outcome that one can be reasonably substituted for the other. Non-inferiority trials seek to identify new treatments that reduce toxicity, patient inconvenience, or treatment costs without significantly compromising efficacy.

Efficacy Trials

Efficacy designs are very common in oncology trials. Examples include trials that assess the benefit of adding chemotherapy to radiation for the treatment of early-stage cervical cancer or trials that compare standard versus dose-intense platinum regimens for treating ovarian cancer. In each of these cases, the trial seeks to augment the standard of care in order to attain a better treatment response. From the outset of these trials it is recognized that the treatment benefit may be accompanied by an increased risk of toxicity, inconvenience, or financial cost. However, it is hoped that the benefits will be sufficiently large to offset these drawbacks. Suppose treatment A is the standard of care for a particular target disease population. The quantitative difference between treatments with respect to a particular outcome (B-A) can be described on a horizontal axis as in Figure 9.2. If we are reasonably certain that the difference between treatments is less than zero (left of 0) then we would consider treatment A to be better. On the other hand, if the treatment difference is greater than zero (right of 0) then we would conclude that the new treatment, B, is better. Furthermore, we can use dotted lines to

demarcate on this graphic a region in which the difference between A and B is small enough to warrant no clinical preference for A or B. Consider the results from a trial expressed as the estimated difference between treatments and the corresponding 95% or 99% confidence interval superimposed on this graph. The confidence interval depicts those values of the treatment difference that can reasonably be considered consistent with the data from the trial. An inconclusive trial is characterized by having such broad confidence intervals that the data cannot distinguish between A being preferred or B being preferred (Fig. 9.2). This is a typical consequence of a small trial. On the other hand, if the confidence interval entirely excludes the region where A is better than B, then we can conclude that B is significantly better than A (Fig. 9.2). Note that in this case the lower bound of the confidence interval may extend into the region of clinical indifference, but the confidence interval must exclude the region below (left of) 0 difference.

Equivalency Trials

The equivalency study design is perhaps a misnomer, since it is actually impossible to generate enough data from any trial to definitively claim that the two treatments are equivalent. Instead, an investigator typically defines the limits for treatment differences that can be interpreted as clinically irrelevant. If it is a matter of opinion what differences in effect sizes can be considered clinically irrelevant, this issue can become a major source for controversy in the final interpretation of the trial results. Survival or progression-free survival endpoints are seldom used in equivalency trials; however, bio-equivalency designs are sometimes used for drug development. For example, if one agent is known to influence a particular biologic marker, then it may be desirable to design a trial to determine whether a new agent is as effective at modifying the expression of this biomarker. In this case, an investigator has some notion about the acceptable range of activity that can be considered clinically biologically equivalent. These studies are designed so that within tolerable limits, the treatments can be considered equivalent.

Notice that the results from the inconclusive trial in Figure 9.2 cannot be interpreted as demonstrating equivalency. Even when the estimated difference between the treatments is nearly zero, the confidence interval cannot rule out treatment differences that would lead to preferring A or B. Caution should be exercised in interpreting the results from studies that conclude

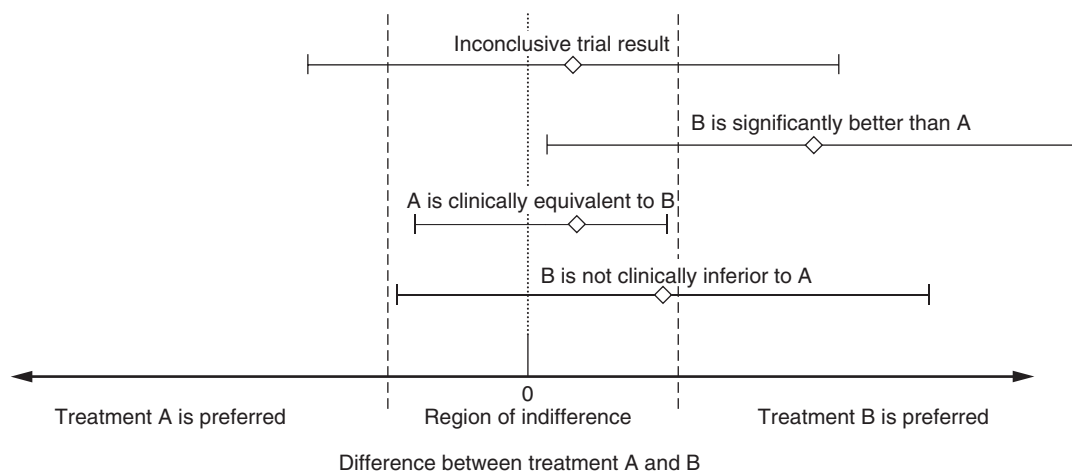

FIGURE 9.2. Graphical representation of the point estimates and confidence intervals describing the results from four hypothetical trials.

“therapeutic equivalency” when only a small difference between treatments with regard to the outcome is observed and it is declared to be not statistically significant. Even results from moderately large trials, which suggest therapeutic equivalence, may in fact be due to inadequate statistical power to detect clinically relevant differences.

Non-inferiority Trials

A non-inferiority study design may be considered when the currently accepted standard treatment is associated with significant toxicity and a new and less toxic treatment becomes available. The goal of this type of study is to demonstrate that substituting the new treatment for the current standard treatment does not appreciably compromise efficacy (49–52). Referring to Figure 9.2, the trial seeks to provide sufficient evidence to be reasonably certain that the difference between A and B lies above the lower boundary of the indifference region. This lower boundary is often called the “non-inferiority margin.” Notice that if an investigator wishes to be reasonably certain that the new treatment does not sacrifice *any* activity of the standard treatment (treatment A) then the non-inferiority margin is set to zero. However, this would be equivalent to an efficacy design (described above).

The justification for the non-inferiority margin selected in a particular study is often controversial. If this margin is set too low, then the study has an unacceptably high probability of recommending an inferior treatment. If it is too high, then the trial utilizes too many clinical and financial resources. In order to select an appropriate margin of non-inferiority it is important to recognize that even though a non-inferiority trial may explicitly compare only two treatments, implicitly there is a third treatment to be considered. Suppose that several historical studies indicate that treatment A is better than a placebo for treating a specific disease. In this case, the goal of a non-inferiority study is to demonstrate that a new experimental treatment, B, does not significantly compromise efficacy when compared to currently accepted active standard treatment, A. However, it should also demonstrate that B would have been better than a placebo, if a placebo had been included in the current trial. In other words, the current trial will directly estimate the effectiveness of B relative to A, but it must also indirectly consider the effectiveness of B relative to the previous control treatment (placebo in this case). This indirect comparison relies on obtaining a reliable and unbiased estimate of the effectiveness of the current active control to the previous control from previous trials. Sometimes the margin of non-inferiority is expressed as a proportion of the effectiveness of A relative to the previous standard treatment. For example, a non-inferiority study could be designed to have a high probability of concluding that a new treatment retains at least 50% of the activity of the standard regimen, A. Note that an investigator may decide that she is unwilling to give up any of the benefit attributed to the current standard treatment. In this case, the margin of non-inferiority is set at zero (Fig. 9.2) and the design is the same as the efficacy trial. Indeed, an efficacy trial can be considered a study in which the investigator is willing to accept the new treatment B, only if the trial results indicate that B is superior to A.

Obtaining reliable estimates for the activity of the currently accepted active standard treatment can be a very troublesome aspect of non-inferiority oncology trials. For example, cisplatin 75 mg/m² and paclitaxel 135 mg/m² infused over 24 hours was the first platinum-taxane combination to demonstrate activity in the treatment of advanced ovarian cancer (53). Subsequently, several trials were conducted to assess whether carboplatin could be safely substituted for cisplatin (54–56) or whether taxotere could be substituted for

paclitaxel (57). However, there has been some controversy about the size of the benefit provided by paclitaxel (58). An investigator can reasonably ask, “What is the effect size of paclitaxel and how much of this effect can I reasonably be certain is preserved by taxotere?”

Randomized Phase 3 Trials

There are several design features that may be considered for phase 3 trials. Some are more pertinent than others to gynecologic oncology trials. The most important feature to be considered is treatment randomization. A study with this feature, a randomized clinical trial (RCT), has several scientific advantages. First, both the known and unknown prognostic factors tend to be distributed similarly across the treatment groups when a trial implements randomized treatments. Second, a potential source of differential selection bias is eliminated. This bias could occur when there is an association between treatment choice and prognosis. It need not be intentional. When a physician’s interest in a trial or a patient’s decision to participate in the trial depends on the assigned treatment, a nonrandom association between treatment and prognosis can be introduced. Finally, randomization provides the theoretical underpinning for the significance test (59). In other words, the probability of a false-positive trial as stated in the study design is justified with randomization. It is important to recognize that these advantages, which are provided by randomizing the study treatments, are forfeited when all of the randomized patients are not included in the final analyses. All randomized patients registered on the trial should be included in the final analysis in order to promote the validity of the conclusions.

It is sometimes argued that since many factors that influence prognosis are known, perhaps other approaches to allocating treatments can be considered and statistical models should be used to adjust for any imbalances in prognosis. However, the conclusions from this type of trial must be conditioned on the completeness of knowledge about the disease and acceptability of the modeling assumptions. If the disease is moderately unpredictable with regard to the outcome, or the statistical model is inappropriate, then the conclusions are suspect. Results from nonrandomized studies can polarize the medical community. They frequently provide enough evidence for those who already support the conclusions but insufficient evidence for those who are skeptical.

Kunz and Oxman (60) have compared the results from overviews of randomized and nonrandomized clinical trials that evaluated the same intervention. They reported that the nonrandomized studies tended to overestimate the treatment effect from the randomized trials by 76% to 160%. Schulz et al. (61) compared 33 randomized, controlled trials that had inadequate concealment of the random treatment assignments to those studies that had adequate concealment. They found that those with inadequate concealment tended to overestimate the treatment effect (relative odds) by 40%. Some investigators do not appreciate the importance of concealment and will go to considerable lengths to subvert it (62). When the randomization technique requires pregenerated random treatment assignments, one must guarantee that the investigators who are enrolling patients do not have access to the assignment lists.

The patient-physician relationship can occasionally be challenged by introducing the concept of treatment randomization (63). Patients may prefer a sense of confidence from their physician regarding the “best” therapy for them. However, physicians involved in an RCT must honestly acknowledge that the best therapy is unknown and that an RCT is preferred to continued ignorance. One survey of 600 women seen in a breast clinic suggested that 90% of women prefer their doctor

to admit uncertainty about the best treatment option rather than give them false hope (64).

Randomization Techniques

The simplest approach to randomization is to assign treatments based on a coin flip, sequential digits from random number tables, or computerized pseudo-random number generators. On average, each individual has a defined probability of being allocated to a particular study treatment when they enter the study. Although this approach is simple, the statistical efficiency of the analyses can be enhanced by constraining the randomization so that each treatment is allocated an equal number of times. Permuted block randomization is sometimes used in order to promote equal treatment-group sizes. A block can be created by shuffling a fixed number of cards for each treatment and then assigning the patients according to the random order of the deck. After completing each block there are an equal number of patients assigned to the treatment groups. For example, consider a trial comparing treatments A and B. There are six possible ways the deck will be ordered when the block size is four: AABB, ABBA, BBAA, BABA, ABAB, and BAAB. A sufficient number of assignments for an RCT can be created by randomly selecting a series of blocks from the six distinct possibilities. There are three features of blocked randomization that may be problematic. First, the probability of a particular treatment being allocated is not the same throughout the study, as in simple randomization. Taking the example above, every fourth treatment is predetermined by the previous three allocations. Second, the use of small blocks in a single-institution study may undermine concealment and allow an investigator to deduce the next treatment. This potential problem can be corrected by continually changing the block size throughout the assignment list. Third, large block sizes can subvert the benefits of blocking. As block sizes increase, the procedure resembles simple randomization.

The statistical efficiency of the study can be further enhanced by stratifying patients into groups with similar prognoses and using separate lists of blocked treatments for each stratum. This procedure is called stratified block randomization. It is worth noting that using simple randomization within strata would defeat the purpose of stratification, since this is equivalent to using simple randomization for all patients. Likewise, trials that stratify on too many prognostic factors are likely to have many uncompleted treatment blocks at the end of the study, which also defeats the intent of blocking (65).

When it is desirable to balance on more than a few prognostic factors, an alternative is dynamic randomization, a particular type being minimization. Whereas stratified block randomization will balance treatment assignments within each combination of the various factor levels, minimization tends to balance treatments within each level of the factor separately. Each time a new patient is entered into the study, the number of individuals who share any of the prognostic characteristics of the new patient is tabulated. A metric that measures the imbalance of these factors among the study treatments is computed as if the new patient were allocated to each of the study treatments in turn. The patient is then allocated to the treatment that would favor the greatest degree of balance. In the event that the procedure indicates equal preference for two or more possible treatment allocations, simple randomization can be used to determine the individual's treatment assignment.

Masking Treatment

Concealment. Concealment refers to the procedure in which the assigned study treatment is not revealed to the patient or the investigator until after the subject has successfully enrolled into the study. The purpose of concealment is to eliminate a

bias that can arise from an individual's decision to participate in the study depending on the treatment assignment (66). Concealment is an essential component of randomized clinical trials.

Blinding. Blinding is a procedure that prevents the patient or physician from knowing which treatment is being used. In a single-blinded study patients are unaware of which study treatments they are receiving. A double-blinded study results in a situation in which neither the patients nor the healthcare providers are aware of that information. One purpose of blinding is to avoid measurement bias, particularly differential measurement bias (see the Endpoints section). This type of bias occurs when the value of a measurement is influenced by the knowledge of which treatment is being received (see the Historical Perspective section). It can occur when the measurement of an endpoint is subjective. Most methods for assessing pain are subjective and require treatment blinding in order to promote the validity of the study.

Oncology trials frequently do not implement blinding for several reasons. It is rather difficult to blind treatments when various treatment modalities are used (e.g., surgery versus radiation therapy, or intravenous versus oral administrations), when good medical practice is jeopardized (e.g., special tests are required to monitor toxicity), or when it is logistically difficult (e.g., the evaluating physician must be kept isolated from the treatment of the patient). In the absence of blinding, care should be taken that the method of measuring the endpoint is precisely stated in the protocol and consistently applied to each patient uniformly. Trials that assess quality of life or relief from symptoms should give serious consideration to treatment blinding.

Schulz et al. (67) reviewed 110 randomized clinical trials published between 1990 and 1991 in four journals of obstetrics and gynecology. Thirty-one of these trials reported being double-blinded. However, blinding seemed to be compromised in at least three of the trials. Schultz et al. concluded that blinding should have been used more often, despite frequent impediments.

Placebo. A placebo is an inert treatment, usually in a self-administered form (e.g., tablet). Placebos blind patients and also, usually, physicians to the knowledge of whether they are receiving the active or inert treatment. Placebos are frequently used in trials where there is no accepted standard treatment and the endpoint is susceptible to measurement bias. The use of a placebo is also important when the endpoint can be affected by the patient's psychological response to the knowledge of receiving therapy combined with a belief that the therapy is effective. This phenomenon is aptly named the "placebo effect." In such circumstances, the use of a placebo provides a treatment-to-control comparison that measures only the therapeutic effect. Note that the placebo effect is a distinctly different type of measurement bias from those that have been previously discussed.

GOG Protocol 137 (A Randomized Double-Blinded Trial of Estrogen Replacement Therapy Versus Placebo in Women With Stage I or II Endometrial Adenocarcinoma [IND #43,226]) is a randomized, double-blinded comparison of estrogen replacement therapy versus a placebo in women who have had a total abdominal hysterectomy and bilateral salpingo-oophorectomy for early-stage endometrial cancer. One primary reason for the use of a placebo in this trial was the potential for differential measurement bias being introduced by the physician monitoring patients on estrogens much more closely.

Sham procedures are similar to placebos in their function. The sham procedure is one that mimics the experimental procedure under study (excluding the therapeutic portion) to the extent that patients are blinded to whether they received the experimental component of the intervention. Careful ethical considerations must precede the use of a placebo or sham procedure in any clinical trial (68).

Factorial Designs

Factorial designs enable several interventions to be studied simultaneously. For example, each patient enrolled onto a study may be randomly assigned to receive one of two different chemotherapy regimens in addition to two being randomized to receive one of two different radiation regimens. The key assumption necessary for a factorial design is that all treatments can be given simultaneously without interaction or interference.

The term *factorial* arises from historical terminology in which the treatments were referred to as factors. Each factor has corresponding levels; for example, an investigator may wish to compare a study agent administered at three dose levels: high dose, medium dose, and none. The total number of factor combinations being studied is the product of the number of levels for each factor or treatment. For example, a trial that evaluates treatment A at three levels and treatment B at two levels is called a 3-by-2 (denoted 3×2) factorial design. If the relative effects due to the various levels of treatment A are independent of the levels of B, the two treatments (A and B) can be evaluated simultaneously. The factorial design provides a significant reduction in the required sample size when compared to trials that study A and B separately.

The most commonly utilized factorial design is the 2×2 factorial design, which includes two distinct treatment regimens at each of two factor levels. For example, suppose individuals entering a cancer prevention trial are randomly assigned to receive vitamin E (placebo-A or 50 mg/day) and beta-carotene (placebo-B or 20 mg/day) in a 2×2 factorial design. In this case, the factors are vitamin E and beta-carotene, while the respective factor levels are placebo-A or 50 mg/day for vitamin E, and placebo-B or 20 mg/day for beta-carotene. There are four treatment combinations. In a standard 2×2 design the main effect of vitamin E can be ascertained by utilizing information from each of the four treatment groups. In some studies, however, the main effects may be of secondary importance as compared to the “interaction” between each factor. An interaction exists when the effect due to one of the factors (i.e., treatment A) depends on the level of the other factor (treatment B). In drug discovery, a “positive” interaction may imply a synergistic effect of two drugs in combination, i.e., the effect of the combination therapy is greater than the sum of the individual additive effects. Reliable tests of an interaction require a relatively large number of patients in each of the four treatment groups. This testing, in turn, reduces the advantage of the factorial design over a standard four-arm study. Attention to the statistical power of such tests is an important part of interpreting the study results (69–71).

DIAGNOSTIC STUDIES

In a diagnostic study the objective is to develop a model that accurately predicts a particular disease state based upon other clinical information. In cancer-related diagnostic models this predictive information typically consists of some combination of demographic risk factors, medical history information, imaging data, and biomarker data, and can consist of a combination of qualitative and quantitative information. The simplest diagnostic model consists of a single binary marker of disease, e.g., whether a biomarker has positive expression (yes/no).

In order to determine the utility of a given diagnostic model several global measures of accuracy have been defined. These are described below. However, it must first be noted that a critical feature of these models is the actual *true* diagnosis of disease, oftentimes referred to as the “gold standard.” If the gold standard diagnosis is not easily ascertained, this can in turn influence

the empirical estimates of accuracy of a given diagnostic model in terms of biasing the results in either the positive or negative direction. In certain instances, the gold standard determination is clear cut, such as death or no death. However, in other instances the absolute determination is made by a committee of experts; for example, a panel of radiologists who may come to a consensus regarding a cancer/no cancer diagnosis would be referred to as the “gold standard committee.” When designing a study to develop a diagnostic test, the accuracy of the gold standard determination is a vitally important consideration.

Under the assumption that the gold standard diagnosis is correct, the accuracy of a binary disease marker can be simplified. The quantities most often used for assessing overall accuracy include prevalence, sensitivity, specificity, accuracy, and positive predictive value (PPV). If we let Pr denote the probability of an event, T represent the test result being positive (+) or negative (–), and D represent the disease diagnosis as it is determined by the gold standard being present (+) or absent (–), then the following definitions apply:

$$\begin{aligned} \text{Prevalence} &= Pr(D+) = \text{Probability of having the disease determined by the gold standard.} \\ \text{Sensitivity} &= Pr(D+|T+) = \text{Probability of having the disease among those who test positive.} \\ \text{Specificity} &= Pr(D-|T-) = \text{Probability of not having disease among those who test negative.} \\ \text{Accuracy} &= Pr(D+|T+) \times Pr(D+) + Pr(D-|T-) \times Pr(D-) = \text{Probability of the test correctly classifying an individual.} \\ \text{PPV} &= Pr(D+|T+) \times Pr(D+)/\text{Accuracy} = \text{Probability of correctly diagnosing positive disease proportional to all correct diagnoses.} \end{aligned}$$

Empirical estimates of these quantities are merely estimates of simple proportions or a combination of proportions conditional on the disease and test state.

Consider two separate tests (generically Test A and Test B) evaluated in two hypothetical studies involving 1,200 individuals and summarized in Table 9.1a. The calculations for the empirical estimates are demonstrated in Table 9.1b. Test A and Test B are equally accurate, with an estimated accuracy of 0.87. Specifically, each test is expected to correctly classify 87% of those tested in the population consisting of individuals with or without disease. Note, however, that in both instances the probability of the test being positive among those individuals with disease is quite low with PPVs of 14% and 8% for Test A and Test B, respectively. This is particularly noteworthy given the relatively high sensitivity and specificity

TABLE 9.1A

RESULTS FROM TWO HYPOTHETICAL SCREENING TRIALS

TEST A	T–	T+	
	D+	140	60
D–	100	900	1000
	240	960	1200
TEST B	T–	T+	
	D+	80	120
D–	40	960	1000
	120	1080	1200

TABLE 9.1B

RELATIVE ACCURACY COMPARISONS OF TEST A VERSUS TEST B

Estimates	Test A	Test B
Prevalence	$200/1200 = 0.17$	$200/1200 = 0.17$
Sensitivity	$140/200 = 0.70$	$80/200 = 0.40$
Specificity	$900/1,000 = 0.90$	$960/1,000 = 0.96$
Accuracy	$0.70 \times 0.17 + 0.90 \times 0.83 = 0.87$	$0.40 \times 0.17 + 0.96 = 0.83 = 0.87$
PPV	$0.70 \times 0.17/0.87 = 0.14$	$0.40 \times 0.17/0.87 = 0.08$

Note: PPV, positive predictive value.

values for Test A (70%) as compared to Test B (40%). In general, the lower the prevalence is for a given test with fixed accuracy, the lower the PPV. In other words, for very rare diseases it is nearly impossible to obtain high PPV values even for tests with good sensitivity and specificity. This concept is extremely important when considering screening studies across large groups of subjects when the diagnosis of interest has very low prevalence, yet the accuracy measure appears relatively high.

What happens in the setting where a researcher is interested in a marker of disease that is measured on a continuous or discrete scale and/or would like to combine information from several variables in order to construct a diagnostic model? In the instance of a single continuous marker of disease, the problem is often framed in terms of determining an optimal cut point so that the continuous marker is transformed into a simple binary value. In the case where we are combining several pieces of information, the problem statistically reduces to a data dimension reduction problem that ultimately transforms a multivariate set of measurements into a single measure. One such technique is to utilize a logistic regression model, regressing the gold standard on the diagnostic variables of interest and then using the predicting probability of disease as the single univariate measure, which in turn then needs to be transformed to a single dichotomized measure. Other popular approaches to this aspect of data reduction in diagnostic testing problems include neural networks and classification trees.

Once the problem has been reduced down to a single continuous measure the next step is to examine the various potential threshold values from which a positive or negative diagnosis will be arrived at. One approach toward examining all possible thresholds is through the use of receiver operating characteristic (ROC) curves. An ROC curve is a plot of the estimated probability of a positive test result among individuals with disease (sensitivity) on the y-axis versus the estimated probability of a positive test result among individuals without disease (1-specificity) on the x-axis across all possible threshold values or cut points. (See Figure 9.3 for an example of an empirical ROC curve.) In essence, each point on the ROC curve represents one possible threshold value. The nature of the step function feature of the plot represents the empirical nature of the estimate, that is, for real data there are only a finite number of potential cut points. The area under the ROC curve provides a global measure of accuracy and ranges from 0.5 (worst case) to 1.0 (perfect diagnostic accuracy). This measure is sometimes denoted as the C statistic. For our example plot the estimated area under the ROC curve is $C = 0.83$. The area under the ROC curve has a similar interpretation as the measure of accuracy defined above. Specifically, the model is expected to accurately predict approximately 83% of the cases correctly over all possible decision rules. Once the ROC curve has been generated and the diagnostic model appears to have good relative accuracy, how does one

determine the “best” decision threshold? In essence, the best threshold value determination comes down to putting more or less weight on sensitivity relative to specificity as it pertains to the specific clinical setting. There is not a one-size-fits-all approach in determining the best sensitivity-to-specificity trade-off. Oftentimes, however, if sensitivity and specificity are given equal weight, a good rule of thumb is to utilize the threshold value that corresponds to the point on the ROC curve that is closest to the upper left-hand corner. In our example plot given in Figure 9.3 this point is marked approximately above with “*”. Once an acceptable cut point has been defined, additional estimates for the diagnostic test of interest, such as the PPV, may be calculated as they were in the previous example.

The next issue of concern with respect to diagnostic model building is whether or not the model that has been fit based on a given diagnostic study will perform as well on a *future* sample of patients. As a general rule of thumb, when we optimize the fit of a model involving limited available data, there is a tendency to overestimate the accuracy of a diagnostic test relative to future performance. One commonly used strategy for assessing this bias is to divide the study sample into two distinctly separate sets: a training set and a validation set. The training set is used to develop a statistical model that provides the desired accuracy for classifying individuals into diseased and nondiseased categories. This modeling process is often called a supervised analysis, since it involves knowing the true disease state of each individual. In the validation phase the exact same classification

FIGURE 9.3. Empirical receiver operator characteristic curve.

procedure that was developed using the training set is applied to individuals in the validation set. The predicted disease state is compared to the actual disease state. The validation phase provides more realistic estimates of the accuracy of the classification procedure with respect to its performance in practice. Modifying the classifier in order to improve accuracy in the validation phase would introduce biases due to overfitting and therefore defeat the purpose of a validation phase. When designing a study to develop a new diagnostic test, one needs to consider not only the sample size needed for the training phase, but also the sample size needed for the validation phase. For smaller pilot studies where a validation phase is not feasible, there are statistical methods that can be employed in order to reduce biases from overfitting. However, the most meaningful diagnostic studies contain a true validation component.

STUDIES INVOLVING ADVANCED EXPERIMENTAL BIOTECHNOLOGIES

Many modern day experimental and study designs now involve data generated from advanced biotechnologies such as expression microarrays, comparative genomic hybridization microarrays, single nucleotide polymorphism platforms, and proteomic platforms. These biotechnologies are typically designed for simultaneously performing a large number of assays (e.g., possibly greater than 1,000,000) on a given sample or pair of samples. The quantification of the assay results can involve multiple layers of data processing, and methods for inference utilizing such quantified values can be quite complex. *It is important to note that the naïve analyses of such datasets can have profound negative consequences (72) and that the development of optimal experimental/study designs and optimal data analytic methodologies are open and active areas of research (73,74).* There is currently a pressing need for the development of improved methodologies for the analysis of data generated by advanced biotechnologies. The complexity of the problems being addressed by research efforts involving advanced experimental biotechnologies, coupled with the complexities of the technologies (both physical and methodological) being brought to bear on problems, often can only be managed by research teams composed of diverse collections of investigators. Often such teams must not only include bench scientists and clinicians, but also scientists with expertise in biostatistics, computational sciences (e.g., high-performance computing) and bioinformatics. Indeed, the development and proliferation of collaborative research efforts involving advanced biotechnologies are part of a larger trend in which the practice of “team science” is becoming much more prevalent. For example, the National Institutes of Health (NIH) has recently implemented a multiple principal investigators (PI) model (<http://grants.nih.gov/grants/multi%5Fpi/>) to accommodate “projects or activities that clearly require a ‘team science’ approach.”

Although advanced biotechnologies present new and important avenues to conduct research, it is important to approach the utilization of such technologies with reasonable expectations. Such technologies are not as automated as a naïve researcher might expect. The analysis of such datasets often requires the investment of significant sweat equity. For example, such datasets often require meticulous inspection to eliminate samples and spot assays of poor quality. “Garbage in, garbage out” is a common expression in data analytic circles (75) and reflects the belief that even when the best of data analytic methodologies is applied to data of poor quality, the results can also be expected to be poor. This is true for data analyses in general, but the expression is particularly relevant

to analyses involving advanced biotechnologies given the size and nature of the datasets that they generate. Once the data is cleaned and incorporated into an appropriate analysis plan, researchers must also contend with the time-consuming task of inspecting the possibly high-dimensioned results of their experiment/study. Researchers new to such experiments/studies should understand that high-dimensioned data are not guaranteed to provide low-dimension result (e.g., a single highly significant gene), especially for exploratory studies, which are typically underpowered.

Researchers wishing to conduct research involving advanced biotechnologies such as microarrays are strongly encouraged to review the materials presented in Dupuy and Simon (2007) (72). The manuscript provides a review of 90 published outcome-related microarray studies as well as an invaluable set of guidelines for the statistical analysis and reporting of such studies. Several general concepts related to the analysis of such datasets are presented below.

Multi-stage Analyses

The analysis of advanced biotechnical data often involves the implementation of multiple data analytic steps that form a composite analysis. Multiple assays are performed and quantification of their outcomes is stored in a raw data set, which is typically a matrix with dimensions equal to the number of samples crossed with the number of assays performed on each sample. For example, for the 244K Agilent array comparative genomic hybridization (aCGH) arrays, the number of assays is ~244K where each assay corresponds to a two-color competitive hybridization. Typically, tumor and control samples are labeled with different fluorescent dyes (i.e., cy3 and cy5) and the relative fluorescence of the dyes at each spot on the array is used to measure the outcomes of the competitive hybridizations. The quantification of this relative fluorescence is rather complicated as it involves spot identification and determining a summary intensity value for each spot, since spots may not have a uniform intensity. There are many competing heuristics that provide such measures and it is an open area of research. Once assay values have been obtained (usually from imaging heuristics), the data is often subjected to a first stage of analyses, which involves the application of algorithms designed to correct and normalize/standardize the raw dataset. The second major stage of the composite analysis often involves inference on the population from which the assayed samples can be considered a representative sample; inference that is conducted via the application of statistical methodologies to the processed dataset.

It is commonly assumed that the application of algorithms designed to correct and normalize/standardize a raw biotechnical dataset will provide processed data that is devoid of meaningful systematic biases and spurious correlations. Whenever possible, the results from any analysis involving advanced biotechnologies should be interrogated to ascertain whether such an assumption is warranted. It should also be noted that proper experimental/study design can minimize the extent to which biotechnical data must be normalized/standardized and corrected, and that improper design can provide data that may be impossible to correct (76–78).

Multiple Hypothesis Testing

Dupuy and Simon (2007) (72) noted that the analyses of microarray experiments can usually be assigned to general classes such as outcome-related gene finding, class discovery, and supervised prediction. The authors defined outcome-related gene finding as “generally involving statistical methods

to identify genes that were differentially expressed according to two categories.” Such concepts extend to the analysis of other advanced biotechnologies and usually involve a large number of univariate tests (e.g., tests for differential expression in the case of expression arrays).

Certain complications present themselves when the number of univariate tests greatly exceeds the number of samples that were assayed—complications that are often ascribed to the “curse of dimensionality” (79). In the context of multiple testing the large number of tests presents challenges with respect to error control—challenges that can be particularly difficult to manage if the number of samples is relatively small and the univariate tests are under powered. Table 9.2 provides a summary of the possible outcomes of a set of m univariate tests where m_0 of the tests are true null hypotheses and $m - m_0$ of the tests are not true null hypotheses. The table entries U, V, T, S, and R depend upon the application of a given test function (i.e., a function that applies a test statistic to the data and determines whether the test result is “significant”). Note that V and T denote the total number of type I and type II errors, respectively. The expected value (i.e., the average or “expected” outcome that would be observed if the experiment were replicated many times) of both of these counts is of particular importance. For example, if univariate t-tests for differential expression were conducted for each of 10,000 genes and each test was conducted at a significance level of 0.05, then the expected value of V would be $0.05 \times 10,000 = 500$. Hence, such an analysis can be expected to produce, by random chance alone, approximately 500 spuriously significant findings. Conducting each test with a type I error rate of 0.05 controls the comparison-wise type I error rate but this control does not extend to the complete family (e.g., the set of 10,000 tests in the present example) of tests. The probability of committing at least one type I error across a family of tests is referred to as the family-wise error rate (FWER) and equals $1 - (\text{probability of committing no type I errors}) = 1 - 0.95^{10,000} \approx 1$ for the given example. Therefore, if the goal of the analysis is to identify a set of significant genes that is unlikely to contain spuriously significant results, then conducting each univariate test at a level of 0.05 would be ill advised.

Statistical methods exist for the control of the FWER and are well described by Dudoit et al. (2003) (80). The most common of these include the Bonferroni, Sidak, and minP methods, with the Bonferroni correction being the most conservative but easiest to implement. To control the FWER at 0.05 the Bonferroni correction specifies that the comparison-wise error rate be controlled at $0.05/m$. For the given example, this would correspond to a comparison-wise error rate of $0.05/10,000 = 0.000005$ and would provide an FWER of $1 - (0.999995)^{10,000} = 0.0488 < 0.05$. Controlling the FWER is considered to be a conservative method of error control because it often requires that the univariate tests be conducted at comparison-wise error rates that are quite small.

A popular alternative to the control of the FWER is the control of the false discovery rate (FDR). The false discovery rate corresponds to the expected value of the ratio of false discoveries

to the total number of discoveries (i.e., the expected value of $\frac{V}{R}$). Control of the FDR is appropriate in cases where researchers are willing to accept a certain percentage of spurious findings within their final list of significant findings. Development of methodologies for the control of the false discovery rate is an open and active area of research and the reader is referred to Cheng and Pounds (2007) (81) for a useful review of this topic.

Developing and Validating Classifiers

The development of classifiers of prognostic value (e.g., a gene expression signature that can predict clinical outcome) is an important and very active area of research. As with the multiple testing procedures, the development of classifiers is also complicated by the curse of dimensionality. Namely, when the number of features (e.g., a subset of assays) is much larger than the number of samples, it is often possible to overfit the data and identify perfect (with respect to the observed data) but spurious (with respect to the clinical population from which the samples were obtained) classification rules. Classifiers are commonly developed using either split sample or cross-validation procedures. In the former case, the assayed samples are split into training and test sets whereby the data in the training set is used to develop the classifier and the data in the test set is used to validate it. In the latter case, the data is partitioned into training and test sets multiple times and the validation results are, in essence, averaged over all such partitionings. Cross-validation procedures are mathematically more attractive, but a split sample approach with an independent and blinded test set provides the greatest protection against intentional or unintentional reporting biases (e.g., it prevents researchers from running multiple classifiers under multiple settings and only reporting the classifier that achieved the highest level of performance with respect to the test set). Hastie et al. (2001) (82) provide an overview of many of the basic methodologies for building classifiers. Dupuy and Simon (2007) (72) provide useful guidelines for their implementation.

HYPOTHESIS TEST

A hypothesis is a conjecture based on prior experiences that leads to refutable predictions (83). A hypothesis is frequently framed in the context of either a null or an alternative hypothesis. A null hypothesis may postulate that a treatment does not influence patients’ outcomes. The alternative hypothesis is that a particular, well-defined treatment approach will influence the patients’ outcomes to a prespecified degree. These hypotheses cast the purpose of the trial into a clear framework. A type I error is committed when the null hypothesis is in fact true, but the results of the study lead the investigator to incorrectly conclude it to be false. Committing a type I error would be disastrous if it means discontinuing the use of an active control treatment that is well tolerated and substituting an experimental therapy that is more toxic but, in reality, no better. A type II error is committed when the null hypothesis is

TABLE 9.2

CATEGORIZATION OF THE OUTCOMES OF m UNIVARIATE TESTS

	Number declared not significant	Number declared significant	Total
Number of true null hypotheses	U	V	m_0
Number of not true null hypotheses	T	S	$m - m_0$
Total	$m - R$	R	m

not true, but the study results lead the investigator to conclude that it is true. Prospectively quantifying the acceptable probabilities of these errors provides the underpinning for determining the appropriate design and sample size of a particular trial.

p VALUE

Some researchers are overly fond of reporting *p* values. At times statisticians play the role of the conservative physician, cautiously prescribing a significance test only when it is appropriate. There is a general concern that the *p* value is overused, even abused, and overemphasized. A common misconception is that the *p* value is the probability that the null hypothesis is true. The null hypothesis is either true or false, and so it is therefore not subject to a probability statement. It is the inference that an investigator makes, based on his data, that is susceptible to error.

Misconceptions about the *p* value (or significance level) may arise in part from a poor distinction between the *p* value and the α level (the type I error) of a study (84). The α level is the probability of the test statistic rejecting the null hypothesis when it is true. It is specified during the design phase of the study and is unaltered by the results obtained. The *p* value results from a statistical test on the observed data. It is the probability of the observed result or a more extreme result, given that the null hypothesis is true. R. A. Fisher, who is credited with developing the concept of the *p* value, suggested that it be used as a measure of credibility for the null hypothesis. Neymann and Pearson developed the notion of acceptance and rejection regions for the null hypothesis based on a critical value. Consequently, the concepts of type I and II errors were spawned. Fisher was very much against this “black and white” approach to measuring the evidence of the true state of reality.

The *p* value is not without problems. First, it confounds the relative treatment benefit and the amount of data (sample size) (85). Suppose two trials studying the same disease and the same treatments yield the same *p* value but one study is four times larger than the other. Assuming both were well-designed studies, one should have much more confidence in the estimate of the benefit from the larger trial. In short, the *p* value tells us little about the size of the treatment effect.

Second, important clinical differences and statistically significant differences do not correspond as frequently as they should. A large meta-analysis, which combines the results from several clinical trials, may yield a statistically significant difference that is not considered important clinically. Conversely, the literature contains many small trials with non-significant results that are statistically underpowered and cannot rule out clinically important differences (86).

Third, a *p* value of 0.05 is not necessarily a compelling result. Suppose a trial is properly designed to limit the probability of type I error to 5% (a two-tail test) and type II error to 10% for a treatment difference, *D*, which is considered the smallest clinically relevant difference. Also, suppose the trial is properly executed and the final *p* value equals precisely 0.05. In this case, the relative benefit between treatment groups would only be approximately 60% of the specified difference, *D* (84). Ironically, this statistically significant estimate of the treatment benefit is not within the range of clinically relevant differences specified by the study investigators. Furthermore, suppose that after reviewing this study result, the investigators agree that the benefit is clinically important and they wish to repeat the study exactly in order to confirm the original study result. These investigators will be surprised to learn that the size of their second trial is wholly inadequate to detect the treatment difference that was observed in the first trial. In fact, if the second trial is only as large as the first trial, then the

probability of the second trial committing a type II error is 50%. That is, the probability of obtaining a statistically significant result from the second trial is no better than obtaining tails with the flip of a coin (84). These results are perhaps counterintuitive, but they emphasize the shortcomings of overinterpreting *p* values.

DATA MONITORING

Data monitoring can be classified into three categories: administrative, quality control, and endpoint monitoring. Observing extremely poor accrual in a trial that questions the feasibility of completing the trial is an example of administrative monitoring. Any evaluation of an actively accruing trial that addresses whether the study will produce valid results is quality control monitoring. Endpoint monitoring is when comparisons are made of the endpoints between treatment groups. This last category is the only one that attempts to test the hypothesis earlier than the formal end of the trial. Although much of the statistical methodology for data monitoring was published 20 or more years ago, formal plans for data monitoring have only become routine and expected in RCT designs in the last several years. The most uncomplicated situation is when an ongoing trial provides incontrovertible evidence that one of the treatments is inferior. In this situation the need to close the trial (or the arm using the inferior treatment) becomes essential. The challenge in a data monitoring plan is the definition of “incontrovertible evidence.” The sophistication of data monitoring statistical methods and the formality associated with a data monitoring committee stem from a simple premise that knowledge of benefit (or harm) of an experimental treatment accumulates slowly over time. Many trials can be monitored because patients are enrolled over a period of years and differences in patient outcome may emerge between treatment groups before other patients are even enrolled. Endpoint monitoring was initially driven by the ethics of do no harm (see the Ethics section). However, endpoint monitoring has expanded to include terminating a trial due to the lack of improvement among those in the experimental group. Continuing the trial in this situation is not as much an ethical dilemma as a poor use of clinical resources. This type of data monitoring is referred to as futility analysis. The term is ideal in that it conveys the thought that continuing the trial is futile in the hopes of seeing a significant improvement in the experimental group when compared to the control group. Unless futility analysis is specially mentioned, the remaining discussion involves the more common data monitoring for dramatic differences.

The cost in monitoring endpoints (for the purpose of stopping the trial) is subtle and influences the characteristics of the hypothesis tests. Most physicians’ understanding of statistics comes from frequentist theory and fixed sample size designs. Fixed sample size designs evaluate a hypothesis using a test statistic once at the end of the study (see the Hypothesis Test section). Data monitoring for the purpose of stopping the trial early, and thus varying the sample size, is in direct conflict with fixed sample size methods. The specific problem is that the rule that was established to declare significance (i.e., rejecting the null hypothesis) for a one-time test at the end of the trial is no longer appropriate when conducting the test multiple times throughout the study. Figure 9.4 is a theoretical illustration of how defining statistical significance is a by-product of how often the emerging data is to be analyzed. The lines in the graph display the evolving *p* values for 20 fictitious RCTs in which there were no differences in the effect of treatment (i.e., the null hypothesis is true). The thick horizontal line demarcates the conventional boundary for declaring statistical significance

FIGURE 9.4. Continual monitoring of 20 trials. Conventional significance level under null hypothesis.

for a statistical test performed once at the end of the study. Note that if the data were analyzed only once at the end of these trials, only one trial in 20 (1/20 or 5% error) would be considered “significant.” However, if the data are monitored throughout the trials, then four additional trials reach or exceed the critical boundary, and therefore $([1 + 4]/20)$ 25% of these trials would be erroneously considered “significant.” This represents a fivefold increase in the type I error since all 20 trials were simulated under the null hypothesis. This figure illustrates why interim monitoring rules must be structured appropriately in order to properly control the experimental errors. Notice that the four additional lines that attained p values ≤ 0.05 eventually return to a nonsignificant p value. This illustrates that it is not the act of monitoring data that causes the increase in the type I error but rather premature study closure and declaring “significance.”

Data monitoring has a much greater impact than changing the rules for declaring “significance”; it also changes the meaning of the p value and confidence interval estimates. Reporting fixed sample size p value in a trial that achieves the entire sample size but had data monitoring procedures is technically incorrect. However, some authors ignore this fact to avoid the complexity that would result by providing adjusted p values. Also, data monitoring affects the estimation of the statistical parameters. The parameter associated with the hypothesis being tested is biased when interim stopping rules are in use. For example, a trial that is stopped early due to extreme improvement in the survival rate among the experimental group will likely provide overly optimistic estimates of the reduction in the mortality rate. Another cost to data monitoring is that the decision to stop a trial early may preclude the study from properly addressing all of the research objectives. For example, the Women’s Health Initiative (the component that evaluated estrogen plus progestin in healthy postmenopausal women with an intact uterus) was terminated early in the follow-up phase due to the alarming increase in breast cancer risk in the treated group and the lack of any evidence of reducing coronary heart disease events (87). The study’s Data Monitoring Committee voted to unblind the study treatments and release results early. All study participants were made aware of the deleterious effects so that they could consider the consequences of continuing treatment. Any endpoints that depended on long-term follow-up may no longer be feasible due to the fact that so many women stopped their study treatments.

Ideally, investigators should have a thorough understanding of the options and the consequences of monitoring clinical

trials. It is only then that they will be able to provide guidance to the statistician in order to implement the optimal monitoring plan for the trial under design that is ethical, efficient, and valid.

ETHICS IN CLINICAL TRIALS

Historically, there have been many personal views expressed regarding the appropriateness of clinical studies involving human beings. Specifically, Claude Bernard in 1865 wrote, “Medicine by its nature is an experimental science, but it must apply the experimental method systematically.” Prior to World War II, clinical trials tended to be small and, therefore, they did not attract significant debate. However, at the Nuremberg Trials following World War II, it became apparent that Nazi physicians and military officials had performed strange and cruel experiments on war prisoners. These egregious violations of ethical conduct horrified the world and led to the development of the first international codes of ethics for human experimentation. Most notable of these is the Nuremberg Code, which was adopted in 1947. These ethical standards were intended to apply not only to war crimes, but to human experimentation in general (88). The Nuremberg Code advanced 10 principles (89):

1. The subjects of a trial should provide voluntary consent.
2. Consent to participate is an ongoing process, which an individual can revoke at any time.
3. The study should provide worthwhile results unavailable by other means.
4. The design should reflect the current state of knowledge from animal studies or other empirical studies.
5. The study procedures should be conducted so as to avoid unnecessary injury or suffering.
6. The risk to the subject should be consistent with the study benefits.
7. No deaths or disabling injury can be expected to result from the study procedures.
8. Appropriate precautions must be taken to protect subjects from any harm.
9. The assessment of risk and benefit is a continuous process. An investigator is obliged to terminate the trial when the risk of injury is imminent.
10. The study should be planned, executed, and reported by qualified individuals.

Unfortunately, at the time these codes were adopted they had very little practical influence on the practices of human experimentation within the U.S. medical community. Many investigators considered them unrelated to clinical trials (90). Also, some important issues were not addressed in these guidelines, such as the inclusion of individuals who are mentally or physically unable to provide an informed consent.

Based on the standards set forth at the Nuremberg Trials, the World Medical Association (WMA), at its 18th Assembly held in Helsinki, Finland, in 1964, adopted recommendations to guide physicians who participate in medical research involving human subjects. This document has become known as the Helsinki Declaration (91). It has been subsequently amended several times and most recently at the 52nd General Assembly, in Edinburgh, Scotland, in 2000. The current guidelines concede that “medical progress is based on research that ultimately must rest in part on experimentation involving human subjects.” It stresses that the risks to an individual incurred through participation in a research trial must be balanced against the potential benefits. While all subjects must be adequately informed of the goals, procedures, anticipated benefits, and potential hazards, ultimately, responsibility for the human subject must always rest with a medically qualified person and never with the research subject him- or herself. Finally, in research involving human beings, “the interests of science and society should never take precedence over considerations related to the well-being of the subject” (91).

A few years after the Helsinki Declaration was adopted, Henry Beecher published an article that identified 22 clinical trials with serious deficiencies in clinical ethics (92). Each trial violated one or more of the principles advanced in the Helsinki Declaration and endangered the health or the life of the subjects. Many of these studies were conducted at prominent U.S. university medical schools, and many were either federally funded or funded by well-known pharmaceutical companies. In order to explain why an investigator would participate in these studies, Beecher suggested that the pressures for career advancement and promotion might have influenced ambitious physicians. Shortly afterwards, the Tuskegee and Willowbrook incidents also captured national attention. In the first incident the U.S. Public Health Service monitored 201 men in Tuskegee, Alabama, with advanced syphilis to determine the natural history of this disease. This study continued despite the availability of an effective treatment. In the second incident mentally handicapped children at the Willowbrook Hospital in New York State were intentionally infected with viral hepatitis.

In reaction to these incidents the U.S. Congress established the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research by passing the National Research Act of 1974. The purpose of this commission was to investigate the ethical problems in clinical research. This act also mandated that all research studies funded entirely or in part by the federal government be reviewed by Institutional Review Boards (IRBs). The commission described the role of the IRBs and provided ethical guidelines for research involving human subjects. These guidelines are presented in the Commission’s 1978 Belmont Report. There are three important ethical principles for clinical research articulated in this report: respect for persons, beneficence, and justice.

The principle of respect for persons acknowledges that autonomous individuals, who are properly informed, should be free to exercise self-determination. At the same time, it recognizes that not all individuals are capable of self-determination and these persons must be protected (93,94). The informed-consent process arises from this principle. The principle of beneficence acknowledges that there is often a potential for both benefit and harm to the subjects of clinical research. This principle not only requires that there be a favorable balance

toward benefit, but that the potential for harm be minimized and justified. The principle of justice requires that the burdens and benefits of research be distributed fairly. An injustice occurs when one group bears a disproportionate burden of research while another reaps a disproportionate share of its benefits. Therefore, those obstacles that tend to limit access to clinical trials, such as study eligibility criteria, must be appropriately justified or else eliminated (see the Eligibility Criteria section).

The actualization of these principles can be controversial. For example, some authors have noted that there is a natural tension between the science and practice of medicine. On one hand, physicians have an uncompromisable covenant of loyalty and fidelity with their patients. This obliges the physician to exercise his or her best judgment in making treatment recommendations for each individual. The “randomized clinical trial routinely asks physicians to sacrifice the interests of their patients for the sake of the study” (95). On the other hand, there are many diseases in which the best available treatment is not known, or worse, the recommended treatment is based on limited scientific data and hunches that may be ineffective or even harmful. Historical examples include bezoar stone as a general antidote, bloodletting or purging for dysentery (5), thalidomide for sedation of pregnant women, and antiarrhythmic drugs following a myocardial infarction (96).

Dichotomizing the role of a physician as either caregiver or scientist is problematic. These roles should be viewed as part of a continuum that requires balance. “The tension between the interdependent responsibilities for providing personal and compassionate care, as well as scientifically sound and valid treatment, is intrinsic to the practice of medicine today. This tension is structurally part of the medical profession’s covenant with the human community, not merely the expression of an individual physician-investigator’s disordered intentions” (97). Not every medical issue is amenable to an experimental study. The efficacy of penicillin and the hazards of smoking were recognized without subjecting them to the rigors of a randomized clinical trial. Even among those issues that can be studied, it is not always clear that they should be. There certainly are many instances when clinical trials have been initiated in the absence of an ethical consensus (98,99).

This dichotomized view of the physician’s role arises from the physician’s responsibility to both the individual patient and the community. However, clinical trials are not the only instance when ethical consideration of the individual and the collective ethics can conflict. For example, it may be in the best interest of an individual to always be operated on by the most experienced surgeon, but society needs inexperienced surgeons to gain experience for future patients (100). The rising cost of health care also makes it necessary to frequently weigh the needs of the individual against the community’s resources. This dichotomy in the physician’s role leads to an artificial double standard, one for the practitioner and another for the investigator. Physicians who are not involved in clinical trials are no less obligated to inform their patients of treatment alternatives, as well as of the potential risks and benefits of each alternative. Also, respect for a patient’s right to self-determination is appropriate regardless of whether the patient is involved in a clinical trial (89).

Another controversial area in clinical trials occurs when a new therapeutic approach consists of the standard therapy augmented with a promising new experimental drug. The experimental therapy is frequently associated with more risks than the standard approach. The justification for the randomized trial arises from the uncertainty over whether the additional risks may be offset by the benefits of new treatment. However, when given a choice between standard therapy and randomization, some patients with a generally fatal disease prefer to refuse randomization and “take their chances” with

the experimental treatment outside the study. In this case, some investigators are reluctant to expose a patient to the risks of an unproven therapy, *outside* of a clinical trial. It has been suggested that this provides another example of when clinical trials “violate the physician-patient relationship, forcing investigators to use patients instead of treating them as individuals” (63). Markman (101) has proposed another twist on this same issue. When paclitaxel was first being evaluated in ovarian cancer trials (in 1990), the supply of the drug was limited and it was not generally available outside of a clinical trial. The only chance a patient had to receive paclitaxel in front-line therapy was to accept randomization with a clinical trial. In this case the patient’s choice was to receive standard therapy or consent to a randomized trial in return for a 50-50 chance of getting the experimental therapy.

There are ethical considerations that must be addressed at every point throughout a study, beginning with its design. “An experiment is ethical or not at its inception; it does not become ethical *post hoc*” (92). The study must begin with clear and meaningful objectives that are worthy of investigation. Studies that address unimportant issues cannot be ethically justified. The study methods and design follow directly from these objectives. Since a study needs to be both scientifically and ethically justified, the investigators involved in the study must be both technically and humanely competent (89). Technical competence implies an appropriate level of education, knowledge, certification, and experience, while humanistic competence implies both compassion and empathy. The execution of the study must be devoid of scientific misconduct. Scientific misconduct includes any behavior that compromises the validity of the findings or violates the rights of the subjects who participate in the study (102). Since misconduct can arise from either fraud or incompetence, constant vigilance is the only countermeasure.

Finally, since those physicians not involved in the study base their judgments about the internal and external validity of the study on summaries, all publications must be prepared accurately, completely, and objectively.

CHAPTER 10 ■ DIAGNOSTIC IMAGING TECHNIQUES IN GYNECOLOGIC ONCOLOGY

DARCY J. WOLFMAN, SUSAN M. ASCHER, HEDVIG HRICAK, CIRRELLA COOPER, AND LESLIE SCOUTT

INTRODUCTION

This chapter addresses the role of diagnostic imaging in evaluating gynecologic malignancy. Comprehensive imaging of the female pelvis can be achieved using a combination of ultrasound (US), computed tomography (CT), magnetic resonance imaging (MRI), and 2-[¹⁸F]-fluoro-2-deoxy-D-glucose positron emission tomography (FDG-PET). The objectives of imaging in gynecologic oncology are straightforward: primary tumor detection and characterization, image-guided percutaneous biopsy, staging, monitoring treatment response, and detecting tumor recurrence. Each imaging modality listed above is appropriate only in certain clinical situations and this chapter discusses not only what is possible in imaging of the female pelvis, but also what is appropriate for a given clinical situation. In some instances, more than one modality may be appropriate, and it is best to discuss the clinical question with the radiologist to determine which modality will be most useful. As with any changing technologic arena, imaging strategies are not static and require continuous updating and reevaluation.

IMAGING MODALITIES

Ultrasound

US is considered the initial imaging modality of choice in the workup of most pelvic disorders. Currently, the accepted roles of US in women with suspected gynecologic malignancy include characterization of adnexal masses to help differentiate benign from malignant ovarian masses, identification of endometrial abnormalities in women with intermenstrual or postmenopausal bleeding, and detection of primary or recurrent gestational trophoblastic disease in women with elevated serum beta human chorionic gonadotropin (β -hCG) levels. US is also used to guide biopsy of primary pelvic tumors and/or metastases and to guide drainage of postoperative fluid collections such as lymphoceles, seromas, or abscesses. The role of US in screening high-risk patient populations for ovarian or endometrial carcinoma remains controversial.

US offers many advantages: it is relatively inexpensive, is widely available, provides multiplanar imaging, and is without known risk. However, US has many limitations as well: it is operator dependent; it is a limited, targeted exam; and image quality may be significantly degraded by patient body habitus and/or bowel gas. Transvaginal ultrasound (TVS)

provides the best spatial and soft-tissue resolution, but it comes at the cost of a significant decrease in the size of the field of view. Sonohysterosalpingogram (SHg), which utilizes TVS while distending the endometrial cavity with fluid, can be useful in evaluating the endometrium.

Computed Tomography

CT is the primary imaging modality for evaluating the overall extent of a known gynecologic malignancy and for detecting residual and recurrent pelvic tumors. CT staging is more accurate than clinical staging in locally advanced disease and in cancers with a high propensity for lymphatic or peritoneal metastases. CT can also survey the brain, chest, and upper abdomen to provide information about extrapelvic disease. CT-guided biopsy can confirm metastatic spread of disease. Small and difficult to access masses are sometimes more readily biopsied using CT fluoroscopy (1).

Advantages of CT include ready availability, short scanning times, large field of view, and high spatial resolution. The advent of multidetector CT (MDCT) using continuous spiral (helical) acquisitions and multirow detector arrays (4-, 16-, 32-, and 64-slice systems) allows for faster scanning with higher image quality. Rapid technologic advances in MDCT include the ability to obtain submillimeter slice thickness, multiphasic contrast studies (such as arterial and venous phase enhancement after a single injection), CT angiography, endoluminal “fly-through” techniques (as used in CT colonoscopy), and rapid three-dimensional (3-D) reconstructions.

Disadvantages of CT include the use of ionizing radiation, degradation of image quality by patient body habitus or metallic implants, such as a hip prosthesis, and the morbidity and mortality associated with iodinated contrast agents. Despite technical improvements, CT remains of limited utility in the detection of primary gynecologic malignancies and the characterization of early-stage disease.

Magnetic Resonance Imaging

There is substantial evidence supporting the usefulness of MRI in staging gynecologic malignancies. MRI has been shown to be superior to CT in the staging of endometrial and cervical cancers (2,3). MRI may also be useful in the staging of ovarian cancer and gestational trophoblastic disease (GTD). In addition, MRI can often differentiate radiation fibrosis from recurrent tumor (4) and is useful in the detection of recurrent cervical

cancer. The accuracy of MRI assessment of lymph node invasion is similar to that of CT; both rely on size criteria to detect adenopathy (5). In addition, MRI-guided biopsies are gaining wider clinical acceptance.

Although MRI is still relatively expensive, it minimizes costs in some clinical settings by limiting or eliminating the need for more expensive and/or more invasive diagnostic or surgical procedures (6,7). There are at least three cost-minimizing indications for MRI in the evaluation of women with gynecologic malignancy: (a) the staging of invasive cervical carcinoma as an adjunct to clinical examination; (b) the preoperative management of women with endometrial cancer (8); and (c) the characterization of adnexal lesions when US and clinical examination are indeterminate (6,7). In addition, a meta-analysis of imaging endometrial cancer found that MRI was the best modality for multifactorial assessment (8).

Advantages of MRI include superior soft-tissue contrast, absence of ionizing radiation, multiplanar capability, and relatively fast (i.e., breath-hold and breathing-independent) techniques. MRI is the modality of choice for patients with allergies to iodinated intravenous contrast media or renal impairment. However, clinicians should be aware that gadolinium contrast agents used in MRI have recently been associated with the development of nephrogenic systemic fibrosis (NSF), a rare progressive connective tissue disease, in patients with end-stage renal disease and/or acute renal failure. Current recommendations from the American College of Radiology (9) include immediate dialysis after administration of a gadolinium contrast agent and a risk-benefit assessment on the use of gadolinium contrast in this patient population.

One disadvantage of MRI is the longer scan times when compared to CT. In addition, MRI is contraindicated in patients with pacemakers, cochlear implants, certain vascular clips, metallic objects in the eye, and neural stimulators. Furthermore, some patients may experience claustrophobia and may require sedation in order to complete a diagnostic examination.

Positron Emission Tomography

PET with the glucose analog FDG images tumors by showing areas of increased glucose uptake (10). FDG-PET thus takes advantage of a biochemical change (the accelerated rate of glycolysis) associated with malignancy that often precedes, and can be more specific than, the structural changes visualized by more conventional imaging means. This capability is the biggest advantage FDG-PET has over other modalities. FDG-PET does not have the same spatial resolution or soft tissue contrast as US, CT, or MRI, but image fusion techniques that overlay FDG-PET images onto anatomic images are available. PET-CT scanners, which are equipped with both PET and CT detectors, allow both modalities to be performed at once and have gained wide clinical acceptance.

In recent years, research has shown that FDG-PET is useful for the detection of recurrent ovarian, cervical, and endometrial cancer and for the staging of cervical cancer. As further research is done, more applications of FDG-PET in evaluation of gynecologic malignancies will become known.

There are several disadvantages of FDG-PET. False negatives can occur with lesions smaller than 1.0 cm and with certain tumor types that demonstrate low metabolic activity. False-positive results can be seen with several inflammatory disorders such as tuberculosis and granulomatous disease.

Excretory Urography

The use of excretory urography in the evaluation of gynecologic malignancies has been on the decline for several years; it is neither sensitive nor accurate in delineating tumor extent

and bladder invasion (11). Today, cross-sectional examinations provide similar and, in most instances, additional information.

Barium Enema

Barium enema (BE) in the workup of gynecologic pelvic cancers is also on the decline. If BE is used, signs of bowel involvement include fixation and tethering of the bowel wall, irregular serrations at the mass-colon interface, an annular defect from circumferential involvement, and mucosal ulceration and fistulization from complete transmural invasion. Unfortunately, these signs are not specific for involvement from gynecologic cancer (12). In fact, BE has a low positive yield when used in the routine evaluation of women with gynecologic malignancy—it is useful only in the workup of women with advanced disease for the detection of specific complications (13). Cross-sectional imaging has the advantage of providing information about structures surrounding the bowel and, thus, eliminates the need to infer this information indirectly from findings on BE.

EXAMINATION TECHNIQUES AND NORMAL ANATOMY

Ultrasound

Techniques

Adequate ultrasound evaluation of the female pelvis requires a transvaginal approach. By placing the transducer closer to the organs of interest, less penetration of the US beam is necessary and a higher frequency probe can be used. The use of a higher frequency transducer, typically 5.0 to 7.5 MHz, results in significantly improved spatial resolution and fewer imaging artifacts in comparison to transabdominal imaging but at the cost of a smaller field of view. Hence, transabdominal imaging must be considered an important complementary imaging technique if the mass is larger than the TVS field of view, the ovaries are displaced out of the pelvis, the ovaries are not visualized because of the presence of bowel gas, or to evaluate important ancillary findings such as hydronephrosis, ascites, peritoneal and/or hepatic implants, and liver metastases. Transabdominal imaging also provides a better overall view of the pelvis and the relationship of female pelvic organs to the pelvic sidewall and bladder.

Patients undergoing TVS are examined with an empty bladder in the supine position with the knees flexed and the hips slightly elevated and externally rotated. A gel-filled condom is placed over the 5.0- to 7.5-MHz probe, which is inserted into the vagina following application of an external lubricant. Transabdominal pelvic imaging is performed with a 3.5- to 5.0-MHz curved array transducer using a distended urinary bladder as an acoustic window to view the female pelvic organs.

Three-dimensional ultrasound is a new ultrasound technique that has been shown to decrease scanning time and possibly improve diagnostic confidence in pelvic imaging (14,15).

Sonohysterography (SHG) is a technique that is increasingly performed to better evaluate the endometrium (Fig. 10.1). With this technique, sterile saline is infused into the endometrial cavity under continuous TVS guidance. The sterile saline distends the endometrial cavity, separating the anterior and posterior endometrial layers and outlining the endometrial surface.

To perform a SHG, a baseline TVS examination is initially done. After insertion of a single-hinged speculum, the cervix is cleansed with Betadine and a 5F to 7F catheter is threaded through the cervical os. The catheter should be flushed with saline prior to insertion to remove the air from the lumen of

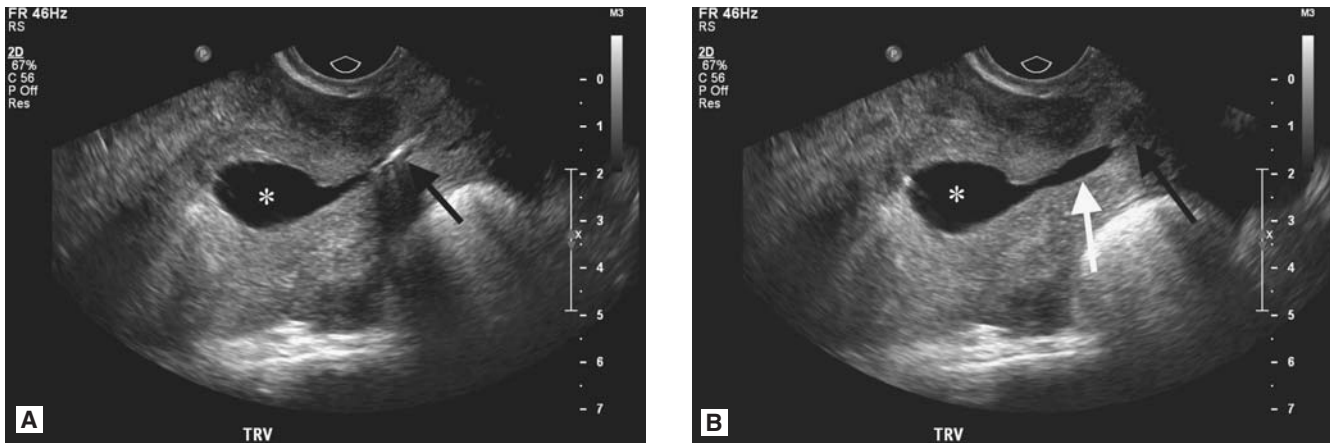

FIGURE 10.1. Normal sonohysterosalpingogram. Endometrial cavity is distended with fluid (white asterisk). Catheter (black arrow) is within the lower uterine segment (A) and then is pulled back (B) to allow visualization of the endometrial cavity within the lower uterine segment (white arrow).

the catheter. A balloon catheter may be used, but care should be taken to remove the air from the balloon before insertion. The speculum is removed and the endovaginal probe reinserted. Under continuous ultrasound imaging, 10 to 60 mL of sterile saline is slowly infused and images are obtained in both sagittal (long axis) and transverse (short axis) planes (16,17). If a balloon catheter is utilized, it should be deflated at the end of the procedure to allow complete visualization of the lower uterine segment. Antibiotic prophylaxis can be considered in patients who normally take prophylactic antibiotics prior to dental work. Premedication with nonsteroidal anti-inflammatory agents will minimize uterine cramping. Contraindications to SHG include hematometria and acute pelvic inflammatory disease.

Three-dimensional SHG is becoming more commonly used. This technique reduces operator dependence and length of examination time and has been reported to provide significant additional information in a majority of patients (18).

Normal Uterus

The normal myometrium (Fig. 10.2) is homogeneous in echotexture and intermediate in echogenicity. Anechoic tubular structures separating the outer one third from the inner two thirds of the myometrium represent the arcuate vessels, which

FIGURE 10.2. Normal uterus on ultrasound. Uterine myometrium demonstrates a homogeneous echotexture (white arrow). The endometrium is a highly echogenic thin line (black arrow). Note the trace amount of anechoic fluid in the endometrial canal.

are best seen on color flow imaging. The internal os can be recognized as a slight constriction of the uterine contour. Uterine volume is calculated using the formula $1/2 (L \times W \times D)$.

The endometrium should be measured at the thickest part of the endometrial stripe in the uterine fundus on a midline sagittal image, and by convention is always reported as a double-layer measurement. The normal endometrium is highly echogenic. However, the thickness and echotexture of the endometrium vary with the hormonal status of the patient. At the end of the menses, the endometrial stripe is highly echogenic and measures approximately 2 to 3 mm. During the proliferative stage, the endometrium becomes less echogenic and thickens, reaching a maximum of 8 mm. Before ovulation, a trilaminar appearance of the endometrium has been described. The central thin echogenic line represents a reflective artifact and/or mucus and secretions between the anterior and posterior layers of the endometrium. Subjacent is the second layer, which is the relatively hypoechoic functionalis layer. The third layer is the surrounding deeper basalis layer, which remains echogenic. Following ovulation, the functionalis layer becomes thicker and more echogenic than during the secretory phase such that the entire stripe may reach 15 mm in thickness and is more uniformly echogenic just prior to menstruation (19). In some patients, the innermost layer of myometrium is relatively hypoechoic compared to the immediately subjacent endometrium and is termed the subendometrial halo. The subendometrial halo is less commonly visualized in postmenopausal women. Neither the subendometrial halo nor fluid or debris within the endometrial cavity should be included in measurements of the endometrial stripe. At SHG, the endometrium should be homogeneous, symmetric, and regular without mass effect. The sum of the width of the two layers should not exceed the maximum acceptable width for the patient's hormonal status.

The uterine artery originates from the internal iliac artery. Pulse Doppler examination will demonstrate a high impedance waveform characterized by an early diastolic notch and relatively little diastolic flow. Only minor changes occur in the uterine artery waveform during the menstrual cycle.

In postmenopausal women, the uterine corpus shrinks until it approximates the length of the cervix. The endometrium atrophies and should appear as a thin, regular echogenic line <5 mm in width (20). In women taking hormonal replacement therapy (HRT) less uterine and endometrial atrophy occurs (21). Women taking sequential HRT are best examined following withdrawal bleeding and the progesterone phase of their cycle when the endometrium is expected to be at the thinnest.

FIGURE 10.3. Normal ovary on ultrasound. Ovarian parenchyma demonstrates a homogeneous echotexture with multiple anechoic follicles (arrows).

Normal Ovaries

The US appearance of the ovaries (Fig. 10.3) also changes with the patient's hormonal status. The premenopausal ovary has a relatively homogeneous outer cortex with a more echogenic central medulla. Small anechoic follicles are common. At ovulation, one follicle becomes dominant, reaching a maximum diameter of 2.0 to 2.5 cm. Following ovulation, the corpus luteum develops. The corpus luteum may contain debris and/or hemorrhage and often involutes, appearing to be crenelated just prior to menstruation. The ovaries atrophy with menopause and contain fewer follicles. Therefore, postmenopausal ovaries are more difficult to visualize with ultrasound. In women taking HRT, less ovarian atrophy will occur and follicles will continue to develop.

Doppler evaluation of ovarian blood flow is best performed during days 3 to 7 of the menstrual cycle. The ovary undergoing ovulation in a given cycle demonstrates a relatively high-velocity, low-resistance arterial waveform with continuous forward diastolic flow. The contralateral ovary will typically demonstrate a higher-resistance low-velocity arterial waveform with either very low or no diastolic flow.

Computed Tomography

Techniques

CT studies of the pelvis require contrast opacification of the distal small bowel and colon. In some centers, patients receive 500 mL of a 2% barium solution the evening preceding the examination and an additional 500 mL 45 minutes before the CT scan. In other protocols, the patient receives 600 to 1,000 mL of dilute oral contrast at least 1 hour before the examination, coupled with a 200-mL dilute contrast enema. Iodinated intravenous (IV) contrast is used in pelvic CT imaging to opacify the bladder and ureters, to differentiate contrast-filled blood vessels from adjacent lymph nodes, to enhance the myometrium, to visualize the endometrial cavity, and to delineate hypodense tumor boundaries from contiguous normal organ parenchyma.

MDCT is the standard of care in most hospital and outpatient settings. Optimal IV contrast enhancement for these faster scanners requires a mechanical power injector to administer 100 to 120 mL of IV contrast at a rate of 2 mL/s or more. Scan parameters including injection rates, scan delays, and collimation vary based on the specific protocol used and

FIGURE 10.4. Normal uterus on CT. Uterus (white asterisk) is a triangular-shaped soft-tissue density posterior to the bladder (black asterisk) and anterior to the bowel (black X).

imaging objective. With MDCT, it is easy to obtain multiphase contrast examinations with arterial and venous phase images. Increased radiation exposure for multiple passes must be balanced with the likelihood of increased clinical yield. The enormous data sets generated by MDCT studies require sophisticated software and computer workstations to fully exploit the technology (1).

Normal Uterus and Pelvic Structures

On CT, the vagina, cervix, and uterine corpus can be differentiated based on both morphologic and enhancement characteristics. The uterine corpus appears as a triangular or ovoid soft-tissue mass posterior to the urinary bladder (Fig. 10.4). The cervix is a more rounded structure. At the level of the fornix, the vagina has a flat rectangular or crescentic shape. Following bolus intravenous contrast administration, the myometrium in the uterine corpus enhances to a greater degree than that of the cervix. The endometrium can often be delineated from the enhancing myometrium. The broad and round ligaments can be seen coursing laterally and anteriorly, respectively. Occasionally, the uterosacral ligaments are depicted as arc-like structures extending from the cervix to the sacrum.

Normal Ovaries

In the premenopausal patient, the normal ovaries are routinely seen, usually posterolateral to the uterine corpus. Their uniform soft-tissue density is punctuated by small cystic regions representing follicles (Fig. 10.5). In the postmenopausal patient, the ovaries are small and less readily detected.

Magnetic Resonance Imaging

Techniques

It is recommended that patients fast for 4 to 6 hours before an MRI examination or be given an antiperistaltic (e.g., 1.0 mg glucagon intramuscularly). The routine use of bowel contrast agents is controversial, but some investigators advocate the administration of varying amounts (typically 400 to 600 mL) of oral contrast 10 to 40 minutes prior to an MRI examination (22). When an oral contrast agent is used, the antiperistaltic is given just before scanning to optimize image quality (23). Gadolinium contrast (0.1 $\mu\text{mol/kg}$) is administered intravenously to opacify vessels, to highlight tumor interfaces, to

FIGURE 10.5. Normal ovary on CT. Ovary (black arrow) is a soft-tissue density with small cystic spaces corresponding to follicles. Note the uterus (white arrow) adjacent to the right ovary.

assess lymph nodes, to detect fistulas, and to identify local, regional, and distant metastases. Patients are usually scanned in the supine position, with the bladder empty at the beginning of the study.

Using a high field strength (≥ 1 tesla) MRI system and a phased-array body surface coil, high-resolution T2-weighted (T2W) images are obtained in under 5 minutes using fast-spin echo technique (FSE) (24). Recently, parallel imaging has been gaining momentum. Parallel imaging allows for faster acquisition of T2W-FSE sequences by a factor of two or provides twice the spatial resolution for a given acquisition time. Although there are even faster imaging techniques (e.g., breath-hold FSE and breathing-independent half Fourier acquisition single-shot turbo spin echo [HASTE]), they do not have the same spatial resolution as FSE and therefore cannot replace T2W-FSE for evaluating the primary tumor and extent of disease (24,25). These other T2W sequences (e.g., rapid acquisition relaxation enhanced [RARE], HASTE), however, are particularly attractive for performing MRI urography (MRIU) as an adjunct to T2W-FSE images (26).

Normal Uterus and Pelvic Structures

Pelvic anatomy is exquisitely demonstrated on MRI scans. On T1-weighted (T1W) sequences, the normal pelvic musculature and viscera demonstrate homogeneous low to medium signal intensity. Cortical bone demonstrates low signal intensity and fatty marrow is high in signal intensity. Similarly, intrapelvic fat demonstrates high signal intensity.

It is the soft-tissue contrast afforded by T2W sequences, however, that is the basis for the strength of MRI in pelvic imaging. On these sequences, the uterus, cervix, and vagina all exhibit distinct layers of different signal intensity—the so-called zonal architecture (Figs. 10.6 and 10.7). The endometrium shows high signal intensity, usually higher than the signal intensity of subcutaneous fat. The peripheral myometrium is intermediate in signal intensity, being higher in signal intensity than striated muscle. Interposed between these two layers is a narrow band of decreased signal intensity, the junctional zone, which corresponds to the innermost myometrium (Fig. 10.6). The signal properties of the junctional zone reflect its lower water content, compared with the rest of the myometrium, which may be a function of its decrease in extracellular matrix per unit volume (27,28). The three zones seen on MRI images are not comparable to the different zones seen on US (29). The endometrium is well visualized with MRI, including the varying width of the endometrium (both leaflets) seen with the menstrual

FIGURE 10.6. Normal uterus on MRI. Sagittal T2W image through the uterine midline. The uterine zonal anatomy is seen with the intermediate-T2W-signal myometrium (long black arrow), low-T2W-signal junctional zone (white arrow), and high-T2W-signal endometrium (short grey arrow).

cycle (30). In postmenopausal women not receiving exogenous hormones, uterine zonal anatomy is indistinct, and the endometrium typically measures less than 3 mm (30).

The cervix also demonstrates zonal architecture on T2W sequences (Fig. 10.7). There is an inner area of high signal intensity, which is believed to represent epithelium and mucus; a middle area of predominantly low signal intensity, which is believed to represent fibrous stroma with a higher cell count or more nuclei; and an outer area of medium signal intensity,

FIGURE 10.7. Normal cervix on MRI. Sagittal T2W image through the cervix. The cervical zonal anatomy is apparent with an innermost high signal layer (long black arrow), outermost intermediate signal layer (short grey arrow), and a low signal layer in between (white arrow).

which is believed to represent fibrous stroma with a lower cell count or fewer nuclei and a high degree of vascularity (31,32). The use of pelvic surface coils has revealed yet another cervical layer: interposed between the high-signal-intensity endocervical canal and the low-signal-intensity fibrocervical stroma is a feathery layer of intermediate signal intensity, which is thought to represent the mucosal folds or plicae palmatae.

T2W images of the vagina reveal two zones, the bright vaginal mucosa and the intermediate-signal-intensity vaginal wall. The low-signal-intensity ligamentous structures are identified by their anatomic location.

Following the administration of gadolinium contrast, the zonal anatomy of the uterus is demonstrated on fat-saturated T1W images. The endometrium and outer myometrium enhance to a greater extent than the junctional zone. Similarly, in the cervix, the inner cervical mucosa and outer smooth muscle enhance more than the fibrocervical stroma. The parametrial tissues, vaginal wall, and submucosa also enhance after gadolinium contrast administration.

Normal Ovaries

On T1W images, the ovaries display homogeneous low to medium signal intensity, whereas on T2W images (Fig. 10.8), the follicles become brighter than the surrounding stroma. The normal fallopian tubes are not routinely imaged because of their small size and tortuous course.

Positron Emission Tomography

Techniques

Patient preparation is crucial to high-quality FDG-PET imaging. Physiologic uptake of tracer needs to be limited in order to achieve the best signal-to-noise ratio. After intravenous injection, FDG is distributed by the bloodstream and taken up by glycolytically active tissues including the brain, myocardium, liver, spleen, bone marrow, gastrointestinal tract, testes, and skeletal muscle. Other less common sites of FDG uptake include the endometrium, breast, major and minor salivary glands, and brown fat. FDG is excreted by the kidneys and therefore intense uptake can be seen in the renal collecting systems, ureters, and bladder.

The patient is asked to fast for at least 4 hours prior to the FDG-PET scan in order to keep insulin levels low. Elevated

insulin levels drive FDG into skeletal muscle, often leading to a nondiagnostic examination. Blood glucose is checked prior to FDG injection. Blood glucose levels less than 200 mg/dL are acceptable at most institutions. If blood glucose levels are found to be above this level, most institutions will not perform the study or will evaluate the situation on a case-by-case basis. Specific protocols are used for diabetic patients.

Bladder/urine activity cannot be removed, but steps are taken to reduce the amount of activity. Adequate hydration and frequent urination, including voiding immediately prior to imaging, are used to help reduce this activity. Some centers use IV hydration. However, care should be taken to ensure that no dextrose is in the IV fluid.

Patients are asked to not engage in any heavy activity or gum chewing the day before the FDG-PET exam. After the injection of 5 to 10 mCi FDG intravenously, the patient is asked to lie quietly in the supine position without talking in order to limit skeletal muscle FDG uptake. Imaging occurs 60 to 90 minutes after FDG injection and lasts 30 to 45 minutes, depending on the specific protocol.

Normal Pelvic Structures

In premenopausal patients, uterine and ovarian FDG uptake is related to the menstrual cycle. Ovarian FDG uptake occurs in the late follicular to early luteal phase of the menstrual cycle. The most intense endometrial FDG uptake occurs during the first 3 days of the menstrual cycle (33). Therefore, premenopausal patients should be imaged a week before to a few days after menstruation.

There is no physiologic uptake of FDG in the uterus or ovaries of postmenopausal patients (33). No studies to date have evaluated physiologic uptake of FDG in the uterus and ovaries in women on tamoxifen or HRT.

CERVICAL CANCER

Introduction

Cervical cancer is typically detected clinically (Pap smear and/or physical exam), with imaging being most often reserved for staging, monitoring treatment, and detecting recurrence in patients with advanced disease. US, CT, MRI, and FDG-PET all play a role in the management of patients with known cervical cancer.

Primary Detection and Characterization of Cervical Cancer

Cervical cancer is usually detected by physical exam or from results of a Pap smear. Imaging rarely plays a role in the primary detection and characterization of cervical cancer.

Ultrasound

Early cervical carcinoma is difficult to detect with either trans-abdominal or transvaginal sonography. Transrectal ultrasound (TRUS) can sometimes allow better visualization of the uterine cervix (34). High-frequency 20-MHz miniature intracervical US probes are a promising technique in the evaluation of cervical cancer. These probes are able to detect early cancers (invasion >5 mm) (35,36). However, more research is needed before this technique is useful clinically.

On US, cervical tumors are hypoechoic or isoechoic masses with ill-defined margins. Occasionally, a hypoechoic cervical tumor can mimic a cervical myoma. If the tumor obstructs the endocervical canal, hydrometra and/or hematometra will be present, which is readily detectable with US.

FIGURE 10.8. Normal ovary on MRI. Axial T2W image showing the normal ovary (black arrow) with intermediate-T2W-signal stroma and high-T2W-signal follicles. Note the uterus in the midline (white arrow) with a posterior fibroid (white asterisk).

FIGURE 10.9. Cervical mass on MRI. Sagittal T1W post-contrast fat-saturated image demonstrating an enhancing cervical mass (arrow).

Magnetic Resonance Imaging

The ever-increasing body of literature on MRI and cervical cancer suggests that MRI is superior to US for delineating the primary tumor site and size. These MRI advantages are primarily due to the superior soft-tissue contrast of MRI and the ability to define the tumor in the orthogonal plane (37,38). On T2W images, the characteristic feature of cervical cancer is an intermediate-signal-intensity mass. The T2W signal intensity of the tumor is usually greater than the normal low T2W signal intensity of the fibrocervical stroma.

On T1W images, cervical tumors are usually isointense compared to the normal cervix and may not be visible. Gadolinium contrast highlights tumor heterogeneity and aids in the differentiation of viable tumor from debris and necrosis (39). Primary cervical tumors demonstrate increased early enhancement relative to the normal adjacent cervical stroma (Fig. 10.9). On later postcontrast T1W images the tumor enhancement becomes less marked, and on delayed images the tumor may be isointense or hypointense compared to the adjacent normal cervical stroma (40). Dynamic imaging may improve the detection of small lesions and assessment of stromal invasion (40,41). Signal-intensity-versus-time curves, however, do not appear to make a significant contribution to the evaluation of tumor aggressiveness (42).

In contrast to squamous-cell cervical carcinoma, adenoma malignum, a rare form of cervical adenocarcinoma, is depicted as a high-signal-intensity multicystic lesion on T2W sequences. The tumor extends from the endocervical glands to the deep cervical stroma and may mimic nabothian cysts. On postcontrast T1W images, solid portions within the tumor enhance, which is a feature that helps distinguish adenoma malignum from nabothian cysts (43).

Primary Detection and Characterization of Cervical Cancer Recommendations

Cervical carcinoma is most commonly detected by physical exam or from the results of a Pap smear. MRI is the current study of choice if imaging is necessary in this situation.

Staging Cervical Cancer

Recommendations for diagnostic evaluation of tumor staging derive from the International Federation of Gynecology and Obstetrics (FIGO) clinical staging system and are based on findings from physical examination, colposcopy, lesion biopsies, chest radiography, cystoscopy, sigmoidoscopy, intravenous urography (IVU), and BE. When compared with surgical staging, clinical FIGO staging is flawed, with a reported error rate of 17% to 67%. These sobering statistics primarily reflect failure to identify parametrial extension (38,44,45). The detection of parametrial invasion is crucial in the treatment decision process. The staging accuracy for both BE and IVU are dismal, with both tests being positive only in advanced disease. Whereas hydronephrosis or a nonfunctioning kidney can be detected with IVU, it is insensitive to tumor extent (46,47). Furthermore, clinical FIGO staging does not include evaluation of lymph node metastases. Although cross-sectional imaging is not mandated by FIGO, many women are referred for cross-sectional imaging to stage cervical cancer when advanced-stage disease is suspected.

Ultrasound

Transabdominal sonography plays a limited role in the staging of cervical cancer and is inferior to other cross-sectional modalities in this role. Although the improved spatial resolution achieved with TVS and TRUS is helpful in the evaluation of tumor size and locoregional extent, poor soft-tissue contrast impedes differentiation between tumor and normal adjacent cervical, uterine, parametrial, and vaginal tissue (48,49). Sonographic findings in parametrial invasion include irregularity or loss of the normal cervical contour (50). Pelvic sidewall involvement is diagnosed on US by a parametrial soft-tissue mass or tumor extension to the sidewall and/or encasement of the iliac vessels (50). Bladder invasion is suggested by loss of the fat plane between cervix and bladder or direct extension of the tumor mass through the bladder wall. Enlarged pelvic lymph nodes may also be detected.

One study reports an overall accuracy of 83% for TRUS in the staging of cervical cancer (50). The accuracy increases to 87% for parametrial involvement, with a sensitivity of 78% and a specificity of 89%. Unfortunately, these results have not been reproduced, limiting enthusiasm for this modality. Most agree that both the soft-tissue contrast and field of view with US are too limited to allow adequate evaluation of the parametria. Therefore, US is significantly limited in its usefulness in the staging of patients with cervical cancer.

Computed Tomography

CT has been used extensively for staging cervical cancer, and its strengths and limitations are well known. Intravenous contrast is essential to delineate the interfaces of tumor, normal cervical stroma, and myometrium and to differentiate normal parauterine fat margins from irregular hypodense borders caused by tumor infiltration.

CT staging criteria are derived from FIGO staging (Table 10.1). Stage I cervical cancer is confined to the cervix. Tumor confined to the cervix does not alter the normal, smooth, well-defined cervical contour; periureteral fat planes are preserved; and there is neither stranding of the parametria nor a parametrial soft-tissue mass. The primary tumor may appear as diffuse cervical enlargement or as a discrete low-attenuation cervical mass. The regions of decreased attenuation are a function of tumor necrosis/ulceration and/or inherent differences in the attenuation between tumor and normal cervical tissue. Distinguishing tumor from the normal cervix is often problematic, as half of cervical tumors show isoattenuation to normal

TABLE 10.1**CORRESPONDING CT FINDINGS FOR STAGING CERVICAL CANCER**

Stage 0		No tumor present
Stage I	IA	No tumor present
	IB	No tumor present or tumor does not alter cervical contour
Stage II	IIA	Thickening of vaginal wall (upper two thirds)
	IIB	Irregular lateral cervical margin parametrial mass or strands Obliteration of periureteral fat
Stage III	IIIA	Thickening of vaginal wall (lower one third)
	IIIB	Tumor extends to obturator internus, piriformis, or levator ani muscles Dilated ureter
Stage IV	IVA	Thickening, nodularity, or serration of bladder or rectal wall Obliteration of perivesical or perirectal fat
	IVB	Tumor in distant organs

cervical stroma on CT (2). Obstruction of the endocervical canal by cervical tumor can result in uterine enlargement with a fluid-filled endometrial cavity (51).

Stage II cervical cancer extends beyond the cervix to involve the upper two thirds of the vagina (stage IIA) or the parametria, but not the pelvic sidewall (stage IIB). Intravaginal tumor (stage IIA) is best staged by clinical examination (Fig. 10.10) (52). CT criteria for parametrial invasion (stage IIB) include irregularity or effacement of the lateral cervical margins, thick parametrial soft-tissue stranding, an eccentric soft-tissue mass, and/or obliteration of the normal periureteral fat planes. Diagnosis of early parametrial invasion is problematic on CT as irregular cervical margins and prominent parametrial soft tissue can be simulated by parametritis associated with previous uterine curettage or cervical conization. Loss of the periureteral fat plane around the pelvic ureter is the only reliable finding of parametrial tumor extension but indicates advanced disease (47,53).

Stage III cervical carcinoma involves either the lower third of the vagina (stage IIIA) or the pelvic sidewall (stage IIIB). Stage IIIA cervical cancer is best staged clinically. Stage IIIB tumors appear as irregular soft-tissue strands extending to the piriformis, levator ani, and/or obturator internus muscles. Alternatively, confluent soft-tissue masses may envelop the pelvic sidewall musculature and iliac vessels. A fat plane of 3 mm or less between a parametrial mass and the pelvic sidewall indicates stage IIIB disease, since clinicians consider tumor to involve the sidewall if they are unable to interpose their fingers between the tumor and pelvic sidewall during pelvic examination under anesthesia (51). Detection of hydronephrosis also indicates stage IIIB disease. CT is more accurate than IVU in demonstrating the exact site of ureteral obstruction and the entire course of a hydroureter even in the absence of renal function (47,54).

Stage IVA cervical carcinoma indicates spread of tumor to adjacent pelvic organs, while stage IVB indicates spread of disease to distant organs. CT criteria for urinary bladder or rectal invasion (stage IVA) include focal loss of the normal perivesical/perirectal fat plane accompanied by asymmetric wall thickening, nodular indentations or serrations along the bladder or

FIGURE 10.10. Stage IIA cervical cancer on CT. Axial (A and C) and coronal (B) contrast-enhanced CT images. Cervical enlargement secondary to a low attenuation cervical mass (black asterisk in A and B). Cervical mass extends into the vagina (black asterisk in C). Note fluid-filled endometrial canal (white asterisk in B) secondary obstruction of the endocervical canal. Note the well-opacified left ureter (white arrow in A and B) with a preserved periureteral fat plane.

rectal wall, an intraluminal tumor mass, and/or a vesicovaginal or rectovaginal fistula (Fig. 10.11) (52). Early invasion of the bladder or rectum is not reliably detected by CT. Distant disease (stage IVB) is detected in the usual manner.

FIGURE 10.11. Stage IVA cervical cancer on CT. Contrast-enhanced CT images at two levels (A and B). Images demonstrate a heterogeneous mass arising in the cervix (black asterisk) with extension into the uterus (white arrow in A) and bladder (black arrow in B). Note the loss of the normal periureteral fat plane around the left ureter (white arrow in B).

Although the FIGO system does not include lymph node status, the presence of adenopathy affects prognosis. Detection of pathologically enlarged paraaortic or inguinal lymph nodes by CT is considered to be extrapelvic tumor extension and correlates with stage IVB disease. Lymph nodes greater than 1 cm in the short axis are considered to be pathologically enlarged. Adenopathy with central necrosis is associated with a high likelihood of metastatic disease (55). However, lymph node enlargement may also be secondary to benign inflammatory or reactive hyperplasia and, conversely, normal-sized lymph nodes may contain microscopic tumor foci. CT-guided biopsy can be useful to further assess patients with suspected nodal disease.

CT is often used for the staging of advanced cervical carcinoma because of the large field of view, widespread availability, and large numbers of experienced readers. However, CT has many limitations including poor detection of small primary tumors, parametrial invasion, and early invasion of the rectum and bladder. The diagnosis of stage IIB disease may be crucial to determine which patients are candidates for surgical resection. In the largest study to date the sensitivity, specificity, and negative predictive value (NPV) of CT in staging cervical carcinoma of stage IIB or greater were 42%, 82%, and 84%, respectively (56). Recent studies have shown that the staging accuracy of CT (53%) is better than that of clinical examination (47%) (57). Despite its limitations, CT is a valuable complement to clinical staging because of its accuracy in detecting advanced disease. In fact, 92% of stage IIIB through IVB lesions are accurately staged with CT (47).

The use of MDCT may help improve the accuracy of CT in cervical cancer staging by imaging thinner tissue slices, improving spatial resolution, and utilizing multiplanar reformatted images (58). However, more research is needed in this area.

Magnetic Resonance Imaging

The most recent literature suggests that MRI is superior to CT and clinical examination in the staging of cervical cancer (56,57). For this reason, MRI is becoming more frequently used in the staging of cervical cancer. MRI staging criteria are derived from FIGO staging conventions (Table 10.2).

An intact area of low T2W signal intensity, representing normal peripheral fibrous cervical stroma, is a reliable indication that the tumor is confined to the cervix (stage IB) (37,38,59).

Vaginal tumor involvement (stage IIA or IIIA) is recognized by segmental disruption of the intermediate- to low-signal-intensity vaginal wall on T2W images (37,60). However, vaginal tumor involvement is best staged by clinical examination. MRI determination of parametrial tumor extension (stage IIB) includes both morphologic and tissue signal alterations. Criteria include an irregular lateral cervical margin, prominent parametrial strands, eccentric parametrial enlargement, loss of parametrial fat planes on T1W images, and/or abnormal high-signal tumor extending through the low-signal-intensity ring of fibrocervical stroma into the parametria or cardinal-uterosacral ligaments on T2W images (37,38,59).

MRI criteria for pelvic sidewall extension (stage IIIB) are tumor extending beyond the lateral margins of the cardinal

TABLE 10.2

CORRESPONDING MRI FINDINGS FOR STAGING OF CERVICAL CANCER (T2W OR CONTRAST-ENHANCED T1W IMAGES)

Stage 0		No tumor present
Stage I	IA	No tumor present
	IB	Partial or complete disruption of low-signal-intensity stromal ring with intact tissue surrounding tumor
Stage II	IIA	Segmental disruption of low-signal-intensity vaginal wall (upper two thirds)
	IIB	Complete disruption of low signal intensity stromal ring with tumor extending into parametrium
Stage III	IIIA	Segmental disruption of low-signal-intensity vaginal wall (lower one third)
	IIIB	Tumor extends to obturator internus, piriformis, or levator ani muscles Dilated ureter
Stage IV	IVA	Signal loss of low-signal-intensity bladder or rectal wall
	IVB	Tumor in distant organs

ligaments and loss of the normal low signal intensity of the piriformis, levator ani, and/or obturator internus muscles on T2W images (Fig. 10.12) (37). The presence of hydronephrosis also indicates stage IIIB disease.

In stage IVA disease, there is segmental loss of the normal low-signal-intensity wall of the bladder or rectum. This is best seen on T2W and/or contrast-enhanced T1W images. Distant disease (stage IVB) is detected in the usual manner. The presence of abnormal paraaortic or inguinal lymph nodes also indicates stage IVB disease.

Recent studies have shown the overall staging accuracy of MRI in cervical carcinoma to be high at 77% to 93% (57,61). The accuracy for the detection of parametrial invasion is also high, ranging from 94% to 95% (61). However, the sensitivity for parametrial invasion on MRI was low, 38% (61).

Surface coil imaging (e.g., endovaginal, endorectal, or phased-array coil) results in higher spatial resolution than conventional body coil imaging. When compared with body coil images, endorectal coil images provide greater anatomic

detail and better highlight the tissue planes between the tumor and normal structures (62). Whether these imaging improvements change patient management, however, is controversial. Results from one study indicated that the use of an endorectal coil improved accuracy in detecting parametrial invasion. Accuracy was 95% with the endorectal coil as opposed to 79% with a body coil (62). Other studies, however, have found no statistically significant difference in overall staging accuracy between the endorectal coil and the phased-array coil or between the phased-array coil and the body coil (89% vs. 89% and 91% vs. 89%, respectively). Nor was it possible to prove a significant difference in accuracy for detecting parametrial invasion (93% vs. 96% and 95% vs. 94%, respectively) (63).

Positron Emission Tomography

FDG-PET has been shown to be useful in the staging of advanced cervical cancer, especially the detection of pathologic lymph nodes. Although adenopathy is not part of the

FIGURE 10.12. Stage IIIB cervical cancer on MRI. Axial T2W (A) and T1W post-contrast fat-saturated images at the same level (B) and slightly cranial (C). Images demonstrate a cervical mass (white arrow) with adjacent intermediate T2W signal and post-contrast enhancement (black arrows) extending to the pelvic sidewall bilaterally.

FIGO staging system, it is considered stage IVB disease and is therefore crucial information when developing a treatment plan (Fig. 10.13). Conventional cross-sectional imaging modalities rely on size criteria for the diagnosis of adenopathy and, as such, microscopic disease is often not detected.

FDG-PET is better than the conventional imaging modalities in the detection of adenopathy in patients with cervical cancer. Reinhardt et al. (64) found that in the detection of involved lymph nodes, sensitivity, specificity, and positive predictive value (PPV) were 91%, 100%, and 100%, respectively, for FDG-PET, as compared to 73%, 83%, and 67%, respectively, for MRI. Another study demonstrated that the accuracy of FDG-PET in the detection of lymph node metastasis was 88%, compared to 75% with MRI (48). A recent study concluded that pretreatment FDG-PET compatible with abnormal lymph node uptake predicted disease recurrence and altered treatment management decisions in some patients (49).

Staging Cervical Cancer Recommendations

MRI outperforms clinical and CT staging for cervical cancer. In the largest study to date, Hricak et al. (56) determined that MRI performs significantly better in the detection of cervical tumors. Further, the sensitivity in detecting stage IIB disease or greater was 29% for clinical staging, 42% for CT, and 53% for MRI. Another study found that for staging, MRI had significantly

higher accuracy (86%) than clinical staging (47%) or CT (53%) (57). Another recent study showed that MRI is superior to both CT and clinical examination for evaluating uterine body involvement and measuring tumor size (65). Moreover, when pretreatment MRI is used to guide clinical management decisions, it has been shown to help minimize costs. In a study by Hricak et al. (6), the use of MRI findings to guide treatment decisions in women with cervical cancer greater than 2 cm in diameter resulted in a decrease in the number of diagnostic tests ordered and a decrease in the number of invasive procedures performed. In fact, therapy based on MRI findings led to a net cost savings of \$401 for all patients and \$449 for patients with stage IB disease.

Recent work has shown that FDG-PET is superior to both CT and MRI for the evaluation of adenopathy in patients with cervical cancer (48,64). However, more research is needed in the use of FDG-PET in the primary staging of cervical cancer before widespread clinical use.

In the meantime, MRI appears to be the modality of choice for the preoperative evaluation of women with cervical cancer, with FDG-PET being used in certain situations. MRI should be performed in women with primary tumor with a transverse diameter greater than 2 cm on clinical examination, women with primary tumor that is endocervical or predominantly infiltrative and cannot be accurately assessed clinically, and women who are pregnant or have concomitant uterine lesions, making it difficult to assess the primary tumor by other means (6,53,66).

FIGURE 10.13. Stage IVB cervical cancer on FDG-PET. FDG-PET (A), CT (B), and fused PET-CT (C) images show increased FDG uptake (arrow in A). PET-CT image demonstrates that the increased FDG uptake corresponds to the pelvic lymph node (arrow in C). Pelvic lymph node on CT alone (arrow in B) does not meet criteria for an abnormal lymph node.

Monitoring Treatment Response and Detecting Recurrent Cervical Cancer

Ultrasound

TRUS has a role, albeit small, in the evaluation of recurrent cervical cancer and for biopsy guidance in selected patients (67). Reports from one study indicate that in approximately 25% of cases, TRUS provides information that is complementary to that obtained from CT. TRUS is most likely to be helpful in patients with small-volume recurrence in areas of previous irradiation (67). Unfortunately, differentiation between radiation fibrosis and recurrent disease cannot be made on the basis of US soft-tissue appearance or Doppler vascularity. However, TRUS can be used to guide biopsy of these areas. Furthermore, because of its limited field of view, TRUS is not useful in the assessment of the cephalic extent of tumor, abnormalities of the upper urinary tract, or the presence of extrapelvic metastases (67). However, hydronephrosis is easily detected by transabdominal imaging, which can also serve to guide stent placement. Both TRUS and TVS also have an important role, complementary to CT and MRI, in detecting complications of therapy or advanced disease such as lymphoceles, fistulae, or abscesses.

Computed Tomography

CT has been used extensively to monitor patients with a history of cervical cancer and plan subsequent therapy (47,68,69). Serial CT scans provide an objective measure of tumor response to radiation therapy or chemotherapy in nonsurgical candidates. Compared with its use for initial staging of cervical cancer, CT has higher sensitivity and specificity and a lower false-negative rate when used for the detection of recurrent disease (68).

Recurrent tumor is often found in the central pelvis, the surgical bed, the vaginal cuff, and/or the preserved cervix. CT features of recurrent pelvic tumor include soft-tissue asymmetry, soft-tissue mass with hypoattenuation tumor foci, compression and invasion of adjacent organs, and/or tumor extension to the pelvic sidewall, the iliopsoas muscle, and/or the innominate bone. Pelvic and paraaortic nodal metastases are also often present in patients with recurrent disease and are well depicted by CT (69).

Complications of therapy and/or advanced disease are well delineated on CT. Fistula formation, to the bladder and/or rectum, is well evaluated with CT. CT is also useful for detecting and defining the site of ureteral obstruction, which is common in patients with recurrent cervical cancer (70).

Radiation therapy changes of the intact uterus are characterized by bilateral parametrial "whiskers" or poor definition and irregularity of the parametria without pelvic sidewall extension. Other classic radiation-induced changes on CT are thickening of the perirectal fascia, widening of the presacral space, a thick-walled bladder and rectum, a diffuse increase in the density of fat in the posterior pelvis, and thickening of small bowel loops in the pelvic inlet (71). A major limitation of CT is the inability to reliably differentiate postirradiation or postsurgical fibrosis from recurrent tumor (47,68).

In patients with equivocal findings, CT-guided fine-needle aspiration or core biopsy is an accurate way to differentiate recurrent tumor from posttreatment changes (71). In some cases, however, dense fibrous tissue surrounding nests of tumor cells may lead to a false-negative biopsy.

Because of the extensive use of pelvic radiation therapy as well as improved CT imaging techniques, detection of recurrent disease outside the pelvis is increasing (72). CT is useful for the assessment of metastases to solid organs (particularly the

liver, lungs, and adrenal glands), the peritoneum and omentum, and the osseous structures.

Magnetic Resonance Imaging

Residual or recurrent cervical cancer demonstrates intermediate signal intensity on T1W images and heterogeneous high signal intensity on T2W images, whereas uninvolved cervical stroma retains its low signal intensity (73–75). Lesions larger than 1 cm are accurately depicted, but smaller lesions are more difficult to assess because of partial volume averaging and limits in spatial resolution with MRI. On T2W images, tumor extension into the rectum and/or bladder is seen as disruption of the low-signal-intensity walls of these structures. The appearance of pelvic sidewall involvement is similar to that described earlier for the extension of a primary tumor.

MRI is the most utilized modality for differentiating recurrent tumor from posttreatment fibrosis secondary to irradiation, chemotherapy, and/or surgery (75). In a patient with a history of remote radiation therapy (>1 year), radiation-induced changes tend to be of low signal intensity on both T1W and T2W images, whereas recurrent tumor tends to be of moderate to high signal intensity on T2W sequences. In this situation (remote radiation treatment), the difference in signal intensity between posttreatment fibrosis and recurrent tumor is statistically significant, and a sensitivity of 86% and a specificity of 94% have been reported for detection of recurrent cervical cancer (76). Contrast enhancement may further aid in the detection of recurrent cervical cancer since recurrent tumor shows early enhancement compared with benign conditions. The accuracy of dynamic contrast-enhanced MRI for identifying recurrent disease approaches 85% compared to 64% to 68% for unenhanced T2W images (4,77).

Positron Emission Tomography

FDG-PET has been shown to be useful in the restaging of potentially curable recurrent cervical cancer (Fig. 10.14) and in the evaluation of patients with previously treated cervical cancer and unexplained tumor marker elevation. In a recent study, FDG-PET was shown to have a sensitivity of 96%, specificity of 84%, and accuracy of 92% in the detection of recurrent cervical cancer (78). In this study, 40% of patients diagnosed with recurrence received therapy with curative intent. Although more research needs to be done, there is hope that FDG-PET imaging will have a favorable impact on prognosis and survival.

In patients who have received treatment for cervical cancer and have unexplained elevations in tumor markers, FDG-PET is an excellent imaging choice. In one study, FDG-PET was performed on patients previously treated for cervical cancer with unexplained elevated serum squamous cell carcinoma antigen (SCC-Ag) and no evidence of recurrent disease on conventional imaging. The FDG-PET scans were positive in 94% of patients with documented recurrence (79).

Monitoring Treatment Response and Detecting Recurrent Cervical Cancer Recommendations

For the routine surveillance of patients with a history of cervical cancer and to diagnose complications from advanced cervical cancer or treatment, CT is the study of choice. In order to differentiate recurrent tumor from posttreatment fibrosis, MRI is the study of choice. Both MRI and CT have been used, with limited success, in monitoring response to therapy. In patients with suspected recurrence because of unexplained elevated tumor markers, and in patients with potentially curable recurrent cervical cancer, FDG-PET is the study of choice. More research is needed in the use of FDG-PET in monitoring cervical cancer treatment and detecting recurrent disease.

FIGURE 10.14. Recurrent cervical cancer on FDG-PET. FDG-PET (A), noncontrast CT (B), and fused PET-CT (C) images. Increased FDG-PET uptake in the left supraclavicular region (arrow in A) corresponds to a left supraclavicular lymph node on CT (arrow in B). Fused image demonstrates that the increased FDG uptake corresponds to the left supraclavicular lymph node (arrow in C).

Summary

Cervical cancer is most often diagnosed clinically with imaging reserved for staging, monitoring treatment response, and detecting recurrence. Cervical cancer staging is most accurately done with MRI; however, recent research suggests that FDG-PET may be the best staging technique for cervical cancer. More research is needed before staging with FDG-PET is routinely used. Both CT and MRI have utility in monitoring treatment response and detecting recurrent cervical cancer. In certain clinical scenarios, FDG-PET is useful for monitoring treatment response and detecting recurrence.

ENDOMETRIAL CANCER

Introduction

Endometrial carcinomas are typically diagnosed by endometrial biopsy or dilation and curettage (D&C). US remains the primary imaging modality to evaluate the endometrium, especially in patients with postmenopausal bleeding. Most other cross-sectional imaging studies are reserved for the evaluation of the extent of disease (3,39,80–83). Imaging criteria for staging of endometrial cancer is surgical–pathological and

based on the FIGO classification. CT and MRI are the most useful modalities to stage endometrial carcinoma. Evaluation for recurrent disease does not often require imaging as most recurrences occur at the vaginal cuff, which is well evaluated by physical exam. However, in cases of recurrent metastatic disease or for problem solving, CT, MRI, and PET may all be useful depending on the clinical question.

Primary Diagnosis of Endometrial Cancer

Endometrial biopsy and/or D&C has traditionally been the gold standard for histologic diagnosis of endometrial pathology. However, if routine endometrial sampling were performed in all women with postmenopausal bleeding, only one of every ten samples would be expected to be positive. In addition, significant sampling error has been reported with false-negative rates ranging from 2% to 6% (84,85). In order to decrease unnecessary endometrial biopsies, screening patients with postmenopausal bleeding with TVS and/or SHG has been advocated (86–91).

Double layer endometrial thickness greater than 4 or 5 mm on TVS is used as the sole ultrasound criterion for determining whether endometrial sampling is warranted in postmenopausal patients (Fig. 10.15) (86,87). This endometrial thickness is based on numerous trials that looked to establish a threshold

FIGURE 10.15. Thickened endometrium on ultrasound. Gray-scale ultrasound image through the sagittal midline of the endometrial canal demonstrating marked thickening of the hyperechoic endometrium (arrow).

endometrial thickness in postmenopausal patients below which endometrial pathology is unlikely. However, the specificity of this criterion is low, ranging from 59% to 63% (87,92).

When endometrial thickness is greater than 5 mm, endometrial sampling is suggested not only because of increased posttest probability of endometrial carcinoma, but also because of the inability of TVS and/or SHG to differentiate accurately between benign and malignant causes of endometrial thickening (88,93–95). In a meta-analysis of 35 articles including 5,892 women, Smith-Bindman et al. (87) reported that using a cut-off of 5 mm for endometrial thickness, 96% of women with endometrial cancer had an abnormal TVS. In this series, a woman with a 10% pretest probability of endometrial carcinoma and a negative TVS had a posttest probability of endometrial carcinoma of only 1%. They concluded that TVS is highly accurate in identifying a subgroup of patients at extremely low risk, obviating the need for endometrial sampling in these patients.

In women taking HRT, the specificity of the 5 mm cut-off is even lower, as HRT increases endometrial thickness. However, since the pretest probability of endometrial carcinoma is also likely increased in these patients, the same cut-off value of 4 or 5 mm is generally used. In women on sequential HRT regimens, scanning should be performed after the progesterone part of the cycle when the endometrium is expected to be at its thinnest.

Investigators have attempted to correlate the morphology of the endometrium on US with histology in order to increase specificity. Endometrial cancer tends to be an irregular, heterogeneous mass, whereas endometrial hyperplasia tends to be more homogenous and echogenic. Cystic areas within the endometrium are more often associated with polyps, cystic endometrial hyperplasia, or tamoxifen use (96–98), rather than with endometrial carcinoma. However, there is considerable overlap of these morphologic features. The most specific and only reliable US finding for endometrial carcinoma is invasion of the myometrium or disruption of the subendometrial halo by an endometrial mass.

On SHG, endometrial carcinoma is most commonly depicted as a broad-based, irregular mass (Fig. 10.16) (99). Difficulty in distending the endometrial cavity has also been described (100). Three-dimensional SHG has been reported to be more accurate than either TVS or two-dimensional (2-D) SHG for the diagnosis of endometrial carcinoma. Endometrial volume and thickness are reported to be higher in patients with postmenopausal bleeding and endometrial carcinoma than in patients without endometrial carcinoma (101).

FIGURE 10.16. Thickened endometrium on sonohysterosalpingogram. Sagittal midline gray-scale image from a sonohysterosalpingogram. Note the thickened, irregular endometrium (white arrow). Catheter with deflated balloon can be seen in the lower uterine segment (gray arrow).

Doppler US has not been shown to be useful in distinguishing benign from malignant endometrial pathology as a wide range of peak systolic velocities and resistive indices is reported for benign and malignant endometrial pathology (102). However, benign endometrial polyps are more likely to have a single feeding vessel, whereas cancers more often have numerous feeding vessels and generalized increased vascularity (103).

Staging Endometrial Cancer

Staging in endometrial carcinoma is surgical–pathological and based on the FIGO classification. US, CT, and MRI all have utility in the staging of endometrial carcinoma.

Ultrasound

The role of ultrasound in staging endometrial carcinoma is limited to evaluating stage I disease by assessing the depth of myometrial invasion. According to the FIGO classification, stage IA indicates tumor confined to the endometrium; stage IB indicates tumor invading less than one half of the myometrium; and stage IC indicates tumor invading more than one half of the myometrium. For endometrial carcinoma to be considered stage IA by ultrasound criteria the myometrial/endometrial interface should be smooth and regular and the hypoechoic subendometrial halo, if present, should be regular, symmetric, and uninterrupted. Myometrial invasion is documented when the tumor mass disrupts the subendometrial halo and/or extends into the subjacent myometrium. TVS has been reported to have a sensitivity of 77% to 100%, a specificity of 65% to 93%, and an overall accuracy of 60% to 76% in assessing the degree of myometrial invasion (104–106). Understaging can occur with microscopic or minimal myometrial invasion. In addition, assessment of myometrial invasion is more difficult when the myometrium is thinned or distorted by fibroids (104). Three-dimensional SHG has been reported to be more accurate in detecting myometrial and cervical invasion by endometrial carcinoma (107).

Computed Tomography

CT is widely used for the staging of endometrial cancer (68,108,109). CT staging criteria, based on the FIGO classification, for endometrial carcinoma have been well described (Table 10.3). IV contrast, as well as good bowel opacification with oral and/or rectal contrast, is necessary for adequate CT

TABLE 10.3**CORRESPONDING CT FINDINGS FOR STAGING ENDOMETRIAL CARCINOMA**

Stage I	
IA	Normal myometrium enveloping central low-attenuation tumor
IB	Normal myometrium enveloping central low-attenuation tumor <50% myometrial invasion
IC	Normal myometrium enveloping central low-attenuation tumor 50% myometrial invasion
Stage II	Central low-attenuation tumor extends into cervix
Stage III	
IIIA	Irregular uterine configuration Parametrial or pelvic sidewall extension Adnexal mass
IIIB	Thickening of vaginal wall
IIIC	Regional lymph nodes >1 cm in diameter in short axis
Stage IV	
IVA	Thickening or serration of bladder or rectal wall Obliteration of perivesical or perirectal fat
IVB	Tumor in distant organs or anatomic sites

evaluation. On noncontrast CT, endometrial carcinoma is the same attenuation as the normal surrounding myometrium, making evaluation difficult. On contrast-enhanced CT, endometrial carcinoma appears as a hypodense mass relative to the normal myometrium.

In stage I disease, the tumor may reside solely within the endometrial cavity as a diffuse, circumscribed, vegetative, or polypoid mass, or it may invade the adjacent myometrium (Fig. 10.17). If myometrial invasion is detected on CT, this usually corresponds to invasion of greater than one third to

one half of the myometrium (109). Tumor may also occlude the cervical os or vagina, resulting in uterine obstruction. In these instances, CT demonstrates an enlarged uterus with a distended, fluid-density endometrial cavity surrounded by contrast-enhanced myometrium of varying thickness. Demonstration of intrauterine gas usually indicates a necrotic neoplasm, gas introduced by curettage or endometrial biopsy, or a fistula secondary to tumor invasion (110). Rarely, in this circumstance, does gas represent pyometria.

In stage II disease, there is endometrial tumor involvement of the cervix, which is characterized on CT as cervical enlargement greater than 3.5 cm in diameter and heterogeneous low-attenuation areas within the fibromuscular cervical stroma (Fig. 10.18).

Stage III disease, parametrial extension, is depicted by a loss of the normal periureteral fat. Pelvic sidewall involvement is indicated by the depiction of less than 3 mm of intervening fat between the soft-tissue mass and the pelvic sidewall (45). Fallopian tube and/or ovarian involvement are also consistent with stage III disease.

Stage IV disease, pathologically enlarged lymph nodes and distant metastases, are detected in the usual manner on CT.

The utility of CT in patients with stage I and II disease is limited. CT accuracy in these cases is variable, ranging from 58% to 92% (69). Detection of stage I disease had an accuracy of 76% in one study (108). In another study, CT had a specificity of 42% for detection of deep myometrial invasion (stage IC) and a sensitivity of only 25% for cervical involvement (stage II) (111).

The greatest clinical impact of CT use is in confirming parametrial and sidewall extension in stage III tumors and in detecting pelvic adenopathy and metastatic disease. Stage III tumors may be upstaged if extrapelvic metastases are depicted on CT studies (69). The accuracy of CT in patients with stage III or IV disease is 83% to 86% (69).

Limitations of CT include a tendency to understage endometrial carcinoma because of a failure to detect microscopic parametrial, lymph node, bowel, or bladder invasion (69). CT is also particularly unreliable in the determination of myometrial invasion in elderly women with atrophic myometrium and a polypoid tumor in the endometrial cavity (69,108,109).

FIGURE 10.17. Stage I endometrial cancer on CT. Contrast-enhanced CT images (A and B) demonstrate enhancing tumor (white arrows in A and B) within an enlarged endometrial canal. Note the myometrial invasion (black arrow in B).

FIGURE 10.18. Stage II endometrial cancer on CT. Contrast-enhanced CT images (A and B) demonstrate enhancing tumor within the endometrial canal (white arrow in A) with associated low attenuation enlargement of the cervix (white arrow in B) indicating cervical involvement of tumor.

Magnetic Resonance Imaging

Contrast-enhanced MRI is considered the most accurate imaging method for staging endometrial carcinoma (106). MRI staging criteria based on the FIGO classification have been well described (Table 10.4). Most MRI scans in women with endometrial cancer are performed after diagnostic D&C, and it is important to recognize post-D&C hemorrhage on MRI, which can be seen as a linear focal signal void. The results of at least one study indicate that this finding does not interfere with MRI staging evaluation of the uterus (112).

On unenhanced T1W images, endometrial carcinoma is isointense with the normal endometrium, and small tumors do not expand the canal. Therefore, these cancers usually go undetected on unenhanced T1W images. With larger tumors, the endometrium is thickened and may be lobulated or irregular on T1W images. Although endometrial cancer may demonstrate homogeneous high signal intensity on T2W sequences, it is more typically heterogeneous and may even be low in signal intensity. The MRI appearance of endometrial carcinoma is not specific and can also be seen with uterine fluid (hematometra or pyometra), submucosal degenerating leiomyoma, endometrial hyperplasia, endometrial polyps, and blood clots (80).

Routine use of gadolinium contrast is necessary for MRI evaluation of endometrial carcinoma. Following gadolinium

TABLE 10.4

CORRESPONDING MRI FINDINGS (T2W OR CONTRAST-ENHANCED T1W IMAGES) FOR STAGING ENDOMETRIAL CARCINOMA

Stage 0	Normal or thickened endometrial stripe
Stage I	
IA	Thickened endometrial stripe with diffuse or focal abnormal signal intensity Endometrial stripe may be normal Intact junctional zone with smooth endometrial–myometrial interface
IB	Signal intensity of tumor extends into myometrium <50% Partial or full-thickness disruption of junctional zone with irregular endometrial–myometrial interface
IC	Signal intensity of tumor extends into myometrium >50% Full-thickness disruption of junctional zone Intact stripe of normal outer myometrium
Stage II	
IIA	Internal os and endocervical canal are widened Low signal of fibrous stroma remains intact
IIB	Disruption of fibrous stroma
Stage III	
IIIA	Disruption of continuity of outer myometrium Irregular uterine configuration Adnexal mass
IIIB	Segmental loss of hypointense vaginal wall
IIIC	Regional lymph nodes >1 cm in diameter in short axis
Stage IV	
IVA	Tumor signal disrupts normal tissue planes with loss of low signal intensity of bladder or rectal wall
IVB	Tumor in distant organs or anatomic sites

contrast administration, there is early enhancement of endometrial cancer relative to the normal endometrium, allowing the identification of small tumors, even those contained by the endometrium. Contrast-enhanced images also differentiate viable tumor from necrosis, providing a more accurate assessment of tumor volume. Similarly, the distinction between tumor and endometrial fluid is obvious after gadolinium contrast administration; the former enhances, whereas the latter does not. The dynamic contrast-enhanced appearance of endometrial cancer has been described in a number of reports. Tumor conspicuity was more pronounced on dynamic enhanced images than on standard postcontrast T1W images, although the tumors themselves enhanced heterogeneously (109,113).

The MRI correlates of surgical FIGO subdivisions for stage I tumors have been described. Tumors are considered to be confined to the endometrium (stage IA) when the junctional zone is preserved. Alternatively, in cases without a visualized junctional zone, as is common in postmenopausal women, stage IA disease is characterized by a sharp tumor–myometrium interface. In stage IB disease, there is disruption of the junctional zone with an irregular myometrial–endometrial interface, and/or there is tumor of high T2W signal intensity in the inner half of the myometrium with preservation of the outer myometrium. In contradistinction, stage IC disease is characterized by high-T2W-signal-intensity tumor that extends into the outer myometrium with a thin, intact outer rim of normal myometrium.

Stage II tumors are characterized by widening and expansion of the cervical canal, with associated heterogeneity of the cervical stroma. Assessment of cervical involvement is facilitated by the multiplanar capabilities of MRI and dynamic contrast-enhanced sequences (Fig. 10.19) (82).

Extraserosal invasion (stage III) is depicted on T2W images as high-signal-intensity tumor extending beyond the outer uterine borders (80). Focal disruption of the normally low-signal-intensity wall of the bladder or rectum signifies stage IVA disease (66). Pathologically enlarged lymph nodes and metastatic disease are diagnosed in the usual fashion on MRI.

Reports of the overall MRI accuracy in staging of endometrial carcinoma range from 70% to 94% (39,80,81,114). Reports of accuracy in evaluation of myometrial invasion (stage I) on T2W images vary from 58% to 88% (80,81,113–117). Limitations of nonenhanced T2W-MRI staging of endometrial carcinoma include difficulty in differentiating tumor from some benign entities, difficulty in determining myometrial invasion in postmenopausal women with poorly defined or absent junctional zones, and difficulty in detecting extrauterine spread. High-resolution T2W images increase the conspicuity of the tumor–myometrial interface and the high soft-tissue contrast allows accurate determination of cervical involvement. And although there are single-institution studies of high-resolution T2W staging with a phased-array coil that report accuracy rates equal to those of dynamic contrast-enhanced imaging for the evaluation of myometrial and cervical invasion (118), to date these have not been reproduced in multi-institutional trials. Accuracy rates for the determination of cervical invasion using high-resolution T2W images are 82% to 91% (118,119).

These limitations have been at least partially overcome by the routine use of gadolinium contrast. Static contrast-enhanced MRI increases the accuracy of determining myometrial invasion to 68% to 78% (39,83,113,117,119). However, dynamic contrast-enhanced MRI is the best MRI technique for detection of myometrial invasion, with an accuracy of 85% to 93%, compared with 68% to 78% for static contrast-enhanced images and 58% to 88% for T2W images (72,113).

FIGURE 10.19. Stage II endometrial cancer on MRI. Sagittal T2W MRI image. The endometrial canal is expanded and contains heterogeneous signal (white asterisk). There is loss of the normal junctional zone along the posterior aspect of the uterus (white arrow); furthermore, the cervix is heterogeneous (grey arrow), compatible with tumor involvement.

Staging Endometrial Cancer Recommendations

Several studies suggest that MRI outperforms conventional CT in the assessment of depth of myometrial invasion (3). Two studies have reported that TVS is equivalent to T2W-MRI in evaluating myometrial invasion (68% to 69% vs. 68% to 74%) (116,117), but contrast-enhanced MRI is superior to TVS (85% vs. 68%) (117). A meta-analysis of studies showed significant differences in the accuracy of assessment of myometrial invasion among CT, TVS, and MRI. Contrast-enhanced MRI was significantly better than TVS and showed a trend toward better performance than CT (82). A follow-up meta-analysis and Bayesian analysis limited to detecting deep myometrial invasion also found contrast-enhanced MRI to be superior to other modalities (72).

Detecting Recurrent Endometrial Cancer

Endometrial cancer tends to recur locally in women treated with surgery alone. The most common site of local recurrence is the vaginal cuff. Because the vaginal cuff is amenable to physical examination in the majority of patients, imaging is usually reserved for problem solving in this group of patients. For patients who fail radiation therapy, either alone or in combination with surgery, recurrences tend to be distant disease. In these cases, CT or MRI is usually performed (Figs. 10.20 and 10.21). Detection of distant metastases by CT or MRI is performed in the usual fashion for these modalities.

FDG-PET has recently been evaluated for use in detecting recurrent endometrial carcinoma. In patients who are evaluated with FDG-PET after therapy, the sensitivity and specificity in detecting recurrent disease have been found to be 96% to 100% and 78% to 88%, respectively (120,121). Also, several studies have shown that FDG-PET in combination with anatomic imaging (CT and/or MRI) is more sensitive, specific, and accurate than anatomic imaging alone in detecting recurrent endometrial carcinoma (121,122).

Summary

In patients without a diagnosis of endometrial carcinoma, but with a clinical concern (e.g., postmenopausal bleeding), TVS is the study of choice. SHG, 3-D TVS, and 3-D SHg can also be helpful for primary detection of endometrial carcinoma.

The imaging evaluation of patients with known endometrial cancer is a function of physical examination, tumor type, and tumor stage. A chest radiograph is the only imaging study necessary in the majority of patients diagnosed with low-grade, clinical stage I tumor—that is, tumors that have a low pretest probability of extrauterine disease. However, TVS is also reasonable for estimating myometrial invasion in patients with a low pretest probability of myometrial involvement.

In patients with a high pretest probability of extrauterine disease (e.g., high tumor grade, aggressive cell type, suspicious physical examination, positive endocervical curettage, or elevated serum CA125), more extensive imaging is indicated. There is a growing body of evidence that dynamic contrast-enhanced MRI is more sensitive, specific, and accurate than CT and TVS in the staging of endometrial carcinoma. CT, however, remains an acceptable alternative. No studies to date have evaluated the utility of FDG-PET imaging in the staging of endometrial carcinoma. However, this is an area where FDG-PET may prove useful in the future.

For the detection of recurrent disease, FDG-PET combined with CT and/or MRI has preliminarily been shown to be superior to CT and/or MRI alone (120,121). However, because these studies involved only a small number of patients, more work in this area is needed and CT and/or MRI alone remains an acceptable alternative.

GESTATIONAL TROPHOBLASTIC DISEASE

Introduction

Gestational trophoblastic disease (GTD) encompasses a spectrum of placental lesions including hydatidiform mole, invasive mole, choriocarcinoma, and placental site trophoblastic tumor. The role of imaging in GTD is primarily to document metastatic disease or to evaluate for persistent disease. No specific imaging findings allow differentiation between the different GTD lesions (123–125).

Primary Detection, Characterization, Staging, and Monitoring for Recurrence of Gestational Trophoblastic Disease

Ultrasound

TVS is considered the study of choice in the evaluation of suspected GTD. In patients with GTD, TVS examination most commonly demonstrates a soft-tissue mass distending the endometrial cavity. Typically, the mass is echogenic and heterogeneous, containing numerous cystic spaces (Fig. 10.22A) (126–128). In the case of complete hydatidiform mole, the

FIGURE 10.21. Endometrial cancer recurrence on CT. Axial contrast-enhanced CT images through the lower chest (A) and pelvis (B) of the same patient. Images demonstrate lung nodules (white arrows in A) and a soft-tissue mass with osseous destruction (white arrow in B) both proven to be recurrent endometrial cancer.

small cystic spaces correspond to the hydropic villi (126). Hydropic degeneration of the placenta may have a similar US appearance. The mass is usually extremely vascular, demonstrating increased vessel density and an abnormal uterine arterial waveform characterized by high peak systolic velocity and high diastolic blood flow (low resistance index [RI]) compared to the normal uterine arterial waveform (129). Irregularity of the border of the mass or asymmetric extension of the mass into the myometrium suggests myometrial invasion.

The ovaries may become enlarged with numerous theca lutein cysts (Fig. 10.22C and D). This ovarian enlargement can result in symptomatic ovarian torsion or hemorrhage (130). However, theca lutein cysts may not be detected in the early stages of the disease (127).

US can be helpful in assessing for persistent or recurrent disease by documenting an endometrial mass. Persistent GTD can be treated with US-guided direct injection of methotrexate (131).

GTD is the most common cause of uterine vascular malformations. These vascular malformations usually present after treatment is complete and can be easily diagnosed with US. Recently, it has been shown that these vascular malformations can be treated with uterine artery embolization (132).

Computed Tomography

The role of CT in the evaluation of GTD is primarily limited to the detection of metastatic disease. Uterine enlargement is the most common CT feature of GTD. Following administration of intravenous contrast, uterine enhancement is typically heterogeneous with focal enlargement or irregular hypodense regions within the myometrium (Fig. 10.22B) (130,133). These low-attenuation areas correspond to foci of hemorrhage and/or necrosis (133). Contrast-enhanced CT often demonstrates vascular uterine lesions and dilated uterine vessels in the broad ligaments (130).

Locoregional spread is characterized by avidly enhancing soft-tissue nodules in the parametria and/or obliteration of the pelvic fat and/or muscle planes.

GTD spreads hematogenously, with the lungs being the most common site of metastatic disease. Metastases to the lung, liver, and brain are vascular and prone to hemorrhage (130). CT detects these metastatic lesions in the usual manner. Trophoblastic emboli to the lungs may produce symptoms of acute pulmonary embolism and occasionally result in large intravascular masses (130).

FIGURE 10.22. Hydatidiform mole on ultrasound and CT. Gray-scale sagittal ultrasound image of the uterus (A) demonstrating an echogenic, heterogeneous mass within the endometrial canal (white arrows in A). Axial contrast-enhanced CT image (B) in the same patient demonstrates enhancing soft-tissue displacing the endometrial canal (white arrow in B). Gray-scale ultrasound image (C) of the right ovary and contrast-enhanced CT image (D) through the pelvis in the same patient demonstrating bilaterally enlarged ovaries with innumerable theca lutein cysts (white arrows in C and D).

FIGURE 10.23. Partial mole on MR. Sagittal (A) and axial (B) T2W MRI images demonstrating a heterogeneous mass within the uterus (white arrows). Fetal abdomen (black arrow in A) and umbilical cord (black arrow in B) can be seen adjacent to the mass.

Magnetic Resonance Imaging

MRI is primarily used for staging and detecting recurrent disease. On T2W images, GTD is seen as a heterogeneous, predominantly high-signal-intensity mass that obliterates the normal uterine zonal anatomy (Fig. 10.23) (46). On T1W images, the mass may be isointense or hyperintense compared to the adjacent normal myometrium. The tumors are hypervascular, and enlarged vessels in the broad ligament and the uterus are depicted as signal voids on both T1W and T2W images. Following gadolinium contrast administration, the tumors avidly enhance and multiple enlarged vessels are often seen. MRI is able to depict tumors that invade the myometrium but spare the endometrium, a cause of nondiagnostic and/or false-negative D&Cs.

MRI is also useful in the identification of extrauterine pelvic spread to the parametria, adnexa, and vaginal fornices (46). Parametrial involvement is seen on MRI as high T2W signal masses within the parametria that avidly enhance after gadolinium contrast. MRI is better at detecting parametrial involvement than US. MRI is the preferred method for determining vaginal spread of tumor. Vaginal involvement is identified on MRI as a high-T2W-signal-intensity mass within the vagina with associated gadolinium contrast enhancement. Metastatic disease is usually hypervascular and is detected in the usual manner.

Another role of MRI is to monitor patients' response to therapy. MRI findings of regression of vascular abnormalities, development of intralesional hemorrhage, and return of normal uterine zonal anatomy parallel a favorable response to chemotherapy (46). Normal uterine zonal anatomy should be seen 6 to 9 months after treatment (46).

Positron Emission Tomography

Very little data is available in the use of FDG-PET with GTD. The little data that is available has shown that FDG-PET may be helpful in the detection of metastatic disease and recurrent disease. One recent study found that FDG-PET might be useful in the detection of metastatic disease (134). Another recent study demonstrated that FDG-PET plus CT was helpful in 43.8% of patients when compared with CT alone (135). More research into the use of FDG-PET is needed before the clinical utility of this modality is established.

Summary

Imaging plays an important, albeit limited, role in the evaluation of GTD. US, CT, and MRI all play a role in the evaluation of suspected and documented GTD. The limited data available on the use of FDG-PET in the setting of GTD suggest that this modality may be useful for the detection of metastatic disease and the evaluation of recurrent GTD.

OVARIAN CANCER

Introduction

The detection of early ovarian cancer is difficult for a variety of reasons and currently involves a combination of physical examination, CA125 levels, and TVS. At present, there is no screening strategy that reliably detects early ovarian cancer.

Because of this, ovarian cancer is often not diagnosed until it has spread to other organs. Two staging systems for ovarian cancer exist, the TNM (tumor, node, metastasis) system and the FIGO staging system. US, CT, MRI, and FDG-PET all have a role to play in the accurate staging of ovarian cancer. These modalities also play a role in the monitoring of therapy and detection of recurrent disease.

Primary Detection and Characterization of Ovarian Cancer

The 5-year survival rates for stage I and stage II ovarian cancer are 80% to 90% and 70%, respectively (136); however, the 5-year survival rate for stages III and IV ranges from 5% to 50%. Therefore, if more ovarian cancers were detected as stage I disease rather than stage III or IV disease, 5-year survival would dramatically improve. Unfortunately, there are no good screening methods for ovarian cancer at present; most use a combination of physical exam, CA125 levels, and TVS.

Ultrasound

US plays a crucial role in the detection and characterization of adnexal masses and is an important component of screening programs for women at high risk for ovarian carcinoma. US is the initial imaging modality of choice for characterizing an ovarian mass as benign or malignant.

The early diagnosis of ovarian carcinoma when cure is possible but tumors are clinically asymptomatic (silent) is made difficult by the low prevalence of ovarian carcinoma in the general population. Therefore, efforts at screening patients for ovarian carcinoma have focused on high-risk populations. Risk factors include older age, high socioeconomic status, factors that increase the number of ovulatory cycles such as early menarche, nulliparity, late-onset menopause, and having a first-degree relative with ovarian carcinoma (137,138). Approximately 10% of ovarian carcinomas are believed to be due to an inherited susceptibility. Three syndromes have been described: the breast/ovarian cancer syndrome; the Lynch 2 syndrome, or the hereditary nonpolyposis colorectal cancer syndrome; and hereditary site-specific ovarian cancer. In 1994, a National Institutes of Health (NIH) consensus conference (139) recommended that screening be offered to women with two or more first-degree relatives with ovarian carcinoma. It is also recommended that women with an inherited predisposition to ovarian cancer be screened (139,140). In practice, many women with a single first-degree relative are enrolled in screening programs.

Most screening programs for ovarian cancer rely on a combination of physical examination, serologic markers, and TVS. The results of these screening trials have consistently demonstrated that US detects more stage I ovarian carcinomas than CA125 levels and physical examination (141). Nonetheless, very few stage I carcinomas have been found in such screening programs (142). The most recent data from the Prostate, Lung, Colorectal, and Ovarian (PLCO) Cancer Screening Trial (143) demonstrated that the PPV value for invasive cancer was 1.0% for an abnormal TVS, 3.7% for an abnormal CA125, and 23.5% if both tests (CA125 and TVS) were abnormal. Only one study has demonstrated ovarian cancer screening trials to have a survival benefit. Van Nagell et al. (144) reported a decrease in case-specific ovarian cancer mortality with 89.9% 2-year and 77.2% 5-year survival in women with US-detected ovarian carcinoma.

Ultrasound is considered the initial imaging modality of choice to differentiate a benign from a malignant clinically suspected ovarian mass. Although a likely benign mass can be

followed or removed by a general gynecologist, suspicion of a malignant ovarian mass initiates referral to a gynecologic oncologist who can better perform the more complex therapeutic and staging cytoreduction surgery for ovarian carcinoma. Morphologic features remain the primary criteria for differentiating complex ovarian masses as benign or malignant on US. Hence, TVS is the critical US imaging approach because of the improved spatial and soft-tissue resolution afforded by the higher frequency endovaginal probe. Nonetheless, transabdominal ultrasound remains an important, complementary component of the US examination when a larger field of view is required—for example, if a mass is displaced out of the pelvis or is so large that it is incompletely visualized by TVS. In addition, transabdominal imaging is required for evaluation of secondary findings in ovarian cancer, such as ascites, peritoneal implants, or hydronephrosis. Such findings can be important not only to confirm the impression of malignancy but also for staging.

Numerous studies have reported that when strict US criteria and a pattern recognition approach for identification of benign ovarian masses are used, US examination has a near 95% to 99% NPV in excluding malignancy (145–147). US features consistent with benign etiology include smooth, thin walls; few, thin septations; absence of solid components or mural nodularity; as well as pattern recognition for certain benign diagnoses. Simple cysts will be anechoic with a smooth, thin wall and posterior acoustic enhancement. Hemorrhagic cysts or endometriomas (Fig. 10.24) may contain uniform low-level echoes but should still demonstrate a smooth, thin wall and increased through transmission. Hemorrhagic cysts may contain complex internal echoes; however, the appearance of the internal echoes should change over time and should never demonstrate internal vascularity. Several US patterns associated with dermoid cysts have been described including uniform increased echogenicity with posterior acoustic attenuation, echogenic shadowing mural nodules, and layering with or without floating debris.

Conversely, mural nodules, mural thickening or irregularity, solid components, thick septations (>3 mm) (Fig. 10.25), and associated findings such as ascites, peritoneal implants, and/or hydronephrosis suggest malignancy. Such US descriptors have been reported to have a high sensitivity but lower specificity for malignancy (144,146,147). The lower specificity reflects overlap in the imaging appearance of benign, borderline, and malignant lesions. For example, benign lesions such as hemorrhagic cysts, cystadenomas, or cystadenofibromas may have thick septations and apparent mural nodules; borderline

FIGURE 10.24. Endometrioma. Gray-scale ultrasound image demonstrating uniform low-level internal echoes (white asterisk) and increased through transmission (black asterisk).

FIGURE 10.25. Solid and cystic ovarian mass on ultrasound. Gray-scale (A) and color Doppler (B) images demonstrate a mostly cystic mass (white arrows) with an associated solid component (grey arrows). Note the internal flow within the solid components (black arrow in B).

tumors may have minimal findings; and Brenner's tumors, fibromas, and fibrothecomas are solid but benign (Fig. 10.26). Furthermore, pedunculated fibroids, dermoids, and endometriomas can masquerade as solid ovarian lesions.

The use of color and pulse Doppler in the evaluation of ovarian masses is controversial, with some investigators considering blood flow characteristics to be merely confirmatory but others considering the Doppler examination to be a helpful discriminator (148–150). Tumor neovascularity is known to be characterized by an increased number of often tortuous vessels with arteriovenous shunts. Malignant neovascularity lacks the normal amount of smooth muscle cells in the vessel walls. Researchers had hoped that Doppler evaluation, which could potentially assess vascular compliance or resistance as well as vessel morphology, density, and distribution, would be helpful in characterizing ovarian masses. Malignant lesions more often demonstrate increased vessel density and tortuosity than benign lesions, but significant overlap exists. Malignant ovarian lesions also tend to demonstrate higher peak systolic velocities and lower resistive indices than benign masses, but again, considerable overlap exists and no discriminatory cut-off values are accepted (148–150).

Three-dimensional US is a new imaging technique that may improve characterization of adnexal masses. In one early

study of 71 pelvic masses, 3-D power Doppler US improved the specificity and PPV compared to conventional 2-D US from 54% to 75% and from 35% to 50%, respectively (151). Further research is needed with this technique to better define its role in the characterization of adnexal masses.

Scoring systems have been proposed to standardize evaluation of ovarian masses in an attempt to improve specificity (152,153). Using a stepwise logistic regression analysis to determine the most discriminating gray-scale and Doppler sonographic features of malignancy, Brown et al. (153) reported that a multiparameter approach, which assessed for nonhyperechoic solid components, central blood flow on color Doppler, ascites, and thick septations, had a 93% sensitivity and specificity for malignancy. To achieve 100% sensitivity, specificity dropped to 86% in this study (153). However, Timmerman et al. (154) have reported similar findings and interobserver variability when readers used subjective criteria for evaluating ovarian masses.

Computed Tomography

CT is not the study of choice to evaluate a suspected ovarian lesion; however, ovarian lesions are detected incidentally on CT and can be characterized. In studies of adnexal lesions, the

FIGURE 10.26. Ovarian fibroma. Gray-scale ultrasound (A) and axial CT (B) images. On ultrasound (A), the lesion is a solid mass (white asterisk) with homogeneous decreased echogenicity with associated dark shadowing (white arrow). A CT scan (B) of the same patient demonstrates a solid homogeneous left adnexal mass (black arrow).

FIGURE 10.27. Poorly differentiated ovarian carcinoma on CT. Axial contrast-enhanced CT image demonstrating an adnexal mass with both solid (black arrow) and cystic (white arrow) components.

sensitivity, specificity, and accuracy of CT for characterizing benign versus malignant lesions are reported to be 89%, 96% to 99%, and 92% to 94%, respectively (155,156).

On CT, ovarian cancer demonstrates varied morphologic patterns, including a multilocular cyst with thick internal septations and solid mural or septal components, a partially cystic and solid mass, and a lobulated, papillary solid mass (Fig. 10.27). The outer border of the mass may be irregular and poorly defined, and amorphous, coarse calcifications and contrast enhancement may be seen in the cyst wall or soft-tissue components. Since the CT appearance of ovarian metastases is indistinguishable from a primary ovarian neoplasm, the stomach and colon should be carefully examined as potential primary tumor sites when an ovarian mass is detected on CT (157).

Magnetic Resonance Imaging

MRI functions as a complementary exam to US in the evaluation of a suspected ovarian lesion. To optimize MRI detection and characterization of an adnexal mass, contrast-enhanced protocols and attention to eliminating, or at least limiting, bowel motion are needed. Additionally, imaging should be performed with a phased-array surface coil to maximize spatial resolution.

Primary and ancillary criteria have been proposed for the characterization of an adnexal mass as being malignant. In a study of 60 lesions (158), statistical analyses yielded the following five significant primary criteria for malignancy: size greater than 4 cm, solid mass or large solid component, wall thickness greater than 3 mm, septal thickness greater than 3 mm, and/or the presence of vegetations or nodularity and necrosis (Fig. 10.28). Four ancillary criteria of malignancy were also statistically formulated: involvement of pelvic organs or pelvic sidewall; peritoneal, mesenteric, or omental disease; ascites; and adenopathy. When gadolinium contrast-enhanced T1W and unenhanced T1W and T2W images were analyzed collectively, the presence of one or more of the five primary criteria, coupled with a single criterion from the ancillary group, correctly characterized 95% of malignant lesions (158). These rates reflect improvements in lesion characterization produced by the addition of gadolinium contrast to the protocol and have been reproduced in other studies (159,160).

As with CT, disease metastatic to the ovary is often indistinguishable from primary ovarian cancer on MRI scans and both the colon and the stomach should be examined as potential primary tumor sites if an ovarian mass is detected on MRI (157,161).

Ovarian masses at times can grow large and it can be difficult to determine the organ of origin on US and/or CT. Uterine fibroids and other pelvic masses can also grow to a large size and mimic an ovarian tumor. The multiplanar capabilities of MRI are helpful in this situation and often help to delineate the organ of origin of a large pelvic mass.

FIGURE 10.28. Solid and cystic ovarian mass on MR. Sagittal T2W (A) and T1W contrast-enhanced fat-saturated (B) images. The cystic components are high signal on the T2W image (black asterisk) and do not enhance on the T1W post-contrast fat-saturated image (white asterisk). Abnormally thickened wall is intermediate signal on the T2W image (black arrow) and enhances post contrast (white arrow).

Positron Emission Tomography

FDG-PET has little clinical role in the primary detection of a pelvic mass. However, FDG-PET appears to be promising for the characterization of ovarian masses because of its potential to detect tumor prior to significant morphologic changes. This is important, as currently most patients with ovarian cancer present late in their disease owing to a lack of early clinical or imaging manifestations. A study by Hubner et al. (162) found good correlation between FDG-PET and histologic findings in women with suspected ovarian cancer imaged prior to laparotomy. Specifically, the sensitivity, specificity, accuracy, PPV, and NPV of FDG-PET were 83%, 80%, 82%, 86%, and 76%, respectively. A recent study found that PET-CT imaging had a sensitivity of 100% and a specificity of 92.5% for the detection of a malignant mass (163).

Recommendations for Primary Detection and Characterization of Ovarian Cancer

Several studies have compared MRI to CT and US for characterizing adnexal masses, with mixed results (159,164,165). One study found that low-field-strength MRI was equivalent to CT for this determination, with accuracies of 86% and 92%, respectively (156). Another study suggested that TVS was superior to unenhanced MRI for lesion characterization (166), and yet another study found that the specificity of MRI with intravenous contrast was higher than that of TVS (97% vs. 69%) (164). Both TVS and MRI with gadolinium contrast have high sensitivity (97% and 100%, respectively) in the identification of solid components within an adnexal mass. MRI, however, shows higher specificity (98% vs. 46%) (165). Furthermore, MRI was shown to be the most efficient second test when an indeterminate ovarian mass was detected at gray-scale US and provides the greatest change in posttest probability when compared to combined color and gray-scale US and CT (167).

At present, the relatively high cost of MRI precludes its use as a screening modality, and US should be used for this indication. However, MRI is most appropriately used for characterization of an adnexal lesion in cases where US and clinical examination are indeterminate (7,167). Further research is necessary to determine the role of FDG-PET and/or PET-CT in the primary detection and characterization of adnexal masses.

Staging Ovarian Cancer

Cross-sectional imaging is widely accepted and more commonly used in the evaluation and staging of ovarian carcinoma than for other gynecologic malignancies. Two staging systems exist for ovarian cancer: the TNM system and the FIGO system. The FIGO system is surgically based and is the more frequently used of the two systems, and it will be the staging system referred to in the remainder of this chapter. Imaging is an adjunct to surgical staging. It is useful in the detection of pathologic adenopathy, the presence of which may alter staging and therapy. Although barium enema and excretory urography are still performed at some institutions, these studies are not recommended as routine staging procedures (168).

Ultrasound

US has a limited role in the staging of ovarian cancer except for detecting the presence of ascites. Transabdominal US is an excellent modality not only for identifying ascites, but for guiding paracentesis as well. However, the detection of stage II and III disease by US is limited. Peritoneal implants can sometimes be documented on careful US examination. The specificity of US examination in documenting abdominal spread of disease has been reported to be slightly higher than that of CT

or MRI (169). However, the sensitivity of US for the detection of implants less than 2 cm (stage IIIB) is lower than that of CT or MRI owing to a limited field of view and decreased spatial and soft-tissue resolution (169,170). US, therefore, should only be used for specific indications.

Computed Tomography

CT is the primary cross-sectional imaging modality used to stage ovarian cancer. For this indication, CT should be performed with both oral and IV contrast. Opacification of the bowel with oral contrast is crucial for the detection of peritoneal implants on CT.

Stage I ovarian cancer is limited to either one (stage IA) or both (stage IB) ovaries. The presence of malignant ascites with tumor confined to one or both ovaries is stage IC disease. Ascites on CT is easily identified; however, the distinction between stage IC and stage III, or peritoneal, disease is often difficult to make and has significant clinical implications. In one series of patients, the presence of ascites on CT had a PPV of 72% to 80% as a sign of peritoneal metastasis (171).

Stage II disease occurs when there is direct extension into or implants on the uterus and/or fallopian tubes (stage IIA) or the rectum, bladder, and/or peritoneum (stage IIB). The presence of stage IIA or IIB disease with malignant ascites is stage IIC disease (Fig. 10.29). Irregularity or obliteration of the fat plane between the uterus and the ovarian mass indicates stage IIA disease. Loss of the normal fat plane around the rectum or bladder, less than 3 mm between the tumor and the pelvic sidewall, and/or displacement or encasement of the iliac vessels indicates stage IIB disease (172).

Stage III disease is defined as the presence of extra-pelvic peritoneal and/or lymph node metastasis. Microscopic extra-pelvic peritoneal implants are stage IIIA disease and are not detectable with CT. Stage IIIB, extra-pelvic peritoneal implants less than 2 cm and stage IIIC (Fig. 10.30), extra-pelvic peritoneal implants larger than 2 cm or lymph node metastasis are sometimes detectable with CT.

CT detection of peritoneal implants depends on several factors including location, the presence or absence of surrounding ascites, and size. The three sites most commonly involved are the right subphrenic space, the greater omentum,

FIGURE 10.29. Stage IIC serous papillary ovarian carcinoma. Axial CT image with oral and intravenous contrast. Obliteration of the fat plane between the solid and cystic ovarian mass (black arrow) and uterus (white arrow). Note fluid in the endometrial canal (black asterisk) secondary to obstruction. Ascites (white asterisk) is also present.

FIGURE 10.30. Stage IIIC serous papillary ovarian carcinoma. Axial CT images with oral and IV contrast (A–C). Images demonstrate bilateral ovarian solid and cystic masses (black arrows in A), omental (white arrow in B), subcapsular liver (black arrow in C) and splenic (white arrow in C) implants, and ascites (white asterisk in A–C).

and the pouch of Douglas (173). The presence of surrounding ascites aids in the detection of small peritoneal implants by increasing their conspicuity. In addition, the presence of ascites on CT is suggestive of peritoneal spread, as previously discussed. Size plays an important role in the reliable detection of peritoneal implants. Peritoneal implants smaller than 1 cm are not consistently detected on CT, especially in the absence of ascites, with a sensitivity of only 14% to 27% in this situation (172,174). However, the use of coronal and sagittal reformatted images allows for better detection of smaller lesions and has the potential to improve the sensitivity of CT (175).

Mesenteric metastases appear on CT scans as either round or ill-defined soft-tissue masses surrounded by small-bowel loops and mesenteric fat, or as thickened leaves of the mesentery caused by tumor coating the peritoneal surfaces. Omental metastases are characterized as stranding or soft tissue nodules embedded in omental fat or the replacement of the omental fat with thick, nodular tumor (“omental cake”) along the greater curvature of the stomach, in the gastrosplenic ligament, or

anterior to the transverse colon and small bowel in the lower abdomen (Fig. 10.31) (176). The sensitivity of CT for detection of omental metastasis is reported to be 80% to 86% (172,174). Capsular implants on the surface of the liver are seen as soft-tissue nodules studded along the peritoneal surface of the liver. Prominent hematogenous spread to the liver can occur in ovarian cancer and is considered stage IV disease, but it is unusual and should raise the suspicion for a gastrointestinal primary tumor.

Lymph node metastases are defined by a size criterion on CT as having a short axis greater than 1 cm. As with other malignancies, this criterion is flawed, as it does not take into account microspread of tumor.

Stage IV disease is defined as liver parenchymal metastasis and/or disease outside the peritoneal cavity (lung, bone, brain, etc.). These findings are diagnosed on CT in the usual manner.

The sensitivity of CT for the detection of extrapelvic disease is approximately 95% to 100% for liver involvement and 50% to 60% for nodal involvement (172,174). Overall staging

FIGURE 10.31. Omental implants on CT. Axial CT image through the lower abdomen demonstrating omental caking (arrows).

accuracy for CT has been reported to be 77% (172). CT also has a high PPV for imaging bulky disease and is therefore useful for identifying patients with inoperable disease (172,174).

Magnetic Resonance Imaging

Although CT is the primary cross-sectional imaging modality used to stage ovarian cancer, MRI can be useful in certain situations (contrast allergy, renal failure, etc.). In fact, the overall staging accuracy of MRI in patients with ovarian malignancy is 75% to 78% (158,172), which is comparable to that of CT.

Stage II disease, direct extension into or implants on the uterus and/or fallopian tubes (stage IIA) or the rectum, bladder, and/or peritoneum (stage IIB), is well depicted on MRI. Invasion is characterized by a tumor/normal structure interface of greater than 90% or direct soft-tissue extension with irregular margins into the adjacent structure. Accuracy ranges from 70% to 94% for the assessment of spread of ovarian tumor to the uterus, bladder, rectum, and pelvic sidewall (172).

Depiction of stage III disease on MRI is aided by the use of T1W fat-suppressed gadolinium contrast-enhanced sequences. T1W fat-suppressed contrast-enhanced sequences are used to depict intra-abdominal disease (i.e., omental, peritoneal, and mesenteric metastases), which enhance and have high-signal intensity contrasting with the low signal intensity of intra-abdominal fat. This technique makes lesions as small as 1 cm conspicuous (159).

Stage IV disease is diagnosed in the usual manner on MRI.

Positron Emission Tomography

The role of FDG-PET in the initial staging of ovarian cancer is controversial. However, at least one study has demonstrated FDG-PET to be a useful adjunct in the initial staging of ovarian cancer. In this recent study, the addition of FDG-PET imaging to CT alone increased staging accuracy from 79% to 81% within the pelvis and from 85% to 93% outside the pelvis (177).

Staging Recommendations

CT is the primary modality for staging ovarian cancer. The few prospective studies comparing CT and MRI found that MRI was at least equivalent and, in some cases, superior to CT for showing the relationship between tumor and adjacent pelvic structures and delineating the intra-abdominal extent of disease (159). The use of MRI, however, is limited by longer exam time, limited availability, expense, and lack of widespread reader experience. US has limited usefulness in the

staging of ovarian cancer, but can be helpful in specific circumstances such as identifying ascites or guiding paracentesis. The use of FDG-PET for the initial staging of ovarian cancer is controversial. Further research is needed to determine the appropriate role for FDG-PET in this situation.

Detecting Persistent or Recurrent Ovarian Cancer

Imaging, especially US and CT, has been used to detect persistent or recurrent ovarian cancer and to document tumor response to subsequent therapy. Recently, FDG-PET has been shown to be valuable for the detection of recurrent disease.

Ultrasound

US plays a limited role in the detection of recurrent ovarian cancer. US has the greatest sensitivity in detecting recurrent tumor in the pelvis or around the liver and right hemidiaphragm in the setting of ascites (178). However, the sensitivity of US in detecting microscopic disease, miliary peritoneal seeding, and macroscopic disease less than 2 cm of the peritoneum and/or omentum is poor (178,179). Additionally, small, plaque-like lesions on the pelvic peritoneum or lesions high in the false pelvis are often missed on US (179). Therefore, US is not sufficient to replace second-look laparotomy (which is still performed in some centers) in making patient-management decisions (178). Despite these limitations, US can reliably confirm a clinical suspicion of gross macroscopic recurrent disease (Figs. 10.32 and 10.33) and is more accurate than clinical examination (178,179). US can also be used to guide biopsy of areas of suspected recurrence.

Computed Tomography

CT is the most commonly used cross-sectional imaging modality for the detection of recurrent ovarian cancer (Figs. 10.34 and 10.35). Although the use of CT allows assessment of more potential sites of tumor recurrence than US, it too has significant limitations. In the detection of persistent or recurrent ovarian cancer, the sensitivity of conventional CT is 51% to 84% and its specificity is 81% to 93% (180–183). False-positive results are usually caused by misdiagnosis of adherent bowel loops as a tumor mass. The sensitivity of CT for disease detection is proportional to lesion size (180). Many studies report limitations in the detection of small (1- to 3-cm) tumor nodules in the mesentery and omentum, and along peritoneal surfaces (180,181). However, the use of sagittal and coronal reformatted images improves the detection of peritoneal implants (175). Nevertheless, a negative CT does not exclude microscopic disease or small tumor implants and thus cannot substitute for second-look laparotomy in some patient populations (180,181,183). Serum levels of the tumor-specific antigen CA125 and FDG-PET can help to differentiate patients with small-volume disease and a false-negative CT from those with a true negative CT (181).

If recurrent ovarian cancer is detected by CT, determination of nonresectability is an important next step. Currently, there is no consensus on CT criteria that determine nonresectability. However, in a recent study, Funt et al. (184) determined that hydronephrosis and invasion of the pelvic sidewall were most indicative of tumor nonresectability. CT-guided biopsy can be used to confirm suspected recurrence (181).

Magnetic Resonance Imaging

MRI can be useful for the detection of recurrent disease, especially in patients unable to undergo CT (due to contrast allergy, renal failure, etc.) (Figs. 10.36 and 10.37). Few studies

FIGURE 10.32. Ovarian cancer recurrence on ultrasound. Gray-scale images from two different patients demonstrating recurrence at the vaginal cuff. Image (A) shows a solid mass (white arrow) arising from the right side of the vaginal cuff (black arrow). Image (B) shows a solid and cystic mass (white arrow) arising from the left side of the vaginal cuff (grey arrow). Note the full bladder in image (B) (asterisk).

have compared MRI to second-look laparotomy. In the largest series to date, gadolinium contrast-enhanced MRI detected residual tumor in women treated for ovarian cancer with accuracy, PPV, and NPV that were comparable to those of laparotomy (185). Reports from another study, using recurrent tumor size greater than 2 cm as a criterion for inoperability, suggest that the accuracy of MRI is 82% for identification of patients who would not benefit from second-look surgery. The accuracy rate decreased to 38%, however, for lesions less than 2 cm in size (186).

Positron Emission Tomography

Although CT and MRI are the most commonly used imaging modalities for the detection of recurrence, they are both limited in the detection of disease smaller than 2 cm, as discussed above. FDG-PET has been shown to be an extremely useful adjunct in the evaluation of recurrent ovarian cancer (Fig. 10.38). A recent study by Torizuka et al. (187) concluded that FDG-PET is more accurate than conventional imaging (i.e., CT/MRI) with sensitivity, specificity, and accuracy of 80%, 100%, and 84%, respectively, compared to 55%, 100%, and 64% for conventional imaging alone. Studies have also demonstrated

that the sensitivity, specificity, and accuracy of conventional imaging increase from 73%–76% to 83%–92%, 75%–83% to 92%–100%, and 73%–74% to 86%–94%, respectively, with the addition of FDG-PET (188,189).

Recommendations for Detecting Persistent or Recurrent Ovarian Cancer

When disease recurrence is suspected, complete abdominal-pelvic evaluation with conventional imaging is advised. Both contrast-enhanced CT and MRI offer a comprehensive examination, albeit one that is limited in its detection of small tumor nodules. Both have comparable sensitivity, specificity, and accuracy (183). The additional use of FDG-PET has been shown to be extremely useful in this situation and should be considered as an adjunct to, rather than a replacement for, conventional imaging.

Summary

A large number of factors make the early detection of ovarian cancer difficult. Furthermore, results from screening trials have been disappointing with few early ovarian cancers

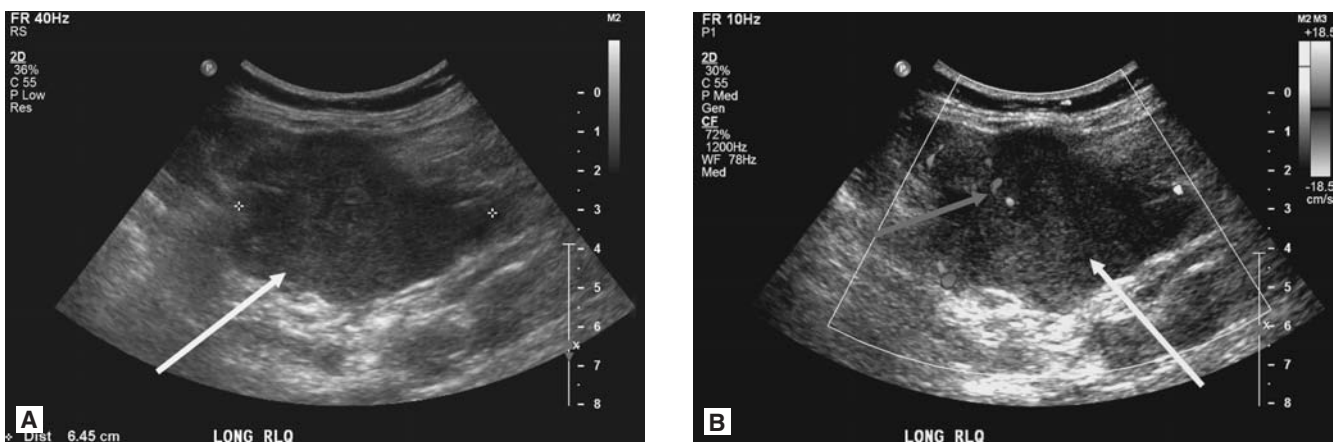

FIGURE 10.33. Ovarian cancer recurrence on ultrasound. Patient presented with a palpable right lower quadrant lesion and a history of ovarian cancer. Gray-scale (A) and color Doppler (B) images demonstrate a solid mass (white arrow) with internal flow (grey arrow) that proved to be recurrent ovarian cancer.

FIGURE 10.34. Ovarian cancer recurrence on CT. Solid and cystic mass (white arrow) along the left side of the vaginal cuff (black arrow).

detected. Therefore, most ovarian cancers are not detected until they are at an advanced stage. US is the study of choice for the primary detection and characterization of a suspected ovarian mass. Contrast-enhanced MRI is valuable in cases where an adnexal mass is suspected but US is indeterminate (167). CT and MRI are both useful for the initial staging of ovarian cancer. Initial research into the use of FDG-PET for the initial staging of ovarian cancer is promising, but more work in this area is needed. For the detection of recurrent ovarian cancer, a combination of conventional imaging, CT or MRI, and FDG-PET appears to be the most beneficial. New techniques, such as dual time point FDG-PET imaging, are currently being investigated. Preliminary data indicate that this technique may help to distinguish benign processes, especially inflammatory ones, from malignant lesions (190), but further research is required.

FIGURE 10.35. Recurrent ovarian cancer on CT. Contrast-enhanced CT images in a patient with a remote history of ovarian cancer. Soft-tissue nodularity within the mesentery (white arrow in A) and cystic mass (white arrow in B) adjacent to the iliac vessels (black arrow in B) are recurrent ovarian cancer.

VAGINAL CANCER

Vaginal cancer is most often diagnosed and staged clinically. Diagnostic imaging is often performed only for the detection of pelvic adenopathy or metastatic disease.

There is virtually no role for diagnostic imaging in the primary detection and characterization of vaginal cancer. On MRI, vaginal tumors appear isointense on T1W sequences and may only be apparent if they alter the vaginal contour (66). On T2W sequences, a vaginal tumor appears as an intermediate- to high-signal-intensity soft-tissue mass.

Staging of vaginal cancer is most often clinical; however, MRI has a limited role in the staging of vaginal cancer. MRI criteria that correlate to the FIGO staging scheme have been developed. Stage I disease is defined as tumor that has invaded the epithelium but is confined to the vaginal mucosa. These lesions may be occult on MRI, or there may be abnormal high T2W signal penetrating the vaginal wall. The surrounding perivaginal fat is preserved.

Vaginal tumor that has invaded the paravaginal tissues but does not involve the pelvic sidewall is considered stage II disease. With stage II disease, the normally high-T2W-signal paravaginal fat is invaded by intermediate-signal tumor.

Tumor that extends to involve the pelvic sidewall and/or pelvic adenopathy defines stage III disease. Tumor contiguous with the levator ani, obturator internus, or the piriformis muscle is diagnostic of pelvic sidewall invasion. Pelvic adenopathy is diagnosed in the usual manner on MRI.

Stage IV is defined as tumor invading the bladder and/or rectum and/or extrapelvic spread of disease. MRI is particularly well suited for imaging stage IV disease because of its multiplanar capabilities. Invasion of the bladder and/or rectum is diagnosed by identifying disruption of the normal high-T2W-signal mucosa of the bladder and/or rectum. Extrapelvic metastases are diagnosed in the usual manner.

Although these staging criteria have been developed, care must be taken when using MRI for the evaluation of vaginal cancer. It has been shown that inflammatory changes and/or congestion of the vagina may appear similar to carcinoma (60).

FIGURE 10.36. Ovarian cancer recurrence on MRI. Axial T2W (A) and T1W post-contrast fat-saturated (B) images. Images demonstrate a solid and cystic enhancing mass in the right pelvis (arrows).

CT and US have little role in the staging of vaginal cancer, although CT can be used for the detection of pelvic adenopathy.

Complications from vaginal cancer and/or vaginal cancer treatment can be imaged with US, CT, and/or MRI depending on the clinical concern. Known complications include fistulae, fluid collections, and post-radiation therapy colitis. Fistulae are best diagnosed with contrast-enhanced CT or MRI.

Very little data is available on the utility of FDG-PET with vaginal cancer. However, a recent study demonstrated that FDG-PET was superior to CT in the detection of the primary tumor and pelvic adenopathy in patients with vaginal cancer (191). While more research is needed in this area, this research is promising.

Summary

Overall, diagnostic imaging plays a limited and directed role in the evaluation of vaginal cancer. Although preliminary results of FDG-PET and vaginal cancer are promising, more research is needed before this modality is used clinically.

VULVAR CANCER

Vulvar cancer is diagnosed and staged clinically. Diagnostic imaging is limited to searching for deep pelvic adenopathy in patients with known inguinal lymph node metastasis. Lymph node status plays an important role in the staging, treatment, and prognosis of patients with vulvar cancer. However, to date no imaging modality has been shown to be adequate in the evaluation of deep pelvic adenopathy in patients with vulvar cancer.

There is no role for diagnostic imaging in the primary detection and characterization of vulvar cancer. Vulvar cancer appears on US as a soft-tissue mass with internal vascularity (Fig. 10.39). On CT, vulvar cancer appears as a nonspecific soft-tissue mass. On MRI, this type of cancer demonstrates intermediate signal intensity on T1W sequences and high signal intensity on T2W sequences.

In select cases, CT and MRI may be used to evaluate for tumor extension into adjacent structures (i.e., urethra) (85). MRI may also be used to differentiate recurrence from post-therapy

FIGURE 10.37. Recurrent papillary ovarian carcinoma at the vaginal cuff on MRI. Sagittal T2W (A) and axial T1W post-contrast fat-saturated (B) images. Images demonstrate a solid and cystic enhancing mass (white arrow) at the vaginal cuff (grey arrow).

FIGURE 10.38. Recurrent ovarian carcinoma on FDG-PET. FDG-PET image (A), noncontrast CT image (B), and fused PET-CT images demonstrating an area of focal increased activity in the right pelvis (arrow in A) corresponding to soft-tissue density on CT (arrow in B). Fused PET-CT image demonstrates that the focal increased activity definitely corresponds to the focal soft-tissue density (arrow in C).

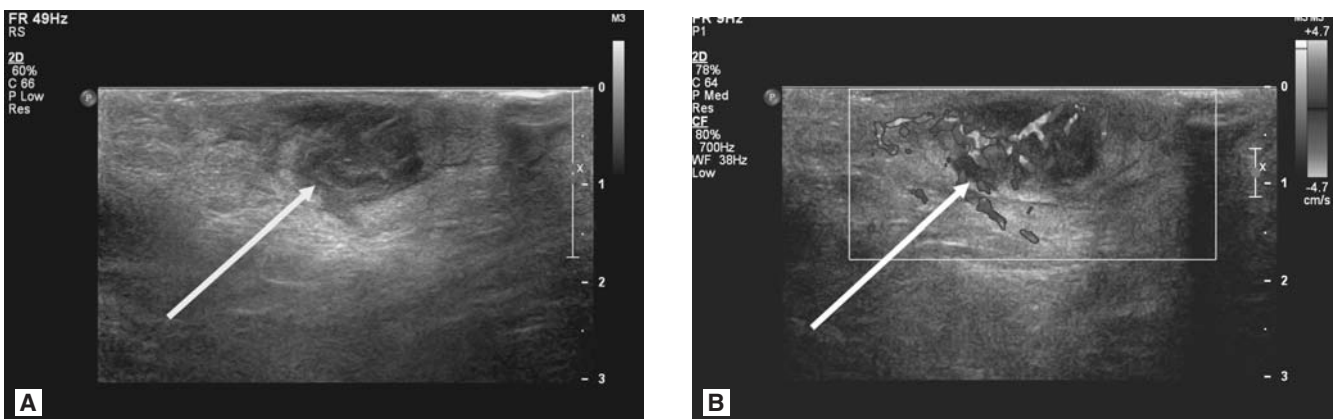

FIGURE 10.39. Vulvar mass on ultrasound. Gray-scale (A) and color Doppler (B, *See color plate section*) images demonstrating a hypoechoic solid vulvar mass with internal flow (arrow).

changes, with the former demonstrating high signal intensity on T2W images and the latter demonstrating intermediate signal intensity on T2W sequences.

Pelvic adenopathy in vulvar cancer is usually diagnosed by surgical lymph node dissection. US combined with fine-needle aspiration biopsy (FNA) has recently been shown to influence surgical management with sensitivity, specificity, NPV, and PPV of 80%, 100%, 93%, and 100%, respectively (192).

Very little research has been done on the use of FDG-PET for vulvar cancer. In one recent study, the detection of pelvic adenopathy with FDG-PET was evaluated. FDG-PET had a sensitivity of 80%, specificity of 90%, PPV of 80%, and NPV of 90% in the detection of pelvic adenopathy (193). Although these results are promising, more research in this area is needed.

Summary

Diagnostic imaging is not routinely used in the management of patients with vulvar cancer. Recent research, however, has shown that US combined with FNA may be useful for evaluating pelvic adenopathy (192). The utility of FDG-PET for vulvar cancer appears promising.

CONCLUSION

Increased use of CT and MRI for staging gynecologic pelvic malignancies has led to a significant decline in the use of conventional and invasive radiologic studies such as intravenous urography and barium enema. In addition, transabdominal US is no longer used for primary gynecologic cancer staging. TVS, however, in conjunction with Doppler US, is helpful in characterizing ovarian and endometrial masses, with TRUS being reserved for evaluating cervical cancer.

CT maintains a high-profile role in pelvic imaging because of its lower cost, high spatial resolution, fast examination time, and wide availability. It ably detects adenopathy and guides percutaneous biopsy of metastases and recurrent tumor. CT has been proven useful for the staging of ovarian cancer, cervical cancer, endometrial cancer, and GTD, and for the evaluation of recurrent pelvic malignancies.

MRI has been gaining favor for gynecologic pelvic cancer staging because of its superb soft-tissue contrast and multiplanar imaging capabilities. It also has advantages over CT for patients allergic to iodinated intravenous contrast or with impaired renal function. Early reservations about MRI, vis-à-vis long scanning times and lack of oral contrast, no longer apply. MRI shows excellent soft-tissue contrast between tumor, cervical stroma, endometrium, myometrium, uterine ligaments, parametrial fat, and blood vessels. Most comparative studies show MRI to have advantages over CT and US in the local staging of cervical and endometrial cancers. MRI is also useful for the detection of recurrent cervical cancer and the staging of GTD.

FDG-PET and PET-CT are increasingly being used to evaluate gynecologic malignancies. Studies have shown the utility of FDG-PET in the detection of recurrent ovarian, cervical, and endometrial cancer. Also, FDG-PET may be useful in the staging of cervical cancer. Further research in this area will help define the clinical role of FDG-PET in the evaluation of gynecologic malignancies.

FUTURE DIRECTIONS

Future innovations in gynecologic oncology imaging will go beyond anatomy to focus on function. Specifically, functional imaging aims to provide *in vivo* cellular characterization and,

ultimately, biologic signatures for both premalignant and malignant conditions. Functional technologies range in maturity: (a) reasonably established (e.g., MRI spectroscopy), (b) less well developed (e.g., MRI with ultrasmall superparamagnetic iron oxide [USPIO] particles), and (c) nascent technologies (e.g., electron paramagnetic resonance imaging [EPRI]). These technologies will likely have a twofold impact on cancer incidence and mortality by allowing (a) improvements in existing methods (e.g., use of USPIO particles as a supplement to routine MRI imaging) and (b) development of new approaches to detect early or preinvasive cancers that traditionally have low survival rates and no proven early-detection algorithms (e.g., optical coherence tomography for surface epithelial ovarian cancer) (194).

Advances in functional imaging raise issues in data management and display. Image fusion, which marries anatomic and functional data, coupled with soft-copy display, will provide roadmaps for gynecologic cancer prevention and treatment.

THERAPEUTIC
MODALITIES AND
RELATED SUBJECTS

CHAPTER 11 ■ PERIOPERATIVE AND CRITICAL CARE

JAMES J. BURKE II, JANET L. OSBORNE,
AND CHRISTOPHER K. SENKOWSKI

Surgery remains the mainstay of treatment for women with gynecologic malignancies. Ultimately, outcomes of the surgical intervention rest with the gynecologic oncologist in concert with anesthesiologists, nursing staff, stomal therapists, physical therapists, pharmacists, social workers, and the social network/support of the patient as well as others. Careful assessment of the patient prior to surgery can lead to improved outcomes and minimize surprises in the postoperative period. Should the need arise, prudent consultation with other medical specialists prior to or following surgery can further enhance patient care, and result in better outcomes.

The chapter has been divided into two sections: preoperative care/risk recognition and postoperative care/critical care. Within each section, clinical information has been arranged by organ system and recommendations are based upon evidence (when available). The critical care section provides basic yet practical information for the reader so that comanagement of the critically ill gynecologic oncology patient with an intensivist may be seamless.

PREOPERATIVE RISK ASSESSMENT

Initial Preoperative Evaluation

When patients are found to have a gynecologic malignancy (or suspicion is high as in the case of an adnexal mass), hopefully they are referred to a gynecologic oncologist for consultation and ultimate treatment. During this meeting, the gynecologic oncologist should take a thorough history, assessing for comorbid conditions, which may impact perioperative risk (1). Similarly, a thorough physical examination, looking for signs of diseases of which the patient is unaware, will aid in finding diseases that can impact surgical outcome. Review of accompanying medical records and radiographs is important. Ultimately, those patients who will benefit from surgery will be identified and will be deemed operative candidates, operative candidates who need further evaluation from specialists prior to surgery, or inoperable candidates. Subsequent discussions should focus on the course of treatment. If surgical, the planned operative procedure should be described to the patient in nonmedical terminology. Attendant risks of the procedure should be described to the patient as well as alternatives for therapy (if they exist). The length of time for the operation and length of anticipated hospital stay should be estimated for the patient and her family. These elements of the treatment plan constitute *informed consent*, and should be documented in the medical record by the physician at the initial consultation. Preferably, this “consenting” should be done before the patient

is in the preoperative holding area on the day of her surgery. Should further evaluation be needed from a specialist (e.g., a cardiologist or a pulmonologist), a letter outlining the proposed surgical intervention should be sent to the consultant.

Ideally, laboratory data will be dictated by findings from the history and physical examination. However, most institutions have a battery of required laboratory testing prior to surgical intervention. A logical review of laboratory testing is available and we refer the reader to this review (2). Table 11.1 shows recommendations for laboratory testing prior to surgery, the incidences of abnormalities that influence changes in surgical management, and the indications for each test. Further, minimal evaluation for specific comorbid disease states will be presented in the following sections of this chapter.

If the patient’s condition requires the possibility of a stoma(s) (colostomy or urostomy), consultation with an enterostomal therapist for marking of the planned stoma(s) should be considered. During this visit, the therapist will take into account the location of the patient’s “waist,” how she wears her clothing, the types of clothing she wears, and the location of the future stoma when she stands or sits. In addition, the therapist can initiate education on the function and care of the stoma(s).

Should the proposed surgery result in a marked change of body image or possible sexual dysfunction (e.g., exenteration, radical vulvectomy, or vaginal reconstruction), consultation with prior patients who have successfully recovered from similar operations may be warranted. In addition, these patients may benefit from psychological counseling prior to their surgery.

Assessment of Cardiac Risk

Any gynecologic oncologist must be aware of the underestimation of cardiac disease in women when evaluating cardiac risk preoperatively. In the last decade, a great deal of literature has been published on this subject. In 2001, the National Heart, Lung, and Blood Institute (NHLBI) launched the Heart Truth Project to promote education about heart disease among women (3). Statistics have shown that only one of three primary physicians correctly cited coronary artery disease as a leading cause of death in women. Similarly, studies have demonstrated that women are less often counseled on cardiac risk factors, less often prescribed lipid-lowering medications, less often offered invasive procedures, and less often prescribed cardiac rehabilitation. Further, compared to men, women who had a myocardial infarction (MI) had a greater interval from onset of pain until arrival at hospital, were less likely to be treated with thrombolytics and beta-blocking agents, were less often evaluated with invasive methods, had higher rates of reinfarction, and had greater mortality (3).

TABLE 11.1**RECOMMENDED PREOPERATIVE LABORATORY ASSESSMENTS WITH INDICATIONS FOR TESTING**

Test	Incidence of abnormalities that influence management (%)	Indications
Hemoglobin	0.1	Anticipated major blood loss or symptoms of anemia
White blood cell count	0.0	Symptoms that suggest infection, myeloproliferative disorder, or myelotoxic medications
Platelet count	0.0	History of bleeding diathesis, myeloproliferative disorder, or myelotoxic medications
Prothrombin time	0.0	History of bleeding diathesis, chronic liver disease, malnutrition, recent or long-term antibiotic use
Partial thromboplastin time	0.1	History of bleeding diathesis
Electrolytes	1.8	Known renal insufficiency, CHF, medications that affect electrolytes
Renal function	2.6	Age >50 years, hypertension, cardiac disease, major surgery, diabetes, medications that affect renal function
Glucose	0.5	Obesity or known diabetes
Liver function tests	0.1	No indication. Consider albumin measurement for major surgery or chronic illness
Urinalysis	1.4	No indication
Electrocardiogram	2.6	Age >50 years; known CAD, diabetes, or hypertension
Chest radiograph	3.0	Age >50 years; known cardiac or pulmonary disease; symptoms or exam suggesting cardiac or pulmonary disease.

Note: CAD, coronary artery disease; CHF, congestive heart failure.
Source: Adapted from Smetana GW, Macpherson DS. The case against routine preoperative laboratory testing. *Med Clin N Am* 2003;87:7–40, with permission.

In the assessment of perioperative risk, cardiac risk factors are certainly one of the top concerns for clinicians. There have been a number of reviews and different systems created for the purposes of assessing cardiac risk for patients undergoing noncardiac surgery (4–7). Realize that approximately 1 in 12 patients (>65 years old) will have significant coronary artery disease (8). It is estimated that over 30% of patients undergoing major elective surgery have at least one cardiac risk factor (9).

Cardiac risk indices have been published by at least 10 different investigators (10). Goldman et al. published the Multifactorial Index of Cardiac Risk (MICR) in 1977 (11). This risk index was the first large, prospective, multivariate analysis of patients undergoing noncardiac surgery. They used definite endpoints of cardiac death, ventricular tachycardia, pulmonary edema, and myocardial infarction. The MICR involves nine independent risk factors to create a point risk index and predict morbidity and mortality (Tables 11.2 and 11.3). One weakness of this index is underestimating risk in vascular surgery patients. Nonetheless, these criteria have been validated and have stood the test of time. In response to

a shift in the literature from calculation of risk with indices to clinical decision making, especially in regard to the need for preoperative evaluation, the American College of Cardiology/American Heart Association (ACC-AHA) guidelines were developed (12). Recently, the AHA updated guidelines for cardiovascular disease prevention in women (13). This document provides risk classification of coronary vascular disease (CVD), based upon clinical criteria and/or the Framingham 10-year global risk score (14) (Table 11.4). This CVD stratification has not been assessed specifically for preoperative risk assessment, but provides classification of women who may need further (noninvasive or invasive) evaluation.

Clearly, the approach to the patient must include a careful history and physical examination. Initially, age greater than 70 years was thought to be a risk factor for cardiac morbidity, but a recent clinical trial showed no increased independent risk for cardiac complications (15). Any prior history of cardiac disease such as angina, MI, arrhythmia, pulmonary edema, or valvular disease must be elaborated. Patients with unstable angina, recent myocardial infarction, class III-IV heart failure,

TABLE 11.2**MULTIFACTORIAL INDEX OF CARDIAC RISK (MICR)**

Risk factor	Points
S3 gallop or increased jugular venous pressure	11
Myocardial infarction in previous 6 months	10
More than five premature ventricular ectopic beats per minute	7
Rhythm other than sinus or premature atrial contractions	7
Age >70 years	5
Emergency noncardiac operative procedure	4
Significant aortic stenosis	3
Poor general health status	3
Abdominal or thoracic surgery	3
Possible total	53

decompensated congestive failure, or aortic stenosis present the highest risk. These patients will likely require further invasive testing.

In patients without overt cardiac risks, other factors are considered to be helpful for uncovering subclinical disease. Classically, these risk factors are smoking, hyperlipidemia, hypertension, and diabetes mellitus.

In 2002, the ACC-AHA published guidelines to direct invasive, interventional evaluations (12). The classification defines clinical predictors as major, intermediate, and minor. In addition, the guidelines now utilize functional capacity in terms of metabolic equivalents (METs), with a level <4 being considered poor. The ability to climb one flight of stairs or walk up a hill would classify the patient in the >4 group (12).

Testing available for further evaluation includes both invasive and noninvasive methods. Echocardiography can predict postoperative congestive heart failure (CHF) in patients with ejection fractions (EFs) less than 35% (16). Unfortunately, echocardiography cannot reliably predict ischemia. However, echocardiography is quite useful in the evaluation of valvular diseases and for follow-up of patients with known left ventricular (LV) dysfunction.

Exercise or pharmacological stress testing provides valuable information for perioperative ischemic risk. Nuclear scintigraphy with evaluation of perfusion defects has shown a positive predictive value of 12% to 16% and a negative predictive value of 99% (17). Dobutamine stress echocardiography has shown similar predictive values.

The ACC-AHA recommendations provide a way to segregate patients who should have their surgery delayed for further

TABLE 11.4**CLASSIFICATION OF CVD RISK IN WOMEN**

Risk status	Criteria
High risk	Established coronary heart disease Cerebrovascular disease Peripheral arterial disease Abdominal aortic aneurysm End-stage or chronic renal disease Diabetes mellitus 10-year Framingham global risk >20% ^a
At risk	≥1 major risk factors for CVD, including: Cigarette smoking Poor diet Physical inactivity Obesity, especially central adiposity Family history of premature CVD (CVD at <55 years of age in male relative and <65 years of age in female relative) Evidence of subclinical vascular disease (e.g., coronary calcification) Metabolic syndrome Poor exercise capacity on treadmill test and/or abnormal heart rate recovery after stopping exercise
Optimal risk	Framingham global risk <10% and a healthy lifestyle, with no risk factors

Note: CVD, coronary vascular disease.

^aOr at high risk on the basis of another population-adapted tool used to assess global risk.

cardiac evaluation because of a recent MI; who should have their CHF optimized; or who should optimize control of dysrhythmias. In selected patients, it may be that coronary revascularization, angioplasty, stent placement, or valve replacement is prudent before the planned noncardiac surgery (12).

The risks of reinfarction after a recent MI are clearly related to the timing of an event, which could precipitate an MI. However, these rates have been declining secondary to improved perioperative care. Reported reinfarction rates have dropped from 37% in patients undergoing surgery within 3 months following MI to more recent figures of 5% to 10%. The rates fall even further the longer the interval from the original MI, with rates of reinfarction being 2% to 3% in the 4 to 6 months following and 1% to 2% after 6 months (18).

TABLE 11.3**MULTIFACTORIAL INDEX OF CARDIAC RISK (MICR), CARDIAC RISK CLASS, MORBIDITY, AND MORTALITY**

Cardiac risk (%)	Total points	Morbidity (%)	Mortality (%)
Class I	0–5	0.7	0.2
Class II	6–12	5.0	1.6

Perioperative Beta Blockade

In 1996, a multicenter, randomized, placebo-controlled trial was published that evaluated the use of beta blockade with atenolol versus placebo in patients undergoing noncardiac surgery (19). Although no differences in perioperative mortality or MI were seen, the atenolol group had significantly fewer ischemic episodes (24% vs. 39%). Furthermore, in a 2-year follow-up, the atenolol group had a decreased mortality (9 vs. 21 deaths) and decreased number of cardiac events (16 vs. 32). Based on the findings of this study, patients with or at risk for coronary artery disease should receive preoperative and postoperative beta blockade.

Pulmonary Risk Assessment

Postoperative pulmonary complications represent a significant cause for morbidity and mortality in patients undergoing elective surgery. Approximately 25% of deaths within the early postoperative period (first week) are related to pulmonary issues. Pulmonary complications after major abdominal surgery range from 20% to 30% (20). Laparotomy results in a 45% decrease in vital capacity and a 20% reduction in functional residual capacity (FRC) (21). When the patient is in the supine position, FRC is reduced below alveolar closing volume (i.e., the volume at which point alveoli start closing), which results in atelectasis (22).

When examining risk factors for postoperative pulmonary problems, a number of issues surface. General medical status (e.g., functional status, obesity, nutrition) is related to postoperative pulmonary complications (PPCs) (23). A history of congestive failure, renal failure, poor mental status, and immunosuppression are all associated with a higher PPC rate (24). Surgical issues such as the type of incision (thoracic and upper abdominal being worse than midline or lower abdominal), duration of anesthetic (>2 hours), the use of a nasogastric tube (increased risk), and the use of parenteral (increased risk) versus epidural (decreased risk) analgesics are all correlated with PPC incidence (25).

In terms of direct pulmonary risk factors, the most common preexisting pulmonary disease is chronic obstructive pulmonary disease (COPD) (26). These patients retain carbon dioxide, have poor gas exchange, and have an increased residual volume. Smoking, history of dyspnea, pneumonia, and sleep apnea are other risk categories. Patients with asthma and other restrictive lung diseases (low forced vital capacity [FVC] with normal forced expiratory volume in the first second of expiration [FEV₁]/FVC ratio) have minimal increased risk for PPCs (27).

When interpreting the usual preoperative radiographic and laboratory values, several caveats must be kept in mind. A preoperative chest radiograph in normal adults has no predictive value other than providing essential baseline data for an at-risk patient. Arterial blood gas analysis in prospective trials has been shown not to be useful in providing risk stratification. However, it is useful in providing baseline data for patients with preexisting disease, that is, COPD (28). Preoperative pulmonary function tests (PFTs) have few supporting clinical trials other than in preparation for lung resection, where they are clearly beneficial (29). A consensus statement was forwarded from the American College of Physicians in 1990 that recommended preoperative PFTs in the following settings: in patients with a history of smoking or dyspnea scheduled to undergo upper abdominal operations, coronary bypass, or lung resection; in patients with unexplained pulmonary disease; and in patients with planned extensive lower abdominal, head and neck, or orthopedic operations (30). It would appear from the data that PFTs are overutilized. In the case of major abdominal surgery in a patient with moderate to severe COPD, however, they may aid greatly in risk stratification and in providing baseline data.

Preoperative and perioperative strategies for reducing risk of PPCs include pulmonary expansion, smoking cessation, and optimization of gas exchange. Although preoperative and postoperative incentive spirometry has shown mixed results in reducing the rate of pulmonary complications, it continues to be widely recommended (31), and it should be considered as a preventive strategy for any patient undergoing laparotomy. In order to maximize patient compliance, preoperative counseling and education is necessary. Clearly, COPD must be optimized with control of infection and maximizing medical regimens. Reactive airway disease should be prevented with the use of perioperative inhalation therapy such as beta agonists. Steroid therapy is generally reserved for patients already utilizing them as part of their medical regimen. These steroid-dependent patients will need stress-dose steroids to prevent insufficiency (see "Adrenal Suppression" section). Prophylactic antibiotics are not indicated in COPD patients to prevent pulmonary infections.

Smoking-cessation programs have had an unclear effect on postoperative pulmonary complications (32). Although the data consist of poorly controlled trials, it appears that short-term abstinence (<8 weeks from the time of surgery) may actually increase the complication rate (33). Abstinence for greater than 10 weeks showed complication rates similar to nonsmokers (34). Unfortunately, the long-term success rate of smoking-cessation programs is low, and in the case of malignancy, the gynecologic oncologist rarely has the opportunity to delay the operation for 8 to 10 weeks.

Endocrinologic Risk Assessment

Diabetes

The incidence of diabetes is rising because of the obesity pandemic, the sedentary lifestyle of Americans, and the rapidly aging population (35). Interestingly, one third to one half of these patients are unaware that they have diabetes and are currently receiving no treatment. It is only during preoperative evaluation for elective surgery or acute hospitalization that most of those patients will be diagnosed (36). Understanding the basic physiology of diabetes and how it impacts perioperative risk is crucial for the surgeon.

There are two types of diabetes of concern for the surgeon. Type 1 diabetes occurs as a result of insulinopenia, with all type 1 diabetics being insulin dependent. In the absence of sufficient insulin, these patients are prone to ketosis. Type 1 diabetics account for approximately 10% of all diabetics. Type 2 diabetes occurs as a result of insulin resistance and impaired insulin secretion. Type 2 diabetics may be treated with diet alone, oral hypoglycemic agents, or insulin. These patients account for approximately 90% of all diabetics (37). Intraoperative as well as postoperative glycemic control is dictated by the type of diabetes a patient has.

When evaluating patients with diabetes for surgery, attention should be directed toward the long-term complications of diabetes, as these can impact perioperative risk. Most complications of diabetes are related to microvascular changes, such as diabetic retinopathy, neuropathy, nephropathy, and cardiovascular disease (38). In addition to a thorough history and physical examination, preoperative studies should include an electrocardiogram to rule out a prior "silent" MI (especially in patients with diabetes for more than 10 years); serum creatinine, blood urea nitrogen, and urinary analyses to assess renal function; and a hemoglobin A_{1c} to evaluate recent glycemic control. Should abnormalities be found, consultation with an appropriate specialist should be entertained (39). Ultimately, the type of diabetes, preoperative glycemic control, the extent and magnitude of the intended surgery, the elective or emergent nature of that surgery, and other comorbid medical conditions

will affect the metabolic changes these patients face intraoperatively and postoperatively.

The physiologic changes that diabetic patients encounter during surgery all result in a hyperglycemic state. The stress of surgery increases secretion of epinephrine, norepinephrine, cortisol, and growth hormone, all of which directly antagonize insulin action (40,41). In addition, gluconeogenesis and lipolysis are increased with mobilization of glucose precursors, and a net protein catabolism ensues. All of these factors affect ketosis and acidosis and require intraoperative glucose measurement, especially if the surgery lasts longer than 2 hours.

Although diabetic patients with vascular disease are at risk of silent postoperative MI and acute renal failure, postoperative infections (respiratory, urinary, and wound infections) account for about two thirds of all postoperative complications and 20% of all postoperative deaths among diabetics undergoing surgery (42,43). Hyperglycemia has been shown to impair phagocytic function and chemotaxis of granulocytes when glucose levels are higher than 250 mg/dL (44). Other wound complications such as superficial wound dehiscence or fascial dehiscence are common among diabetic patients because of suppressed collagen synthesis by glucose levels higher than 200 mg/dL (45).

Although no prospective studies demonstrating better perioperative outcome from tight glycemic control in diabetics undergoing surgery have been done, several retrospective studies of diabetics undergoing cardiac surgery suggest a lower incidence of postoperative wound infections and complications (46–48). Similarly, a randomized prospective study of intensive insulin therapy (maintaining glucose levels between 80 and 110 mg/dL) versus conventional insulin therapy (glucose levels between 180 and 200 mg/dL) in critically ill postoperative patients demonstrated a 46% reduction in episodes of septicemia and a 34% reduction of in-hospital mortality (49).

Glycemic control during surgery will depend upon the type of diabetes the patient has, the medications currently being utilized for treatment, the expected length of time that the patient will be nil per os (NPO), and the type of surgery the patient is having. Patients who are taking oral hypoglycemic agents for control should not take their morning dose on the day of surgery (because of the longer half-life of metformin and

chlorpropamide, patients should be instructed to stop these medications 24 to 48 hours prior to surgery) (39). Table 11.5 shows recommendations for management of diabetic patients undergoing surgery (39).

Thyroid Disorders

When patients give history of hypothyroidism or hyperthyroidism during evaluation for surgery, thyroid-stimulating hormone (TSH) and thyroxine (T4) levels should be obtained. The primary objective is to determine if the patient is euthyroid or mildly abnormal prior to surgical intervention so as to avoid the complications of myxedema or thyroid storm in the postoperative period.

Decisions to operate on patients with hypothyroidism will depend upon the level of hypothyroidism and the urgency of the surgery. Hypothyroidism can influence many physiologic functions such as myocardial function, respiration, gastrointestinal motility, hemostasis, and free water balance (39). Although there have been no prospective, randomized studies looking at the surgical outcome of hypothyroid patients versus controls, several retrospective case-matched control studies have evaluated hypothyroid patients undergoing surgery. A study by Weinberg et al. demonstrated no differences between hypothyroid and euthyroid controls for perioperative complications. In addition, no differences in outcome were seen when hypothyroidism was stratified by thyroxine levels. The investigators concluded that patients with mild to moderate hypothyroidism should not be denied needed surgery in order to correct the metabolic problem. They further stated that insufficient numbers of patients with severe hypothyroidism precluded recommendations for perioperative care of these patients (50). In another retrospective study, Ladenson et al. reviewed perioperative complications among hypothyroid patients undergoing surgery, finding more intraoperative hypotension in noncardiac surgery, more heart failure in cardiac surgery, and more gastrointestinal and neuropsychiatric complications. They also noted that patients were unable to mount fever in the face of infection, although infection rates were not different. Further, no differences were found in the

TABLE 11.5

MANAGEMENT OF DIABETES MELLITUS DURING SURGERY

Type	Minor surgery	Major surgery
TYPE I		
DM on insulin therapy	1/2–2/3 of usual AM insulin dose SC	IV insulin infusion during surgery—frequent blood glucose monitoring necessary
TYPE II		
DM controlled with diet alone	No insulin during surgery	No insulin during surgery
DM controlled with oral medications	No insulin during surgery	Insulin may be required during surgery—frequent blood glucose monitoring may be required
DM poorly controlled with oral medications	Insulin may be required during surgery—frequent blood glucose monitoring may be required	IV insulin infusion during surgery—frequent blood glucose monitoring necessary

Note: DM, diabetes mellitus; IV, intravenous; SC, subcutaneous.

duration of hospitalization, perioperative arrhythmias, delayed anesthesia recovery, pulmonary complications, or mortality (51).

Patients with mild to moderate hypothyroidism requiring urgent surgery may have it without delay. These patients may have more minor complications of ileus, postoperative delirium, or infection without fever. Patients with severe hypothyroidism (myxedema coma, decreased mentation, pericardial effusions, heart failure, or very low levels of thyroxine) who are to undergo urgent/emergent surgery will need intravenous thyroxine and stress-dose glucocorticoids (see "Adrenal Suppression" section) started prior to, during, and continued after surgery (52). Patients who develop seizures, coma, unexplained heart failure, hypothermia, prolonged ileus, or postoperative delirium should be evaluated for undiagnosed hypothyroidism or myxedematous coma (53–55).

Patients using thyroid replacement preparations can have their doses withheld during the immediate postoperative period until they are able to tolerate oral intake, as the half-life of these drugs is 5 to 9 days (39).

Most complications occurring in hyperthyroid patients undergoing surgery involve cardiac function, as T4 and T3 have a direct inotropic and chronotropic effect on the heart. Atrial fibrillation occurs in 10% to 20% of patients (56–59). The greatest perioperative risk for patients who have undiagnosed hyperthyroidism or who are inadequately treated is a rare, yet life-threatening, condition known as thyroid storm. Thyroid storm should be considered in any postoperative patient with fever, tachycardia, confusion, cardiovascular collapse, and death (60, 61).

Patients with mild hyperthyroidism may have surgery with preoperative beta blockade. However, patients with moderate or severe disease should have surgery canceled until a euthyroid state is attained.

Thyrotoxic patients who require emergent/urgent surgery need premedication with antithyroid agents, beta blockade, and corticosteroids. Antithyroid medications include thionamides, propylthiouracil (PTU), and iodine. Methimazole is a thionamide drug that blocks thyroid hormone synthesis, and iodine blocks thyroid hormone release (62,63). Because adrenal reserve may be low in these patients, stress-dose steroids (see "Adrenal Suppression" section) should be administered prior to and following surgery (64). Should thyroid storm occur, treatment with beta blockade, thionamides, iodine, and corticosteroids should be instituted. It is important to give the thionamides at least 1 hour prior to iodine administration to prevent uptake of iodine and synthesis of further hormone. Occasionally, supportive care in the intensive care unit (ICU) with correction of cardiac dysfunction and electrolyte abnormalities may be necessary (39).

Adrenal Suppression

Corticosteroids are used to treat a myriad of diseases, and it is not unusual to obtain a history from patients revealing steroid usage. It is important to ascertain the type of steroid used, the dosage prescribed, the duration of treatment, and whether or not a tapering schedule was used in stopping the medication.

Although some case series demonstrate biochemical evidence of hypothalamic-pituitary axis (HPA) suppression after exogenous steroid usage, none has demonstrated frank adrenal insufficiency, hypotension, and shock in surgical patients (65). However, recommendations for stress-dose steroids perioperatively have been made to prevent the occurrence of this life-threatening situation in patients with either "presumed" or documented HPA suppression. Giving stress-dose glucocorticoids needs to be weighed against the potential side effects of the drug (such as poor wound healing, fluid retention, and increased risk of infection) versus the benefits of supporting the HPA axis in a surgically stressed patient.

Three tiers of chronic glucocorticoid usage and subsequent HPA axis suppression have emerged. Several studies have shown that steroid equivalent to 5 mg of prednisone as a single morning dose, alternate-day short-acting steroids given as a morning dose, and any dose of steroid given for less than 3 weeks seldom results in clinical suppression of the HPA and requires no stress-dose steroids perioperatively (66–68). However, patients who are chronically taking 20 mg prednisone (or equivalent) per day for more than 3 weeks or who appear clinically cushingoid require stress-dose steroids based upon the type of surgical stress (69) (Fig. 11.1). Patients whose steroid usage falls in between the first two tiers are more controversial and may require HPA testing to ascertain the functionality of the adrenal gland (70).

Renal Risk Assessment

Chronic kidney disease affects 8 million Americans, with most having a glomerular filtration rate (GFR) of less than 60 mL/min/1.73 m² (71). The most common form of renal failure facing the surgeon is acute renal failure (ARF) occurring during the postoperative period. This condition will be discussed below in the section on postoperative/critical care. However, with the aging population, increasing prevalence of diabetes and hypertension, and the advances in dialytic therapy, the number of patients living with end-stage renal disease (ESRD) is increasing. Therefore, surgeons must be cognizant of the potential perioperative risks associated with these patients.

The causes of ESRD are predominantly diabetes and hypertension, which account for 68% of patients with ESRD (72). As such, patients with these underlying diseases tend to have other comorbid conditions such as coronary artery disease and peripheral vascular disease. Obviously, patients with ESRD have problems with fluid balance, electrolyte levels, and acid-base management. Furthermore, with reduced or absent renal function, these patients metabolize drugs such as antibiotics, anesthetics, and analgesics poorly. Finally, patients with ESRD are immunocompromised and are more susceptible to infections postoperatively. Taking this complex picture into consideration, the morbidity rate among ESRD patients undergoing surgery is 54% (range, 12% to 64%) and the mortality rate is 4% (range, 0% to 47%) (73).

Evaluation of ESRD patients undergoing surgery should focus on three areas: cardiac evaluation, fluid and electrolyte management and anemia, and bleeding diatheses. Of course, glycemic control for diabetics and blood pressure control for hypertensives are obvious. Cardiac disease is the leading cause of death among ESRD patients (72,74). Unfortunately, a large proportion of these patients have asymptomatic coronary artery disease (23% to 40%) (75,76), with 75% of diabetics being asymptomatic (77,78). Therefore, these patients need formal cardiac clearance from a cardiologist prior to surgical intervention.

ESRD patients who are dependent upon dialysis will need to be euvoletic prior to surgery. Thus, communication with the patient's nephrologist is paramount. Details about the operation should be discussed, with planned preoperative dialysis (without heparin 24 hours prior to surgery) and postoperative dialysis on the day of surgery for large intraoperative fluid loads. Electrolytes should be monitored in the immediate postoperative period, with hyperkalemia being aggressively managed with dialysis or medically if necessary. Hyperkalemia may be treated with glucose and insulin, which will drive the NaK-ATPase pump resulting in an increase of intracellular potassium and a lowering of extracellular potassium. Ten milliliters of calcium gluconate can afford cardioprotection and membrane stabilization in patients with abnormal electrocardiograms (ECGs). Finally, 40 g of sodium

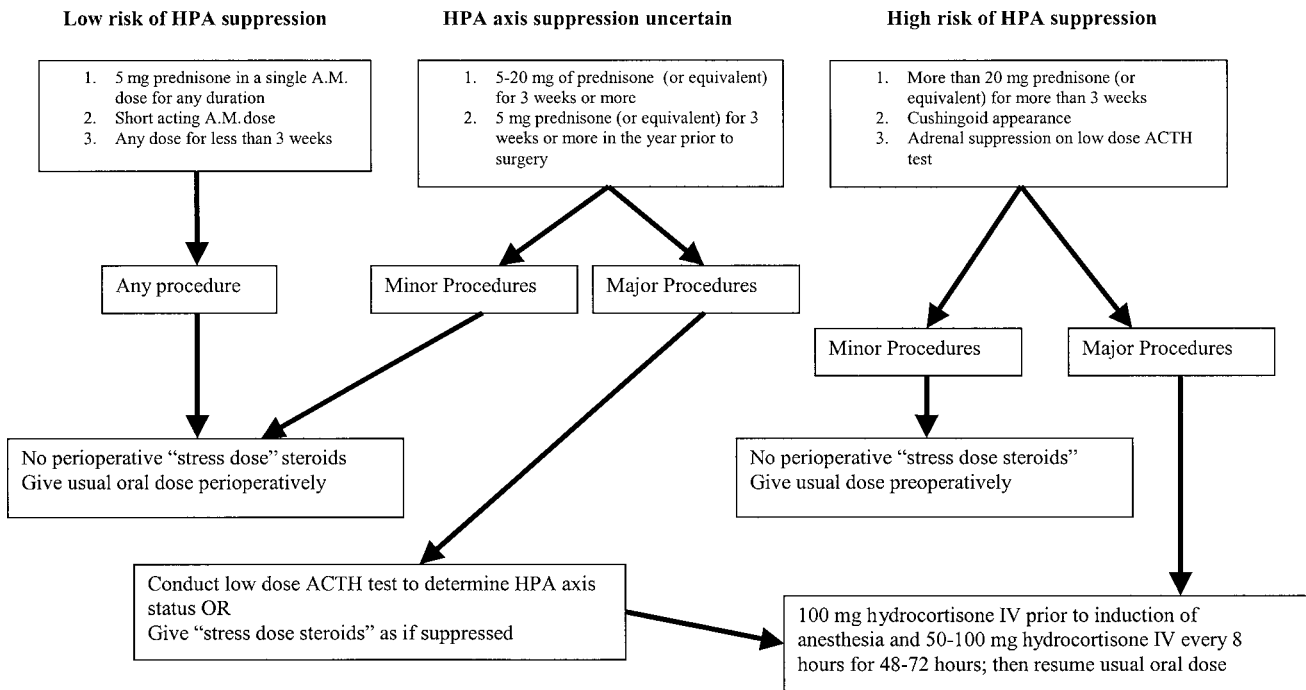

FIGURE 11.1. Algorithm for stress-dose steroids. ACTH, adrenal corticotropin hormone; HPA, hypothalamic-pituitary-adrenal axis; IV, intravenous. *Source:* Adapted from Schiff RL, Welsh GA. Perioperative evaluation and management of the patient with endocrine dysfunction. *Med Clin North Am* 2003;87(1):175-192, with permission.

polystyrene sulfonate (Kionex, Kayexalate) dissolved in 80 mL of sorbitol may be given orally, or alternatively 50 to 100 g in 200 mL of water may be given rectally as a retention enema by inserting a Foley catheter into the rectum and filling the balloon. These administrations should be repeated every 2 to 4 hours until the potassium level is in a normal range (see section below on potassium derangements). Caution with the use of this resin in postoperative patients is urged as intestinal necrosis can occur (79).

Patients with ESRD usually receive erythropoietin to maintain hemoglobin levels. In urgent situations, transfusion of blood is necessary to maintain hemoglobin prior to and during surgery. Uremic patients may have platelet dysfunction resulting in bleeding (80). If a patient has demonstrated prior bleeding because of uremic platelet dysfunction, these patients must be treated with 1-deamino-8-D-arginine vasopressin (dDAVP) intravenously or intranasally and with cryoprecipitate to prevent bleeding during surgery (81). In addition, patients may be treated with intravenous conjugated estrogens (0.6 mg/kg) if they are given 4 to 5 days prior to surgery (82).

Drug administration in ESRD must be done judiciously with careful attention to the pharmacokinetics of particular drugs. Multiple guidelines exist that can direct drug dose reductions for patients with ESRD (83).

Hepatic Risk Assessment

The incidence of liver disease in gynecologic oncology is not known. However, patients may present with a history of cirrhosis or acute or chronic hepatitis in conjunction with a gynecologic malignancy. Awareness of liver disorders and how they impact the perioperative risk is necessary to avoid unnecessary morbidity and mortality.

As mentioned earlier, thorough preoperative evaluation of patients includes a comprehensive history and physical examination, with further laboratory testing based upon historical

and physical findings. Routine testing of liver function in asymptomatic patients rarely yields abnormal levels or changes in perioperative management (2). However, patients with histories of jaundice, blood transfusions, the use of alcohol or other recreational drugs, hepatitis, or physical findings of icterus, hepatosplenomegaly, palmar erythema, or spider nevi should be tested to rule out occult or active liver diseases (84).

Patients with acute hepatitis (viral or alcohol induced) should have surgery delayed until the acute phase of the disease process has passed and liver function tests have returned to normal. The older literature has demonstrated mortality rates of 0% to 58% in this patient group (84). Contrarily, patients with chronic hepatitis tolerate surgery well with no mortality (85,86).

Surgical risk in patients with cirrhosis of the liver is significant and correlates directly with the Child-Turcotte classification (Table 11.6). This system takes into consideration five components, three of which are subjective. Nonetheless, for predicting operative outcome, this system is quite reproducible and has been validated in a number of studies (87-90). Postoperative mortality rates have been shown to be 10% in Child class A and 30% and 80%, respectively, for Child classes B and C (87,89). Patients with cirrhosis of the liver also have coagulopathies, which need to be corrected prior to surgery. Vitamin K administration, fresh frozen plasma, or cryoprecipitate may be administered to correct the prothrombin time to within 3 seconds of normal. Figure 11.2 presents an algorithm for patients with liver disease facing surgery (84).

Finally, selection of medications in patients with hepatic dysfunction needs to be done judiciously. Patients with liver dysfunction are particularly susceptible to anesthetic effects such as changes in hepatic metabolism of medications and changes in hepatic blood flow. Alterations in the type and the dose of an agent are necessary to avoid postoperative hepatic dysfunction and hepatitis. Postoperative pain management with narcotic agents needs to be reduced by as much as 50% to account for the altered hepatic metabolism in these patients (91).

TABLE 11.6**CHILD-TURCOTTE CLASSIFICATION AND OPERATIVE MORTALITY**

Group designation	A (minimal)	B (moderate)	C (advanced)
Serum bilirubin (mg/dL)	<2.0	2.0–3.0	>3.0
Serum albumin (g/dL)	>3.5	3.0–3.5	<3.0
Ascites	None	Easily controlled	Poorly controlled
Neurologic disorder	None	Minimal	Advanced, coma
Nutrition	Excellent	Good	Poor, wasting
Operative mortality	10%	30%	80%

Preoperative Nutritional Assessment

Clearly, the status of nourishment plays an important role in the way patients respond to the various stresses of their cancer care. The broader consideration of nutrition in gynecologic cancer patients is discussed in Chapter 33. The intent of this section is to present the concepts of preoperative nutritional evaluation and nutritional support of the gynecologic oncology patient. Early refeeding in the postoperative patient as well as enteral and parenteral nutritional support in the critically ill gynecologic patient are discussed later.

The prevalence of malnutrition among cancer patients has been shown to be quite high (92,93). In addition, a direct correlation between the level of malnutrition and surgical outcome has been demonstrated (94,95). Specific rates of malnutrition among gynecologic oncology patients have been described. Tunca showed a high prevalence of severe protein malnutrition among ovarian cancer patients without gastrointestinal involvement. However, he was unable to demonstrate malnutrition among other gynecologic cancer sites (96). Orr et al. have shown increased rates of malnutrition with increasing stages of cervical cancer among patients (97). Recently, Santoso et al.

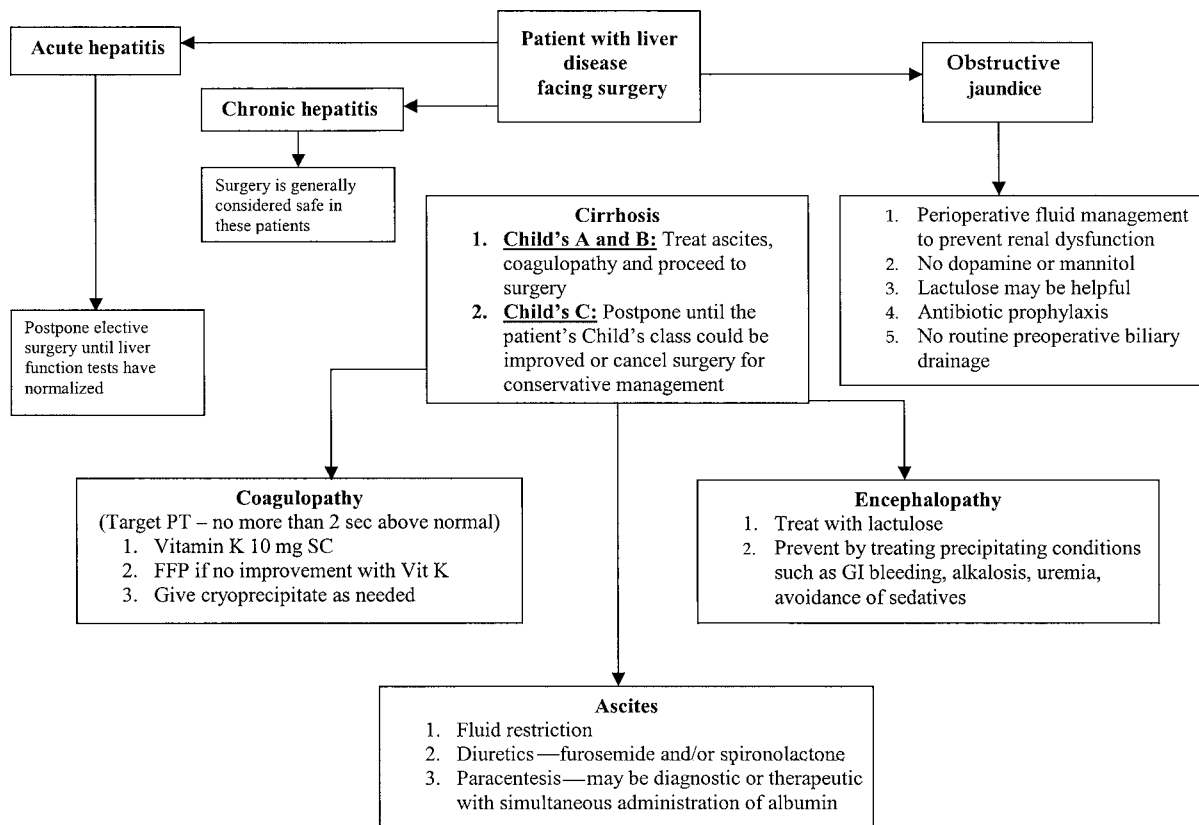

FIGURE 11.2. Perioperative assessment of the patient with liver disease. FFP, fresh frozen plasma; GI, gastrointestinal; SC, subcutaneously. Source: From Rizvon MK, Chou CL. Surgery in the patient with liver disease. *Med Clin North Am* 2003;87:211–227, with permission.

demonstrated that 54% of their patients admitted to the gynecologic oncology ward (medical and surgical admissions) demonstrated malnutrition. Most of their patients had cervical or uterine carcinomas, were obese, and were admitted for major abdominal surgeries (98). The question remains, how best to assess patients for nutritional status and what intervention(s) can correct deficiencies, producing improved postoperative outcomes?

Simply attaining a history of weight loss (amount and over what duration) can identify patients who may be malnourished, especially if the weight loss is greater than 10% of the patient's normal weight (99). However, recalled weights may be inaccurate and require corroboration of family members or comparison to prior recorded weights (100). Other important historical elements that may identify patients who are at risk are the type and/or duration of any "diets," recent surgical interventions, radiation or chemotherapy treatment, nausea or vomiting, and a history of alcohol or drug abuse (101).

Other methods for assessing nutritional status include body measurements and laboratory values. Table 11.7 lists these measures of nutritional depletion. The anthropometric measurements assess fat stores (the triceps skin fold) and protein stores (mid-arm circumference). The resulting measurements are compared to standard tables of these measurements and a percentage is calculated to arrive at the level of depletion (or nourishment). Although the measurements are quite easy to obtain, there is a lack of standardization of measurement techniques, which can introduce error and produce inaccurate assessments of nutritional status. Total lymphocyte count is calculated by multiplying the percentage of lymphocytes, determined in the differential by the total white blood cell count. Several conditions can affect the percentage of lymphocytes, such as infection or recent chemotherapy or radiation administration, producing artificially low levels of lymphocytes and inaccurate nutritional assessments. A serum albumin level is usually included in most complete metabolic profiles. Because the half-life of serum albumin is 20 days, levels can give a picture of the patient's visceral protein stores over longer periods of time. However, the plasma level of serum albumin can be affected by the patient's volume status and events that increase catabolism, all of which may interfere with the clinical usefulness of this assessment method (102).

Several schemes have been developed to combine several of the measures in Table 11.7 and correlate them to surgical outcomes. The prognostic nutritional index (PNI) has been studied the most (98,103). This index combines the triceps skin fold, the serum albumin and transferrin levels, and delayed hypersensitivity response to mumps, tuberculin, and *Candida* antigens. Because it requires measurements of immune response,

it is a cumbersome index to complete and probably has little clinical utility. Serum albumin emerges as the single test with the most predictive value of poor operative outcome due to malnutrition. Santoso et al. found that albumin levels correlated with the PNI and predicted longer lengths of stay for hospitalized, malnourished patients (98). Gibbs et al., through the National Veterans Affairs Surgical Risk Study, found that albumin levels less than 2.1 mg/dL were associated with an increased surgical morbidity from 10% to 65% (especially in predicting sepsis and major infections), as well as an increased 30-day mortality from 1% to 29% (104). Further, Delgado-Rodriguez et al. showed that lower levels of serum albumin were predictive of longer lengths of stay, increased rates of nosocomial infections, and in-hospital deaths among a general surgical population. This group of investigators also correlated their outcome measures to lower levels of high-density lipoprotein-cholesterol fractions (105).

Finally, studies have shown that experienced clinicians are able to assess nutritional status subjectively, as well as through objective laboratory or anthropometric measures, merely by obtaining a history and examining the patient (106,107).

Since the mid 1980s several trials of total parenteral nutrition (TPN) to correct deficiencies preoperatively in order to improve operative outcomes were done. This controversial practice was called into question and ultimately answered with several prospective, randomized trials, which defined patients who would benefit from such repletion. The largest trial, the Veterans Affairs Cooperative Study, randomized 395 mostly male, surgical (abdominal or noncardiac thoracic surgeries) patients to receive at least 7 days of preoperative and 3 days of postoperative TPN or to receive no perioperative nutritional supplementation. The TPN group had a greater number of infectious complications, mostly among patients classified as borderline or mildly malnourished compared to the unfed patients (14.1% vs. 6.4%). However, a subset of severely malnourished patients derived benefit from lower operative complication rates (5% vs. 43%, $p = 0.03$) without incurring an increase in infectious complications. The overall 30- and 90-day mortality rates were not different between the groups (108). A similar study by Bozzetti et al. randomized severely malnourished patients undergoing resection of gastric or colonic malignancies to 10 days of preoperative TPN and 9 days of postoperative TPN or no supplementation. His group showed that noninfectious postoperative complication rates were lower among the TPN group versus the unfed control group (12% vs. 34%, $p = 0.02$) (109). Although the method of nutritional assessment was different in these two studies, it is clear that patients assessed to be severely malnourished should be considered for preoperative TPN prior to abdominal surgery.

TABLE 11.7

MEASUREMENT OF NUTRITIONAL DEPLETION

Parameters	Mild	Moderate	Severe
Triceps skin fold (TSF), % standard	50–90	30–50	<30
Mid-arm muscle circumference (MAMC), % standard	80–90	70–80	<70
Albumin g/dL	3.0–3.4	2.1–3.0	<2.1
Total lymphocyte count (TLC) Cmm	1,200–1,500	800–1,200	<800
Weight loss, % initial			
In 1 week	<1	1–2	>2
In 1 month	<2	2–5	>5
In 3 months	<5	5.0–7.5	>7.5
In 6 months	<7.5	7.5–10.0	>10.0

PREPARATION FOR SURGERY

Infection Prophylaxis

Surgical site infections (SSIs) account for nearly 40% of nosocomial infections in surgical patients and occur in up to 20% of patients undergoing abdominal surgery (110,111). They are a significant source of postoperative morbidity resulting in longer hospital stays, increased rates of intensive care unit admissions, hospital readmissions, and subsequently increased costs. Patients who develop an SSI have a mortality rate two to three times that of uninfected patients (112,113). Patient and operative environmental factors influence surgical infection rates. The goal of preoperative skin preparation is to reduce the risk of SSI by reducing the microbial count to a subpathogenic level in a time-efficient and atraumatic manner. A meta-analysis of six trials concluded that although whole-body scrubs or showers with antiseptic agents such as chlorhexidine or povidone-iodine prior to surgery reduce bacterial counts on the skin, this practice did not reduce wound infection rates (114). Patients undergoing surgery should simply be instructed to bathe or shower normally the night or morning prior to surgery, removing any debris from the skin surface.

Inappropriate hair removal techniques can traumatize the skin and provide an opportunity for colonization of microorganisms. There is no evidence that hair removal prior to surgery will prevent or reduce SSI. To the contrary, meta-analysis evaluating hair removal techniques demonstrated a twofold increase in SSI when patients underwent hair removal by shaving versus clipping (115). Hair is generally sterile and therefore does not need to be removed unless the hair around the incision will interfere with the operation. When hair removal is necessary the simplest and least irritating method of hair removal is an electric or battery-powered clipper with a disposable head (110,115). Some infection control experts advocate removing all razors from hospitals and operating rooms (116).

The use of prophylactic antimicrobials plays a large role in reducing the rates of SSI and should be used in clean or clean-contaminated operations, which include most procedures performed by gynecologic oncologists. Factors that increase the risk of postoperative infection in women undergoing radical pelvic surgery include longer duration of surgery, extremes of age, increased blood loss, anemia, potential hypothermia, poor nutritional status, the presence of tumor, prior pelvic irradiation, diabetes, obesity, peripheral vascular disease, and a history of post-surgical infection (110,117). Prophylactic antibiotics should provide coverage consistent with the microbial milieu most likely to be encountered. In gynecologic oncology surgery, potential infecting organisms are coliforms, enterococci, streptococci, clostridia, and bacteroides.

Several guidelines for antibiotic prophylaxis in surgery have been published (110,111,118–120). Most recommend cefazolin for gynecologic procedures. Because of its longer half-life and broad spectrum coverage, cefotetan had been the preferred antibiotic for prophylaxis in longer radical gynecologic operations and was also recommended for prophylaxis prior to colorectal surgery (118); however, it is no longer available. An appropriate alternative for surgical procedures with a higher chance of bowel resection or injury is cefazolin plus metronidazole or ampicillin-sulbactam (120). Cefoxitin is another option, but availability has been limited. Most patients with a penicillin allergy can be treated with cefazolin; however, when allergy prohibits the administration of a cephalosporin, alternative regimens are clindamycin with gentamicin, a fluoroquinolone, or aztreonam (111). Itani et al. reported on a randomized, double-blinded trial in patients undergoing elective colorectal surgery that suggested ertapenem as an effective

alternative to cefotetan (121). Ertapenem has received FDA approval for prophylaxis for elective colon resection; however, the 2006 Medical Letter guidelines caution against the routine use of ertapenem for surgical prophylaxis due to cost and concerns that this practice may result in increased rates of antibiotic resistance (120).

In order to achieve and maintain effective tissue levels, parenteral antibiotics should be given within 1 hour (between 1 and 2 hours for fluoroquinolones and vancomycin) prior to skin incision as a loading dose (111). For patients weighing >70 kg, the dosage should be doubled (i.e., cefazolin 2 g intravenously [IV]) or weight-based dosing should be used. Repeat doses should be given intraoperatively for surgeries lasting longer than 3 to 4 hours or when blood loss exceeds 1,000 mL (118,120). Guidelines from the National Surgical Site Infection Project recommend that prophylactic antibiotic use for abdominal or vaginal procedures end within 24 hours of the operation (111). The majority of the published evidence supports the use of an appropriately timed administration of a single dose of antibiotic and that repeat doses postoperatively are unnecessary and subject the patient to the potential emergence of resistant organisms (110,111,118,120).

Bowel Preparation

It is generally accepted that full mechanical bowel preparation is indicated when intestinal injury or bowel resection is anticipated. Mechanical bowel cleansing is considered to be a crucial factor in preventing postoperative infectious complications and disruption of bowel anastomosis. Mechanical bowel preparation has several advantages unrelated to the risk of infection. It facilitates palpation of the entire colon during laparotomy. It may decrease operative time by enabling the surgeon to work with a clean bowel and improve handling during bowel anastomosis or repair. Furthermore, removal of solid material from the gastrointestinal tract prior to laparoscopy may improve exposure and lessen the chance of injury from manipulation of a heavy and distended feces-laden colon with the relatively traumatic laparoscopic grasping instruments.

Historically, clearing the colon in preparation for surgery was a complicated procedure requiring several days of clear liquid diet, cathartics, enemas, and preoperative hospitalization. The introduction of polyethylene glycol (PEG) electrolyte solution in the early 1980s revolutionized bowel preparation (122). PEG is an isoosmotic solution with especially designed electrolyte concentrations that result in virtually no net absorption of ions or water, and large volumes can be administered without significant fluid or electrolyte alterations. Several randomized studies have demonstrated that bowel cleansing with PEG can be performed safely as an outpatient preparation prior to colorectal surgery without increasing complication rates (123). Bowel preparation with PEG has some disadvantages. It requires oral intake of 4 L of a salty-tasting solution over a relatively short period of time. Many patients experience nausea, vomiting, and abdominal bloating and discomfort, and are unable to drink the required volume.

Sodium phosphate is an osmotic cathartic that provides quality bowel cleansing while avoiding the need to ingest a large volume of solution (124,125). Generally, a 45-mL dose (or two doses taken 4 hours apart) is taken with at least four glasses of clear liquid with each dose. Colonic cleansing with this method may cause intravascular volume contraction in some patients. A randomized, blinded study showed that rehydration with a carbohydrate-electrolyte “sport” drink resulted in significantly less intravascular volume contraction as compared to rehydration with water (126). A meta-analysis of eight blinded studies that compared sodium phosphate to PEG for colonoscopy preparation suggests that sodium phosphate is an effective, better tolerated, and less costly regimen (127).

Comparisons between these two preparations have also been studied in patients undergoing colorectal surgery with similar results (125,128). The use of sodium phosphate is not recommended for patients with renal insufficiency, symptomatic CHF, and liver failure with ascites (129). Hyperphosphatemia, hypernatremia, hypocalcemia, and hypokalemia have been reported after bowel preparation with sodium phosphate, but generally without clinical significance (124,125,127,130). However, serious and fatal metabolic derangements have been reported, and caution should be used in elderly patients or when prescribing multiple dose regimens (129–132). The FDA suggests obtaining post-treatment laboratory evaluation (basic metabolic panel, calcium, phosphate), especially if more than 45 mL is taken in a 24-hour period (129).

Although regarded as being essential in preventing complications of colorectal surgery, the necessity of mechanical bowel cleansing has been strongly disputed for the past 15 years. The claims that preoperative mechanical bowel preparation reduces anastomotic leakage and SSI are based on observational studies and expert clinical experience. Since 1992 several prospective randomized trials reported that elective colon and rectal surgery may be performed safely without mechanical bowel preparation. All patients in these trials received systemic antibiotics. However, the majority of these trials were greatly underpowered with a 60% or greater chance that a type II error occurred (133,134). In 2004, Bucher et al. published a meta-analysis of 1,297 patients from seven randomized, controlled trials and concluded that mechanical bowel preparation does not reduce the incidence of infectious complications and may be harmful with respect to leakage at the anastomosis (135). Another meta-analysis of 1,592 patients (nine trials) came to the same conclusions and stated that the dogma that mechanical bowel preparation is necessary before elective colorectal surgery should be reconsidered (136). In a survey of members of the American Society of Colon and Rectal Surgeons, essentially all routinely used mechanical bowel preparation, although 10% questioned its importance. Of the 515 surgeons who responded to the questionnaire, 47% routinely used sodium phosphate, 32% routinely used PEG, and 14% alternated between the two agents (137).

The importance of appropriate intravenous antimicrobial prophylaxis in patients undergoing colorectal surgery is well established and was discussed earlier in this chapter. There are conflicting opinions and data regarding whether preoperative oral antibiotics as part of a bowel preparation add any additional benefit for reduction of SSI (138,139). Although there are still strong proponents of this practice (140), oral antibiotic usage with preoperative mechanical bowel cleansing is declining (137).

Blood Transfusion Prophylaxis

Medications associated with increased bleeding risks need to be stopped prior to surgery. Elderly patients are more likely to be taking daily aspirin, nonsteroidal anti-inflammatory medications, platelet aggregation inhibitors, and anticoagulants. It will take approximately 4 days after warfarin therapy is discontinued for the international normalized ratio (INR) to reach 1.5 for those patients with INR levels between 2.0 and 3.0. Many patients on warfarin do not need to be covered with heparin therapy preoperatively. Administration of treatment-dose intravenous heparin or low-molecular-weight heparin (LMWH) while the INR is subtherapeutic is recommended for patients with a history of mechanical mitral valve, ball and cage valve, acute venous, or arterial thromboembolism within 3 months of surgery, or atrial fibrillation with a history of thromboembolic stroke (141). Patients also need to be asked about over-the-counter drug and dietary supplement usage. *Ginkgo biloba*, garlic supplements, ginseng, and vitamin E

have antiplatelet activity and may enhance bleeding risk (142). If possible, anemia should be corrected preoperatively. The use of recombinant human erythropoietin with concurrent iron and folic acid supplementation 2 to 3 weeks preoperatively has been shown to reduce allogeneic blood transfusions in patients undergoing elective surgery (143). It has been estimated that 60% of all blood transfused in the United States is given to surgical patients. Transfusion rates of approximately 5% have been reported for patients undergoing abdominal hysterectomy for benign disease (144). Radical procedures performed for the treatment of gynecologic malignancies are associated with an estimated blood loss of 1,000 mL or greater. Transfusion rates for patients undergoing radical hysterectomy have been reported as high as 80% (145), but rates of 10% to 20% are more typical in the recent literature. There is a growing demand by patients for better information about their care, risks involved, and alternatives available. Transfusion-associated risks should be explained to the patient as part of routine preoperative counseling. The risk of transfusion-transmitted infection of human immunodeficiency virus, hepatitis B virus, and hepatitis C virus from red blood cell transfusion is estimated at 1:2.1 million units, 1:250,000 units, and 1:1.9 million units, respectively (146). Although these rates have significantly decreased in the last decade with the introduction of new screening technologies, transmission of other agents, bacterial contamination, transfusion reactions, increased infection complications, and immunosuppression remain risks of allogeneic blood transfusion (147,148). Increasing awareness of these adverse effects has prompted both physicians and patients to search for alternatives to the use of donor blood in the perioperative period.

Since the mid 1980s preoperative autologous blood donation (PABD) has been utilized in order to avoid allogeneic blood transfusion in patients undergoing elective surgery where excessive blood loss is anticipated. Although this practice decreases homologous blood use, 15% of autologous donors will still receive allogeneic transfusions, and 50% of units collected are not used and must be discarded (149). Furthermore, PABD greatly increases the likelihood of any transfusion being necessary and is not without medical risks. Severe reactions during autologous donation occurred at a rate of 0.32% per unit collected and 0.75% per donor. Serious incidents during blood collection that required hospitalization were 12 times more likely in PABD compared to allogeneic donors (150). Transfusion to the wrong recipient, bacterial contamination, febrile non-hemolytic reactions, and allergic reactions have also been reported with autologous transfusion. The cost-effectiveness of PABD has been found to be extremely poor and has steadily deteriorated over the decade (149,151,152).

Acute normovolemic hemodilution (ANH) is an autologous blood-procurement strategy that is equivalent to PABD in reducing allogeneic transfusion needs. Its clinical utility has been extensively studied in patients undergoing radical prostatectomy, total joint replacement, and, more recently, major colorectal surgery. During ANH, blood is procured in the holding or operating room and replaced simultaneously with colloid and crystalloid until a target hematocrit level of 28% is reached or blood volume of 1,500 mL is removed (153). The patient's blood becomes diluted and the amount of actual red cell mass lost during surgery is reduced. ANH obviates the costs of blood testing, storage, or wastage because all blood collected during ANH is kept in the operating room and returned to the patient before the end of surgery. It is simple to perform and more convenient for the patient. Since the blood is collected at point-of-care there is no possibility for clerical error or contamination. ANH has been shown to be a cost-effective yet underutilized strategy to reduce allogeneic blood transfusions (153–155). ANH in which the blood is kept in a continuous circuit with the patient is often a workable alternative for a Jehovah's Witness patient (153,156).

Special Considerations for Obese Patients

Coexisting medical disorders, including coronary artery disease, hypertension, obesity-hypoventilation syndrome, obstructive sleep apnea, adult-onset diabetes mellitus, pulmonary hypertension, gastroesophageal reflux, impaired cardiac function, and hypercoagulability are common in morbidly obese patients and contribute to increased perioperative morbidity and mortality. These comorbidities may not have been previously diagnosed and symptoms may not manifest themselves until the patient undergoes physiologic stress related to surgery. For example, baseline pulmonary function studies of markedly obese patients demonstrate mild hypoxemia; decreased vital capacity, tidal volume, and expiratory reserve volume; increased resistance; and ventilation-perfusion inequalities (157). During the postoperative period, severe hypoxemia may occur secondary to sedation, pain, immobility, atelectasis, and anemia, leading to cardiac arrhythmia or ischemia. A thorough preoperative medical evaluation is necessary to detect coexisting disease and minimize surgical risk. A comprehensive review of the pathophysiology associated with morbid obesity is beyond the scope of this chapter, and we direct the reader elsewhere for a thorough review (158).

Surgery in morbidly obese patients poses many challenges for teams on both sides of the surgical drape. The primary concern of the anesthesiologist is gaining adequate control of the airway. The combined problems of increased aspiration risk, rapid oxygen desaturation caused by decreased functional residual capacity, baseline hypoxemia, and increased oxygen demand, in addition to technical difficulties due to anatomic fat deposits, make intubation a high-risk procedure. An awake, fiberoptic-assisted intubation is often the technique of choice for obtaining an airway. Extubation should be delayed until the patient is fully awake and ideally sitting upright (159). There are technical operating room and instrumentation issues, which need to be addressed as well. Standard operating tables, stretchers, and hospital beds have weight limits, which have prompted specifically designed wider and sturdier models for the obese patient. Staff and patient safety during transfer of the patient from the operating table to the bed or gurney is also a concern in the extremely obese patient and must be taken into consideration. Proper retractors and extra long instruments are essential and may not be available in all hospitals. Although these practical considerations are ostensibly mundane, failure to prepare will obviate a successful outcome, add frustration to all involved, and possibly put the patient at risk.

Recent reports in the gynecologic oncology literature suggest performing panniculectomy to improve exposure of the peritoneal cavity and pelvic structures (160–162). Although this is a relatively straightforward procedure, it does require some experience and planning for optimal results. Hospital credentialing of surgical privileges may require the involvement of a plastic surgeon or proctoring until proficiency is demonstrated. In addition, since panniculectomy is considered a cosmetic procedure, many insurers may require prior authorization with documentation of medical necessity or may deny any reimbursement.

CRITICAL CARE AND POSTOPERATIVE MANAGEMENT

Cardiovascular Issues

Monitoring Issues

There are many tools at the hands of the modern-day clinician when it comes to monitoring the cardiovascular function of the patient. Clinical examination, heart rate, blood pressure,

and ECG are a few. In the critical care setting, the addition of the arterial catheter, central venous pressure, and pulmonary artery catheter increases sophistication. Most patients in the ICU can be managed with simple clinical parameters. Fluid status can be assessed by daily weights, pulse rate, blood pressure, and urine output. Continuous ECG monitoring is helpful for detecting arrhythmias and ischemia. Central venous pressure (CVP) is often used for assessment of volume status and a crude estimation of cardiac function. If a patient has a central line then a port can be continuously transduced for CVP. It is a common mistake among novices to evaluate a single reading of CVP rather than reviewing the trend. When the CVP is correlated with volume status, the resulting graph is a scatter graph (i.e., no correlation). There is only correlation over time and in response to, for example, fluid challenges, transfusion, or therapy. One must remember that the CVP is a pressure measurement and not the desired measurement of volume (preload). Therefore, only crude estimations of fluid status can be made. When the status of a patient's cardiac output or fluid state is unclear, a pulmonary artery (PA) catheter (e.g., Swan-Ganz catheter) may be helpful.

These catheters are placed via a central vein (subclavian or jugular) as a central line. The catheter has a balloon-tipped transducer and is "floated" into the pulmonary artery. Waveforms of the right ventricle, pulmonary artery, and pulmonary capillary wedge pressure (PCWP) are directly visualized as the catheter progresses through the heart (Fig. 11.3), and confirmed placement is verified by chest radiograph (Fig. 11.4). Complications of placement include pneumothorax, arrhythmia, line sepsis (2%), and, rarely, pulmonary artery rupture. The PA catheter allows the measurement of cardiac output and oxygen delivery and estimation of preload by obtaining the pulmonary artery occlusive pressure (PAOP) or PCWP, the "wedge."

A number of formulas for calculation of hemodynamic parameters are crucial in utilizing the PA catheter for the care of the critically ill patient (Table 11.8). Assessment of preload is desirable for determining fluid administration or diuretic requirements for patients. The ideal measure of preload would be left ventricular end-diastolic volume; however, since this is unobtainable with current technology, intensivists settle for "the wedge" as an estimation. By inflating the balloon placed in the pulmonary artery, a direct column of standing fluid exists between the left atrium, through the pulmonary vasculature, and back to the balloon (transducer). The PAOP can be measured and is a crude reflection of left atrial pressure. If the PAOP is elevated, the preload is adequate (or excessive), and if it is low, the patient may be volume depleted. These measurements, as previously mentioned with CVP, are dynamic and trend is important. For example, if the PAOP is low and a fluid bolus is given, the PAOP should increase if the diagnosis of volume depletion was correct.

Thermodilution techniques are used to calculate cardiac output by injecting saline via a proximal port in the PA catheter and measuring the thermal changes at the distal tip of the PA catheter. By combining the preload assessment provided by the PAOP and the calculated cardiac output, differentiation between volume depletion and cardiogenic disease states can be made (see section on shock). Newer PA catheters have been developed that can calculate right ventricular ejection fraction.

By taking a blood sample from the tip of the PA catheter, the most desaturated blood in the body is retrieved. In normal circulation, the blood from the superior vena cava and the inferior vena cava mix and the blood from the coronary sinus is added to give a sample known as the mixed venous blood. By evaluating the oxygen saturation of this blood, oxygen delivery can be calculated (Table 11.8). This measurement is perhaps the most important function of the PA catheter, and current technology allows this function to be continuous via

FIGURE 11.3. Pulmonary artery catheter wave form readings as the catheter passes through the heart into the pulmonary artery. Y-axis is reading in millimeters of mercury (mm Hg).

an infrared sensor at the tip of the PA catheter. For example, if oxygen delivery is determined to be low, there are only three situations that can be influenced by the clinician: increase cardiac output (with fluid, chronotropes, or inotropes), increase the hemoglobin, or increase the oxygen saturation. In a patient with a major operation and medical comorbidities, the measurement of a normal oxygen delivery provides reassurance to the clinician that end organs are being perfused.

Calculation of the systemic vascular resistance (SVR) is also possible with a PA catheter. Because the SVR is a calculated

value and not directly measured, inaccuracies are inherent and overinterpretation of this value is cautioned. Rather than relying on the calculated SVR, the clinician should have complete understanding of the measured blood pressure and cardiac output and the ramifications therein to make therapeutic decisions (the SVR combines the two previously mentioned measured variables).

In one study of ovarian cancer patients undergoing cytoreductive surgery, 18% of patients had indications for PA catheter use (163). Because of the issues of volume status in

FIGURE 11.4. Chest radiograph showing proper placement of pulmonary artery catheter in the pulmonary artery (arrow shows tip of pulmonary catheter).

TABLE 11.8

HEMODYNAMIC FORMULAS

Cardiac output (CO) = stroke volume (SV) \times heart rate (HR) [4–8 L/min]

Cardiac index (CI) = CO/body surface area (BSA)

Systemic vascular resistance (SVR) = mean arterial pressure (MAP) – central venous pressure (CVP) \times 80/CO [800–1,200 dyne/s/cm²/m²]

Arterial O₂ content (CaO₂) = (1.36 (hemoglobin) (oxygen saturation) + 0.003 (partial pressure of oxygen) [20 mL O₂/dL])

O₂ delivery (DO₂) = CO \times CaO₂ \times 10 [600–1,000 mL O₂/min]

O₂ availability (O₂AVI) = CI \times CaO₂ \times 10 [500–600 mL/min/m²]

O₂ extraction ratio = (CaO₂ – CvO₂)/CaO₂ [25%]

Note: Values in brackets are normal values.

these patients, PA catheter placement for postoperative fluid management may be especially helpful.

Acute Postoperative Myocardial Infarction

MI usually manifests with acute chest discomfort, elevated cardiac enzymes, and ECG changes. Dyspnea, diaphoresis, nausea, and anxiety may also be associated. Risk factors that increase mortality from postoperative MI include female gender, advanced age, tachycardia, hypotension, and CHF (164). Treatment includes ICU monitoring with continuous ECG monitoring and supplemental oxygen, aspirin 325 mg immediately, sublingual nitroglycerin, and morphine sulfate as needed until pain resolves. Beta-blockers have been shown to decrease mortality by decreasing fatal arrhythmias and are also part of the early treatment regimen. An evaluation for heparin therapy or thrombolytics can be made in consultation with a cardiologist.

Congestive Heart Failure

Patients with known CHF will be risk stratified, as previously mentioned, before major elective surgery. However, in the postoperative setting, CHF will present in a number of ways (165). Patients with CHF are in a continuous hypervolemic state, and issues of fluid balance (strict “ins” and “outs”) will be paramount during the perioperative period. In difficult cases, insertion of a PA catheter can be very helpful. Judicious fluid administration guided by the PAOP as well as selective use of inotropic support for augmentation of the cardiac output will aid the clinician in a successful outcome in these difficult patients (166).

Inotropes and Vasopressors

A variety of hemodynamically active drugs are available to support the cardiovascular function of patients in the perioperative period (167). In the broadest sense, they can be categorized as vasopressors, which elevate blood pressure, and inotropes, which enhance cardiac output (Table 11.9) (168). When faced with a patient in whom oxygen delivery is low and an increase in cardiac output is desired, inotropes such as dopamine or dobutamine should be used. Dopamine, at lower doses, activates dopaminergic receptors and increases circulation in mesenteric, cerebral, and renal vascular beds. At inter-

mediate doses, dopamine stimulates beta-receptors in the heart and peripheral circulation. This activation causes tachycardia, increasing stroke volume and cardiac output. Increasing cardiac output in this fashion also increases demands for myocardial oxygen and could precipitate angina or an MI (169). At high doses, dopamine acts as an alpha agonist, causing vasoconstriction. Dobutamine is a β_1 agonist with much greater inotropic effect than dopamine and causes peripheral arterial vasodilation, decreasing afterload (this dilation is abrupt and can cause hypotension in some patients). It is the drug of choice for severe heart failure.

Epinephrine is a potent sympathomimetic with varying effects based on the dose. The drug has beta-mimetic effects at lower doses and alpha-mimetic effects at higher doses. Epinephrine causes an acute increase in myocardial oxygen demand and is mainly reserved for cardiac arrest or severe circulatory failure. Norepinephrine and phenylephrine are pure alpha-mimetic agents, utilized for vasoconstriction (neurogenic shock). In most situations of shock, fluid resuscitation is preferred to administration of alpha agents. Although these agents will give a false sense of security that the blood pressure is normal, one must remember that the vasoconstriction underperuses capillary beds, leading to an increased incidence of renal hypoperfusion (renal failure), splanchnic hypoperfusion (resulting in translocation of gut flora), and a myriad of other problems.

Vasopressin has emerged as an option similar to epinephrine with some important differences. This antidiuretic hormone in high doses provides potent vasoconstriction and leads to improved cerebral and coronary blood flow in shock states. Unlike epinephrine, there is less increase in myocardial oxygen demand and less propensity for inducing arrhythmias.

Amrinone (or inamrinone) is a phosphoesterase inhibitor that provides a positive inotropic effect on cardiac musculature while causing vasodilation. It is used in refractory cardiac failure.

Valvular Disease

In a recent study, approximately 4% of patients undergoing elective, noncardiac surgery were found to have clinically significant valvular disease. Important considerations in perioperative management are directed at patients with aortic stenosis (AS) and the level of associated ventricular failure. In addition, these patients need endocarditis antibiotic prophylaxis (Table 11.10). AS is an independent risk factor for poor

TABLE 11.9

VASOPRESSORS: EFFECTS AND DOSAGE

Drug	Systemic vasodilation	Systemic vasoconstriction	Inotropic effect	Chronotropic effect	Dysrhythmias	Dosing
Dopamine	+	0 to +++	++	+++	++	0.5–5 $\mu\text{g}/\text{kg}/\text{min}$ for low range 5–10 mid range 10–20 high range
Dobutamine	++	0 to +	++++	++	+	2.5–20 $\mu\text{g}/\text{kg}/\text{min}$
Epinephrine	++	+++	++++	+++	+++	0.5–10 $\mu\text{g}/\text{min}$

TABLE 11.10

ANTIBIOTIC REGIMENS FOR ENDOCARDITIS PROPHYLAXIS IN HIGH- AND MODERATE-RISK PATIENTS UNDERGOING GENITOURINARY/GASTROINTESTINAL PROCEDURES

Patient type	Antibiotic	Regimen
High-risk patients ^a	Ampicillin plus gentamicin	Ampicillin 2.0 g IM/IV plus 1.5 mg/kg (not to exceed 120 mg) within 30 minutes of starting procedure; 6 hours later, ampicillin 1.0 g IM/IV or amoxicillin 1.0 g orally
High-risk patients ^a allergic to ampicillin/amoxicillin	Vancomycin plus gentamicin	Vancomycin 1.0 g IV over 1–2 hours plus gentamicin 1.5 mg/kg IM/IV (not to exceed 120 mg); complete injection/infusion within within of starting procedure
Moderate-risk patients ^b	Ampicillin or amoxicillin	Ampicillin 2.0 g IM/IV within 30 minutes of starting procedure or amoxicillin 2.0 g orally 1 hour 30 minutes before procedure
Moderate-risk patients ^b allergic to ampicillin/amoxicillin	Vancomycin	Vancomycin 1.0 g IV over 1–2 hours; complete infusion within 30 minutes of starting procedure

Note: IM, intramuscular; IV, intravenous.

^aHigh-risk patients: prosthetic cardiac valves; previous history of bacterial endocarditis; complex cyanotic heart disease (e.g., tetralogy of Fallot); surgically constructed systemic pulmonary shunts or conduits.

^bModerate-risk patients: other congenital cardiac malformations; acquired valvar dysfunction; hypertrophic cardiomyopathy; mitral valve prolapse with valvar regurgitation and/or thickened leaflets.

operative outcome, as previously mentioned (170). Patients with severe AS need valve replacement before elective surgery, whereas patients with mild to moderate AS need careful anesthetic control of blood pressure. Some patients may need intraoperative, continuous transesophageal echocardiography (171). The presence of aortic regurgitation, mitral stenosis, and mitral regurgitation require assessment of left ventricular function for the presence of congestive heart failure. Treatment and support will be related to support of ventricular function. Recently, the American Heart Association revised their recommendations for antibiotic prophylaxis for endocarditis (172). The common antibiotic regimens for endocarditis prophylaxis are presented in Table 11.10 for patients with anatomic cardiac defects and for whom risk is highest for the development of endocarditis after extended gastrointestinal or genitourinary operations.

Arrhythmias

Whenever an arrhythmia occurs in the postoperative setting, myocardial ischemia must first be ruled out (173). If ECG and cardiac enzyme measurement are normal, an electrolyte or metabolic derangement or drug toxicity exists. Fortunately, most arrhythmias in the postoperative period are transient and self-resolving. Asymptomatic arrhythmias, except in the preoperative period (Table 11.2), are generally of little clinical significance. Hypercapnia, hypoxemia, hypokalemia, acidosis, inadequate analgesia, and anemia can all promote cardiac arrhythmias. Supraventricular tachycardia is the most common rhythm disturbance seen in the postoperative period (174). Treatment with cardizem or a beta-blocker is usually effective after correction of the underlying etiology. One significant new development has been the use of amiodarone as first-line treatment of acute-onset atrial fibrillation. Its usage has been associated with a lower incidence of recurrent atrial fibrillation (175).

Pulmonary Issues

Ventilator Management

The ability to provide ventilatory support to the surgical patient has been a tremendous advance in postoperative care. Mechanical ventilators have enabled oncologic surgeons to perform major operations for aggressive control of lesions that were once considered to be unresectable. Although preemptive preoperative therapies attempt to avoid postoperative mechanical ventilation, some patients will require this therapy. Mechanical ventilation must be thought of as providing two functions: ventilation and oxygenation. However, these two functions must be separated and applied independently to each particular situation. A more difficult concept for residents and fellows to understand is that ventilation has nothing to do with oxygenation. Many patients decompensate on the ward despite supplemental oxygen and 100% oxygen saturation because tidal volumes were low and the patient was not ventilating.

When contemplating mechanical ventilation, one must ask two questions: is the patient able to oxygenate her tissues adequately and can she ventilate adequately to maintain normal partial pressure of carbon dioxide (PCO₂) and acid-base function? Adequate oxygenation can be determined by measurement of oxygen saturation and arterial partial pressure of oxygen (PO₂). Targets are generally an O₂ saturation >92% or PO₂ greater than 65 mm Hg. Poor oxygenation may be caused by fluid overload, depressed mental status, underlying pulmonary disease, or shunt. Evaluation of the arterial blood gas will also give a pH and PCO₂ measurement. Patients may hypoventilate for a number of reasons. Postoperative pain may prohibit deep inspiration. Conversely, overuse of pain medication may depress the level of consciousness, leading to fewer and poorer respirations. Atelectasis, pneumonia, and poor pulmonary compliance all lead to difficulties in ventilation. Finally, a bronchial mucous plug or a pneumothorax will lead

life-threatening ventilatory compromise. A respiratory rate greater than 35 per minute or a PCO_2 greater than 55 mm Hg are accepted indications for intubation and mechanical ventilation.

When intubating patients, the size of the endotracheal tube must be considered, as this may impact removal of mechanical ventilation. The larger the tube, the less resistance and the easier it will be for the patient to participate in “weaning” trials to discontinue ventilatory support (176). Typical recommendations are an 8.5-mm tube for women and a 9.0-mm tube for men.

Traditionally, there are pressure-cycled ventilators and volume-cycled ventilators. Pressure-cycled ventilators are used routinely in neonatal ICU patients because overinflation can be dangerous to neonates. In the adult ICU, most ventilators are volume cycled, meaning that the clinician sets the tidal volume, and regardless of the pressures necessary to give the volume, the volume will be delivered. In patients in whom pulmonary compliance is reduced (i.e., due to a stiff lung or acute respiratory distress syndrome [ARDS]), efforts at controlling pressure are important. When setting the ventilator, a number of decisions must be made. The mode of delivery, tidal volume, and rate will determine ventilation, whereas the fraction of inspired oxygen (FIO_2) and positive end-expiratory pressure (PEEP) will determine oxygenation.

Mode

There are a number of ventilator modes. The first developed was controlled mechanical ventilation (CMV), where the tidal volume and rate are set and that is exactly what the patient receives—no more and no less. This mode is very good for patients under general anesthesia or who are paralyzed. However, this mode is very disturbing to the patient who wishes to participate, however slightly, in her own ventilation. This mode has evolved into the current assist/control mode (A/C), whereby the patient is guaranteed the fixed rate and tidal volume but can also trigger breaths in between with a similar tidal volume. In addition, the machine will synchronize the breath when the patient triggers such a breath. This mode provides complete rest for the patient by performing all the work of breathing and is generally used for patients in the immediate postoperative period or for patients whose organ failure or ongoing sepsis is a more pressing concern.

Intermittent mandatory ventilation (IMV) is a mode whereby the clinician sets a rate and a tidal volume, which the machine delivers. Any breath initiated by the patient is delivered in relation to the amount of effort the patient puts forth, meaning a strong effort gives the patient a large breath and a meager effort a smaller one. This is sometimes called a weaning mode. The patient is given full support with rate and tidal volume until she is stronger. The rate is slowly turned down, allowing the patient more frequent, spontaneous breaths until extubation. Synchronized IMV (SIMV) ensures that a machine-delivered breath does not stack onto a patient-initiated breath.

Pressure support ventilation (PSV) is a mode where patient-initiated breaths are given support from the ventilator only during the beginning of ventilation (inspiratory phase). The support is meant to help the patient overcome the large amount of resistance present in the valves of the machine, the ventilator circuit, and the endotracheal tube. By titrating PSV to the spontaneous tidal volume produced by the patient, one can fully or partially support patient breathing and overcome the work of breathing. This mode of ventilation is important during the “weaning” process.

Work of Breathing

When conceptualizing the job of the ventilator, the different types of work must be defined (177). In addition to the physiologic work of breathing that all humans do on a daily basis,

huge workloads are imposed from the resistance of the ventilator equipment (e.g., breathing through a straw analogy). Finally, there is the pathologic work of breathing from the pneumonia, the incision, etc. The intent of mechanical ventilation during disease states is to assume the last two types of “work” so that the patient may convalesce. As a patient improves and the pathologic work has been removed, then the patient should be able to resume normal, physiologic work.

More Advanced Modes of Ventilation

With advanced circuitry and computer microprocessors, newer ventilator modes have been developed. Pressure-regulated volume control (PRVC) has largely replaced AC ventilation (ACV). PRVC provides the same function as AC while preventing overinflation. Recent data have shown that preventing overinflation (or stretch) of alveoli prevents trauma and has a decreased incidence of ARDS (178). PRVC delivers the same tidal volume but changes the flow rate to prevent high pressures by measuring the pressure on a breath-to-breath basis. Volume control (VC ventilation) is a mode whereby a tidal volume target is set and the ventilator continually titrates the amount of PSV to provide this volume. This mode has been termed “autoweat” or “week-end” mode because as the patient gets stronger, he or she will be able to meet the tidal volume setting. In situations where difficulties in ventilation are encountered, such as ARDS, hypercarbia, and acidosis, pressure control (PC) is used. This mode is similar to the neonatal pressure-cycled ventilator where the maximum pressure is set and the flow rate is decreased but the inspiratory time is lengthened to achieve proper ventilation. Airway pressure release ventilation (APRV), high-frequency jet ventilation, and inverse ratio ventilation are other advanced modes beyond the scope of this chapter.

Setting the Ventilator

Initial ventilator settings require a rate of 12 to 14 breaths per minute with a tidal volume of 6 to 8 cc/kg. This is a departure from the traditional 12 cc/kg, which has been determined to result in greater alveolar trauma and increased risk for the development of ARDS (179). After initial setting of the ventilator, measurements of pH, PO_2 , and PCO_2 from arterial blood gas are used to make further ventilator adjustments.

Oxygenation

Oxygenation is controlled by two settings: FIO_2 and PEEP. The inspired oxygen content can easily be controlled on the ventilator, keeping oxygen saturation greater than 92%. Inspired oxygen levels greater than 60% are considered to be potentially toxic, with such levels leading to pathologic changes similar to ARDS with acute inflammation and fibroproliferative changes. Human studies are few and have only examined effects on normal lungs, whereas no studies have clearly delineated the toxic effects of high oxygen levels in patients with underlying pulmonary disease (180). If it is necessary to have oxygen concentrations above 60%, the recommendation is to wean these levels as soon as possible. PEEP is another mechanism for improving oxygenation. In normal physiology, the glottis closes before full expiration, creating a PEEP of approximately 4 cm H_2O , and is termed physiologic PEEP. When ventilating patients, the addition of 5 cm H_2O PEEP is used as a baseline and is increased if added oxygen delivery is required. Increasing PEEP is the preferred method for improving oxygenation in postsurgical patients as opposed to increasing the FIO_2 . Postsurgical patients have atelectasis and shunting secondary to operative pain and anesthesia. The addition of PEEP recruits collapsed alveoli, improving oxygenation and lung compliance. However, the use of PEEP must be balanced by potential adverse effects, which include decreased cardiac output

and the risk for barotrauma. Kirby et al. have shown that PEEP levels of 30 to 40 mm H₂O are easily tolerable in most patients; however, few clinical situations present in which patients need levels of PEEP this high (181).

Weaning From Ventilator

Multiple opinions exist on the techniques of weaning patients from mechanical ventilation, and no prospective randomized trial has proven one method to be superior to another (182). T-piece trials, spontaneous breathing trials, SIMV, and PSV are just a few. The best method of weaning is a treatment pathway agreed upon by clinicians, nurses, and respiratory therapists. Before discontinuing mechanical ventilation, the disease process that required ventilation should have resolved and patients should have proper mental status and the ability to generate a cough. Copious secretions are often an initial reason not to consider weaning or extubation. Criteria for extubation, whether on T-piece or minimal PSV, have traditionally included a respiratory rate less than 35, a PCO₂ less than 50 mm Hg, and a negative inspiratory force (NIF) greater than -20 cm H₂O.

Acute Respiratory Distress Syndrome

ARDS is a condition that has been well recognized and extensively studied (183). It is a form of refractory hypoxemia that can be elicited by a number of insults. In 1994, a consensus of American and European intensivists defined the criteria for ARDS and a lesser form deemed acute lung injury (ALI) (184). Criteria include (a) acute onset after defined insult; (b) bilateral diffuse infiltrates on chest radiograph; (c) no evidence of left atrial hypertension, CHF, or a PAOP less than or equal to 18 mm Hg; and, most importantly, (d) impaired oxygenation. Impaired oxygenation was classified as ALI if the partial pressure of arterial oxygen (PaO₂)/FIO₂ ratio was ≥ 300 mm Hg and ARDS if the PaO₂/FIO₂ ratio was ≥ 200 mm Hg. Postmortem examination of lungs with ARDS shows atelectasis, edema, inflammation, hyaline membrane deposition, and fibrosis. The mortality of ARDS is 30% to 40%. Treatment of these severely hypoxemic patients consists of mechanical ventilatory support with FIO₂ and PEEP. Because of alveolar damage, ventilation/perfusion mismatch occurs, resulting in a worsening shunt fraction and increasing dead space. As the pathologic process continues, not only does oxygenation become difficult, but so also does ventilation as a result of decreased pulmonary compliance. The end result is a hypercapnic state and respiratory acidosis.

The recent ARDS NET trial comparing high tidal volume to achieve normocapnia with low tidal volumes to prevent barotrauma has shown significantly improved survival with the low-volume protective strategy (178). Current strategies employ tidal volumes of 6 cc/kg and accept elevated PCO₂ levels (permissive hypercapnea).

The last 15 years have seen the elucidation of a number of systemic factors that are released upon physiologic insult (185). For example, cytokines, leukotrienes, endothelial adhesion molecules, and interleukins are useful in the defense of the organism, but are systemically detrimental when activated by certain disease states. Investigations of the multiple organ dysfunction syndrome (MODS) where sequential organ failure leads to patient death have given significant credibility to the hypothesis that the lung may be the first organ system susceptible to these circulating inflammatory mediators (186). The pulmonary endothelium is acutely sensitive to circulating cytokines and is the first to manifest damage. In addition to supportive treatment for ARDS, operative injuries or postoperative complications (e.g., intra-abdominal abscess, anastomotic leak) must be sought and ruled out aggressively. ARDS is the result of some inciting cause and does not arise *de novo* as a primary problem.

Pneumonia

Pneumonia is a significant complication in postsurgical patients. Patients requiring mechanical ventilation are particularly susceptible to pneumonia (ventilator acquired pneumonia [VAP]) with rates as high as 30% after 72 hours of ventilation. The mortality rate from VAP ranges from 25% to 50%. The pathogens are often gram negative and resistant to multiple antibiotics. High clinical suspicion and aggressive treatment of VAP is crucial. An exhaustive review of this complicated and serious topic by Chastre and Fagon is recommended for further reading (187).

Pulmonary Embolism and Deep Venous Thrombosis Prophylaxis

The prevention of venous thromboembolism is an important component of perioperative management of the gynecologic oncology patient. The American College of Chest Physicians consensus statement published in 1998 reviews the data exhaustively and provides recommendations (188). Risk factors include age greater than 40 years, prolonged immobility, prior deep venous thrombosis (DVT), cancer diagnosis, major surgery, obesity, CHF, MI, stroke, indwelling femoral catheter, inflammatory bowel disease, estrogen use, nephrotic syndrome, and hypercoagulable states. The incidence of DVT in large groups of general surgical patients is around 20% and increases to 30% in patients with cancer diagnoses. The incidence of pulmonary embolism (PE) is 1.6% with a fatal PE rate of 0.9%. In trials comparing low-dose unfractionated heparin (LDUH) with no therapy in general surgical patients, the DVT rate was decreased from 25% to 8%. These studies also produced a 50% decrease in rate of fatal PE (188). Comparisons of low-molecular-weight heparin (LMWH) versus unfractionated heparin have shown equal efficacy. LMWH may have less bleeding complication (mostly wound hematomas) and greater ease of use with once daily dosing.

Sequential pneumatic compression devices (PCDs) are attractive for patients at risk for bleeding complications. In trials comparing PCD with LDUH, both have shown efficacy. Elastic stockings (Ted's hose) and aspirin usage are not currently recommended as DVT prophylaxis. Recently, studies have shown D-dimer positivity with DVT and PE, but the presence of any released blood or hematoma (i.e., any postoperative patient) makes the D-dimer positivity nonspecific. In the surgical patient, a negative D-dimer makes DVT or PE highly unlikely; however, a positive test is essentially useless.

Patients at low risk (age less than 40 years, no risk factors, and minor surgery) need no prophylaxis, but early ambulation is encouraged. Moderate-risk patients (minor surgery in a patient with risk factors, major surgery with no risk factors) should receive PCD, LMWH, or LDUH, with equal results. High-risk patients require LMWH in addition to PCD.

Diagnosis of DVT is performed by duplex ultrasonography, and treatment is with either heparinization to 1.5 times control prothrombin time or therapeutic doses of LMWH. Diagnosis of PE was traditionally made by pulmonary arteriogram. This practice has recently been abandoned because dynamic contrast-enhanced computerized tomography has better sensitivity. Once diagnosis is confirmed, the patient is anticoagulated with IV heparin or LMWH. Ultimately, the patient is converted to warfarin (Coumadin) therapy for at least 3 months in the case of DVT and 6 months in the case of PE.

Fluid and Electrolyte Issues

Understanding fluid and electrolyte physiology in gynecologic oncology is paramount because of the underlying disease processes that face the gynecologic oncologist and the ultimate,

TABLE 11.11**BODY FLUID COMPARTMENTS**

Total body water	Body weight (%)	Total body water (%)
Total	60	100
Intracellular	40	67
Extracellular	20	33

radical surgical interventions that are needed to treat them. These treatments result in great fluid shifts perioperatively, requiring careful attention to input of fluids (volume and content/type) as well as output from renal and gastrointestinal sources, insensible sources, and drains. Since extensive discussions of these topics can be found elsewhere, this section presents a brief review of normal fluid and electrolyte physiology and discusses strategies for fluid resuscitation and correction of electrolyte deficiencies.

Total body water (TBW) can be calculated by various methods and varies directly with the amount of adipose or lean tissue present in an individual patient. TBW estimates, therefore, must be adjusted based on the adiposity of the patients. In women, TBW accounts for approximately 60% of a patient's weight. TBW is distributed into extracellular fluid (ECF) and intracellular fluid (ICF), with the ECF being further divided into intravascular (one quarter of the ECF) and interstitial (three quarters of the ECF) compartments. The ECF accounts for approximately one third of the TBW, whereas ICF accounts for two thirds (189,190). Direct measurement of the ECF and TBW are possible with the resulting difference being an estimated ICF. Table 11.11 describes the body fluid

compartments and their contributions to body weight. Despite these arbitrary compartments (and electrolyte concentration differences between compartments, which are discussed in the paragraph below), water flows freely across all compartments. Thus, a derangement in one compartment will result in a compensatory change in another (191).

The electrolyte composition of the various compartments is different. Sodium is the predominant cation in the ECF and potassium is the predominant cation of the ICF. Table 11.12 describes the various concentrations of electrolytes in the various fluid compartments. Because of the Donnan principle of equilibration, the content of cations and anions in the interstitial compartment is slightly higher than the intravascular compartment. This principle describes the unique relation between solutions of permeable and impermeable complex anions when these anions are unevenly distributed across a semipermeable membrane. Water, on the other hand, as mentioned earlier, freely equilibrates between the compartments (191).

Effective circulating volume (ECV) is a term used to describe the portion of the ECF that perfuses the organs of the body and affects baroreceptors (see next paragraph). In healthy patients, the ECV equates to the intravascular volume/compartments. But in disease states that increase "third spacing" such as sepsis (leaky capillaries), ascites due to intra-abdominal metastasis, or bowel obstruction with resulting edema and transudation, the interstitial compartment increases at the expense of the intravascular compartment, decreasing the ECV (189).

The osmotic activity of a fluid compartment is affected by the component ions and is described in milliosmoles (mOsm). Normal serum osmolality (in the ECF, of course) averages 290 mOsm/kg of H₂O. Osmoreceptors in the hypothalamus respond to small changes in serum osmolality, increasing or decreasing secretion of antidiuretic hormone (ADH) and modifying the thirst response. These receptors are responsible for the day-to-day fine tuning of fluid balance. Baroreceptors, on the other hand, in the intrathoracic vena cava, the atria, the aortic arch, the carotid arteries, and the renal parenchyma, sense volume changes by changes in pressure. These receptors begin a cascade of mediators such as aldosterone, atrial natriuretic peptide (ANP), prostaglandins, and the renin-angiotensin system, which ultimately result in changes of water and sodium

balance mediated through the kidneys. These baroreceptors have little to do with the day-to-day fluid management and require intravascular losses of 10% to 20% to initiate activity (191).

The goal of fluid resuscitation is to maintain the ECV and return the patient to a homeopathic state. Many gynecologic oncology procedures are lengthy and can result in large blood losses requiring immediate intraoperative replacement. In addition, following procedures where evacuation of large amounts of ascites has occurred and/or “peritoneal stripping” has left denuded surfaces, these patients may have large fluid shifts into the interstitial compartment requiring large volumes of fluid to maintain the ECV. Finally, losses are not water alone and include electrolytes and clotting factors, which may need repletion. Selecting fluids to administer to a given patient is akin to selecting the correct intravenous medication to give; not *all* fluids are for *all* patients. The physician should understand the amount of daily maintenance fluid and electrolytes required by patients, calculate losses (fluid and electrolytes), determine ongoing fluid and electrolyte losses, and replace them with the appropriate fluid and electrolyte combinations. It is easy to fall into the trap of giving all patients an 8-hour rate (125 mL/h) of maintenance fluid. However, an octogenarian, even with normal cardiac and renal function, weighing 50 kg does not need that much maintenance fluid. “Formulas” for calculating appropriate maintenance fluid requirements exist (191), but calculating 30 to 40 mL/kg/day, depending upon body frame size, is a much simpler and quicker estimate of maintenance fluid requirements for patients.

In general, the normal maintenance requirement of sodium is 1 to 2 mEq/kg/day and for potassium 0.5 to 1.0 mEq/kg/day. Table 11.13 lists the various IV fluid preparations available for fluid resuscitation. Which fluid to be used is controversial and driven, in more instances, by “dogma,” varying from physician to physician and institution to institution rather than by evidence. Controversy over which fluid type to use in fluid resuscitation continues to this day. Several meta-analyses have shown no advantage of colloid over crystalloid for resuscitation in surgical patients (192–199). Almost all studies have shown that administered colloid leaks from the intravascular compartment to the interstitial compartment in several hours, decreasing the ECV and requiring further administration of colloid (192–199). The use of colloid has been shown to be advantageous in conditions of hypoproteinemia or malnourished states where patients require plasma volume expansion and cannot tolerate large amounts of fluid (199).

Most of the time patients are given isotonic solutions, such as lactated Ringer’s solution, to cover perioperative losses. In the immediate postoperative course, patients are given their maintenance fluid requirements in addition to the immediate intraoperative losses. It is helpful to convert all losses to equivalents of crystalloid to determine fluid rates. For example, to replace 500 mL of blood loss, one would give 1,500 mL of isotonic fluid, a ratio of 3 mL of crystalloid to 1 mL of blood loss. It is traditional to replace one half of the intraoperative losses in the first 24 hours, with the rest being replaced during the ensuing several days. Other intraoperative losses, which need to be accounted for, are the insensible losses that occur through evaporation from the incision (5 to 10 mL/kg/h of operation) and from the anesthesia circuit and ascites.

Sodium Derangements

Hyponatremia is the most common electrolyte abnormality seen in postoperative patients and is caused by excess free water rather than a depletion of sodium. Increases in free water absorption are mediated by a self-limited, physiologic increase in the secretion of ADH in response to the stress of surgery. Serum sodium levels rarely fall below 130 mEq/L, but may be further exacerbated by intravenous administration of large volumes of hypotonic solutions (i.e., 0.2%, 0.33%, 0.45% sodium solutions). Other disease states can result in a hyperosmolar condition, resulting in a hyperosmolar ECF, causing fluid to shift from the ICF and lowering the sodium levels. These conditions include hyperglycemia, mannitol ethylene glycol or ethanol ingestion, and uremia. For each increase of 180 mg/dL of glucose above 100 mg/dL, there is a concomitant decrease in the serum sodium of 5 mEq/L (198). In addition, during situations where potassium is low, there is a compensatory exchange of sodium for potassium, resulting in hyponatremia. In either of these prior cases, total body sodium does not change. Finally, patients with hyperproteinemia or hyperlipidemia may have falsely low sodium values, which result from errors in the laboratory measurement of sodium. This *pseudohyponatremia* does not result in any symptoms of hyponatremia (191).

The symptoms of hyponatremia are driven by cellular water intoxication and are related to the central nervous system (CNS) (e.g., lethargy, headaches, confusion, delirium, weakness, muscle cramps). The rate at which hyponatremia occurs also determines the symptoms. Chronic hyponatremia tends to be asymptomatic, whereas acute drops in the serum sodium (levels 120 to 130) result in the symptoms listed

TABLE 11.13

ELECTROLYTE CONTENT OF COMMONLY USED INTRAVENOUS ELECTROLYTE SOLUTIONS

5.0% NaCl	855	—	—	—	855	—

Source: Adapted from Wait RB, Kahng KU, Dresner LS. Fluid and electrolytes and acid-base balance. In: Greenfield LJ, Mulholland M, Oldham KT, et al. eds. *Surgery: Scientific Principles and Practice*. 2nd ed. Philadelphia: Lippincott–Raven Publishers, 1997:242–266, with permission.

above. Correction of hyponatremia must be done carefully to avoid central pontine myelinolysis, which results in the "locked-in syndrome."

Because most hyponatremia is related to dehydration (low ECV) simple correction of this state will increase the sodium plasma level. If the patient has a high ECV (such as the syndrome of inappropriate antidiuretic hormone [SIADH] secretion) or is in an edematous state, free water restriction should normalize the sodium level. However, if patients have symptoms of hyponatremia, aggressive replacement of sodium is prudent should the duration of the hyponatremia be determined to be no longer than 48 hours. Hyponatremic states longer than 48 hours increase the risk of central pontine myelinolysis. Chronic cases need replacement at rates not to exceed 0.5 mEq/L/h. Acute cases may be replaced at rates of 5 mEq/L/h.

Hypernatremia is an uncommon finding and is related to large volumes of free water loss (through insensible routes such as breathing, sweating, and ventilation), diabetes insipidus, adrenal hyperfunction, or ingestion or administration of increased sodium solutions. Again, the symptoms are predominantly CNS oriented because of brain cell dehydration. Symptoms rarely occur until serum sodium levels exceed 160 mEq/L. In addition, the rapidity at which the derangement occurs determines the symptoms manifested. Treatment is carefully done with replacement of free water. Replacement too rapidly can cause cerebral edema and herniation. Patients with chronic hypernatremia need free water administration, which decreases the serum sodium no faster than 0.7 mEq/L.

Potassium Derangements

Whereas sodium is the major extracellular cation, potassium is the major intracellular cation by a ratio of 30:1. The intracellular potassium concentrations tend to be relatively constant, whereas the extracellular concentrations vary depending upon renal function/excretion. The majority of potassium secretion occurs in the distal tubule and the collecting duct of the nephron. Secretion is stimulated by increased urine flow, increased sodium delivery, high potassium levels, alkalosis, aldosterone, vasopressin, and β -adrenergic agonists. Insulin causes potassium to move into cells (as previously mentioned), reducing the extracellular concentration of potassium. Serum potassium levels are further affected by the acid-base status of patients. In alkalotic states, the potassium shifts into cells in exchange for hydrogen ions, whereas in acidotic states the exchange is opposite.

The predominant reason for hyperkalemia in a postoperative patient is renal dysfunction or failure. When these patients become critically ill, serum potassium concentrations can increase by 0.3 to 0.5 mEq/L/day in noncatabolic patients and 0.7 mEq/L/day in catabolic patients. It is important to rule out a spuriously elevated level secondary to hemolysis at the time of the blood draw either from too small a gauge of needle or simply from the application of the tourniquet and squeezing (191).

Hyperkalemia changes the membrane potential established by differences between the intracellular and extracellular milieu. This increased concentration has deleterious effects on cardiac muscle function, causing peaked T waves, flattened P waves, prolonged QRS complexes, and deep S waves on the ECG and possibly resulting in ventricular fibrillation and cardiac arrest. Skeletal musculature is also affected with paresthesias and weakness, which can progress to a flaccid paralysis.

Treatment for hyperkalemia has been outlined in the section on renal risk factors. The mainstay is saline diuresis unless ECG changes are present, then infusion of calcium gluconate can be lifesaving. Utilization of 25 to 50 g of glucose and 10 to 20 units of regular insulin can drive potassium intracellularly and transiently lower plasma levels. Ultimately, definitive therapy relies upon increased excretion of potassium. For each

gram of sodium polystyrene sulfonate (Kayexalate, given in the doses previously mentioned) used either orally or rectally, 0.5 mEq of potassium will be removed. Finally, in patients not responding to these therapies or patients with renal failure, hemodialysis may be indicated.

Hypokalemia is caused by decreased intake, increased gastrointestinal losses (vomiting, diarrhea, fistulae), excessive renal losses (metabolic alkalosis, magnesium deficiency, hyperaldosteronism), a shift of potassium into the intracellular space (acute or uncompensated metabolic alkalosis, glucose and insulin administration, catecholamines), or any combination thereof. A reduction of serum potassium by 1 mEq/L represents a total body deficiency of about 100 to 200 mEq. (Remember that total exchangeable potassium is approximately 3,000 mEq with the majority being intracellular and thus the majority of the loss [191].) Symptoms of hypokalemia cause ECG changes with flattening of the T waves, depression of S-T segments, prominent U waves, and prolongation of the Q-T interval. Treatment is accomplished by replacement of potassium either orally or intravenously, depending upon the severity of symptoms and whether or not the patient is able to take oral preparations. Intravenous replacement of potassium can be done at approximately 10 mEq/h and should not be more concentrated than 40 mEq/L. If less fluid is desired, 20 mEq can be placed in 100 mL, but administration should not exceed 40 mEq/h (191).

Magnesium Derangements

Most magnesium in the body is confined to the intracellular space and bone. Less than 1% of total body magnesium is in the serum. Of the magnesium in the serum, 60% is ionized, 25% is protein bound, and 15% is complexed with nonprotein anionic species (191). Magnesium is absorbed in the small intestine, directed by levels of vitamin D, and filtered by the kidney for excretion. Approximately 40% of renally excreted magnesium is reabsorbed in the ascending loop of Henle. Loop diuretics, hypermagnesemia, hypercalcemia, acidosis, and phosphate depletion result in increased excretion of magnesium.

Patients with renal failure and receiving magnesium-containing antacids or laxatives can become hypermagnesemic. In addition, patients with acidosis and dehydration may become hypermagnesemic. Patients present with CNS depression, loss of deep tendon reflexes, and ECG changes (prolonged P-R interval and QRS complex) in the face of elevated magnesium levels (greater than 8 mg/dL). As levels rise, patients will develop coma, respiratory failure, and/or cardiac arrest. Acute treatment of hypermagnesemia is slow IV infusion of 5 to 10 mEq of calcium. Because the etiology of this condition is usually renal failure, withholding magnesium-containing preparations may be all that is necessary. In severe instances, hemodialysis is required.

In gynecologic oncology patients, the overwhelming reason for hypomagnesemia is a history of cisplatin administration. However, other conditions such as hypoparathyroidism, malabsorptive states, chronic loop diuretic use, and the diuretic phase of acute renal failure can cause hypomagnesemia. Symptoms are similar to hypocalcemia with muscle weakness, fasciculations, tetany, hypokalemia, and ECG changes (Q-T prolongation, torsade de pointes). Treatment can be accomplished with oral preparations in less acute situations. However, large doses may produce diarrhea, worsening the situation. Intravenous boluses of 2 to 3 g followed by infusions of 1 to 2 mEq/kg/day can be utilized for patients with severe symptoms.

Calcium Derangements

Almost all the calcium in the body is in bone, stored as hydroxyapatite crystals, and provides a supply that can be exchanged to the serum. Calcium homeostasis is controlled by

parathyroid hormone (PTH), controlling intestinal absorption of calcium, renal excretion of calcium, and exchange of calcium from the bone. In the serum, calcium exists in three phases: 45% as an ionized form, which is responsible for most of the physiologic function of calcium; 40% in a protein bound form, bound mostly to albumin; and 15% in a nonionized form, complexed with nonprotein anions that do not easily dissociate. A serum total calcium level is usually obtained when assessing calcium homeostasis, as measurement of ionized calcium is cumbersome. The total calcium levels change by 0.8 g/dL for each 1 g/dL change of albumin (up or down) (191).

In gynecologic oncology patients with hypercalcemia, the underlying malignancy is usually the etiologic agent. Hypercalcemia may be caused by direct bony involvement or, more commonly, secretion of PTH-like peptides and/or other humoral factors, which increase serum calcium levels. Other reasons for hypercalcemia include primary, secondary, or tertiary hyperparathyroidism, thiazide diuretic use, or lithium usage (191,200). Patients present with muscle fatigue, weakness, confusion, coma, ECG changes (shortening of the Q-T interval), nausea, and vomiting. The goal of treatment is to increase calcium excretion and stop bone turnover in order to decrease serum total calcium. Initial measures include vigorous hydration (200 mL/h) with 0.9% or 0.45% saline solutions. Furosemide or other loop diuretics may be helpful in patients with borderline cardiac function or in patients with fluid overload. If the underlying malignancy is a breast carcinoma, patients may respond to high doses of steroids to reduce calcium levels. Other pharmacologic agents have been developed to stop bone resorption and reduce serum calcium levels. Calcitonin (4 IU/kg every 12 hours via subcutaneous or intramuscular injection) has a rapid onset of action and works by interfering with osteoclast maturation at several points (200). However, the duration of response is usually about 48 hours because of down-regulation of calcitonin receptors by osteoclasts. Bisphosphonates have emerged as the drug of choice for treatment of hypercalcemia in malignancy. These agents work by inhibiting osteoclast activity and survival. The nitrogen-containing bisphosphonates are the most potent. Pamidronate (approved in 1991) and zoledronic acid (approved in 2001) are utilized in the United States. Another agent, ibandronate, is utilized in Europe but has not been approved for use in the United States. Zoledronic acid is the current drug of choice because of its proven superiority over pamidronate (201). The effective dose of zoledronic acid is 4 mg infused over 15 minutes and dosed every 3 to 4 weeks. Serum calcium levels return to normal in approximately 10 days and duration of response lasts approximately 40 days (202). Surgical resection is the treatment of choice for primary, secondary, or tertiary hyperparathyroidism (191,200).

Hypocalcemia is caused by hypoparathyroidism, hypomagnesemia, pancreatitis, and malnutrition. Patients present with tetany, hyperactive deep tendon reflexes, a positive Chvostek sign, positive Trousseau sign, and ECG changes (prolonged Q-T interval, prolonged S-T segment). Low levels of calcium may be present because of low albumin levels, but these levels do not affect the ionized portion of calcium and usually do not cause symptoms. Symptomatic hypocalcemia can be treated with intravenous infusion of either calcium gluconate or calcium chloride at a rate not to exceed 50 mg/min. Calcium chloride dissociates into the ionized form of calcium more readily and is the treatment of choice to raise serum ionized calcium level.

Acid-Base Disturbances

Optimum cellular function requires a very narrow range of pH for chemical reactions to occur normally. Several buffering systems exist within the body to maintain this optimum pH. The predominant buffering system is the carbonic acid-bicarbonate buffering system. Derangements in the concentration of bicarbonate (HCO_3^-) or in concentrations of carbon dioxide (CO_2) result in acid-base disorders. Because the kidneys control excretion/generation of bicarbonate and the lungs exchange CO_2 , these organs play a central role in the compensation of any acid-base disorder. Therefore, four situations arise in acid-base balance: metabolic acidosis and alkalosis, and respiratory acidosis and alkalosis. Compensatory mechanisms exist in each situation in order to blunt the effect on pH (Table 11.14).

Metabolic Acidosis

Most clinically significant metabolic acidosis occurs with a net loss of bicarbonate either due to direct loss or when consumption is greater than generation. Situations where extra renal losses of bicarbonate occur include diarrhea, gastrointestinal fistulae, and urinary diversions (ureterosigmoidostomy or ureteroileostomy, which result in reabsorption of NH_4Cl from urine). Certain disease states result in the production of organic acids (ketoacidosis and lactic acidosis), which consume bicarbonate and outpace the renal compensatory mechanisms. Similarly, overdoses of certain drugs (e.g., aspirin) or ingestion of toxins (e.g., ethylene glycol, methanol) consume bicarbonate and outpace the renal compensatory mechanisms. Renal acidosis occurs when the intrinsic acid-excreting function of the kidney malfunctions, resulting in retention of acid and consumption of bicarbonate without concomitant regeneration of bicarbonate. These are classified as renal tubular acidosis (RTA I, distal tubule dysfunction; or RTA-II, proximal tubule dysfunction). Cardiac effects are the major findings in metabolic acidosis (peripheral arteriolar dilation, decreased

cardiac contractility, and central venous constriction). Other manifestations of metabolic acidosis include gastric distention, abdominal pain, nausea, and vomiting. In surgical patients, lactic acidosis is the primary cause of metabolic acidosis and results from tissue hypoperfusion. Therefore, treatment should be aimed at increasing tissue perfusion with fluid and blood administration. The use of bicarbonate is best reserved for patients with other, not easily reversible causes of metabolic acidosis. Older patients and patients with cardiovascular disease may benefit from administration of bicarbonate. Administration should be instituted when the pH is 7.1 to 7.2. One or two ampules of bicarbonate (approximately 55 mEq/amp) can be administered intravenously, with further administrations being dictated by the pH obtained from an arterial blood gas measurement. In diabetic ketoacidosis, treatment with insulin and glucose infusion should not only reverse the acidosis but also treat the hyperglycemia.

Metabolic Alkalosis

Sustained metabolic alkalosis is an uncommon clinical entity and is related to renal dysfunction. Loss of HCl is the most common reason for an increase in extracellular bicarbonate. This situation occurs with prolonged nausea and vomiting or prolonged nasogastric suctioning of gastric contents. As acid is removed from the gastrointestinal tract, a net gain of bicarbonate occurs. Other situations that can result in metabolic alkalosis include volume contraction, exogenous administration of bicarbonate or bicarbonate precursors (citrate, lactate, or calcium carbonate), hypokalemia, hypercalcemia, hypochloremia, excess mineralocorticoid usage, and high PCO_2 . Patients rarely present with symptoms, as metabolic alkalosis occurs gradually. However, in patients who develop this situation acutely, most symptoms are CNS oriented (e.g., confusion, stupor, coma, muscle fasciculations, tetany). Correction of the underlying disease state usually corrects the metabolic alkalosis. Repletion of electrolyte abnormalities and infusion of appropriate fluids (chloride containing) restore volume and result in normal renal excretion of excess bicarbonate.

Respiratory Acidosis

A depression of the pH occurs when there is hypoventilation. This occurs secondary to airway obstruction, COPD, depression of the respiratory center, impaired excursion of the thorax, or inappropriate ventilatory management in the mechanically ventilated patient. Development of symptoms depends upon the chronicity or acute nature of the event. If chronic, most patients have no symptoms. If it is an acute change, drowsiness, restlessness, headache, or development of a flapping tremor may occur. Treatment of this condition is aimed at the underlying cause of the hypoventilation. In chronic conditions, the hypoxemia, and subsequent hypercapnia, resulting from the hypoventilation may be the sole drive for the patient's respirations. Correction of the hypoxemia may further worsen the respiratory acidosis and must be considered. In general, correction of the PCO_2 must be done slowly because re-equilibration of cerebral bicarbonate concentration lags behind systemic changes (191).

Respiratory Alkalosis

Respiratory alkalosis occurs when the PCO_2 decreases with hyperventilation. Hyperventilation may occur because of hypoxia, drugs, decreased lung compliance, and mechanical ventilation. With drops in the arterial PO_2 , the peripheral chemoreceptors (in the carotid and aortic body) sense this change and result in hyperventilation to increase arterial PO_2 with a resulting decrease in PCO_2 . Because of renal compensatory mechanisms, this condition is usually asymptomatic.

However, in acute situations, patients may have a sensation of breathlessness, dizziness, nervousness with altered levels of consciousness, and tetany. Treatment of underlying hypoxia should address the hyperventilation. If acute symptoms are present, having the patient re-breathe expired air should temporarily relieve the symptoms.

Postoperative Nutritional Issues

As mentioned earlier, the full consideration of nutrition in the gynecologic oncology patient is presented in Chapter 33. In this section, we will discuss early refeeding in the postoperative gynecologic oncology patient, indications for enteral nutrition, and total parenteral nutrition (TPN).

Although malnutrition has been shown to be prevalent among gynecologic oncology patients (98), many patients are adequately nourished, undergo surgery uneventfully, and have return of bowel function in 2 to 5 days while simultaneously resuming oral intake. Recently, several prospective randomized trials have been conducted that demonstrate the utility of early refeeding in the postoperative period. In these studies, patients in the early feeding group were fed on the first postoperative day, with 90% or more tolerating diets. The underlying malignancies, types of operations, and complications occurred at similar rates between the early refeeding and the "traditionally fed" patients in all the studies. The placement of nasogastric tubes (NGTs) for intolerance of diet was low among the studies (less than 10% incidence). Finally, length of hospital stay was shorter among the earlier fed patients (203–208).

The use of the enteral route is preferred in sustaining or repleting patients in the postoperative period after extensive procedures. Enteral nutrition utilizes normal physiologic absorptive mechanisms, maintains gut epithelial integrity, and reduces infectious morbidity (209,210). Studies on nutrition have found that the splanchnic circulation and support of the mucosal integrity of the small bowel may prevent progression to MODS (see Section on Multi-Organ Dysfunction Syndrome). Specifically, the intestinal mucosa will atrophy secondary to lack of luminal nutrients and intermittent activation of the destructive cytokine pathways, and/or intermittent translocation of bacteria into the blood stream will occur. These events result in "priming" neutrophils, which ultimately leads to a full-blown systemic inflammatory response, causing organ damage. A number of well-designed randomized trials have compared early enteral feeds to TPN in patients with pancreatitis, major elective surgery, and trauma (209,210). All of these studies have shown a clear benefit for early enteral feeding, with a decrease in infectious complications (210).

Although considered a nonessential amino acid in nourished, healthy patients, glutamine has emerged as an essential amino acid in patients who are stressed and critically ill. This amino acid has been shown to be an important component in maintaining enterocyte integrity and has now been added to most enteral preparations (101,209,210).

Enteral feeds may be given in a variety of fashions and each is associated with its own type and number of complications. Intra-gastric feeds may be accomplished with NGTs, oral-gastric tubes, or percutaneous endoscopic gastrostomy tubes (PEGs). Intra-gastric feeding has the advantage of utilizing the stomach as a reservoir for bolus feeding. In addition, stretching of the stomach stimulates the biliary-pancreatic axis, which may be trophic to the small bowel. Finally, the gastric secretions mix with the feeding material and decrease the osmolarity, thus reducing the incidence of diarrhea. The main disadvantage of this route of enteral feeding is the increased risk of gastric overdistention with high residual amounts of feeding material and the increased risk of aspiration pneumonia (209). Enteral feeds may also be accomplished through the placement of nasal

tubes, which are positioned into the pylorus, duodenum, or jejunum (such as Dobhoff tubes). These tubes have the advantage of being placed (or migrating) more distal in the upper gastrointestinal tract, greatly reducing the risk of aspiration. These types of tubes are preferred in patients who require long-term ventilation. Because of advances in endoscopic instrumentation, many of the tubes can be placed via this method. At the time of laparotomy, gastrostomy, or jejunostomy, tubes (such as a Stamm or Witzel tube) may be placed. These have the advantage of being placed at the time of major abdominal surgery under direct visualization/palpation. The techniques are described in other texts (209,211). Several enteral feeding preparations are available, but vary from hospital to hospital depending upon formulary makeup. The use of the enteral route is contraindicated in patients with mechanical intestinal obstructions, and for these patients nutritional support can be accomplished through the parenteral route.

TPN took the forefront in nutritional sustenance and replacement in the 1980s. The basic premise of TPN is to provide dietary precursors to maintain anabolic function. TPN can be broken into three components of replacement: glucose and lipid preparations for normal or increased energy expenditures, and amino acid preparations for protein synthesis. Because of the higher osmolar load presented by these preparations, central venous access is necessary for administration. Subclavian, internal jugular, or peripherally inserted central catheters (PICCs) will need to be placed, and they present the first of several potential complications associated with TPN administration. At the time of placement, pneumothorax, intubation of arterial structures, air embolism, or cardiac arrhythmias may occur. Later complications include the possibility of infection at the skin entrance site or line sepsis. Should these infectious complications occur, removal of the catheter and antibiotic administration will be necessary (101).

The Harris-Benedict equation is utilized to calculate basal energy expenditure (BEE) for patients and approximates the BEE of a sedentary, fasting, nonstressed individual (212).

$$\text{BEE} = 666 + (9.6 \times \text{weight [kg]}) + (1.7 \times \text{height [cm]}) - (4.7 \times \text{age [yr]})$$

Because stress of disease and surgical intervention need to be considered, “stress factors” have been developed and are multiplied by the BEE to arrive at kilocalories per day. Stress level multipliers are 1.2 for a resting individual, 1.3 for an ambulatory individual or moderate stress (e.g., systemic inflammatory response syndrome [SIRS], sepsis), and 1.5 for severe stress/burn patients.

After calculation of caloric requirements, the composition of the TPN solution to be administered should be determined. Because there are many different types of TPN preparations available, consultation with the nutrition team or pharmacists

in an individual hospital is necessary to arrive at the desired solution.

In aerobic situations, glucose is the primary substrate for energy expenditure. It provides 3.4 kcal/g and is usually given in a concentrated form in order to provide 70% of the calculated calories. The remaining 30% of calories is provided by lipid preparations. Not only does this component have denser caloric content (it provides 9 kcal/g), but administration precludes the development of a fatty acid deficiency. Adjustment of the composition of TPN may be necessary depending upon the disease state (e.g., more contribution of kilocalories from fat vs. carbohydrate in a ventilated patient because of the respiratory quotient of fat vs. glucose).

Protein requirements are provided by amino acid solutions and are determined by the patient’s age, sex, nutritional status, ongoing stress, and comorbid conditions. In general, 25% of protein requirements are obtained by normal oral intake. The remaining protein comes from breakdown of serum and organic proteins. Thus, periods of prolonged malnutrition, with decreased protein intake, and increased stress of disease will lead to breakdown of visceral protein. An estimate of maintenance protein requirements is 1 g nitrogen per kilogram of body weight. In situations of increased stress, the patient may need 1.2 to 1.5 g/kg in order to maintain and/or replace protein losses. Table 11.15 shows serum protein measurements and their respective half-lives, which are useful for determining anabolic versus catabolic response to TPN treatment. Another method to assess nitrogen balance (positive or negative) is (192):

$$\text{Nitrogen balance} = \text{protein intake}/6.25 - (\text{urinary urea nitrogen} + 4)$$

The amount of protein intake is divided by 6.25 to give the grams of nitrogen taken in. The urinary urea nitrogen is expressed in grams based upon a 24-hour collection. The correction factor of 4 is meant to adjust for the grams of nitrogen lost in the stool or non-urea nitrogen losses.

In addition to these three main components of TPN, daily requirements of vitamins, trace elements, and insulin are necessary to maintain/regain nourishment. Again, these preparations vary by hospital formulary and need consultation with resident pharmacists.

The rate of infusion of TPN needs to be titrated upward to take into account the large glucose load that the patient will be receiving. This lower rate allows the pancreas time to increase insulin secretion in order to meet the glucose load being presented. Similarly, the rate of infusion needs to be decreased when TPN is being stopped to prevent hypoglycemia. During TPN administration, blood glucose measurements by finger stick are required so that hyperglycemia is avoided. For the first several days, measurement of serum electrolytes, with adjustments being made daily, is necessary.

TABLE 11.15

VISCERAL PROTEINS UTILIZED AS INDICATORS FOR NUTRITIONAL STATUS DURING NUTRITIONAL REPLETION

Protein	Normal range	Half-life (days)	Levels low in	Levels high in
Albumin	3.5–5.4 g/dL	18	Liver disease, pregnancy, overhydration, nephrotic syndrome	Dehydration
Transferrin	200–400 mg/dL	8	Chronic infection, chronic inflammation, liver disease, iron overload, nephrotic syndrome	Iron deficiency, pregnancy
Prealbumin	20–40 mg/dL	2	Liver disease, inflammation, surgery, nephrotic syndrome	
Retinol-binding protein (RBP)	3–6 mg/dL	0.5	Liver disease, hyperthyroidism, zinc deficiency, nephrotic syndrome	Renal insufficiency

As previously mentioned, complications from venous access are some of the drawbacks of TPN administration. Other complications include metabolic derangements, which most often are mild but need correcting as soon as they are identified, abnormalities of liver function tests, the clinical significance of which is unclear (101), and cholelithiasis/cholecystitis secondary to gallbladder sludge.

Renal Issues

Acute renal failure (ARF) or hospital-acquired renal insufficiency (HARI) continues to be a common problem among postsurgical patients. Although the incidence of HARI is 1.5 patients per 1,000 admitted, the impact of HARI on morbidity and mortality is quite high (mortality averages 45% but may exceed 80% if dialysis is required). The best methods for preventing HARI are reducing risk factors and reversing the condition by early detection and intervention (213).

When HARI presents in the postoperative patient, causes can be divided into three parts: prerenal, renal, or postrenal (inflow, parenchymal, and outflow). The function of glomeruli to create the urinary filtrate depends upon adequate renal perfusion and represents the prerenal component. If the renal mean arterial pressure (MAP) falls below 80 mm Hg, perfusion of the glomeruli decreases (some disease states require the renal MAP to be higher for adequate perfusion). Many situations can decrease renal MAP and include anesthetics, atherosclerotic emboli, decreased vascular resistance, hypotension, intravascular volume contraction, mechanical ventilation, sepsis, and any form of shock. Autoregulation of the glomeruli can be disrupted by nonsteroidal anti-inflammatory drugs (NSAIDs), angiotensin-converting enzyme (ACE) inhibitors, calcium channel blockers (diltiazem or verapamil), and endotoxins produced by gram-negative sepsis.

Renal parenchymal damage occurs most commonly in the postoperative patient because of prolonged hypotension or direct injury from inflammatory responses initiated by sepsis. In general, if the hypoperfusion is corrected quickly, reversible azotemia, creatinine elevation, and decreased urine output may be the only manifestations. However, prolonged hypoperfusion can cause acute tubular necrosis (ATN), which results in sloughing of renal tubular cells into the tubular lumen and obstruction. In addition, the production of Tamm-Horsfall proteins forms coarse granular casts, inciting an intense inflammatory response, further injuring the renal parenchyma (214,215). Other agents that can induce ATN include aminoglycoside antibiotics and iodinated contrast media. Approximately 15% of patients who receive aminoglycosides will have nephrotoxicity, and serum levels of these antibiotics need to be carefully monitored (216). Iodinated contrast media, used in multiple radiographic procedures, induces ATN by impairing nitric oxide production and increasing free radical formation (217,218). Diabetic patients with creatinine clearance rates less than 50 mL/min are at particularly high risk (219).

The final reason for ARF in the postoperative gynecologic oncology patient is outflow obstruction. Because of the radical pelvic procedures performed by gynecologic oncologists, ureteral injury is possible and needs to be excluded early in the evaluation of patients with ARF. Prompt reversal of the obstruction can further limit renal damage.

In general, expected postoperative urinary output should be maintained at 0.5 mL/kg of weight per hour. Most oliguria can be treated with intravascular expansion in the first 24 to 48 hours postsurgery. Hypoperfusion of the renal parenchyma must be avoided to prevent ATN from occurring. The definition of ARF is not standardized, but includes rising serial creatinine measurements, urine output less than 400 mL/24 hours, or, in drastic situations, the initiation of dialysis (213).

Once diagnosed, calculating the fractional excretion of sodium (FENa) or chloride can help to discern between prerenal causes or renal causes (hypoperfusions versus ATN). The formula is presented below (213):

$$\text{FENa} = (\text{urine Na level} \times \text{serum Cr level}) / (\text{serum Na level} \times \text{urine Cr level}) \times 100\%$$

If the FENa is less than 1% and the urine specific gravity is greater than 1.025, the diagnosis is hypoperfusion. However, if ischemia has occurred, the FENa will be greater than 4% and the urine specific gravity will fall to 1.01 because of tubular damage and loss of renal concentrating mechanisms. One cannot calculate FENa in patients who have received diuretics or hyperosmotic agents (e.g., mannitol or contrast media). If prerenal and renal causes of low urine output have been excluded, ultrasonography may be useful in evaluating for outflow obstruction.

Once the underlying causes for HARI have been eliminated (e.g., hypoperfusion, obstruction, sepsis), only time can be offered as treatment. Therapies such as low-dose dopamine, furosemide, or mannitol administration, or atrial natriuretic peptide use have not demonstrated prevention of or improved recovery from HARI (220–225). Dialysis remains the only intervention that can support patients until return of renal function. Indications for dialysis include (a) hyperkalemia, metabolic acidosis, or volume expansion that cannot be controlled; (b) symptoms of uremia or encephalopathy; or (c) platelet dysfunction inducing a bleeding diathesis (213).

Shock

Definition

Shock is defined in its simplest terms as a decrease in tissue perfusion—a decrease below the lowest metabolic needs of the tissue bed. This usually results in a depletion of stored energy and an increase in anaerobic metabolism with a buildup of lactic acid in addition to other toxic waste products. Hypotension is incorrectly thought of as a defining component of shock. Hypotension often leads to hypoperfusion, but the hypotensive patient is not in shock until evidence of hypoperfusion occurs. Various types of shock exist.

Hemorrhagic Shock

The first thought for a surgeon managing a postoperative patient who manifests signs and symptoms of shock is hemorrhage. Hypovolemic shock secondary to inadequate preload can be the result of excessive or ongoing blood loss or inadequate replacement or both. Certainly after radical debulking procedures or major extirpative procedures, the potential for postoperative hemorrhage exists. Tachycardia, hypotension, and oliguria are typical clinical signs. In the face of these clinical signs, the surgeon should have high suspicion for active bleeding and be preparing to return the patient to the operating room for correction. Measurement of hemoglobin or hematocrit can be normal in the setting of acute blood loss since a decrease in red cells is accompanied by a decrease in mass. Once fluid is given for resuscitation, dilution will occur and the hemoglobin/hematocrit will fall. With invasive monitoring, the CVP will be low, as will cardiac output and the PAOP. As the stroke volume decreases to inadequate amounts, the heart compensates by increasing the heart rate in order to maintain cardiac output. The treatment in these cases is aggressive volume resuscitation and control of ongoing blood loss. The controversy between resuscitation with colloid (albumin, plasma) or crystalloid (normal saline or lactated Ringer's solution) was mentioned earlier in the chapter. However, The Cochrane evidence-based review

on this subject has proclaimed no benefit for colloid and perhaps an increased mortality with colloid (as well as cost). Recently, a large multicenter Australian study began in an attempt to shed more light on this subject, and its results are anticipated. As mentioned earlier, the ratio of crystalloid replacement to blood loss is 3 to 1 (3 cc crystalloid for each estimated 1-cc loss of blood). Blood products including packed red blood cells and fresh frozen plasma (in the case of a coagulopathy) are also indicated.

Endpoints of resuscitation include normalization of serum lactic acid and base deficit. Measurement of the base deficit via an arterial blood gas analysis has become an effective means for following response to resuscitation. Following large operations where patients are admitted to the ICU and where large, expected fluid shifts occur, the base deficit should be monitored serially until it has returned to normal. If a patient has a worsening base deficit (i.e., becomes more negative), then a search for other problems, such as ongoing hemorrhage, subacute anastomotic leak(s), or tissue ischemia, must be made and be addressed before the base deficit will normalize. The base deficit should normalize within the first 24 hours after surgery.

In the case of continued or rapid bleeding, the obvious course of treatment is reoperation. A number of options are now available intraoperatively in these situations. Obvious bleeders are controlled and ligated. Raw surfaces can be coagulated or treated with fibrin sealants. Damage-control packing has been shown to increase survival in the direst situations. Massive transfusion, defined as greater than 1.5 blood volumes, presents a number of additional problems. These patients will have a dilutional coagulopathy, hypocalcemia, and hyperkalemia. After six to eight red blood cell transfusions have been given in rapid fashion for massive bleeding, some would advocate empiric fresh frozen plasma and platelets. Platelet transfusion is indicated for a platelet count <50,000 in the actively bleeding patient. Attention to delivery of warm transfusions is critical as hypothermia and acidosis will promote coagulopathy and worsening in bleeding. Once any of the “lethal triad” is manifested then the operation needs to be quickly terminated even if this means damage-control packing and transport to an ICU setting.

Cardiogenic Shock

A patient with adequate preload who shows signs of poor perfusion secondary to poor cardiac output is categorized as being in cardiogenic shock. The etiology may be a decrease in contractility (secondary to myocardial infarction) or an increase in afterload (severe hypertension). Typically, “pump failure” results in decreased stroke volume and backup of fluid into the pulmonary circulation. This leads to pulmonary edema and decreased oxygen delivery. The most common provocation for pump failure is the overadministration of fluid in a patient with compromised ventricular function. Treatment consists of diuresis and optimization of cardiac output without increasing myocardial oxygen demand (a difficult task). In the case where significant failure has led to hypotension, dopamine and dobutamine are usually the drugs of choice. The usage of these drugs was discussed previously. Digoxin is commonly used for increasing contractility, but its effects are minor in the acute setting. In addition to inotropic support, correction of electrolyte disturbances (particularly potassium, calcium, and magnesium), maintenance of proper systemic oxygen saturation, and analgesia are important factors in decreasing myocardial stress.

Septic Shock

Septic shock has commonly been defined as hypotension related to infection with eventual organ failure secondary to hypoperfusion despite adequate fluid resuscitation. This definition has

changed with that of SIRS and is discussed in the section on “Sepsis and Systemic Inflammatory Response Syndrome” below. Sepsis is defined as a subset of patients with SIRS who have a documented infectious process.

Infectious Disease Issues

Infections in the critically ill patient population are a significant cause of morbidity and mortality. Approximately 45% of ICU patients will have an infection and approximately half of those will have acquired the infection while in the ICU (226). Nosocomial infections are commonly associated with complications of medical or surgical therapy. Patients in the ICU are particularly vulnerable to infection because of decreased host defenses and the high incidence of resistant bacterial isolates found in ICUs. In addition, the presence of indwelling catheters and lines lowers the inoculum needed to cause infection and provides portals of entry (226). Initial therapy involves identifying and eradicating the source of infection and promptly initiating empirical antibiotic therapy aimed at multidrug-resistant gram-negative and gram-positive organisms. If an intra-abdominal or pelvic source is suspected, empiric antibiotic therapy should include anaerobic coverage. Appropriate antibiotic classes include carbapenems, extended-spectrum penicillins, fluoroquinolone-metronidazole, aminoglycoside-metronidazole, or clindamycin combinations (227). In Chapter 30 the management of infections in the gynecologic cancer patient is discussed; therefore, information here is limited to infections pertaining to the critically ill patient.

Fungal Infections

Systemic fungal infections are a significant cause of morbidity and mortality in patients admitted to the ICU. A nonspecific and variable presentation makes the diagnosis of systemic candidal infection difficult. Risk factors that have been associated with candidemia and invasive candidiasis include treatment with multiple antibiotics for extended periods, the presence of central venous catheters, the use of TPN, abdominal surgery, prolonged ICU stay, and compromised immune status (228). Although a positive blood culture is the gold standard for diagnosis, blood culture techniques are relatively insensitive and clinicians frequently must rely on clinical judgment about the probability that candidemia is responsible for a patient's symptoms. ICU patients who have persistent fever, hypothermia, or unexplained hypotension, despite broad spectrum antibiotic coverage, may have candidemia. The initial choice of therapeutic agents depends on the epidemiologic characteristics of the particular ICU and host factors such as the severity of illness, infection site(s), neutropenia, and organ dysfunction. Fluconazole has excellent activity against *Candida albicans*, but infections caused by *Candida glabrata* or *Candida krusei* must be treated with amphotericin B or caspofungin. Amphotericin B should not be used in patients with renal failure, and azoles and echinocandins (caspofungin) should be used with caution in patients with hepatic dysfunction. Antifungal therapy should be continued for 14 days past the first negative blood culture for candidemia or until clinical microbiological or radiographical resolution of the infection (229). In addition to antifungal therapy, it is generally recommended that all patients with candidemia have a dilated eye exam by an ophthalmologist and that all catheters be removed if possible (although tunneled catheters are at less risk) (228).

Abdominal Infections

The diagnosis of an intra-abdominal source of infection can be difficult in critically ill patients. Symptoms such as abdominal pain and peritoneal signs may not be apparent in patients who are obtunded or sedated and on a ventilator. Fever and leukocytosis may be absent in 35% and 55% of peritoneal

infections, respectively (230). Ultrasonography is a useful diagnostic test that can be performed in the ICU and may assist with therapeutic intervention as well. It is extremely sensitive for evaluations of the pelvis and right upper quadrant, but evaluation of the entire abdomen can be limited by bowel gas, surgical dressings, and operator experience. For many of these reasons, a computed tomographic (CT) scan is the preferred study for the evaluation of patients with suspected intra-abdominal infection. To avoid misdiagnosing fluid-filled bowel as a possible abnormal fluid collection, it is essential that contrast agents be used when performing these studies. CT also has limitations, especially when used in the critically ill population. The presence of renal insufficiency precludes the use of intravenous contrast, and ileus or bowel obstruction may prevent complete opacification of the gastrointestinal tract. Diagnostic laparoscopy can be performed in the ICU with minimal anesthesia and is a safe, accurate, and cost-effective alternative to laparotomy when managing suspected intra-abdominal processes (231).

Once identified, an intra-abdominal abscess must be fully evacuated and the source controlled. Radiologically assisted percutaneous drainage has become the preferred method for treating most abscesses located in the abdomen and pelvis. For well-delineated unilocular fluid collections, percutaneous drainage has a success rate better than 80% (232). Percutaneous drainage of complex abscesses or those with an enteric communication has a lower success rate, but remains a reasonable alternative treatment for the high-risk patient (233).

In some cases, surgery may be the only appropriate lifesaving intervention. Timely laparotomy in the critically ill patient with diffuse peritonitis allows for peritoneal toilet, debridement of infected and necrotic tissue, and control or repair of the source. Laparoscopic drainage of complex intra-abdominal abscess has also been reported with good success rates (234). Complex intra-abdominal infections that cannot be effectively controlled by a single laparotomy may be managed best with an open-abdomen approach with temporary wound closure utilizing a composite, negative pressure (vacuum-pack) dressing (235). Potential advantages of the open-abdomen approach include facilitation of repeated debridement, effective drainage, repeat exploration of the peritoneal cavity (at the ICU bedside if necessary), and reduction in intra-abdominal pressure. In general, the intervention that accomplishes the source control objective with the least physiologic upset should be employed (236).

Sepsis and Systemic Inflammatory Response Syndrome

Inflammation is the body's initial response to tissue injury produced by chemical, mechanical, or microbial stimuli. Inflammation is an exceedingly complex cellular and humoral response involving interaction between the complement, kinin, coagulation, and fibrolytic cascades. The goal of inflammation is to enhance the movement of nutrients and phagocytic cells to the injury site in order to prevent invasion of microbes and limit the extension of injury. As a local response, this is beneficial, but appropriate regulation is necessary to prevent a pathologic, exaggerated systemic response, which is clinically identified as SIRS. Sepsis is the clinical syndrome of SIRS that is due to severe infection. The mediator response in SIRS can be divided into four phases based on the cytokine/cellular response: induction, triggering of cytokine synthesis, evolution of cytokine and coagulation cascade, and elaboration of secondary mediators leading to cellular injury. The three most important mediators operating in SIRS appear to be tumor necrosis factor- α (TNF- α), interleukin-1 (IL-1), and interleukin-6 (IL-6). The microcirculation endothelium is the key target for injury in the sepsis syndrome (237).

TABLE 11.16

DEFINITIONS FOR SYSTEMIC INFLAMMATORY RESPONSE AND SEPSIS (SIRS)

SIRS	Two or more of the following in the setting of a known cause of inflammation: Temperature >38°C or <36°C Pulse >90 Respirations >20/min or PaCO ₂ <32 mm Hg WBC count >12,000 or <4,000 cells/mm ³ or >10% band forms
Sepsis	SIRS due to known infection
Severe sepsis	Sepsis with evidence of organ dysfunction, hypoperfusion, or hypotension
Septic shock	Sepsis with hypotension despite adequate fluid resuscitation

Source: Adapted from 1991 American College of Chest Physicians/Society of Critical Care Medicine Consensus Conference definitions.

In 1992, the American College of Chest Physicians and the Society of Critical Care Medicine published definitions for SIRS and sepsis (Table 11.16) with the goal of standardizing terminology to aid clinicians in the diagnosis and treatment and to aid in the interpretation of research in this field (238). Many have criticized the 1992 consensus definitions as too nonspecific to be of use. In 2001, a group of experts reconvened and expanded the list of signs and symptoms of sepsis to reflect clinical bedside experience. In addition to the original criteria, altered mental status, oliguria, skin mottling, coagulopathy, hypoxemia, hyperglycemia in the absence of diabetes, thrombocytopenia, and altered liver function tests can also be used to establish the diagnosis of sepsis (239).

The host response, more than the pathogen, is the primary determinant of patient outcome. Failure to develop a fever, leukopenia, and hypothermia are associated with increased fatality rates in patients with sepsis and are thought to represent abnormalities in the host's inflammatory response. Other risk factors for mortality from sepsis include age greater than 40, underlying medical conditions, malnutrition, immune suppression, and cancer. The presence or absence of a positive blood culture does not influence outcomes; however, sepsis due to a nosocomial infection has a higher mortality than community-acquired infection (240).

Sepsis with acute organ dysfunction (severe sepsis) is a complex condition that represents a major challenge to the critical care team and carries a crude mortality rate of 28% to 50% (241). Gram-negative and gram-positive organisms as well as fungi cause systemic sepsis and septic shock. Early recognition is crucial to patient survival because mortality rates are exceedingly high if the full clinical picture of shock and organ dysfunction develops. Septic shock is divided into an early hyperdynamic state and a late hypodynamic state.

Low systemic vascular resistance, splanchnic vasoconstriction, and increased cardiac output characterize the hyperdynamic phase of shock. Venous capacitance is increased and results in diminished effectiveness of the circulating blood volume. Aggressive volume resuscitation must be provided to restore cardiac preload and ventricular filling. These patients are best managed in an ICU with the placement of an arterial line, a PA catheter, and a bladder catheter. Appropriate cultures should be obtained and intravenous broad-spectrum antibiotics should be started within the first hour of recognition of severe sepsis. Laboratory tests of immediate concern include

arterial blood gas determinations, creatinine, electrolytes, lactate, coagulation panel, and a complete blood count. Oxygenation and ventilation should be optimized with mechanical ventilation if indicated. If hypotension persists after optimization of the PCWP, the use of norepinephrine or dopamine may be necessary. Surgical debridement or manipulation of infected material should not be performed until the patient has been stabilized.

Early goal-directed therapy of the septic patient has been shown to improve survival. During the first 6 hours of resuscitation, the goals of therapy as outlined by the Surviving Sepsis Campaign guidelines include CVP of 8 to 12 mm Hg, mean arterial pressure ≥ 65 mm Hg, urine output ≥ 0.5 mL/kg/h, and central venous or mixed venous oxygen saturation $\geq 70\%$. If during the first 6 hours oxygen saturation goals are not achieved despite appropriate CVP, then transfusion of red blood cells to achieve a Hct $>30\%$ and/or initiation of a dobutamine infusion is the next step (242).

In the hypodynamic phase of septic shock, hypotension results from cardiac output deterioration. The patient is often cool, mottled, oliguric, diaphoretic, and confused. The etiology of the hypodynamic cardiovascular response to sepsis may be inadequate volume resuscitation, underlying cardiac disease, or myocardial dysfunction associated with sepsis. This is a state of gross decompensation with global tissue hypoxia and is associated with greater mortality.

Numerous clinical trials have attempted to find specific agents that could modulate the underlying disease process in sepsis. Candidate therapies included agents that target mediators of inflammatory response, agents that boost the immune system, and prostaglandin inhibitors, but none was shown to be beneficial until recently. The Recombinant Human Activated Protein C Worldwide Evaluation in Severe Sepsis (PROWESS) study is the first clinical trial to show a clinically significant reduction in the 28-day all-cause mortality rate due to severe sepsis (243). This multicenter, prospective, double-blind, placebo-controlled study enrolled 1,690 patients who were randomized to treatment with a continuous infusion of drotrecogin alfa (activated) at a dose of 24 $\mu\text{g}/\text{kg}/\text{h}$ for a total of 96 hours or placebo. Drotrecogin alfa (activated) is a recombinant form of human activated protein C, an endogenous protein with antithrombotic, pro-fibrinolytic, and anti-inflammatory properties that is frequently deficient in sepsis. Eligible patients were 18 years of age or older with a documented or a highly suspicious source of infection, at least three of the SIRS criteria, and evidence of acute end-organ dysfunction, including shock, severe hypoxia, oliguria, or acidosis for less than 24 hours. Patients began treatment within 24 hours of meeting study criteria. Drotrecogin alfa (activated) has significant anticoagulant properties; therefore, patients at high risk of or from bleeding were excluded, as well as those who were pregnant or breast-feeding, had human immunodeficiency virus infection with CD4 cell count $\leq 50/\text{mm}^3$, weighed >35 kg, had a transplanted organ other than a kidney, or were expected to die from non-sepsis-related disease within 1 month. The mortality rate was 30.8% in the placebo group and 24.7% in the treatment arm, with a reduction in relative risk of death of 19.4% and an absolute reduction in risk of death of 6.1% ($p = 0.005$). Although patients considered to be at higher risk of bleeding were excluded, serious bleeding conditions were higher in the drotrecogin alfa (activated) group (3.5% vs. 2.0%, $p = 0.06$). The FDA has approved drotrecogin alfa (activated) for the treatment of patients with sepsis who have a high risk of death. In light of the increased bleeding risk, appropriate patient selection for treatment with drotrecogin alfa (activated) should be an important consideration (242).

In addition to early goal-directed therapy with hemodynamic interventions that balance systemic oxygen delivery

with oxygen demand and the use of drotrecogin alfa (activated), other management strategies have also been shown in randomized, controlled trials to reduce mortality associated with severe sepsis. These include limiting the tidal volume to 6 to 7 mL/kg ideal body weight for patients requiring mechanical ventilation for ARDS, the use of moderate-dose corticosteroids (hydrocortisone 200 to 300 mg and fludrocortisone 50 μg daily) for 7 days in patients with refractory septic shock, and maintaining serum glucose levels <150 mg/dL (242). These therapies are not mutually exclusive and optimal patient management may require a combination of approaches. Some of these strategies vary dramatically from traditional approaches and will require education and established protocols to safely incorporate them into practice.

Multiple Organ Dysfunction Syndrome

Multiple organ dysfunction syndrome (MODS) can be defined as the development of progressive physiologic dysfunction of two or more organ systems after an acute threat to systemic homeostasis (238). Inciting factors are diverse and include SIRS, sepsis, massive trauma, burns, ischemia, and reperfusion injury. Consensus has not been reached as to the criteria used to define this clinical syndrome, that is, which organ systems are important or the degree of physiologic derangement necessary to constitute dysfunction. Pulmonary dysfunction is common and typically develops early in the course of SIRS or sepsis. Renal dysfunction initially is a prerenal azotemia unless the initial insult promoted a sudden oliguric acute tubular necrosis. Hyperbilirubinemia is the earliest marker of hepatic dysfunction. Gastrointestinal abnormalities include ileus, stress ulcers, diarrhea, and mucosal atrophy. The platelet count has been used as a surrogate marker of the hematologic system. Cardiac function is often measured by the degree of hypotension or the need for vasopressors. Deterioration of the nervous system is manifested by encephalopathy and peripheral neuropathies. The treatment of MODS is support of individual organ function and aggressive therapies aimed at correcting the underlying process. Mortality is related to the number of dysfunctional systems and is greater than 80% once four organ systems fail (244).

The Acute Physiology and Chronic Health Evaluation (APACHE) provided population-based estimates of mortality for the day of ICU admission (245). Several versions of the APACHE scoring system have been utilized, most recently APACHE IV. Organ failure scores, such as the Sequential Organ Failure Assessment (SOFA), can help assess organ dysfunction over time and are useful to evaluate morbidity. Independent of the initial value, an increase of the SOFA score (Table 11.17) during the first 48 hours of an ICU admission predicts a mortality rate of 50% or greater, and improvement of cardiovascular, renal, or respiratory SOFA score from baseline through day 1 of ICU admission is significantly related to greater survival (246). It is important to note that these and other outcome prediction models were designed as tools to be used in critical care research in order to stratify patients by severity of illness. They have not been validated for making decisions relating to individual patients.

Abdominal Compartment Syndrome

Abdominal compartment syndrome (ACS) is an important but often unrecognized cause of acute deterioration of a patient after massive fluid resuscitation for septic or hypovolemic shock. Although most commonly associated with trauma patients, it has also been observed in patients with massive ascites, bowel obstruction or ileus, peritonitis, pancreatitis, and intraperitoneal blood. Intra-abdominal pressure (IAP) is usually measured indirectly by a balloon-tipped catheter in the bladder. Intra-abdominal hypertension is defined as an IAP of

TABLE 11.17**THE SEQUENTIAL ORGAN FAILURE ASSESSMENT (SOFA) SCORE**

Variables	SOFA score				
	0	1	2	3	4
Respiratory: PaO ₂ /FIO ₂ , mm Hg	>400	≤400	≤300	≤200 ^a	≤100 ^a
Coagulation: platelets × 10 ³ /μL ^b	>150	150	100	50	20
Liver bilirubin, mg/dL ^b	<1.2	1.2–1.9	2.0–5.9	6.0–11.9	>12.0
Cardiovascular hypotension	No hypotension	Mean arterial pressure <70 mm Hg	Dop ≤5 or Dob (any dose) ^c	Dop >5, Epi 0.1, or Norepi 0.1 ^c	Dop >15, Epi >0.1, or Norepi >0.1 ^c
Central nervous system, Glasgow Coma Scale score	15	13–14	10–12	6–9	<6
Renal creatinine, mg/dL or urine output, mL/d	<1.2	1.2–1.9	2.0–3.4	3.5–4.9 or <500	>5.0 or <200

Note: Dob, dobutamine; Dop, dopamine; Epi, epinephrine; FIO₂, fraction of inspired oxygen; Norepi, norepinephrine; PaO₂, partial pressure oxygen.

^aValues are with respiratory support.

12 mm Hg or greater recorded by a minimum of three standard measurements conducted 4 to 6 hours apart (247). ACS is defined by an IAP of 20 mm Hg or greater and single or multiple organ failure that was not previously present. Although ACS can impair the function of every organ system, it is generally manifested as hypotension, reduced urine output, and decreased pulmonary compliance. Operative decompression of the abdominal cavity with maintenance of an open abdomen via use of temporary closure techniques such as a vacuum pack is the only treatment that reverses the physiological abnormalities resulting from ACS.

Withdrawal of Life-Sustaining Treatment

The decision to withdraw or withhold life-sustaining treatment is most difficult for patients, families, and health professionals. The ethical aspect of foregoing treatment resides in the legal and ethical right of the patient to self-determination. Unfortunately, the majority of critically ill patients are unable to speak for themselves when decisions to limit treatment are considered. Therefore, careful attention must be paid to previously expressed wishes and the input of surrogate decision makers. If a medical power of attorney is not in place, some states stipulate who the surrogate will be by a legal hierarchy. The ethical basis for identification of an appropriate surrogate is primary if none of the preceding legal bases apply. In this situation, the physician and other health care providers have the responsibility to help identify the person or persons who have knowledge of the patient's values and preferences in order to assist with medical decisions on the patient's behalf. This process can become difficult in circumstances when family members or others close to the patient are in disagreement as to who should be the surrogate or what the patient would prefer. In these cases, health care providers should be knowledgeable of applicable legal directives and their ethical responsibility to act in their patient's best interest. Consultation with the institution's ethics committee may be helpful in trying to reach consensus (248). Although not responsible for the

patient's death, those close to the patient often are left with feelings of guilt and anxiety in addition to their bereavement. It is important that the health care providers support the family both before and after the decision to withhold or withdraw life-sustaining treatment has been made.

End of life care of patients in the ICU requires a dramatic paradigm shift in attitude and interventions from intensive rescue-type care to intensive palliative care. When considering the array of interventions that may be discontinued or held, physicians and surrogates should focus on clearly articulating the goals of care. For example, a goal for survival until the patient's important loved ones can gather to say their good-byes may justify short-term continuation of ventilator support. If the only goal is patient comfort, then such treatment should be stopped. The withdrawal of life-sustaining treatment is a clinical procedure that deserves the same preparation and expectation of quality as other medical procedures. Honest, caring, and culturally sensitive communication with the patient's loved ones and the patient, if competent, should include explanations of how therapies will be withdrawn, what symptoms are expected, strategies to assess and ensure the patient's comfort, and information about the expected survival after interventions are withdrawn. Informed consent should be documented along with a formulated plan for withdrawing care (249). Adequate analgesia and sedation should be prescribed to relieve symptoms of pain, dyspnea, and anxiety during the dying process. Intravenous opioids and shorter acting benzodiazepines are the drugs of choice. The clinician's primary goal should be to prevent suffering and ensure the patient's comfort even if doing so unintentionally hastens the patient's death.

Neurologic Issues

The critically ill patient is invariably anxious, stressed, confused, uncomfortable, or in pain from immobility, wounds, preexisting disease, infection, invasive medical interventions, and routine nursing care such as airway suctioning, repositioning, or dressing

changes. The restlessness and distress often associated with critical illness must be quelled with analgesia, sedation, and neuromuscular blockade as a last resort. The Society of Critical Care Medicine and American Society of Health-System Pharmacists (ASHP) clinical practice guidelines for sedation, analgesia, and neuromuscular blockade of the critically ill adult were revised in 2002. This comprehensive document is available online at www.ashp.org (250,251).

Analgesia

Maintaining an optimal level of comfort and safety for critically ill patients is a universal goal for all involved in their care. Unrelieved pain contributes to inadequate sleep and agitation. Pain may contribute to pulmonary dysfunction through localized guarding and generalized muscle rigidity that restricts movement of the chest wall and diaphragm. Unrelieved pain also evokes a stress response characterized by tachycardia, increased myocardial oxygen consumption, hypercoagulability, immunosuppression, and persistent catabolism (252). The combined use of effective analgesia and sedation may ameliorate the stress response and diminish pulmonary complications in postoperative critically ill patients. A comprehensive overview of pain management is covered in Chapter 32; therefore, only key aspects of pain management applicable to patients in the ICU will be addressed.

Pharmacologic therapies include opioids, NSAIDs, and acetaminophen. ASHP guidelines recommend fentanyl, hydromorphone, and morphine given as a continuous infusion or scheduled doses rather than “as needed.” Fentanyl has the most rapid onset and shortest duration, but repeated dosing may cause accumulation and prolonged effects. Fentanyl may also be administered via a transdermal patch to hemodynamically stable patients with more chronic analgesic needs, but it is not recommended for the management of acute pain. Morphine has a quick onset but longer duration of action, so intermittent doses may be given. However, morphine causes histamine release, which contributes to hypotension, especially in a

hemodynamically unstable patient. Hydromorphone’s duration of action is similar to morphine but lacks an active metabolite or histamine release, making it an ideal drug for continuous infusion and for use in patients who cannot tolerate hypotension. Meperidine has an active metabolite that causes neuroexcitation including apprehension, tremors, delirium, and seizures, so its use is not recommended in critically ill patients who may need repeated doses. The characteristics of analgesics and sedatives commonly used in ICU patients are summarized in Table 11.18.

Sedation

Sedatives are commonly used adjuncts for the treatment of anxiety and agitation. The physical environment of the ICU, limited ability to communicate, sleep deprivation, and medical circumstances precipitating the ICU admission are contributing factors creating anxiety in critically ill patients. Efforts to reduce anxiety, including frequent reorientation, provision of adequate analgesia, and optimization of the environment, may be supplemented with sedatives. Agitation is also common in ICU patients; however, not all patients with anxiety will exhibit agitation. Sedatives reduce the stress response and improve tolerance to routine ICU procedures. They may be necessary to facilitate mechanical ventilation. Generally, sedatives should be administered intermittently to determine the dose needed to achieve the sedation goal, but they may be given as a continuous infusion if necessary. Daily interruption of sedative infusion is associated with shorter duration of mechanical ventilation, shorter ICU stays, and fewer instances of posttraumatic stress disorder (253,254). Benzodiazepines are sedatives and hypnotics that cause anterograde amnesia but lack analgesic properties. Midazolam has a rapid onset and short duration of effect with single doses, making it ideal for treating acutely agitated patients or for brief sedation with invasive procedures. Lorazepam has a slower onset but fewer potential drug interactions because of its metabolism via glucuronidation (Table 11.18).

TABLE 11.18

CHARACTERISTICS OF SELECTED ANALGESICS AND SEDATIVES FREQUENTLY USED IN CRITICALLY ILL PATIENTS

Agent	Indication	Active metabolites (effect)	Adverse effects	Intermittent dose (IV) ^a	Infusion dose range
Fentanyl	Pain	No metabolite, patient accumulates	Rigidity with high doses	0.35–1.5 µg/kg q 0.5–1 h	0.7–10 µg/kg/h
Hydromorphone	Pain	None	—	10–30 µg/kg q 1–2 h	7–15 µg/kg/h
Morphine	Pain	Yes (sedation)	Histamine release	0.01–0.15 mg/kg q 1–2 h	0.07–0.5 mg/kg/h
Ketorolac	Pain	None	GI bleeding, renal	15–30 mg q 6 h; decrease if >65 yr; avoid >5 day use	—
Midazolam	Acute agitation	Yes (prolonged sedation)	—	0.02–0.08 mg/kg q 0.5–2 h	0.04–0.2 mg/kg/h
Lorazepam	Sedation	None	Solvent-related acidosis/renal failure in high doses	0.02–0.06 mg/kg q 2–6 h	0.01–0.1 mg/kg/h
Propofol	Sedation	None	Elevated triglycerides	—	5–80 µg/kg/min
Haloperidol	Delirium	Yes (EPS)	QT interval prolongation	0.03–0.15 mg/kg q 0.5–6 h	0.04–0.15 mg/kg/h

Note: EPS, extrapyramidal symptoms; GI, gastrointestinal; IV, intravenous.

^aMore frequent doses may be needed for acute management in mechanically ventilated patients.

Propofol is an intravenous general anesthetic that has sedative and hypnotic properties at lower doses. Like the benzodiazepines, propofol has no analgesic properties. Propofol has a rapid onset and short duration of sedation once discontinued. Propofol is a phospholipid emulsion that provides 1.1 kcal/mL from fat and should be counted as a caloric source. Long-term infusions may result in hypertriglyceridemia and monitoring is recommended after 2 days of use (250). Physiologic dependence and potential withdrawal symptoms have been described in ICU patients who have been exposed to more than 1 week of sedative or narcotic therapy, including the use of propofol (255).

Neuromuscular Blockade

Neuromuscular blocking agents (NMBAs) can be used to facilitate mechanical ventilation, to manage intracranial pressure in head trauma, to ablate muscle spasms, and to decrease oxygen consumption only when all other means to accomplish these aims have failed (251). Pancuronium is a long-acting NMBA that is effective for up to 90 minutes after intravenous bolus dose of 0.06 to 0.1 mg/kg. It can be used as a continuous infusion by adjusting the dose to the degree of neuromuscular blockade that is desired. Since pancuronium is vagolytic, 90% of patients will have an increase in heart rate of greater than 10 beats per minute. For patients who cannot tolerate an increase in heart rate, vecuronium can be used. If neuromuscular blockade is necessary for patients with significant hepatic or renal failure, cisatracurium or atracurium should be used. Patients receiving any NMBA should be assessed using electronic twitch monitoring with a goal of adjusting the blockade to achieve one or two twitches. Before initiating neuromuscular blockade, patients should be adequately medicated with sedative and analgesic drugs as it is difficult to assess pain and anxiety after NMBAs are given. Furthermore, neuromuscular paralysis without sedation is an extremely frightening and unpleasant experience.

Acute quadriplegic myopathy syndrome, also referred to as postparalytic quadriplegia, is a clinical triad of acute paresis, myonecrosis with increased creatine phosphokinase concentration, and abnormal electromyography that is related to prolonged exposure to NMBAs. This is a devastating complication of NMBA therapy and one of the reasons that indiscriminate use of these agents is discouraged. Increased risk of acute quadriplegic

myopathy is associated with the concurrent use of corticosteroids; drug “holidays” may decrease the risk (256).

ICU Syndrome/Delirium

The ICU syndrome, first reported in the 1960s, describes a range of psychological disturbances exhibited by many critically ill patients (257). Other designations commonly used are ICU psychosis and postoperative delirium. The ICU syndrome has been defined as an altered emotional state occurring in a highly stressful environment that may manifest itself in a variety of psychological reactions including fear, memory disturbance, anxiety, confusion, withdrawal, despair, agitation, and disorientation. Sleep deprivation, noise, constant light exposure, restriction of movement, limited ability to communicate, as well as the patient’s preadmission mental state and coping ability have all been reported as causative factors of ICU syndrome. Current medical literature challenges this concept and argues that what is being called ICU syndrome or psychosis is diagnostic of delirium and not due to the ICU environment *per se*. Concerns have been raised that using the term *ICU syndrome* implies that confusion can be expected in the ICU setting and may reduce the vigilance necessary to recognize delirium and identify and treat the physiologic disturbances leading to it (258). Delirium is found in as many as 80% of critically ill patients and is associated with longer ICU admissions and increased mortality (259,260).

Delirium in the ICU setting is commonly caused by metabolic disturbances, hypoxia, electrolyte imbalances, alcohol or drug withdrawal, acute infection, and medications (Table 11.19) (258,260). Many drugs have anticholinergic properties that can exert an additive effect causing neurotoxicity, especially in elderly patients. Anticholinergic-related delirium can be differentiated from other causes of delirium if the mental status clears after administration of the cholinesterase inhibitor physostigmin. Delirium presents in both a hypoactive and hyperactive form. Hypoactive delirium, which is associated with the worst prognosis, is characterized by psychomotor retardation, represents more global cerebral dysfunction, and is manifested by a calm appearance, inattention, and obtundation in extreme cases. Hyperactive delirium is more easily recognized by agitation and combative behaviors. Elderly patients may pose a particular diagnostic challenge when delirium is superimposed on baseline dementia.

TABLE 11.19

COMMONLY USED ICU DRUGS ASSOCIATED WITH DELIRIUM^a

Anesthetics	Anticonvulsants	Atropine ^b
Lidocaine	Carbamazepine	Cimetidine ^b
Propofol	Phenobarbital	Corticosteroids ^b
	Phenytoin	Digoxin ^b
Antibiotics	Antihypertensives	Narcotic analgesics
Amphotericin B	Diltiazem	Fentanyl
Aztreonam	Enalapril	Meperidine ^b
Cephalosporins	Hydralazine	Morphine
Ciprofloxacin	Methyldopa	
Doxycycline	Propranolol	Nitroprusside
Imipenem	Verapamil	Phenylephrine
Metronidazole		Procainamide ^b
Penicillins		Scopolamine ^b
Tobramycin		Tricyclic antidepressants ^b

^aListing is not intended to be all-inclusive.

^bDrugs known to have significant anticholinergic properties.

The medical management of delirium consists of finding and treating underlying medical conditions and then controlling any behavioral disturbances if necessary. Neuroleptic drugs are the first-line agents for the treatment of delirium due to causes other than alcohol withdrawal syndrome, which is managed with benzodiazepines. Haloperidol is the neuroleptic of choice because it has minimal anticholinergic or hypotensive effects. A dose of 2 to 10 mg intravenously can be given every 20 to 30 minutes until agitation resolves. Once the delirium is controlled, scheduled doses every 4 to 6 hours consisting of 25% of necessary loading doses can be used and tapered off over several days. A continuous infusion can also be used (Table 11.18). Patients receiving repeat doses of haloperidol should be monitored for electrocardiographic changes. Extrapyramidal side effects such as rigidity, tremor, or facial tics can be managed with diphenhydramine hydrochloride (250).

CHAPTER 12 ■ SURGICAL PRINCIPLES IN GYNECOLOGIC ONCOLOGY

DENNIS S. CHI, ROBERT E. BRISTOW, AND DONALD G. GALLUP

The management of most human cancers involves multimodal therapy, and this is especially true for female genital malignancies. Although some early gynecologic cancers can be eradicated by surgery alone, and chemotherapy as a single modality can often cure gestational trophoblastic malignancies, the optimal treatment for the majority of gynecologic malignancies requires surgery combined with chemotherapy and/or irradiation.

In this chapter, surgery is discussed both as a separate discipline and as an integral part of multimodal therapeutic planning. Although specific operations and relatively new surgical techniques are described for some disease sites, many procedures are addressed more completely in surgical texts and atlases to which the reader is referred (1–3). The role of surgical intervention in the treatment of gynecologic cancers is addressed herein with a more philosophic approach than would be taken in a surgical atlas. However, select illustrations and tips are included that have enabled us to approach various radical procedures more rapidly and safely. The major goal of this chapter is to give the reader an appreciation and understanding of the surgical principles of the subspecialty of gynecologic oncology.

TECHNICAL ASPECTS OF SURGERY

Many physicians who practice the art and science of surgery tend to focus on the technical craft of the specialty only when teaching young surgeons. At other times, we are acutely aware that the most difficult part of our practice is the decision of whether or not to utilize surgical therapy. Preoperative and postoperative management is also demanding since therapy must be tailored for individual patients depending not only on their specific disease but also on their overall medical status. Owing to the significance of these pressing issues, we often take for granted the many years of preparation and experience in the craft of surgery.

Mastering the skills of surgery involves a thorough understanding of proper technique. It also requires frequent and consistent practice to keep surgical maneuvers well honed. For the student, this means actual practice in tying knots, manipulating instruments, and suturing. For the accomplished surgeon, it means that a sufficient case load must be maintained to ensure adequate practice of the technical art of the specialty. The surgeon should also keep abreast of new suture materials, instruments, and technical developments.

Anatomy

There is no substitute for a detailed knowledge of the anatomy of the pelvis and abdomen. The physician who pursues gynecologic oncology as a career must be completely familiar with the

pelvis, abdomen, retroperitoneum, and the lymphatic drainage of the female genital tract. No amount of surgical skill or knowledge of cancer therapy can compensate for the lack of this knowledge.

Lymphatic drainage from the cervix follows the uterine arteries and cardinal ligaments to the pelvic lymph nodes that include the external iliac, internal iliac (hypogastric), and obturator node groups (Fig. 12.1). From these pelvic lymph nodes, the drainage proceeds superiorly through the common iliac lymph nodes and then up to the paraaortic nodes.

The lymphatic drainage from both the uterine corpus and the ovaries follows one of three routes (Fig. 12.1): (a) along the uterine arteries in the broad ligaments to the pelvic nodes, (b) in channels following the round ligaments to the inguinal lymph nodes, or (c) along the ovarian lymphatics in the infundibulopelvic ligaments directly up to the paraaortic nodes.

The anatomy of the paraaortic lymph nodes has been well described by Fowler and Johnson (4). The paraaortic lymph nodes are part of the lumbar lymph node group. There are three subgroups: preaortic, retroaortic, and lateral aortic (right and left). The preaortic group drains the abdominal part of the gastrointestinal tract down to the mid rectum, whereas the retroaortic group has no special area of drainage. The lateral group receives lymphatic drainage from the iliac lymph nodes, ovaries, and other pelvic viscera (apart from the alimentary tract), and therefore it is this group of nodes that is sampled in the surgical staging of gynecologic malignancies.

There are typically 15 to 20 lateral aortic nodes per side. They are located adjacent to the aorta, anterior to the lumbar spine, extending bilaterally to the medial margins of the psoas major muscles, and up to the diaphragmatic crura (4). The lateral nodes usually dissected in gynecologic oncology span the region from the aortic bifurcation up to either the inferior mesenteric artery (IMA) or the renal veins.

The first major blood vessel encountered during a caudal-to-cephalad paraaortic node dissection is the IMA (Fig. 12.1). The IMA originates from the anterior surface of the aorta approximately 3 to 4 cm above the aortic bifurcation. Next, the right and left ovarian arteries arise from their respective sides of the aorta about 5 to 6 cm above the bifurcation (Fig. 12.1). The right ovarian vein inserts into the right side of the inferior vena cava (IVC) approximately 1 cm below the right renal vein. The left ovarian vein does not insert directly into the IVC, but rather follows a path close to the left ureter inserting into the left renal vein lateral to the left border of the aorta. Three to four pairs of lumbar arteries and veins arise from the posterior surfaces of the aorta and IVC, respectively.

The gynecologic oncologist who operates on patients with advanced ovarian carcinoma often encounters disease spread involving upper abdominal structures such as the diaphragm, liver, pancreas, and spleen. Debulking of tumor from these

FIGURE 12.1. The pelvic and paraortic lymph nodes and their relationship to the major retroperitoneal vessels.

areas has been demonstrated to improve the rate of optimal cytoreduction and subsequent survival (5,6). Anatomic considerations for diaphragm surgery include the relevant hepatic attachments and the underlying central vasculature (7,8) (Fig. 12.2). The anterior hepatic attachment is the falciform ligament, which contains the ligamentum teres in its infrahepatic portion, and attaches the liver to the anterior abdominal wall in its membranous hepatic portion. As the falciform ligament continues superiorly, its peritoneal surface divides laterally on each side to form the anterior right and left coronary ligaments. These coronary ligaments reflect off the liver capsule and delineate the posterior extent of peritoneum covering the superior diaphragm. The IVC lies to the right side of this falciform ligament division. The right and left hepatic veins drain into the anterior surface of the IVC at the level of this peritoneal reflection. The anterior coronary ligaments continue laterally and inferiorly along the posterior liver edge, where they join the posterior right and left coronary ligaments to form the right and left triangular ligaments, respectively. The right triangular ligament reflects from the liver to the diaphragm, right kidney, and right adrenal gland. The left triangular ligament reflects primarily to the diaphragm; the posterior left coronary ligament lies higher than the esophageal hiatus and the esophagus is generally not encountered. The coronary ligaments on each side delineate the larger “bare area” of the liver on the right and a smaller “bare area” on the left, which underlie the central tendon of the diaphragm. The right phrenic nerve penetrates this central tendon lateral to the vena caval foramen on the right and is usually not encountered

until the “bare area” is exposed. The left phrenic nerve may penetrate the left diaphragm muscle above the central tendon and is a consideration during left-sided anterior diaphragm surgery.

In the left upper quadrant of the abdomen, the spleen lies under the 9th, 10th, and 11th ribs. It is situated adjacent and slightly deep to the stomach and colon, lateral to the pancreas, and sits on the superior aspect of the left kidney. The posterior aspect of the spleen is in contact with the adrenal gland as well as Gerota’s fascia of the kidney. The tail of the pancreas often approaches the splenic hilum and sometimes contacts the spleen. The spleen varies in size between individuals, but in general measures 12 cm in length, 7 cm in width, and 3 to 4 cm in width. The peritoneum creates folds that form the suspensory ligaments of the spleen. The four main “suspensory” ligaments are gastrosplenic, splenorenal, splenophrenic, and splenocolic ligaments. The splenophrenic and splenocolic ligaments are avascular. The gastrosplenic ligament contains the short gastric vessels. The splenorenal ligament has an anterior and posterior aspect and surrounds the splenic hilum. The splenic hilum contains the splenic artery, splenic vein, and sometimes the tail of the pancreas. The splenic vessels sometimes branch before entering the spleen. The splenic artery is tortuous and is one of the three branches of the celiac trunk. It runs along the superior aspect of the pancreas and gives rise to the short gastric arteries prior to entering the spleen, which course in the gastrosplenic ligament and supply the portion of the greater curvature of the stomach superior to the splenic artery (Fig. 12.3) (9). The splenic artery also gives rise to the left gastroepiploic

FIGURE 12.2. Peritoneal reflections of the liver: the lesser omentum (hepatogastric and hepatoduodenal ligaments) and its relation to the coronary ligament of the liver and diaphragm. *Source:* Reprinted with permission from Skandalakis JE, Gray SW, Rowe JR, eds. *Anatomical Complications in General Surgery*. artery, which supplies the remainder of the greater curvature of the stomach and the gastrocolic omentum. The splenic vein is slightly inferior and follows the course and branching of the artery.

Patient Positioning

Patient positioning for radical gynecologic oncology procedures is often critical in improving exposure, particularly in obese patients. For most women undergoing radical hysterectomy, ovarian cancer cytoreduction, or pelvic exenterative procedures, we prefer the low lithotomy position using Allen stirrups (Fig. 12.4) (1). The buttocks should protrude 2 to 3 cm over the end of the table. This position allows simultaneous access to the perineum and abdomen. The weight of the leg should be on the foot with the legs well padded and attention paid to prevent pressure on the calf and the peroneal nerve. To further improve pelvic exposure, a blanket or pad can be placed under the small of the back.

Abdominal Incisions

Abdominal incisions in gynecologic oncology vary with the indication for the procedure, associated preoperative conditions (such as the presence of ascites or bowel obstruction), suspicion of upper abdominal pathology, and the presence of a previous abdominal scar. Incisions for surgery for gynecologic oncology patients should be highly individualized. Three basic incisions are used for intraperitoneal exposure (Fig. 12.5) (2). Additionally, extraperitoneal access to the pelvic and paraaortic nodes can be achieved through a J-shaped incision (10) or a “sunrise” incision (11).

Transverse incisions offer the advantages of being the best cosmetic incisions for pelvic surgery while also being the least painful, resulting in less interference with postoperative pulmonary function. In addition, compared to vertical incisions, transverse incisions are allegedly stronger and allow better exposure to the pelvic sidewalls. Many gynecologic oncologists use transverse incisions when performing a radical hysterectomy or pelvic exenteration.

In performing the Maylard incision, it is recommended that the deep inferior epigastric vessels be isolated, sectioned, and ligated prior to dividing the rectus muscle (Fig. 12.6) (2). Occasionally, the pelvic surgeon will make a Pfannenstiel incision and find it inadequate. When more exposure is needed,

FIGURE 12.4. Low lithotomy position using Allen stirrups. *Source:* Reprinted with permission from Morrow CP, Curtin JP, eds. *Gynecologic Cancer Surgery*. New York: Churchill Livingstone; 1996.

FIGURE 12.5. Entry into the abdominal cavity can be made by three basic incisions: (1) the midline incision; (2) the transverse Maylard-type incision from anterior-superior iliac spine to anterior-superior iliac spine; and (3) the Pfannenstiel incision. The latter is not an incision for radical pelvic surgery, but it can be converted to a Cherney-type incision for improved exposure. For the patient who has some type of transverse incision, and for whom later exposure of the upper abdominal cavity is necessary, a midline upper abdominal incision can be separately used. *Source:* Reprinted with permission from Gallup DG, Talleo OE. *Surgical Atlas of Gynecologic Oncology*. Philadelphia: WB Saunders Co.; 1994:44.

the appropriate maneuver is to convert the Pfannenstiel to a Cherney-type incision. This conversion can be accomplished by dissecting the rectus muscles from the pyramidalis muscles and the anterior rectus sheath and then transecting the rectus tendons at their insertion into the pubic bone.

Lymph Node Dissection

The surgical technique used to dissect the pelvic and paraaortic lymph nodes involves either a transperitoneal or extraperitoneal approach. The approach utilized is generally dictated by the primary site of disease and the planned accompanying procedure. In cases of endometrial and ovarian carcinoma where the anticipated procedure includes a hysterectomy and/or surgical debulking, the approach is invariably transperitoneal. However, in the pretreatment surgical staging of patients with advanced-stage cervical cancer, the transperitoneal approach has been associated with significant radiation-induced intestinal morbidity due to postoperative adhesion formation (12). Therefore, current clinical trials that require pretreatment surgical staging recommend that the lymph node sampling be performed via the extraperitoneal approach or by operative laparoscopy (13).

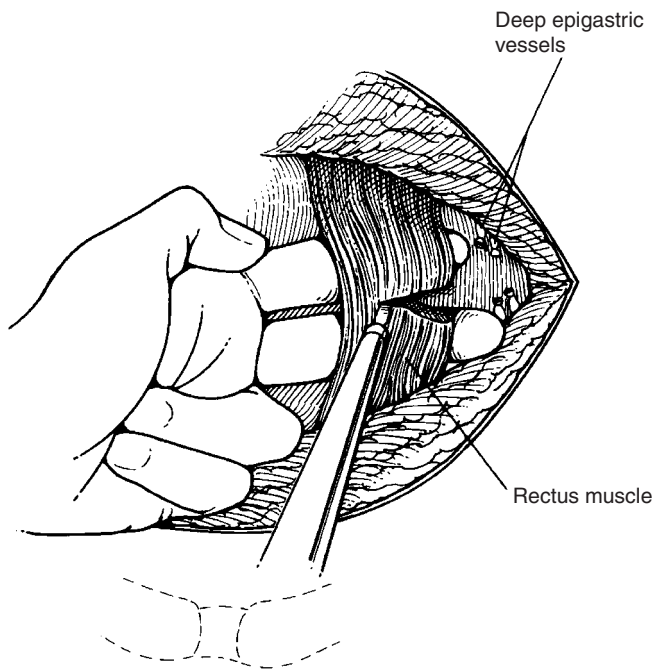

FIGURE 12.6. The Maylard incision. A transverse incision has been made from the anterior-superior iliac spine to the opposite anterior-superior iliac spine. The fascia has been incised transversely. The deep inferior epigastric vessels are located on the lateral and posterior borders of the rectus muscle. They are bluntly dissected from this position by the finger of the operator, isolated, clamped, sectioned, and tied. Only after they are tied should the rectus muscle be incised. This can be done with the Bovie. *Source:* Reprinted with permission from Gallup DG, Talledo OE. *Surgical Atlas of Gynecologic Oncology*. Philadelphia: WB Saunders Co.; 1994:45.

Pelvic Lymph Node Dissection

Whether a transperitoneal or extraperitoneal approach is used, most surgeons initially remove pelvic nodes by excising the loose areolar tissue over the external iliac vessels (Fig. 12.7) (2). The genitofemoral nerve courses laterally to the external iliac artery and should be identified and preserved prior to excising the lymphatic tissue. Mobilization and retraction of the external iliac vessels allows access to the obturator space. The obturator nodes are most easily teased away from the nerve and vessels if one begins the dissection caudad (Fig. 12.8) (2).

Transperitoneal Approach to the Paraortic Nodes

The transperitoneal approach to the paraortic lymph nodes can be accomplished by either the direct or the lateral approach. With the direct approach, the dissection begins with an incision in the peritoneum directly over the common iliac arteries and aorta. The lateral approach starts with an incision in the lateral paracolic gutters with subsequent medial reflection of the right and/or left colon. The advantage of the direct approach is that it involves less dissection of the intestine and ureter, whereas one of its main disadvantages is that it is associated with a greater degree of difficulty in exposing the left paraortic nodes. Consequently, many surgeons sample the right paraortic lymph nodes via the direct approach and use the lateral approach for the left-sided nodes.

With the direct approach to the right paraortic nodes, an incision is made in the peritoneum overlying the right common iliac artery (Fig. 12.9). The incision is carried up over the aorta to the level of the duodenum. If the nodal dissection is to be carried out only to the level of the IMA, the duodenum may not need to be mobilized. Using blunt dissection, the ureter and

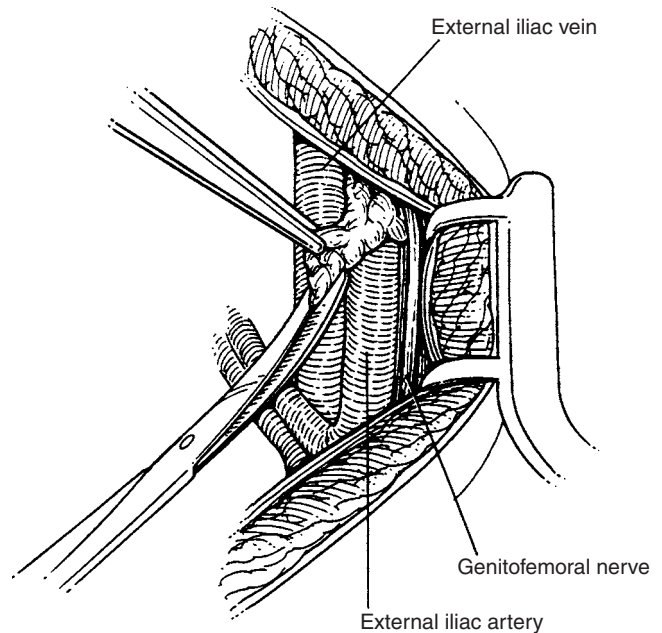

FIGURE 12.7. Starting at the bifurcation of the common iliac vessels, the loose areolar tissue over the vein is excised from cephalad to caudad. Clips should be used at the bifurcation of the common iliac to avoid troublesome bleeding. *Source:* Reprinted with permission from Gallup DG, Talledo OE. *Surgical Atlas of Gynecologic Oncology*. Philadelphia: WB Saunders Co.; 1994:57.

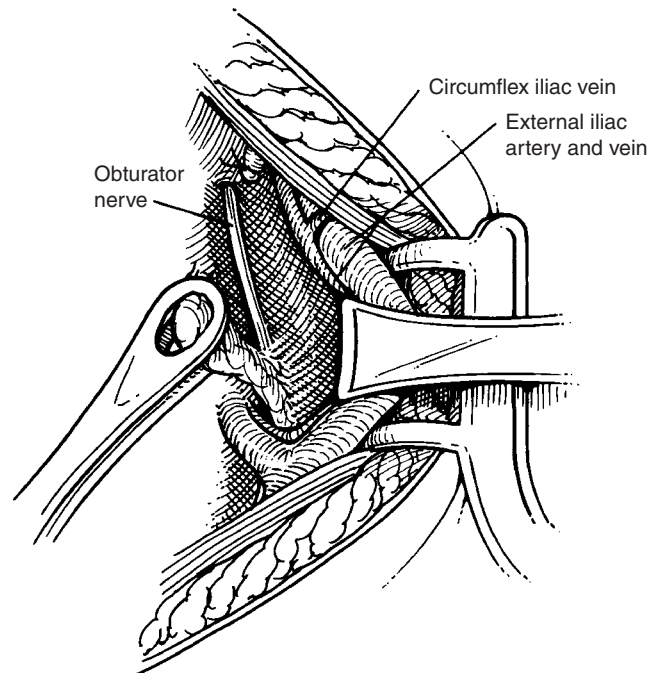

FIGURE 12.8. A vein retractor is used to retract the external iliac veins anterior and lateral to expose the obturator space. Lymphatic tissue is gently teased from the psoas muscle. The entire lymphatic bundle is clamped, sectioned at its caudal end, and ligated at the pelvic sidewall. With the use of the Singley forceps, the lymphatic bundle is bluntly dissected from the obturator nerve and mobilized superiorly. Often, the obturator vein and artery must be sacrificed to obtain access to tissue posterior and lateral to the nerve. Once the tissue is mobilized superiorly, all areolar tissue is cleaned off the hypogastric vessels to the level of the bifurcation of the common iliac artery. The large tissue bundle is clamped and removed en bloc. A tie or clips may be used at the level of the bifurcation. *Source:* Reprinted with permission from Gallup DG, Talledo OE. *Surgical Atlas of Gynecologic Oncology*. Philadelphia: WB Saunders Co.; 1994:58.

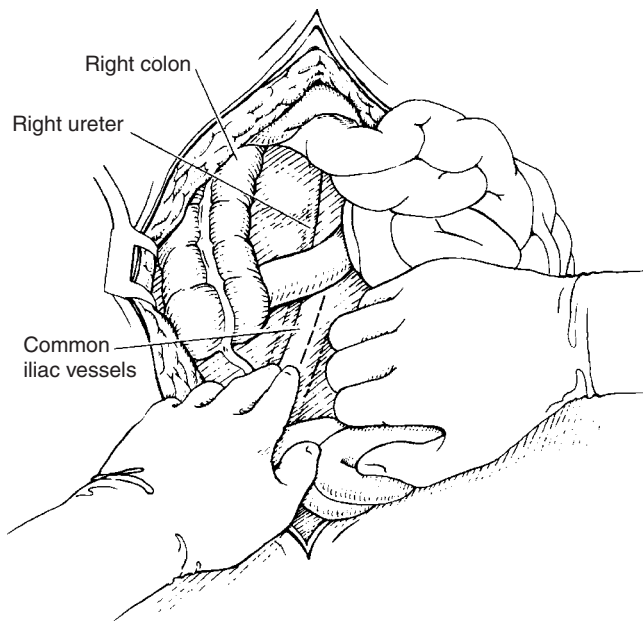

FIGURE 12.9. The small bowel is elevated out of the pelvis placing the mesentery on gentle traction. The right ureter and common iliac artery are identified and the peritoneum overlying the artery is incised.

ovarian vessels are identified and mobilized laterally. The lymphatic tissue lateral to the right common iliac artery is elevated and the caudal end is clipped and divided. The dissection then proceeds in a caudad-to-cephalad direction. A plane is created between the IVC and the lymphatic pedicle. The majority of the right paraaortic nodes overlie the IVC and they are generally easily dissected off the vessel. However, there is a fairly constant

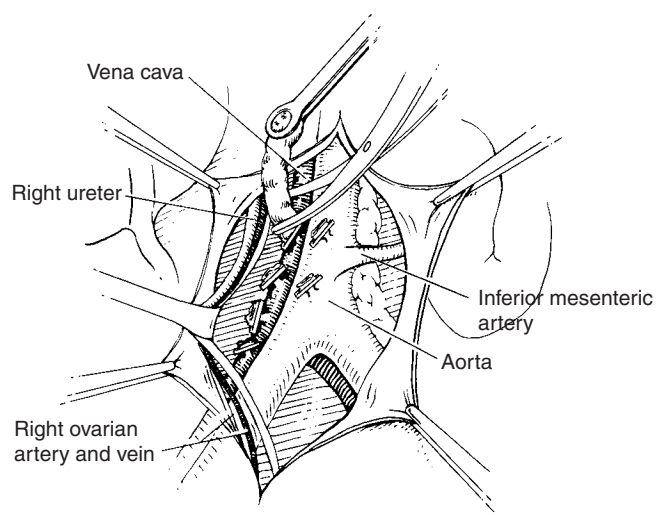

FIGURE 12.10. The specimen is dissected in a cephalad direction. Hemostatic clips are used on either side of the developing pedicle as it is mobilized and divided, and also at the most cephalad extent of the dissection before the specimen is removed.

small vein within the lymphatics anterior to the IVC that inserts just above its bifurcation. If care is not taken to identify and ligate this so-called “fellow’s” vein early in the dissection, it can easily be torn with resultant heavy bleeding (1). When the most cephalad extent of the dissection is reached, the pedicle is clipped and divided (Fig. 12.10).

If the nodes above the IMA need to be sampled, the third portion of the duodenum is mobilized by bilaterally incising the peritoneum around it and then sharply dissecting the areolar

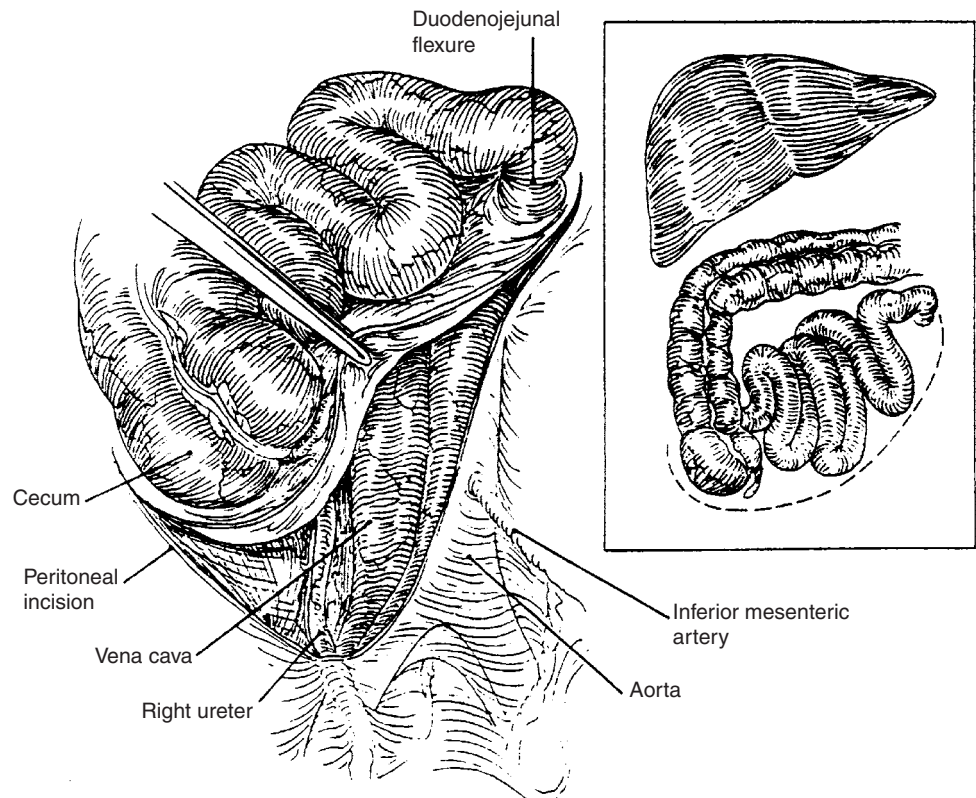

FIGURE 12.11. Extended peritoneal incision. The peritoneal incision is extended over the right ureter around the cecum and the cephalad along the right paracolic gutter. This allows for mobilization of the small bowel mesentery as well as the ascending colon. *Source:* Reprinted with permission from Fowler JM, Johnson PR. Transperitoneal para-aortic lymphadenectomy. *Oper Tech Gynecol Surg* 1996;1:9.

tissue underneath (4). The superior portion of the peritoneal incision can be carried up as high as the ligament of Treitz, which can also be divided if needed. Inferiorly, the peritoneal incision is extended over the right ureter around the cecum and up along the right paracolic gutter to mobilize the small bowel mesentery and part of the right colon (Fig. 12.11) (4). The small bowel can then be packed into the upper abdomen or completely removed from the peritoneal cavity and stabilized outside of the abdominal cavity or put into a bowel bag outside the abdomen. The duodenum is retracted superiorly, allowing identification and ligation of the right ovarian artery and vein. The lymphatic tissue can then be safely dissected off of the right side of the aorta and the anterior surface of the IVC up to the level of the renal veins.

The left paraaortic lymph nodes may be removed through the same peritoneal incision. Sharp dissection is used to identify the left common iliac artery, left side of the aorta, IMA, left ureter, and left psoas muscle (Fig. 12.12). The ureter is again mobilized laterally. The lymphatic tissue lateral to the left common iliac artery and aorta is then removed in a caudad-to-cephalad direction. The left paraaortic lymph nodes lie lateral and partially behind the aorta. In dissecting these nodes, judicious use of vascular clips will help prevent troublesome bleeding from the lumbar vessels. Safe removal of the lymph nodes above the IMA frequently requires identification and division of the left ovarian artery and vein, and occasionally ligation of the inferior mesenteric artery.

To remove right-sided paraaortic nodes via the lateral approach, the right paracolic gutter is incised along the line of Toldt (Fig. 12.13). The peritoneum is elevated off the psoas muscle and the incision is extended up to the hepatic flexure of the colon. Using sharp and blunt dissection, the right colon is reflected medially. The ureter and ovarian vessels can be identified attached to the undersurface of the reflected peritoneum. They may be left attached or mobilized laterally for better exposure. Further medial mobilization of the colon exposes the IVC and aorta. With the essential structures identified, the lymphatic tissue can then be dissected as previously described in a caudad-to-cephalad direction up to the third portion of the duodenum (Fig. 12.14).

FIGURE 12.13. The right paracolic gutter is exposed by medial traction on the ascending colon. The gutter is incised along the line of Toldt.

If the lymph nodes above the IMA need to be sampled, the Kocher maneuver is used to reflect the duodenum medially. The peritoneum lateral to the convexity of the C-curve of the duodenum is incised and the second portion of the duodenum is then dissected off of the IVC. For further exposure, the peritoneal incision along the line of Toldt may need to be extended cephalad to mobilize completely the hepatic flexure of the colon (Fig. 12.15). The right ovarian artery and vein are identified and divided. The right-sided paraaortic lymph

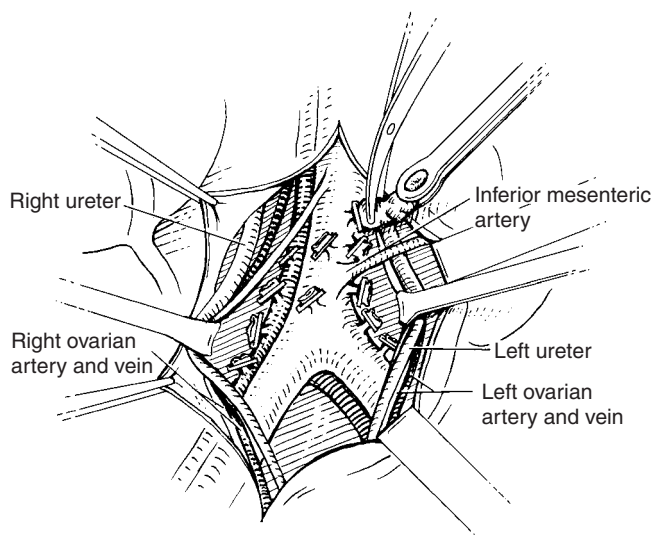

FIGURE 12.12. Removal of the left paraaortic nodes through the same peritoneal incision. The dissection also proceeds in a cephalad direction, again using hemostatic clips on the lateral and medial margins. Care should be taken to avoid injury to the inferior mesenteric artery that arises approximately 3 to 4 cm above the aortic bifurcation.

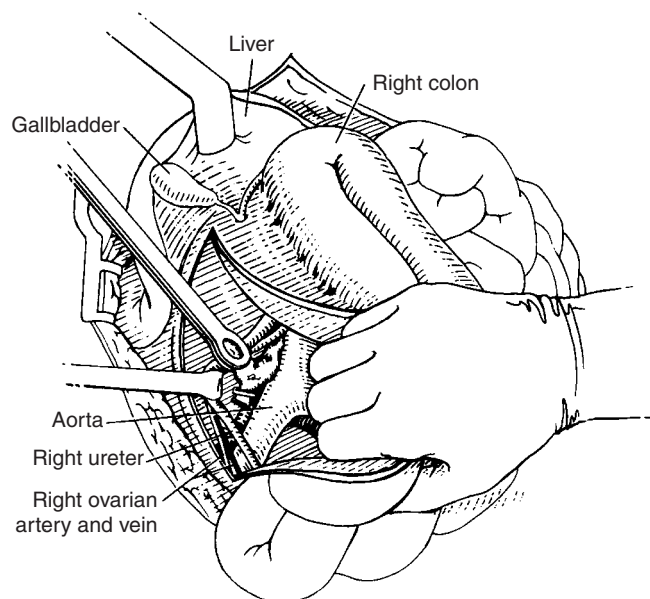

FIGURE 12.14. With the ureter and ovarian vessels identified, the dissection begins at the right common iliac artery and proceeds cephalad up to the third portion of the duodenum.

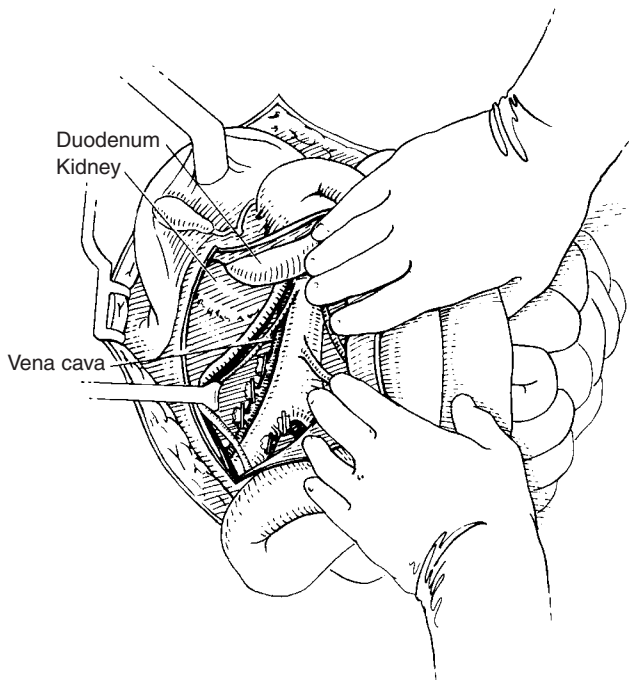

FIGURE 12.15. The Kocher maneuver can be used to gain access to the lymph nodes above the IMA. The peritoneum lateral to the convexity of the C-curve of the duodenum is incised and the second portion of the duodenum is then dissected off of the IVC. The common bile duct and pancreatic duct enter the second portion of the duodenum posteromedially. For further exposure, the incision along the line of Toldt can be extended cephalad to mobilize completely the hepatic flexure of the colon.

nodes are then able to be dissected off of the IVC and right aorta up to the level of the renal vessels.

The lateral approach to the left paraaortic lymph nodes is accomplished in a similar fashion by incising along the line of

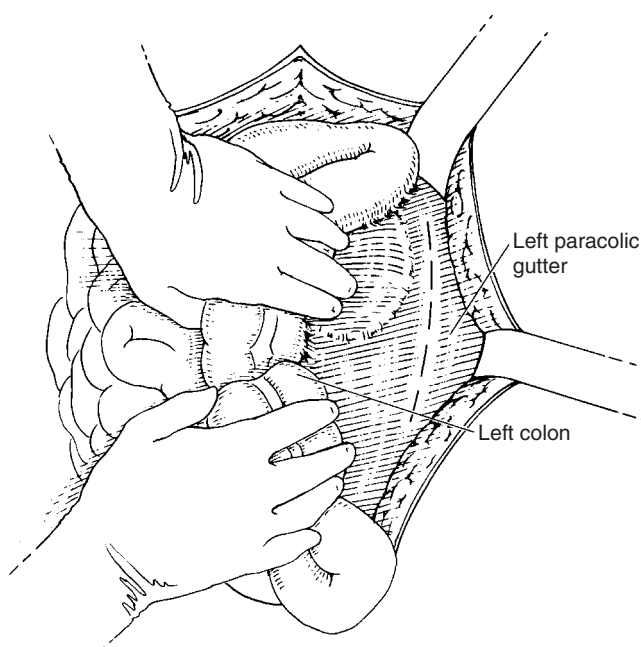

FIGURE 12.16. The lateral approach to the left paraaortic nodes is accomplished by retracting the descending colon medially and incising along the line of Toldt.

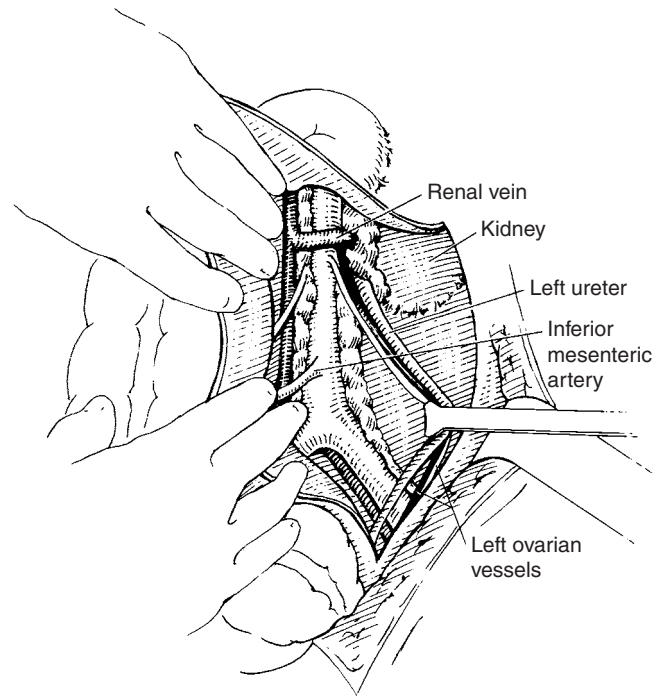

FIGURE 12.17. Using sharp and blunt dissection, the left colon can be mobilized medially, exposing the left ureter, ovarian vessels, and aorta.

Toldt and mobilization of the left colon medially (Fig. 12.16). Again, the ureter and ovarian vessels are identified on the undersurface of the reflected peritoneum, and they may be left attached or mobilized laterally for better exposure (Fig. 12.17). After further mobilization of the left colon and identification of the aorta and the IMA, the left-sided nodes are removed in a caudad-to-cephalad direction (Fig. 12.18). Dissection of the nodes above the IMA requires mobilization of the splenic flexure of the colon, division of the left ovarian artery and vein, and occasionally ligation of the inferior mesenteric artery.

FIGURE 12.18. Dissection begins at the left common iliac artery and proceeds cephalad using hemostatic clips. Care should be taken to avoid injury to the inferior mesenteric artery that arises approximately 3 to 4 cm above the aortic bifurcation.

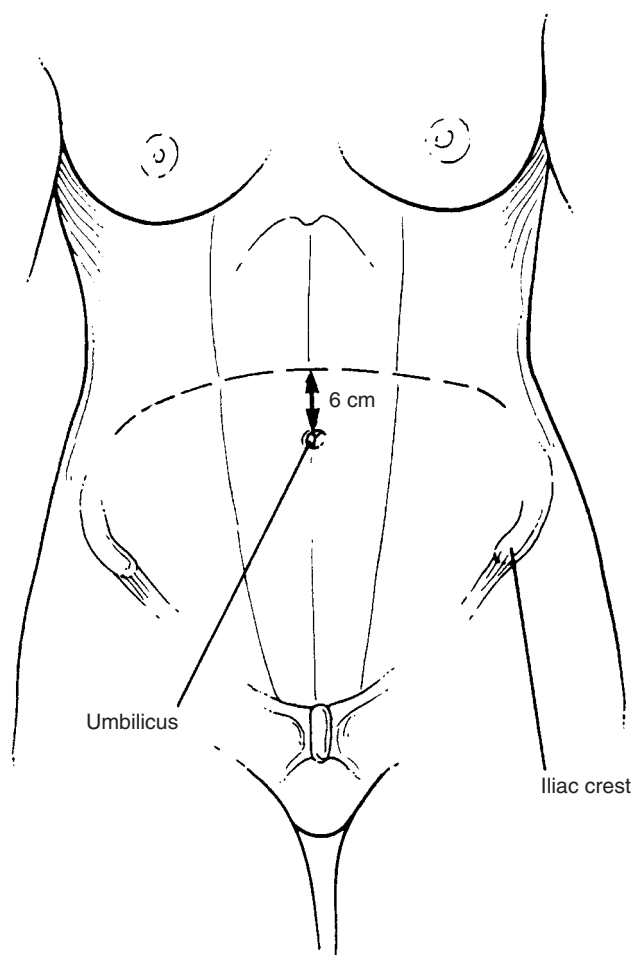

FIGURE 12.19. The “sunrise” incision. In the center, the incision is approximately 6 cm above the umbilicus. The incision is carried laterally in a downward fashion to the level of the iliac crests. *Source:* Reprinted with permission from Gallup DG, Talledo OE. *Surgical Atlas of Gynecologic Oncology*. Philadelphia: WB Saunders Co.; 1994:118.

Extraperitoneal Approach to the Paraortic Nodes

The extraperitoneal approach to the paraortic lymph nodes by means of a supraumbilical transverse sunrise incision was initially described by Gallup et al. (11). The skin incision is made 6 cm above the umbilicus in the midline and is carried laterally and caudad to the level of the iliac crests bilaterally (Fig. 12.19) (2).

The fascia is incised transversely. The rectus muscles are dissected off of the anterior-lying fascia cephalad and caudad. The right rectus muscle is transected. The right transversus muscle is then identified and transected caudally and laterally. The hand of the operator is inserted deep into the incision until the right psoas muscle and external iliac vessels are palpated. The peritoneum is then bluntly dissected from caudad and lateral to cephalad and medial, separating it from the underlying common iliac vessels until the great vessels are exposed (Fig. 12.20) (2). If the peritoneum is inadvertently entered, it must be closed immediately.

After identification of the right ureter and ovarian vessels, the right paraortic nodes can be removed. In thin patients, the left paraortic nodes may be able to be removed through a right abdominal approach. However, if exposure is difficult, the left rectus and transversus muscles can be transected and the peritoneum mobilized medially in a similar fashion to gain access to the left paraortic nodes.

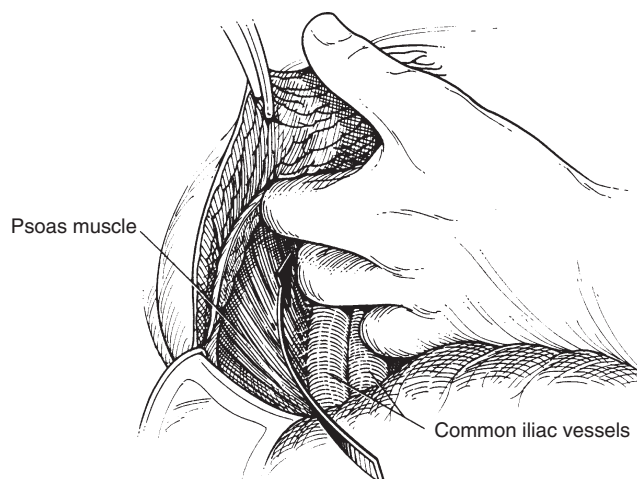

FIGURE 12.20. With the rectus and transversus muscles transected, the operator’s hand is inserted caudad until the psoas muscle and external iliac vessels are palpated. The peritoneum is then bluntly dissected from caudad and lateral to cephalad and medial, separating it from the underlying common iliac vessels until the aorta and vena cava are exposed. *Source:* Reprinted with permission from Gallup DG, Talledo OE. *Surgical Atlas of Gynecologic Oncology*. Philadelphia: WB Saunders Co.; 1994:121.

Radical Hysterectomy

In performing a radical hysterectomy, one of the most troublesome areas is intraoperative bleeding from the lateral cardinal ligament, which is also known as the “web.” In order to have better access and exposure in this area, the surgeon can release the uterus posteriorly in the earlier steps of the procedure. The six classic spaces are developed prior to sectioning the uterosacral ligaments. With maximal mobility of the uterus achieved, the ureter is unroofed from the tunnel of tissue that contains the uterine vessels and its branches (Fig. 12.21).

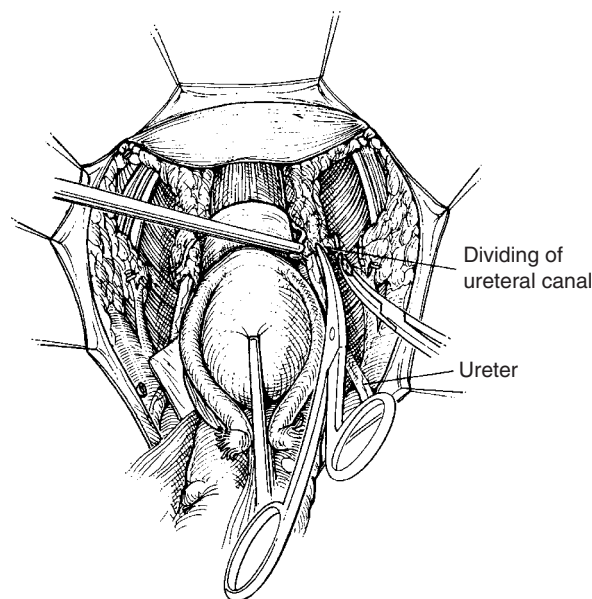

FIGURE 12.21. Dissection of the ureter from the parametrium is begun. The ureteral canal is unroofed by placing traction on the medial stump of the uterine vessels. Because of the rich blood supply from anastomosis of vessels in this area, a clamp-cut technique is often used. *Source:* Reprinted with permission from Gallup DG, Talledo OE. *Surgical Atlas of Gynecologic Oncology*. Philadelphia: WB Saunders Co.; 1994:79.

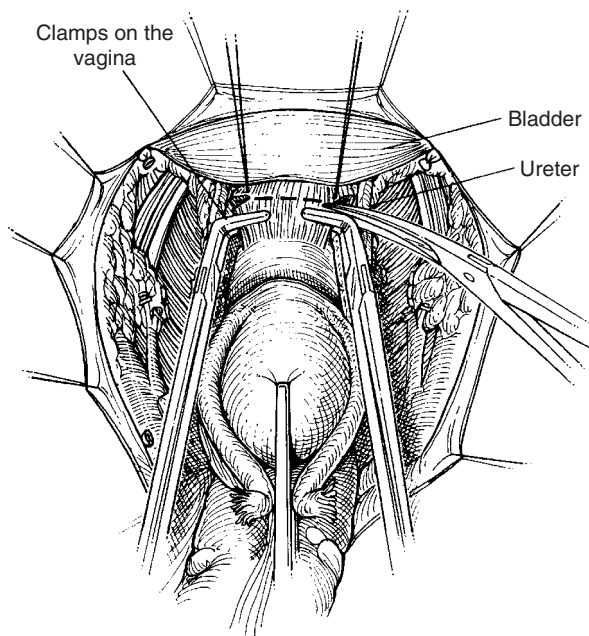

FIGURE 12.22. The vaginal angles are clamped and sectioned after placing right-angle clamps across the proximal vagina. Note the vaginal incision is made caudad to these clamps. *Source:* Reprinted with permission from Gallup DG, Talledo OE. *Surgical Atlas of Gynecologic Oncology*. Philadelphia: WB Saunders Co.; 1994:81.

Once the ureter is unroofed, removal of any remaining cardinal ligament is accomplished with the ureter pulled laterally. To ensure that adequate vaginal margins are obtained, right-angle clamps are placed proximal to the level of resection of the specimen (Fig. 12.22). The pelvic lymphadenectomy can be done prior to or following the radical hysterectomy. The use of closed suction drains is advocated by many, although some avoid their use.

Ovarian Cancer Debulking

The goal of ovarian cancer debulking or cytoreduction is to remove all or as close as possible to all grossly visible and palpable tumor (14). The surgeon operating on patients with advanced ovarian cancer should be familiar with the techniques used to clear tumor from the pelvis and the upper abdomen.

Removal of Pelvic Disease

Ovarian malignancy often presents with large pelvic masses filling the pelvis. An initial incision over the lateral pelvic sidewall just anterior to the external iliac artery will allow adequate visualization of the ureter and the ovarian vessels (Fig. 12.23). The paracolic gutters can be incised cephalad along the avascular line of Toldt for more adequate exposure of the retroperitoneal space. To avoid further troublesome hemorrhage with large adnexal masses, if a hysterectomy is part of the planned procedure, the uterine vessels can be separately isolated and divided similar to a modified radical hysterectomy. When the anatomy is distorted by peritoneal implants, the ureters may need to be followed down to the tunnel and retracted laterally prior to removal of the uterus.

In cases where ovarian tumors are densely adherent to or involve the rectosigmoid, a reverse hysterectomy can often help identify the rectovaginal plane. Once the uterine vessels

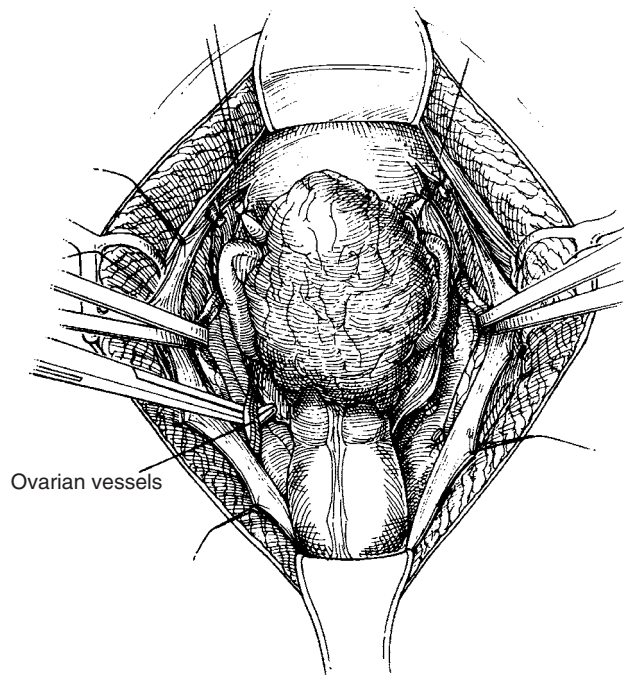

FIGURE 12.23. The ovarian vessels are skeletonized and divided at the pelvic brim. Early control of these vessels will help reduce blood loss during the later dissection. The ureter can be mobilized off the medial leaf of the broad ligament and retracted laterally on a Penrose drain or vessel loop. *Source:* Reprinted with permission from Gallup DG, Talledo OE. *Surgical Atlas of Gynecologic Oncology*. Philadelphia: WB Saunders Co.; 1994:92.

are ligated bilaterally, the vagina is incised anteriorly below the level of the cervix. The posterior vagina is incised after elevating the anterior vaginal flap. The vaginal angles are ligated and the posterior vaginal wall is grasped with Kocher clamps and retracted cephalad (Fig. 12.24). The cardinal and uterosacral ligaments are then clamped and sectioned. Resection of the rectosigmoid with tumor is frequently required to clear all pelvic tumor. Low rectal anastomosis in this setting is generally performed and associated with a low rate of complications in well-trained hands (15,16).

Upper Abdominal Disease

A recent meta-analysis by Bristow et al. demonstrated that expert centers with primary optimal cytoreduction rates of 75% or greater provided their patients with a 50% improvement in overall survival when compared to less experienced centers with primary optimal cytoreduction rates of 25% or less (17). A subsequent study by Chi et al. illustrated that in order to achieve primary optimal cytoreduction rates of 75% or more in advanced-stage ovarian cancer patients, the surgeon's armamentarium should include the ability to remove disease involving upper abdominal structures such as the liver, diaphragm, spleen, and pancreas (5).

Adequate exposure is the most important factor in determining whether resection of diaphragm disease can be performed safely (7). Once an exploratory laparotomy has been performed and the presence of bulky diaphragm disease confirmed on one or both hemidiaphragms, the midline incision is extended to the xiphoid process. For maximum exposure, it can be extended to the sternum to the right of the xiphoid, or in some cases the xiphoid can be divided or removed. The procedure can almost always be performed through this midline incision, and although extending a subcostal incision 2 to 3 cm below the costal margin has been described, we have not generally found this to be necessary.

FIGURE 12.24. The posterior vaginal wall is grasped and retracted cephalad. The uterus can now be sharply dissected off of the rectosigmoid. *Source:* Reprinted with permission from Gallup DG, Talleo OE. *Surgical Atlas of Gynecologic Oncology*. Philadelphia: WB Saunders Co.; 1994:103.

The extent of liver mobilization required depends on the distribution of tumor involving the hemidiaphragm. Large volume disease is common on the right side, and a greater proportion of the right hemidiaphragm is obscured by the liver. A right-sided liver mobilization will be described primarily. Tumor involvement on the left diaphragm is more easily resected without fully mobilizing the liver, although in certain cases splenectomy may be necessary to clear the metastatic deposits on the left diaphragm.

The infrahepatic edge of the falciform ligament containing the ligamentum teres is grasped between two Kelly clamps, and is divided and ligated. The suture on the lower edge is left long to aid with downward traction of the liver and remaining falciform ligament. The falciform ligament should be transected all the way to the coronary ligament. This can be used for traction of the liver. The coronary ligament is incised from the falciform to the right triangular ligament. Care must be taken in the area of the hepatic notch. The hepatic notch contains the right hepatic vein as it enters the inferior vena cava and is found lateral to the union of the falciform and coronary ligaments. If further mobilization of the liver is necessary, the lateral attachments may be incised and the liver bluntly lifted off Gerota's fascia of the right kidney and diaphragm.

The extent of diaphragm peritonectomy is determined by the distribution of the tumor implants and the method can be modified accordingly. When a full right diaphragm peritonectomy is performed, the peritoneum on the anterior edge of the diaphragm is incised along the costal margin using either cautery or Metzenbaum scissors. This anterior free edge is grasped with several Allis or Mixter clamps, which are then retracted inferiorly to visualize the line of attachment between the diaphragm and its overlying peritoneum. The plane between is developed with a combination of blunt and sharp dissection as determined by the patient's tissue laxity and/or

peritoneal adherence. This may not be possible if the tumor has extended through the peritoneum and diaphragm.

If tumor implants are securely fixed to the diaphragm muscle and/or are suspicious for full thickness diaphragm involvement, diaphragm resection should be considered. The technique for diaphragm resection depends largely on the size of the lesion to be resected. Small penetrating lesions can be resected using the EndoGIA stapler alone without entering the pleural cavity. The lesion is grasped with a long Allis clamp, the diaphragm tented downward away from the lung, and the EndoGIA used to staple and divide the tented diaphragm and invasive lesion. Larger lesions require entry into the pleural space and this is generally performed sharply with a Metzenbaum scissors to avoid an inadvertent cautery burn to the lung. Once entered and the lung visualized/retracted, cautery can be used to circumscribe the lesion and resect it en bloc with the peritoneal, muscular, and pleural layers. The defect can almost always be closed primarily with limited tension, using interrupted horizontal mattress or figure-of-eight permanent sutures. Larger defects that cannot be closed primarily without significant tension should be closed with a permanent mesh secured to the peritoneal diaphragm surface with interrupted permanent sutures (18). The majority of patients undergoing diaphragm resection can have their pleural cavity closed and the air from the thorax evacuated using the red Robinson catheter. A purse-string suture is placed widely around the hole and a #14 French red Robinson catheter is passed through the hole into the pleural cavity. The anesthesiologist is asked to give the patient a maximal inspiration, suction may be applied to the catheter, and the catheter is pulled as the purse-string suture is tied down. For patients undergoing more extensive resections or with other reasons to benefit from prolonged pleural drainage, such as pleurodesis, a chest tube can be placed in the operating room and removed postoperatively as required.

To remove tumor from the left upper quadrant, occasionally a splenectomy with or without distal pancreatectomy is required. Usually, the initial step is to enter the lesser sac to evaluate the posterior aspect of the stomach and pancreas. The gastrosplenic ligament and then the short gastrics are carefully divided. The spleen is mobilized medially and out of the left upper quadrant by dividing the splenophrenic and splenocolic ligaments and the other attachments to the adrenal gland and Gerota's fascia of the left kidney. The spleen can now be elevated out of the splenic bed and into the incision. The splenic hilum is now grasped between the fingers. Palpation of the pancreas is attempted. Identification of the pancreas may be facilitated by viewing the hilum posteriorly. The anterior splenorenal ligament is entered sharply. The splenic artery and vein can then be identified. These vessels should be ligated and divided separately. The splenic vessels may also be ligated prior to elevating the spleen in cases where lateral mobilization is not possible secondary to tumor and/or dense adhesions. A linear stapler may be placed across the tail of the pancreas if necessary to remove tumor involving the distal pancreas and/or splenic hilum. Reinforcement of this staple line with 3-0 delayed absorbable suture, either continuously or interrupted, is optional.

Continent Urinary Diversion

Over the past decade, interest in performing continent urinary diversions for patients with gynecologic malignancies has emerged. Most gynecologic oncologists will use a modification of the Indiana (19) or Miami (20) pouch. Poor candidates for continent urinary diversion include those with crippling arthritis or those psychologically unable to tolerate frequent self-catheterization of the pouch.

FIGURE 12.25. The anatomic location and vascularity of the right colon segment utilized for formation of the continent urinary pouch. Illustrated are the anatomic sites of division for creation of the continent pouch. The ascending colon is divided distal to the right colic artery. The terminal ileum is divided approximately 12 cm from the ileocecal valve. The resection can be accomplished with the use of surgical staplers or by intestinal clamps. If the appendix is present, it should be removed. The ileocecal segment has a rich blood supply derived from the right colic artery and the ileocolic artery. If one is performing the Miami pouch type of urinary diversion, the transverse colon would be divided distal to the middle colic artery. *Source:* Reprinted with permission from Gallup DG, Talleo OE. *Surgical Atlas of Gynecologic Oncology*. Philadelphia: WB Saunders Co.; 1994:186.

A modification of these pouches is shown (2). The colon is transected just proximal to the hepatic flexure (Fig. 12.25). The colon is then detubularized by a longitudinal incision along the tinea. The continent mechanism is created by two maneuvers. First, the terminal ileal segment is tapered down over a #14 French Foley catheter by using a gastrointestinal anastomosis (GIA) stapling device along the antimesenteric border of the ileum. The second maneuver is to plicate the ileocecal valve by placing concentric purse-string sutures of 0 silk or polypropylene around it. The ureters are then implanted under direct vision (Fig. 12.26) (2). After closing the pouch, the ileal stoma can be brought out in several areas of the abdominal wall (Fig. 12.27) (2). Some use the umbilicus as the exit site. The ureteral stents can exit the abdomen via the ileal stoma or through separate incisions in the pouch and abdominal wall. The use of a Penrose drain and a cecostomy tube for irrigation to remove mucus is optional.

Abdominal Closure

With the advent of more recently published closure methods and newer suture materials, the vertical, allegedly stronger paramedian incision is unnecessary. A midline incision is preferable in modern-day gynecologic oncology. It is the least hemorrhagic of all incisions, and rapid entry is feasible. Exposure is excellent, and minimal nerve damage occurs.

In the past, many surgeons have advocated the relatively time-consuming Smead-Jones closure (21). However, in the 1980s it was noted that midline incisions could be safely closed with a running, mass closure. In 1989, Gallup et al. (22) reported on 210 patients, most of whom were at high risk for evisceration, who had midline incisions closed with a running, mass closure using #2 monofilament polypropylene

suture. No eviscerations occurred. Since that publication, several gynecologic oncology services have published excellent results using monofilament absorbable or monofilament permanent sutures in a running, mass closure method (23–26). Figure 12.28 illustrates a popular technique utilizing an absorbable suture (2). Eviscerations using this technique almost never occur.

SURGICAL MANAGEMENT OF GYNECOLOGIC CANCER

The gynecologic oncologist must be able to evaluate the woman with a genital tract malignancy, direct her management, perform the necessary surgical procedures, and supervise her postoperative care and surveillance. A patient who is managed by a surgeon who is not a gynecologic oncologist may receive an operative procedure that is inappropriate or inadequate. Over 20 years ago, McGowan et al. (27) reviewed the intraoperative evaluation of 291 women with primary ovarian cancer. Ninety-seven percent of the patients who underwent surgery by a gynecologic oncologist received complete staging operations, but only 52% and 35% had adequate operations by an obstetrician-gynecologist or a general surgeon, respectively.

Two more recent British studies retrospectively analyzed the outcomes of over 1,800 patients with ovarian cancer (28,29). Both studies found on multivariate analysis that patients' survival was adversely impacted when their initial operation was performed by a general surgeon as opposed to a gynecologic surgeon. These results are similar to those obtained by Nguyen et al. in a national survey of ovarian carcinoma (30). Eisenkop et al. analyzed the outcomes of 263 patients with stages IIIC and IV ovarian carcinoma (31). When

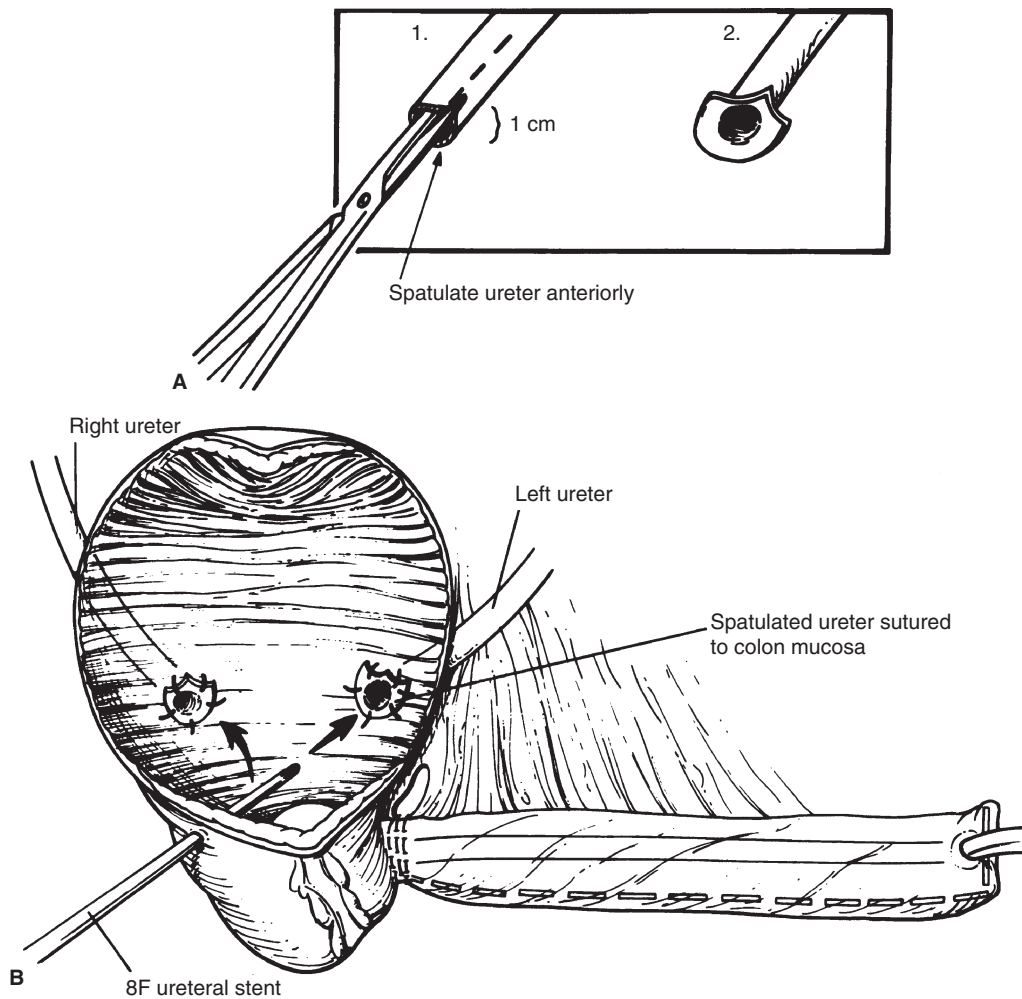

FIGURE 12.26. A, B: Prior to beginning the continent diversion, the ureters have been transected (usually at the pelvic brim) and mobilized so that they are able to be brought to the area where the continent pouch will be located without tension. If necessary, the left ureter can be brought through or under the mesentery of the colon to facilitate its placement into the urinary pouch. An appropriate site is selected on what will be the posterior wall of the pouch, and a long thin clamp is used to perforate the colon and pull the ureter through. An approximately 1-cm segment of ureter is brought into the pouch. For ease of ureterointestinal anastomosis, the ureter should be secured posteriorly to the pouch by suturing the adventitial tissue of the ureter to the seromuscular layers of the pouch with three or four permanent 3-0 sutures. The ureter is spatulated to increase the lumen diameter. The ureter is sutured directly to the colon and is not tunneled. We use 4-0 polyglycolic suture. This is a full-thickness approximation of the colon and ureter. Once both ureters have been sutured into the pouch, two #8 French ureterointestinal stents or long pediatric feeding tubes are placed retrograde into the renal pelvis. If a feeding tube is used, it should be sutured to the ureter with 4-0 chromic to ensure against displacement due to ureteral peristalsis. Note the three concentric sutures at the ileocecal valve. *Source:* Reprinted with permission from Gallup DG, Talleo OE. *Surgical Atlas of Gynecologic Oncology*. Philadelphia: WB Saunders Co.; 1994:191.

the primary surgery was performed by gynecologic oncologists, as compared to general obstetricians-gynecologists and general surgeons, the rate of optimal cytoreduction was significantly higher, the operative mortality substantially lower, and the median survival significantly longer.

Accordingly, other countries have attempted to centralize the care of patients with ovarian cancer so that they are primarily operated on by gynecologic oncologists (32,33). However, patterns of care studies in the United States have demonstrated that a significant percentage of women with ovarian cancer are not receiving their primary treatment from gynecologic oncologists (34,35). Consequently, in this country, many women with ovarian cancer are still not receiving the recommended comprehensive primary surgery (36,37).

In the three decades since the establishment of gynecologic oncology as a subspecialty, cancer therapy has become increasingly sophisticated and complex, and it is difficult for any one physician to master all the skills necessary for treating gynecologic malignancies. More often, we must use multimodal therapy and be involved in multidisciplinary care. There are many medical and radiation oncologists who have specialized in gynecologic cancer, and they are integral members of the multidisciplinary team. The Gynecologic Oncology Group (GOG), with its emphasis on multidisciplinary research, has demonstrated the effectiveness of such an approach.

Another important factor in providing optimal patient care is the environment in which gynecologic oncology is practiced. The facilities used by the gynecologic oncologist should offer

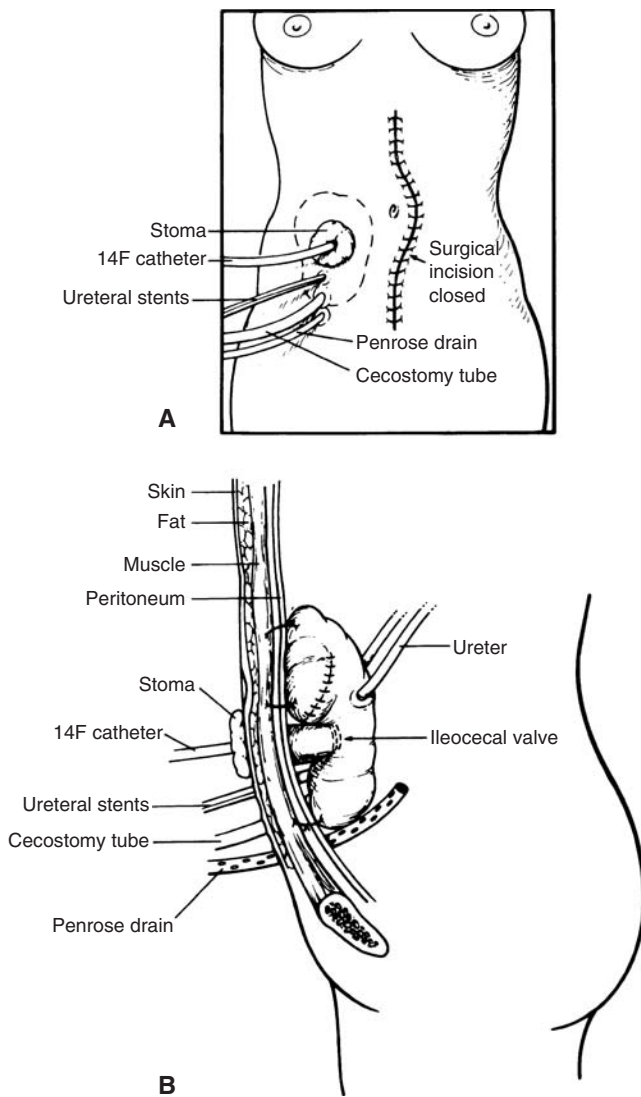

FIGURE 12.27. A, B: The site for the ileal stoma is selected on the anterior abdominal wall and then incised through all abdominal tissue layers. The stoma is created for catheterization and the #14 French catheter should exit the pouch through this stoma. It is critical that the ileal segment be at a 90° angle with the abdominal wall so that catheterization is a “straight shot.” The pouch may be sutured to the abdominal wall to accomplish this. All stents and drainage tubes are brought out through the anterior abdominal wall and secured. The pouch may also be anchored posteriorly (i.e., to the sacrum). *Source:* Reprinted with permission from Gallup DG, Talledo OE. *Surgical Atlas of Gynecologic Oncology*. Philadelphia: WB Saunders Co.; 1994:193.

state-of-the-art radiation therapy and chemotherapy. Patients should receive care tailored to the type and extent of their disease and not be determined by the limitations of the available facilities. Mortality rates for complex oncologic procedures, such as pelvic exenteration, have been demonstrated to be significantly lower in hospitals where the procedures are performed with a relatively high volume as compared to those in which the procedures are performed infrequently (38). The recent meta-analysis performed by Bristow et al. evaluated 81 studies involving 6,885 patients with advanced ovarian cancer (17). This study demonstrated a 50% increase in median survival if patients’ primary surgery was performed at an “expert” center compared to less experienced centers.

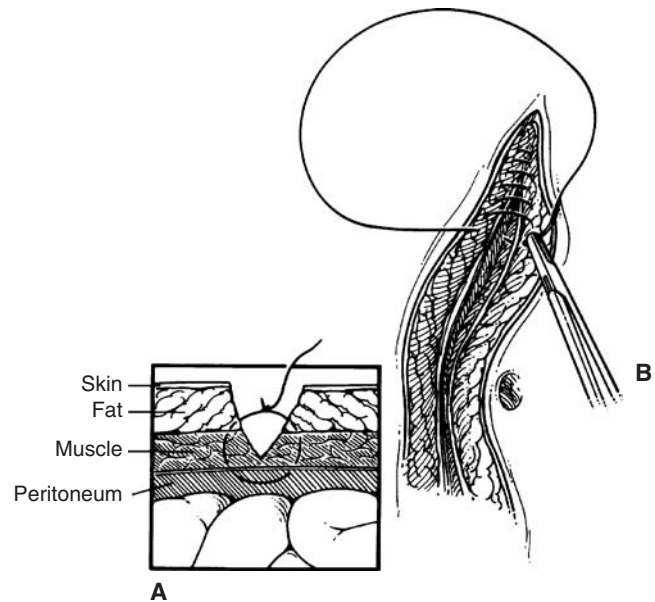

FIGURE 12.28. A running #1 delayed absorbable suture (Maxon or PDS) is used to close midline incisions. One suture is started from the cephalad end. The knots are buried. The sutures are placed approximately 1 cm apart. **A:** The sutures are placed at least 2 cm from the fascial edge. The suture bite should include anterior fascia, a portion of the muscle, and the posterior fascia. The peritoneum is included if it is easily located. **B:** When the midpoint is reached from the cephalad and caudad ends, the sutures are tied and the knot buried. Six throws are used for each knot. *Source:* Reprinted with permission from Gallup DG, Talledo OE. *Surgical Atlas of Gynecologic Oncology*. Philadelphia: WB Saunders Co.; 1994:51.

Early Diagnosis and Prevention

There is a role for early diagnosis and prevention in virtually all female genital cancers. The management of a patient with an abnormal Papanicolaou (Pap) smear allows the gynecologic oncologist to use limited surgery to prevent the development of an invasive malignancy of the cervix or vagina. Guided by colposcopy, the surgeon can employ traditional surgical excision, laser surgery, cryotherapy, or a loop electro-surgical excision procedure (LEEP) to preserve function and prevent cancer. Preinvasive lesions of the vulva can be diagnosed and managed by laser or local excision, thereby potentially avoiding progression to invasive disease and its associated extensive surgical therapy.

The proper management of endometrial hyperplasia can prevent the subsequent development of endometrial cancer. Optimal management requires individualization of treatment. Complex hyperplasia without atypia in a premenopausal patient indicates the need for medical therapy with progesterone, but a similar problem in a postmenopausal patient may indicate the need for a hysterectomy. Atypia in either case requires consideration of hysterectomy to prevent the development of endometrial cancer. It is essential that the gynecologic oncologist recognize the significance of these cancer precursors.

No diagnostic test or early symptoms reliably herald the onset of ovarian or tubal cancer, and no preinvasive lesion has been identified. The only method of prevention for these cancers is surgical removal of the tubes or ovaries before cancer develops. Although quite rare, women can be identified who may have as high as a 40% lifetime risk of developing ovarian cancer. These are women who have a family history of ovarian cancer, who have a family history of breast and ovarian cancer, or who are members of hereditary nonpolyposis colorectal

cancer (HNPCC) families. These cancer-prone families are described elsewhere in this book. These syndromes are seen infrequently, and certain criteria must be fulfilled before the diagnosis can be made. For women who fall into one of these high-risk categories, surgical removal of the tubes and ovaries (and the uterus in HNPCC) should be considered after child-bearing is complete (39,40). Before that time, close monitoring is essential.

The decision to remove the ovaries and fallopian tubes to prevent ovarian cancer is generally accepted for the postmenopausal patient who undergoes an exploratory pelvic operation or a hysterectomy for benign disease. The removal of the fallopian tubes and ovaries represents little additional surgery, and although the chance of the disease in any woman is quite low, prevention is worthwhile because of the lack of an effective screening modality combined with the devastating effects of ovarian and fallopian tube cancer. However, removal of the ovaries and fallopian tubes in premenopausal women is controversial. For a patient younger than 40 years of age, it seems advisable not to recommend removal of the fallopian tubes and ovaries unless she has a familial risk of ovarian cancer. Between the ages of 40 and 50 years, the pros and cons should be carefully discussed with the patient, and her wishes must be taken into account.

Diagnosis and Staging

The diagnosis of any gynecologic cancer requires a surgical biopsy. The manner in which the histologic diagnosis is obtained varies with the disease and the clinical situation. A punch biopsy or an instrument biopsy may be sufficient for the diagnosis of an invasive cancer of the vulva, vagina, or cervix, but an excisional biopsy is necessary for the diagnosis of microinvasive or preinvasive cancer. A fine-needle aspiration biopsy for cytologic analysis may be adequate for establishing the extent of spread of a cancer, but not for providing histologic cell type and grade for the primary diagnosis. The histologic diagnosis of ovarian or fallopian tube carcinoma requires surgical exploration.

The current International Federation of Gynecology and Obstetrics (FIGO) staging system of gynecologic cancers requires surgical staging for vulvar, endometrial, and ovarian cancer. Cervical cancer remains a clinically staged disease, although many centers use surgical staging (by laparotomy or laparoscopy) for treatment planning. No official FIGO staging exists for fallopian tube cancer or uterine sarcomas, but fallopian tube cancers are usually staged on the basis of surgical and pathologic findings similar to ovarian carcinoma. Table 12.1 lists the current methods of staging for the various gynecologic malignancies.

The initial surgical procedure in a patient with known or suspected gynecologic cancer should be performed by a trained gynecologic oncologist because the accuracy of diagnosis and staging significantly influences subsequent therapy. As stated earlier, numerous studies have demonstrated that ovarian cancer staging operations performed by general obstetricians-gynecologists or general surgeons are inadequate much more frequently than if the operation is performed by a gynecologic oncologist. Young et al. (41) reported excellent survival in patients with early ovarian cancer, but stressed that these data were applicable only to patients with adequate surgical staging.

In addition to the anatomic site and stage of disease, the plan of therapy for most gynecologic malignancies is also influenced by the histologic cell type and histologic grade (differentiation) of the cancer. The cooperation of the surgeon, pathologist, and cytologist cannot be overemphasized in the diagnosis and staging of cancer. It is the surgeon's responsibility to provide the pathologist or cytologist with a complete clinical history and an

TABLE 12.1

FIGO STAGING OF GYNECOLOGIC CANCERS

Site	Staging
Vulva	Surgical and pathologic staging
Vagina	Clinical staging
Cervix	Clinical staging
Corpus (endometrium)	Surgical and pathologic staging
Corpus (sarcoma)	None (most use modified clinical endometrial cancer staging)
Fallopian tube	None (most use modified surgical and pathology staging)
Ovary	Surgical and pathologic staging
Gestational trophoblastic disease	FIGO staging (clinical) NIH classification WHO classification (risk-oriented)

Note: FIGO, International Federation of Gynecology and Obstetrics; NIH, National Institutes of Health; WHO, World Health Organization.

indication of what he or she hopes to learn from the anatomic specimen. Without this communication, the pathologist and cytologist will be unable to provide the information needed to direct the clinical care of the patient. Both the pathologist and the cytologist must be sure that the surgeon is aware of any special handling that is necessary for a particular specimen. There is no excuse for misinterpretation of a tissue or cytologic specimen because of a failure in communication.

Surgery as Primary Therapy

Surgery is usually the treatment method of choice for preinvasive diseases of the vulva, vagina, and cervix, for which local excision is both diagnostic and curative. Surgical margins should clear only gross and microscopic disease; removal of large areas of normal tissue is not required. For microinvasive lesions of these organs, wide local excision with a 1- to 2-cm normal tissue margin is appropriate.

Localized disease, such as stage I through stage III vulvar cancer, stage I vaginal cancer, and stages IB1 and IIA cervical cancer, are usually managed by an en bloc radical resection of the primary tumor and regional lymphadenectomy. In these surgical procedures, the operations themselves are designed to be curative without adjunctive therapy unless high-risk conditions are identified. As described in the chapter on vulvar cancer, there is a trend toward more conservative therapy for vulvar malignancies. This allows preservation of normal tissues and prevents some of the disfigurement usually associated with this surgery. Surgery may be curative without adjuvant therapy for other cancers as well, including early-stage endometrial cancer, stage IA ovarian cancer, and early sarcomas of the uterus.

Findings at surgery may indicate the need for additional treatment. This therapy is usually called adjuvant therapy. It is administered because of the potential for occult spread of disease based on a surgical finding (e.g., positive lymph nodes). The use of adjuvant therapy requires that information be available to allow the selection of patients with a high risk of recurrence. These risk groups are defined for each disease site in the appropriate chapters of this book.

Surgery Combined With Other Therapies

In some cancers of the female genital system, surgery is the cornerstone of treatment but is not curative when used alone. Primary cytoreduction of gross disease is vital in advanced

ovarian and fallopian tube cancer, but it is of little benefit without adjunctive therapy. Chemotherapy after surgery is a vital and necessary part of the treatment regimen for these cancers. For patients with clinical stage I or II endometrial cancer who have high-grade cancer or deep myometrial penetration, surgical removal of the uterus is an extremely important part of therapy. However, depending on the histopathologic findings of the surgical specimens, additional regional radiotherapy and/or chemotherapy may be indicated. It is the responsibility of the gynecologic oncologist to coordinate surgical therapy with chemotherapy and/or radiation therapy to ensure that the patient receives optimal care.

Surgery as Salvage Therapy

Occasionally, surgical resection can be curative in patients who have failed other therapies. These surgical procedures are almost always extensive and produce some limitation of function. After the failure of other therapies, radical surgery may be the patient's last chance of survival. The classic examples of this situation are vulvar, vaginal, cervical, or uterine cancers that have failed primary surgery and irradiation or irradiation alone. In such cases, pelvic exenteration with removal of virtually all pelvic tissues may offer the only possibility for a cure. Five-year survival rates of 23% to 61% have been reported after pelvic exenteration (42–44).

The possibility of cure with pelvic exenteration is not without cost. The loss of the bladder and the rectum often requires permanent stomas, and sexual function is impaired or lost in many patients. For some patients, reconstructive techniques can prevent the need for stomas and may also restore sexual function. These procedures are described in detail in other chapters in this book. During the last three decades, improvements in initial surgery and radiation therapy along with refinements in selection criteria have made operations like pelvic exenteration infrequent (45). Today, most patients experience distant failure rather than regional failure, and they are therefore not candidates for attempts at curative pelvic exenteration.

Surgery as salvage therapy may also play an important role in the management of ovarian, fallopian tube, and some endometrial cancers. For patients who have failed initial therapy and chemotherapy, second attempts at cytoreduction may be beneficial, provided that reasonable salvage therapy is available (46–48).

Surgery for Metastatic Disease

In selected cases, distant metastases from gynecologic tumors may be curable by surgical resection, or the resection may produce a prolonged disease-free interval. Fuller et al. (49) reported on 15 patients who underwent pulmonary resection of distant metastases from a variety of gynecologic malignancies. They reported a 5-year survival rate of 36% and a 10-year survival rate of 26%. Patients with solitary metastases had a median survival of 64 months, with a median survival of 48 months for those with multiple metastases. Levenback et al. (50) reported their experience with 45 patients who underwent pulmonary resection of metastases from uterine sarcomas. From the date of the pulmonary resection, the 5-year survival rate was 41%, with a 10-year survival rate of 35%. They found a statistically improved chance of survival for patients who developed pulmonary metastases 1 year or longer from their original therapy and for those with unilateral metastases. There was no statistical difference in survival based on the number of nodules (in one lung), the size of the lesion, the age

of the patient, or the use of postresection adjunctive therapy. However, the small numbers of patients in this study precluded adequate evaluation of these factors.

Resection of intra-abdominal or pelvic disease may offer palliation by removal of tumor bulk or may allow chemotherapy or irradiation a greater chance of eradicating disease. Resection of tumors that have a poor blood supply often leaves behind smaller tumors with a better blood supply that are more amenable to treatment with chemotherapy or irradiation. Resection of bulk disease also increases the number of residual tumor cells that enter the active cell cycle, in which they may be more responsive to these adjunctive therapies. The availability of new techniques for intraoperative electron beam irradiation or intraoperative brachytherapy may result in more utility for resection of distant and regional metastatic disease.

There is increasing evidence that salvage therapy in ovarian and fallopian tube cancers is likely to be effective only in patients with minimal residual disease. Secondary cytoreduction or resection of regional and distant metastases may play an important role in the treatment of these patients. Recent reports have demonstrated promising results with surgical resection of isolated metastases to the parenchyma of the liver and spleen (51,52).

Surgical Procedures for Specialized Care

Surgical placement of indwelling intravenous access systems allows patients to receive chemotherapy and nutritional supplements and to have necessary blood samples drawn with relative ease and comfort. Placement of these devices, usually semipermanent subcutaneous systems, is safe, contributes to the patient's well-being, and allows for more effective therapy.

The use of intracavitary therapy requires the temporary or semipermanent placement of chest tubes or intraperitoneal access devices. Results of many studies confirm that peritoneal access or vascular access devices placed totally beneath the skin have a low infection rate and a low rate of malfunction (53,54). Implanted arterial infusion devices are being evaluated in research studies to allow direct infusion of therapeutic agents into a tumor mass by means of the arterial system. This therapy often requires intra-abdominal surgery to place the device into the appropriate portion of the vascular system.

Surgery for Reconstruction

Reconstructive surgery may be performed at the time of resection of the cancer, as a delayed procedure, or as required therapy to correct a complication of treatment. Vulvar reconstruction is usually done at the time of initial resection and may involve the use of free skin grafts, rotational flaps of adjacent skin and fat tissue, or myocutaneous grafts from the thigh, buttocks, or anterior abdominal wall. Vaginal reconstruction may also be performed, usually as a planned, delayed phase of reconstruction. Vaginal reconstruction requires free skin grafts or myocutaneous flaps depending on the size of the defect and whether or not there has been previous irradiation of the vaginal bed. The techniques of vulvar and vaginal reconstruction are explained in detail in other chapters of the book.

Reconstruction as therapy for complications of treatment may be required for the closure of defects from improper wound healing, radiation necrosis, or tissue loss after extravasation of chemotherapeutic agents. Although free skin grafts may be used to reconstruct surgical wound disruption or tissue loss due to chemotherapy extravasation, radiation necrosis usually requires the use of myocutaneous flaps because of a lack of adequate blood supply in the area of the injury.

Surgery for Palliation

Surgery for palliation may involve resection of tumor to relieve symptoms, or it may involve diversion or bypass of portions of the gastrointestinal or urinary tract to prolong life and provide comfort. Surgical procedures may also be used to provide pain relief by interrupting sensory nerve transmissions. Surgical removal of tumor bulk to provide palliation has been discouraged by many authorities. They point out that without effective adjunctive therapy, tumor regrowth occurs quickly and the surgical procedure proves to be futile. Although this may be true in most cases, the gynecologic oncologist should not uniformly dismiss the concept of surgical palliation. A surgical procedure to provide relief of symptoms is usually considered a failure if the tumor regrows in 6 to 12 months. However, palliative administration of a chemotherapeutic agent for 6 to 12 months is considered to be successful if there is minor tumor shrinkage or stabilization of disease despite the side effects of the chemotherapy. As a surgeon, the gynecologic oncologist must remember that a surgical procedure with limited risk and a reasonable recovery period may provide as much relief as 6 to 12 months of palliative chemotherapy or a course of palliative irradiation. The difficult decision about when to employ surgical palliation requires astute surgical judgment and a realistic assessment of the patient's condition and wishes.

Palliative surgery is more frequently used to relieve specific dysfunctions, such as obstruction of the urinary or intestinal tract. Relief of urinary tract obstruction may be accomplished by ureteroneocystostomy or by urinary conduit depending on the location of the obstruction and the location or extent of disease. A urinary conduit can provide immediate and permanent relief to the patient who has a ureterovaginal, vesicovaginal, or urethrovaginal fistula. It may also provide relief of urinary obstruction, which will prolong life and allow for the administration of additional chemotherapy or irradiation. The judgment of the surgeon and the desires of the patient become essential factors in this decision process. For the patient who is miserable because of constant urinary leakage or who may benefit from additional therapy, the decision to perform a urinary diversion is quite simple. If diversion is done to prolong life, however, the decision must be weighed carefully. For a patient who has a limited life expectancy or is in uncontrollable pain, performing a urinary diversion may do more harm than good.

The gynecologic oncologist must also consider the relative benefits of nonsurgical urinary diversion, such as placement of a ureteral stent or a percutaneous nephrostomy. For many patients, percutaneous nephrostomy is a better choice than surgical intervention. This is particularly true if the aim is to employ adjunctive chemotherapy or irradiation, or if a surgical procedure is not feasible because of medical conditions or other surgical considerations. Unfortunately, a percutaneous nephrostomy cannot help the patient with a fistula because the nephrostomy will not totally divert the urine.

Placement of a ureteral stent, by cystoscopy or antegrade through a percutaneous nephrostomy, is usually better and safer than urinary diversion for the relief of obstruction. Current technology allows the placement of stents that can be left in place for months and can be changed easily over a guide wire by means of the cystoscope.

Intestinal obstruction threatens the patient's quality of life, and the decision of whether to perform an intestinal diversion is usually easy. Deciding whether the operation is feasible can be more difficult. For the patient with localized disease, a diverting colostomy or an intestinal bypass is usually possible and is not very difficult. For the patient with intra-abdominal carcinomatosis, the decision is more complex. The surgeon

may not be able to determine the extent of intestinal involvement preoperatively and may have difficulty deciding whether the surgical procedure will benefit the patient.

Pothuri et al. (55) recently evaluated 68 palliative operations performed on 64 patients with recurrent ovarian cancer and intestinal obstruction. In 84% of cases, a corrective surgical procedure was able to be performed, whereas no corrective surgical procedure was possible for the remaining 16%. Of the 57 cases where corrective surgery was possible, 71% were successfully palliated ("successful palliation" is defined as the ability to tolerate a regular or low-residue diet at least 60 days postoperatively). If surgery resulted in successful palliation, median survival was 11.6 months compared to 3.9 months for all other patients.

THE FUTURE OF GYNECOLOGIC ONCOLOGY

As of 2008, the subspecialty of gynecologic oncology is over 30 years old. From a cadre of farsighted individuals with a variety of training backgrounds, a cohesive subspecialty has developed with consistent standards of training, a system of certification, and recognition in the medical community. None of this has come easily, and we owe a great deal to that first generation of gynecologic oncologists.

Several current issues are affecting the future role of gynecologic oncology within the medical community. Our relationship with our parent specialty of obstetrics and gynecology is being reexamined, as well as our ties with general surgery and urology, specialties with which we often seem even more closely allied. As technologic advances occur, we are becoming more integrated with the specialties of medical oncology and radiation oncology. Although we remain primarily surgeons, and surgery remains our principal mode of therapy, it is critical to emphasize the integrated multidisciplinary management of the patient with gynecologic cancer.

The benefits of multidisciplinary care were recently highlighted in a clinical announcement by the National Cancer Institute (NCI) concerning concurrent chemoradiation for cervical cancer (56). In each of five randomized phase 3 trials of women with various stages of cervical cancer, the addition of chemotherapy to radiotherapy was found to provide a significant survival benefit (13,57–60). The risk of death from cervical cancer was decreased by 30% to 50% with the multimodality approach.

Changes in Surgical Therapy

If the past decade is any indication of the future, significant changes in the technology of surgery can be expected to occur as we proceed through the new millennium. New materials, new surgical instruments, and new devices will be invented, and many of these will make surgical treatment better. Certainly, laparoscopic surgery appears to have made a significant impact on our specialty, as well as on the other surgical specialties.

Innovative methods of supportive care will be developed to further the technical capabilities that we now possess, such as computerized anesthesia machines and transesophageal ultrasound. Anesthetic agents will become better and safer, and will be joined by a new generation of antibiotics and cardiovascular medications. We will be able to treat the older patient surgically with relative safety, which is especially important because of the increased incidence of cancer in the elderly and because of the advancing age of our population. Our responsibilities include staying abreast of these advances and judiciously integrating them into our practices.

Changes in the Indications for Surgery

Early diagnosis will change the indications for surgery and the types of procedures that should be done. We will be able to treat more patients with less disfigurement and with greater preservation of function. A larger proportion of patients will present with early disease, allowing surgery to be used more frequently for definitive cure.

Better adjunctive therapies will increase the importance of initial surgical therapy. More patients will benefit from surgical cytoreduction to minimize disease. The availability of effective irradiation and chemotherapeutic regimens will make adjuvant therapy feasible in more cases, and it will become more important for us to identify risk groups who are likely to develop recurrent disease after surgery.

Multidisciplinary Therapy and Primary Care

In outlining the extent of surgical training required for the gynecologic oncologist, the founders of this discipline were careful to include adequate training that would enable the gynecologic oncologist to become an accomplished abdominopelvic surgeon. The gynecologic oncologist must be trained to perform the gynecologic, gastrointestinal, and urologic surgery necessary to manage gynecologic cancer and its potential complications. As stated by John L. Lewis Jr. (61), in reference to pelvic exenteration by a team of gynecologists, general surgeons, and urologists, "Even when the surgery was successful, the postoperative care required committee meetings and its outcome was often less than successful."

These same founders realized that, although training can produce a qualified surgical oncologist, the complete care of the cancer patient requires knowledge of the basic biologic, physical, and pharmacologic principles of radiation therapy and chemotherapy. This does not mean that the gynecologic oncologist must be a radiation oncologist or a medical oncologist, but it does demand that he or she know enough to ensure proper integration of all therapeutic modalities. Throughout the United States, this collaboration in the care of patients with gynecologic cancer has produced multidisciplinary teams of gynecologic oncologists, radiation oncologists, medical oncologists, and pathologists who provide state-of-the-art cancer care. The GOG, a national cooperative research group, has demonstrated how this multidisciplinary approach to gynecologic oncology research can be achieved.

Despite the emphasis on multidisciplinary care, the gynecologic oncologist should maintain active involvement during all aspects of a patient's care. The principle of being the patient's physician until she is either cured or dies of her disease has been an integral part of our subspecialty and must be maintained. The constant involvement of the gynecologic oncologist through all phases of cancer treatment ensures optimal integration of surgery, irradiation, and chemotherapy. The patient receives continuity of care and the reassurance of a physician who is involved at each stage of her therapy and follow-up.

CONCLUSION

After three decades, the gynecologic oncologist has emerged as a surgical oncologist for women. The specialist has sufficient familiarity with radiation oncology and medical oncology to ensure the proper integration of all modalities of treatment, and he or she is able to apply surgical skills for primary therapy, secondary therapy, reconstruction, and palliation. The gynecologic oncologist stands in the obstetrics and gynecology community but has one foot in the community of surgeons.

The emergence of cooperative research groups, particularly the GOG, has allowed a generation of gynecologic oncologists to develop superior clinical research skills. These skills must be continually stressed in the training of young oncologists and as an integral part of the practice of our subspecialty. A growing number of young oncologists are receiving additional training in basic research. This is vital for the continued development of the subspecialty and for progress toward the prevention and care of gynecologic cancers. Our position in the arena of clinical practice is well established, and we must now establish ourselves equally well as scientists and surgical researchers.

CHAPTER 13 ■ LAPAROSCOPIC SURGERY IN GYNECOLOGIC CANCER

DENIS QUERLEU, MARIE PLANTE, YUKIO SONODA AND ERIC LEBLANC

Laparoscopy became a regular feature in the practice of gynecology during the 1960s. Although it played a role in the early detection of pelvic, mainly ovarian, malignancies (1), the concept of using it in the management of gynecologic cancer did not emerge until the late 1980s. A special mention must be given to Daniel Dargent, who pioneered the concept of laparoscopy in the field of gynecologic oncology. Daniel Dargent, trained as a vaginal surgeon, was dedicated to maintaining the tradition of the Schauta operation, which explains his original design of the radical vaginal trachelectomy. His vast surgical culture extended beyond the field of gynecologic oncology, which explains his adaptation of the urologic concept of selecting for radical surgery only those patients with negative nodes, and for the same reason his dedication to the typically “urologic” extraperitoneal approach. Finally, he was aware of the early development of advanced laparoscopic techniques in Clermont-Ferrand, France. All these combined factors led him to pioneer the developments of extraperitoneal lymph node dissection in the staging of cervical cancer. This chapter is an update, not a complete revision, of the same chapter of the previous edition of this book with Daniel Dargent as the first author. The general style of writing and argumentation of concept have been preserved throughout the previous contribution of Daniel Dargent.

Urologists were the first to consider whether endoscopy could play a role in the management of pelvic tumors. The first report was published in 1980 by Hald and Rasmussen (2). These Danish urologists used an instrument derived from the Carlens mediastinoscope for assessing the iliac nodes in patients affected by urinary bladder or prostatic cancer. The tip of the instrument was placed in direct contact with the iliac vessels after digital preparation was made through a short inguinal incision. Small samples were taken from the tissues surrounding the vessels using forceps introduced through the instrument. The decision to perform radical surgery, which is only of benefit for node-negative patients, was made according to the result of the endoscopic assessment.

When laparoscopic surgery was pioneered in patients affected by gynecologic cancer, the rationale was similar: By assessing the pelvic lymph nodes in patients affected by cervical cancer, candidates for vaginal radical hysterectomy (VRH) could be determined (3). The technique was also similar except that the laparoscope was used instead of direct endoscopy.

THE EARLY YEARS (1987–1992): RETROPERITONEAL LAPAROSCOPIC PELVIC LYMPHADENECTOMY

The first laparoscopic pelvic assessments were performed through two separate inguinal incisions. The view obtained of the pelvic sidewall was much wider than the view obtained with the mediastinoscope, and node sampling was easier with an instrument introduced through a separate port. After a dozen attempts, the technique was refined and required only a supra-pubic midline incision. This approach, panoramic retroperitoneal pelviscopy, was first described in a monograph published in 1989 by Dargent and Salvat (4), who reported the data of 107 procedures. Thereafter, the data for 200 patients' operations performed between December 1986 and February 1991 were detailed in the classic textbook edited by Nichols and published in 1993 (5).

There was some criticism during the 5 years following the initial description of laparoscopic lymphadenectomy. Critics were concerned about operative risks, the limited area of dissection, and oncologic risks (two abdominal implants occurred among the first 200 operations), but the main obstacle was cultural in nature. The surgical anatomy of the retroperitoneal space was unfamiliar to the gynecologic surgeon, especially when viewed through a laparoscope. It was only after Querleu (6) devised the transumbilical transperitoneal laparoscopic approach that the concept of the “oncolaparoscopy” began to emerge.

THE MATURATION PERIOD: 1992–2003

In June 1989, Querleu (6) presented his first report on laparoscopic transumbilical transperitoneal lymphadenectomy as a staging procedure for patients affected by cervical cancer. The technique used was the routine laparoscopic technique: Both broad ligaments were opened using a peritoneal incision made alongside the axis of the iliac vessels, allowing dissection and retrieval of the pelvic nodes under laparoscopic guidance. The data on the first 39 operations were published in 1991 in the *American Journal of Obstetrics and Gynecology* (7).

Months after Querleu's publication, Childers and Surwit (8) published the first two American cases—both patients with endometrial cancer. They added a low para-aortic sampling to the pelvic lymphadenectomy. The operation was completed with a transvaginal hysterectomy.

After these early publications, the concept of laparoscopically assisted surgical staging emerged. That same year, the use of the laparoscope in the management of cervical cancer was reported (9). The "oncolaparoscopic" movement began by (a) applying this new concept to malignancies other than endometrial cancer, (b) increasing the thoroughness of the staging dissection, and (c) combining staging with the preparation for radical vaginal surgery with a progressive move to purely laparoscopic radical surgery.

The transition of laparoscopy-assisted surgical staging from endometrial cancer to cervical cancer was not unexpected. The first reports did not clearly indicate the rationale for the laparoscopic staging, but only demonstrated that the staging was feasible and probably safe (9,10). Subsequently, surgeons began to distinguish the different roles of laparoscopy between early- and advanced-stage disease (11,12). The use of laparoscopic surgery in the management of ovarian cancer was first reported in 1973 (13); however, it was not until 1990 that laparoscopic management of ovarian cancer was first reported (14). Except for the concept of laparoscopic restaging for incidental adnexal cancers, which was accepted after the first reported cases of laparoscopic infrarenal aortic dissection (15), this application remains the most questionable. Endoscopy, specifically inguinoscopy, was also introduced into the management of vaginal and vulvar cancers (16) but never gained acceptance, probably because of the development of the sentinel node technique. With time, laparoscopy found a place in the management of the majority of gynecologic malignancies.

The extent of laparoscopic staging has gone through a pendular development. In its earliest form, laparoscopic lymphadenectomy was limited to the interiliac area (4). The laparoscopic pelvic lymphadenectomy described by Querleu et al. (7) soon progressed to the common iliac area and then to the inframesenteric aortic area (8,17,18). Beginning in 1994 (15), the infrarenal para-aortic nodes were included in laparoscopic dissection, and thereafter Possover et al. (19) described laparoscopic suprarenal retrocrural dissection. It was around this time that the concept of sentinel node biopsy emerged as a procedure that could potentially eliminate the need for systemic dissection. This concept has been combined with laparoscopy to produce a convenient method for carrying out this type of biopsy (20).

Laparoscopy-assisted radical surgery and purely laparoscopic radical surgery were foreseeable developments from the concept of laparoscopic staging. Laparoscopically assisted surgical staging was being established during a period when the use of laparoscopically assisted vaginal hysterectomy was commonplace for benign conditions (21). Thus, it was a natural extension of laparoscopically assisted vaginal hysterectomy to apply it to the treatment of endometrial cancer (8). The use of laparoscopy in the management of cervical cancer was initiated by combining laparoscopically assisted surgical staging with the Schauta radical vaginal hysterectomy (3). Descriptions of the laparoscopically assisted vaginal radical hysterectomy, or coelio-Schauta, began appearing in the early 1990s (22–24), and soon after, series using this new procedure began to appear in the literature (25,26). In spite of this, the use of the laparoscopically assisted vaginal radical hysterectomy remains limited because of the lack of training of most gynecologic surgeons in the field of advanced vaginal surgery. As more surgeons became familiar with the abdominal approach to radical hysterectomy, the use of laparoscopy resulted in the development of laparoscopic radical hysterectomy, which was also initially described in the early 1990s by Canis et al. (27)

and Nezhat et al. (10). Conceptually, this approach is easier to grasp by those more familiar with the abdominal approach, as witnessed by the growing number of publications demonstrating its feasibility and safety (28–30). Laparoscopy has recently also been used to perform pelvic exenteration (31).

OTHER DEVELOPMENTS AND THE QUESTIONS THEY RAISE

The next technical development in the field of laparoscopy may come from robotics. The biggest drawbacks of these robots are the cost and size. For the experienced laparoscopic surgeon, these "heavy" robots have yet to demonstrate an obvious benefit except for fine suturing in which the robot excels. Thus, these robots may eventually be employed when laparoscopic suturing is required, that is, during reconstruction operations following exenterative surgery. As the use of robots grows, these procedures will undoubtedly be further developed.

The future of laparoscopic extirpative surgery is a second point of discussion. The data available on total laparoscopic or laparoscopically assisted radical surgery seem to be comparable to those of open surgery. The radical nature of the surgeries can be preserved with laparoscopy. In general, the operative time is increased, but the blood loss is generally diminished and the postoperative morbidity is improved. However, good level-one evidence regarding the use of laparoscopy is not yet available in the field of gynecologic cancer surgery. During the emergence of laparoscopy, improvements in open abdominal surgery have also occurred. Newer technologies (i.e., Ligasure, Tyco; Biclamp, Erbe, Tübingen, Germany) and better analgesics decrease blood loss, operative time, and postoperative pain for open surgery. Only through well-designed randomized trials will the better surgical approach be determined.

The future of laparoscopically assisted surgical staging is the third point open to discussion. There are no doubts about its feasibility and safety. One can, in spite of the absence of direct manual sensation, assess the peritoneal cavity and the retroperitoneal spaces with the same accuracy as through an open incision. One may also argue that the visual assessment is better thanks to the optical magnification. On the other hand, if doubts exist about the benefits of laparoscopy in extirpative surgery, they do not exist in the specific field of surgical staging. Laparoscopy paralleled with xiphopubic laparotomy or J-shaped large side incisions that were the standard in the past, and is a more acceptable surgical staging procedure. However, in spite of its obvious benefits, laparoscopic staging has been challenged. A recent randomized trial has demonstrated that surgically staged patients with cervical cancer had a worse survival irrespective of the surgical approach used (open surgery or laparoscopy) (32). The results of this trial are largely biased (see below), but one has to recognize that surgical staging has an excellent potential to separate the good and the poor prognostic cases without necessarily improving life expectancy. In the future, prognostic information obtained from newer procedures, such as the sentinel node biopsy, or from the molecular analysis of the tumor itself could replace the information obtained from imaging and surgical staging.

BASIC ELEMENTS OF LAPAROSCOPIC SURGERY

Laparoscopic surgery is usually performed via CO₂ insufflation to create a pneumoperitoneum. There are several techniques used to enter the abdomen for laparoscopic procedures.

“Closed” laparoscopy, employing a Veress needle followed by blind insertion of the first trocar, is favored by many laparoscopic surgeons. Others prefer direct “blind” trocar insertion. The use of disposable trocars with retractable blades for direct trocar insertion does not appear to significantly reduce the risk of bowel or vascular injuries. This is of particular concern since the majority of complications following laparoscopic surgery are related to trocar insertion (33). Conversely, the “open” technique where the fascia and the peritoneum are surgically opened and the trocar inserted under direct visualization is considered by many to be the safest access technique, although this is likely not to be true in patients with a history of laparotomy.

CO₂ Laparoscopy: Closed Versus Open Technique

Bonjer et al. (34) reviewed the literature and compared data between 12,444 open laparoscopic and 489,335 closed laparoscopic cases. Rates of visceral and vascular injury were 0.083% and 0.075%, respectively, after closed laparoscopy and 0.048% and 0.0%, respectively, after open laparoscopy ($p = 0.002$). Mortality rates were 0.003% for the closed and 0.0% for the open laparoscopy technique ($p = \text{NS}$). In another randomized trial of blind versus open laparoscopy for laparoscopic cholecystectomy, the major complication rate was 4% in the blind group and 1.3% in the open group, respectively ($p < 0.05$). Minor complications occurred in 6.7% of patients in both groups (35). In a large series of 2,000 cases performed for general surgery procedures, there was no vascular injury and only one bowel injury with the open laparoscopy technique (36). Perone (37) published a series of 585 cases of laparoscopy using a simplified open technique. There were no technical failures or major complications, despite the fact that nearly 30% of the patients had undergone previous laparoscopy or laparotomy.

Declodt et al. (38) performed laparoscopic surgery in patients with gynecologic malignancies and reported only a 1% complication rate for the open laparoscopy technique, despite the fact that a high proportion of the patients had previous major surgery and/or radiation therapy. In another study of patients who underwent operations for pelvic masses, it was noted that all the vascular injuries occurred during direct trocar insertion in patients without prior abdominal surgery, and the authors now routinely use an open technique in all their cases (39). Altogether, the data seem to indicate that the open laparoscopy technique is safer than closed laparoscopy. A recent large series, however, comparing 8,324 cases of direct laparoscopic entry versus 1,562 cases of open laparoscopy for gynecologic procedures did not show a difference in the rate of major complications. In fact, there were more conversions to laparotomy in the open technique group (40). A recent review on laparoscopic entry concludes that there is no evidence that the open entry technique is superior or inferior to other entry techniques currently available (level II-2C evidence) (41). Authors also conclude that direct entry with shielded trocars may decrease entry injuries. The visual entry cannula system may represent an advantage over traditional trocars, as it allows a clear optical entry; however, that does not necessarily avoid all visceral or vascular injuries (41).

In patients with prior abdominal surgery, using midline incisions, Childers et al. (42) proposed the use of the Veress needle in the left upper quadrant to first insufflate the abdomen prior to the trocar entry. Also, in cases where the risk of injury appears high because of prior abdominal surgery, smaller 5- or 7-mm trocars may be used to enter the abdomen, as opposed to the traditional 10- to 12-mm trocars. Choosing the lateral flank, rather than the midline subumbilical

area, as an entry site may also be useful. This can potentially decrease the risk of damaging bowel loops that could be adherent under the anterior abdominal wall from prior surgeries.

Gasless Laparoscopy

With hopes of decreasing tumor cell spillage, gasless laparoscopy was developed in the early 1990s (43). The gasless system involves lifting the abdominal wall using an abdominal wall-lifting device. Valveless ports and conventional instruments or laparoscopic instruments can be used without gas leak (44,45). Several devices have been developed that avoid the use of CO₂ to distend the abdomen. Two devices frequently used are the Laparolift retraction system (Origin Medsystems, Menlo Park, California, USA) and the Abdo-lift (Karl Storz, Tuttlingen, Germany).

Theoretically, gasless laparoscopy has numerous advantages over the traditional CO₂ laparoscopy: It avoids the problem of CO₂ leakage as well as difficulties associated with creating and maintaining adequate CO₂ pressure. Indeed, high-pressure irrigation and large-volume suction devices can be used without losing the CO₂ gas, which, when lost, can seriously impair adequate visibility. Gasless laparoscopy can also avoid the potential for infectious particles contaminating the CO₂ insufflation gas and the problem of lowering the body temperature (46), thus avoiding potential risks of metabolic and hemodynamic instability from CO₂ insufflation (47). In patients for whom general anesthesia and CO₂ pneumoperitoneum are contraindicated, gasless laparoscopy can be used, as it does not significantly increase the intra-abdominal pressures. The procedure can also be performed under epidural anesthesia and has been successfully performed during pregnancy (48–53).

Galen et al. (45) performed 80 gynecologic procedures using gasless laparoscopy. They compared their gasless laparoscopically assisted vaginal hysterectomy with 150 laparoscopically assisted vaginal hysterectomies performed with CO₂ pneumoperitoneum. They concluded that the Laparolift retraction system satisfactorily maintained visualization during the entire procedure, including the vaginal portion of the surgery. In another series of 49 laparoscopic gynecologic surgeries performed with gasless laparoscopy, the success rate was 90%. It allowed the surgical team to use the vaginal and laparoscopic approaches simultaneously (54). Tintara et al. from Thailand performed 40 gynecologic procedures using gasless laparoscopy and reported no surgical complications. They considered the operative field virtually the same as that of the CO₂ pneumoperitoneum, except in morbidly obese patients (55).

Tintara et al. also recently published a series comparing 31 gasless laparoscopic hysterectomies (GLHs) with 31 total abdominal hysterectomies (56). The operating time was longer by almost 1 hour, but blood loss, hospital stay, and convalescence were lower in the GLH group (56). Comparable results were also reported by others (57). Conversely, a clinical trial of 30 cases looking at the measure of visualization as primary outcome concluded that exposure with conventional laparoscopy using pneumoperitoneum is superior to that offered by gasless laparoscopy (58).

Data in gynecologic oncology are limited. A gasless pelvic lymphadenectomy has been reported by one team (44); the authors retrieved 45 lymph nodes and found this approach satisfactory. On the other hand, Johnson and Sibert (59) reported a randomized comparison of gasless versus CO₂ laparoscopy for tubal ligation and reported markedly increased technical difficulty with the gasless approach. Another group conducted a randomized comparison of gasless and CO₂ laparoscopy in 57 patients undergoing infertility

surgery (60). Six patients in the gasless group had to be converted to CO₂ pneumoperitoneum because of inadequate exposure. The authors concluded that times to achieve exposure and close incisions were longer, and exposure and ease of surgery were worse in the gasless group. They found no advantages to this procedure over the conventional CO₂ approach (60). In a randomized prospective study, postoperative pain appeared to be similar for both techniques in patients undergoing laparoscopic tubal ligation (61).

Currently, gasless laparoscopy is not as widely used as CO₂ laparoscopy and the data on the procedure are more limited. However, the technique does merit further evaluation in oncology patients, particularly because of the concerns that CO₂ pneumoperitoneum may increase tumor spread (see next section on port-site metastasis).

Port-Site Metastasis

There has been increasing concern among surgical oncologists about the apparent increased rate of port-site metastases following laparoscopic procedures. The reported rate of abdominal-wall recurrences from two large studies following traditional abdominal surgery was 1% to 1.5% (62,63). In the last few years, as laparoscopic procedures have become more popular in oncology patients, there have been several reports in the literature of port-site metastases following laparoscopic surgery for a variety of cancers.

Schaeff et al. (64) conducted a literature review of port-site metastasis and found 164 reported cases from 90 publications, including 29 cases in gynecologic procedures. Wang et al. (65) recently conducted a similar MEDLINE search and found that the rate of port-site metastasis in ovarian cancer varies between 1.1% and 13.5%. A recent series of 83 patients who underwent laparoscopy for diagnosis, treatment, or staging of gynecologic cancers shows an overall incidence of port-site metastasis of 2.3%. As expected, the risk was highest in patients with recurrence of ovarian and peritoneal malignancies in the presence of ascites (66). Vergote et al. also observed a high rate of port-site metastasis after laparoscopic surgery in patients with advanced ovarian cancer, but concluded that the prognosis was not worse in those patients and that laparoscopy remains a convenient technique to diagnose advanced ovarian cancer or rule out other primary tumors (67).

Initial reports in gynecologic oncology surgery suggested that patients with adenocarcinomas of the ovaries with ascites and peritoneal seeding were at highest risk for port-site metastasis. Although most reports suggest that port-site metastases occur in advanced-stage cancer and poorly differentiated tumors, thus being an indicator of tumor virulence, there have been worrisome reports of low-stage and well-differentiated tumors causing postlaparoscopy tumor seeding (64). Borderline tumors (65), squamous cell cancers of the cervix (68,70), and adenocarcinomas of the endometrium have also been reported to metastasize to port sites (71). In a recent literature review of 58 reported port-site metastases, Ramirez et al. confirmed that port-site metastases are a potential complication of laparoscopic surgery in patients with gynecologic malignancies, even in patients with early-stage disease (69).

The time period between the laparoscopic surgery and the appearance of port-site metastasis varies between 1 week and 3 years (71). Of concern, a number of port-site metastases have been documented to develop very rapidly after laparoscopic procedures, as early as 1 to 2 weeks. Timely referral for staging and definitive treatment becomes very important, as delays in referral have been shown to increase the rate of port-site metastasis and worsen prognosis. Several measures have been

recommended to decrease the risk of port-site metastasis. These include thorough irrigation of the port sites (72), use of large volumes of saline for lavage of the abdominal cavity (73) and of the port sites (65), slow abdominal-wall deflation, use of a wound protector, and use of a specimen bag to retrieve the specimen (74).

Clearly, morcellation of suspicious solid tumors should be avoided at all cost, and according to Canis et al., if the abdominal wall is protected with a bag and the tumor is not morcellated, the incidence of trocar site metastasis is approximately 1% (75). To further reduce the risk of trocar-site metastasis, some authors recommend the resection of the laparoscopic ports in a full-thickness fashion at the time of the staging laparotomy, ideally within 1 week of the laparoscopic surgery (76–78). Van Dam et al. also recommend closing all the layers of the trocar sites at the end of the laparoscopic procedure, i.e., the peritoneum, the rectus sheath, and the skin. Indeed, in their study, they noted that trocar site metastasis developed in 58% of their patients with only the skin closure of the trocar site compared to 2% of patients with closure of all layers (78).

The causes of port-site metastasis seem to be multifactorial: gas used, local trauma, tumor manipulation, biologic properties of the tumor, and individual surgical skills (64). Wang et al. (65) have identified a number of risk factors associated with port-site metastasis: ovarian cancer, adenocarcinoma histology, peritoneal carcinomatosis, presence of ascites, and diagnostic or palliative procedures performed for malignancy. Based on a review of experimental data, Canis et al. concluded that the risk of dissemination following laparoscopic surgery is increased when a large number of malignant cells are present. For that reason, they suggested that adnexal tumors with external vegetations and bulky lymph nodes should be considered as contraindications to CO₂ laparoscopy (79). Other reported etiologies of port-site recurrence include trauma to the port site from frequent removal of instruments, tumor seeding from removal of the specimen through the port, and potential leakage of ascites (64,65). Trocar-site hematomas seem to also favor the rapid growth of tumor implants.

In an animal model, it was demonstrated that pneumoperitoneum itself may play an important role in the etiology of port-site metastasis (80). Others are concerned about the use of CO₂, as it may increase tumor cell spillage and implantation (81). Local immune suppression and growth-factor secretion may also be involved (82). Recent data from animal studies suggest that the underlying immune or metabolic status of the host has a marked independent effect on tumor spread and implantation (83).

Due to concerns regarding the potential increased risk of tumor dissemination associated with CO₂ laparoscopy, some experts advocate the use of gasless laparoscopy. An animal model comparing gasless laparoscopy, CO₂ laparoscopy, and laparotomy was performed to study peritoneal tumor growth and abdominal-wall metastasis. The study concluded that CO₂ insufflation promotes tumor growth in the peritoneum and is associated with greater abdominal-wall metastasis than gasless laparoscopy. They also found that direct contact between a solid tumor and the port site enhances local tumor growth (81). Other studies in rats have also shown that CO₂ may have an effect on growth stimulation on tumor cells (84), and CO₂ insufflation results in tumor dissemination during laparoscopy, leading to port-site metastasis (85). In these rat models, it appears that gasless laparoscopy may reduce the risk of wound metastasis following laparoscopic surgery for cancer (86). Conversely, using an ovarian cancer xenograft animal model, two recent studies from the same authors seem to indicate that CO₂ laparoscopy has a minor impact on visceral metastasis and survival and has no deleterious effect on tumor growth compared to gasless laparoscopy (87,88). Similar results have

been shown in humans. Abu-Rustum et al. retrospectively reviewed patients with persistent metastatic intra-abdominal peritoneal or ovarian cancer at time of second-look surgery. There was no difference in overall survival between patients who underwent laparoscopy or laparotomy; thus, the authors concluded that CO₂ pneumoperitoneum did not appear to reduce overall survival (89). In fact, a higher rate of port-site metastasis with gasless laparoscopy has been reported in some series (90). In a large review of 2,593 laparoscopic procedures on 1,288 women, all with malignant disease, Abu-Rustum et al. identified seven patients who developed a trocar-related subcutaneous implant. However, there were no “isolated” trocar-related implants noted, and all seven patients had synchronous metastasis or carcinomatosis. The authors argued that subcutaneous implantation should not be routinely used as an argument against laparoscopy (91).

Despite the above data, it is still controversial as to whether the use of gasless laparoscopy will reduce the risk of port-site metastasis. Some argue that the risk of tumor dissemination is just as great with gasless laparoscopy (65,85,92). Others argue that the surgical technique and the thorough lavage of the port site are probably more important than the use of CO₂ (93). Reymond et al. (93) claim that gasless laparoscopy is not the solution to the problem, since numerous port-site metastases have been reported after thoracoscopy where CO₂ insufflation was not used. In their opinion, the surgeon's role in seeding tumor cells is important and can be decreased by avoiding excessive tumor manipulation and frequent replacement of trocars. Variation in surgeons' techniques may explain the large differences in the reported incidence of port-site metastasis (0% to 21%). Meticulous surgical technique and the use of preventive measures will keep the incidence of port-site metastasis to about 1%, comparable to that seen with open laparotomy (93).

Laparoscopic Management of Pelvic Masses

A growing body of literature indicates that the laparoscopic management of pelvic masses is safe and effective. It significantly reduces the length of hospital stay, operative morbidity, and overall postoperative recuperation time. Despite careful preoperative evaluation, it appears inevitable that some of those masses will turn out to be malignant. Proper management and following strict surgical guidelines is very important in achieving optimal results.

Large series reported that among all patients approached laparoscopically for pelvic masses, the overall rate of malignancy is low (Table 13.1) (39,94–110). The rate varies greatly among the studies according to the preoperative selection criteria used and the study design. It is also interesting that the rate of malignancy reported since 1997 seems to be higher. This may be explained by the fact that more surgeons are becoming comfortable with invasive laparoscopic techniques and are thus more likely to approach high-risk pelvic masses laparoscopically.

Preoperative Selection

In 1994, Canis et al. (96) published an extensive, retrospective 12-year analysis with long-term follow-up of 757 patients from 1980 to 1991. All patients had ovarian masses and were managed by laparoscopy. The authors followed a strict set of criteria to select cases for laparoscopic management. The complete preoperative investigation included a pelvic sonogram, CA-125 measurement, and pelvic examination. Obviously

TABLE 13.1

LITERATURE CONCERNING LAPAROSCOPIC MANAGEMENT OF PELVIC MASSES

malignant or suspicious masses were managed with laparotomy. The others underwent a laparoscopic evaluation, which included a peritoneal cytology, cyst puncture, and endocystic evaluation also referred to as "cystoscopy." At laparoscopy, if a malignant mass was encountered or was considered highly suspicious, an immediate midline laparotomy was performed. Following this algorithm, their rate of inadvertent malignancy was 2.5% (19 of 757), including 12 borderline and 7 invasive cancers. Additionally, 27 masses were falsely diagnosed as malignant (3.6%), which means that these patients had an unnecessary laparotomy. Based on that experience, Canis et al. consider laparoscopic management of pelvic masses to be safe and reliable (96).

Although it is generally agreed that by careful preoperative and intraoperative assessment most cancers can be adequately diagnosed and properly managed, the preoperative evaluation is frequently of limited value and cannot discriminate a benign mass from a malignant mass. Benacerraf et al. (111) used sonography to study 100 women undergoing laparotomy for ovarian masses; in their study, sonography was misleading in 15% of cases. Guglielmina et al. (102) reviewed their experience with laparoscopic management of over 800 ovarian cysts and concluded that neither ultrasound nor laparoscopic evaluation can accurately predict the exact nature of an adnexal mass. Even when carefully conducted, preoperative investigation cannot accurately detect all ovarian cancers (103). Maiman et al. (112) noted that four of the so-called "benign" characteristics were present in 31% of the pelvic masses found to be malignant. According to Nezhat et al. (94), neither the CA-125 level, pelvic ultrasound, nor peritoneal cytologic testing had sufficient specificity to predict malignancy.

Laparoscopic Approach

In general, laparoscopic management for pelvic masses is considered safe and effective. There are several reported advantages to this approach: shorter hospital stay, decreased postoperative pain and recovery time, less adhesion formation, decreased hospital cost, and lower complication rate. The failure rate of laparoscopy in removing pelvic masses is low (less than 5%) (10,112,113).

In a randomized trial, Yuen et al. (100) compared laparoscopy with laparotomy in the management of ovarian masses in 102 patients. Exclusion criteria included masses suspicious for malignancy and lesion diameter greater than 10 cm. Their data showed that inadvertent cyst rupture was frequent in both groups and operative time was comparable. The laparoscopic approach was associated with significant reductions in operative morbidity, postoperative pain, required analgesia, hospital stay, and recovery period. Those findings were confirmed by others (14,113–115). Recently, Jennings et al. (116) reported a significantly decreased length of hospital stay without adverse effect on the surgical complication rate in patients undergoing operations in a gynecologic oncology unit.

Concerns Regarding Laparoscopic Management of Pelvic Masses

There are several concerns regarding the laparoscopic management of benign-appearing pelvic masses. These include failure to diagnose malignancy; underestimation of the extent of disease; tumor spillage from rupture of the masses; inability to perform complete staging, implying another surgery for the patient; and, most important, long delays before a staging procedure or definitive treatment that can adversely affect the

ultimate prognosis of the patient (39,117). The risk of port-site metastasis has been discussed extensively above.

Intraoperative Frozen Section

The management of any pelvic mass, either by laparoscopy or by laparotomy, should include access to accurate frozen section, so the necessary procedure can be performed immediately. In one large series, the overall accuracy of frozen section was 92.7% (118). However, in a collected series of over 11,000 laparoscopies for ovarian cysts, Lehner et al. (117) reported that frozen section was obtained at the time of laparoscopy in only 34% of cases. Frozen section was obtained in 40% of cases in the survey of Society of Gynecologic Oncologists (SGO) members by Maiman et al. (112). Also of interest in the latter study is that the average age of patients with invasive cancers was 44 years, and 29% of these tumors were borderline. Ovarian cancer is thus not uncommon in perimenopausal women, and surgeons should always keep a high index of suspicion. A recent series of 141 patients undergoing laparoscopic surgery for a pelvic mass looked at the accuracy of frozen section to guide the surgical management. This study showed that the frozen section diagnosis was accurate in 95.5% of benign tumors, 77.8% of borderline tumors, and in only 75% of cancers (119). These results confirm that frozen section is a useful tool to guide the intraoperative management but also that pelvic masses should always be handled as though they could be malignant (119). The accuracy of the frozen section (FS) is also size dependent: for masses larger than 10 cm, FS becomes less reliable (120). The recent use of magnetic resonance imaging does not appear to be superior to the intraoperative frozen section analysis with regard to the diagnosis of pelvic masses (120). Most authors agree that availability of frozen section at the time of laparoscopy is mandatory, even in younger women, so that a staging procedure can be performed without delay when indicated (39,94,117,121,122).

Tumor Spillage

It remains controversial as to whether intraoperative tumor spillage carries a poorer prognosis. Some authors have noted that preoperative tumor rupture or the presence of ascites may worsen the prognosis (43), while others did not find any difference in survival among stage I patients with intraoperative spillage (121). Mettler et al. (123) found that tumor propagation does not occur in ruptured stage I cases if definitive surgery is performed within 1 week. According to others, the grade of the tumor and the presence of ascites in stage I cancer of the ovary is more important in relation to survival than is rupture of the ovarian capsule at surgery (124,125). Nevertheless, all pelvic masses should be considered potentially malignant, and consequently, all efforts should be made to avoid rupture.

Delayed Staging

Maiman et al. (112) surveyed SGO members with regard to their management of ovarian neoplasms later found to be malignant. The response rate from members was 42% and 42 cases of ovarian malignancy were reported. In that survey, immediate staging had been performed in 17% of cases, delayed in 71% (median, 36 days), and not performed in 12%. The authors raised significant concerns with regard to the negative outcome of some laparoscopically managed ovarian cancers, particularly as it related to the significant number of patients who were not restaged and to the delay between the

initial procedure and the definitive treatment. They concluded that delays of more than 4 weeks had a negative impact on patient outcome.

Blanc et al. (126) conducted a similar multi-institutional French survey and recorded 5,307 ovarian lesions treated laparoscopically, of which 1.4% were malignant. Staging of cancer cases was performed immediately in 25% of the cases, delayed in 58% (median, 78 days), and not performed in 16%. In those who had delayed staging, 22.4% were upstaged.

Kindermann et al. (122) also sent a questionnaire to 273 German departments of obstetrics and gynecology with a response rate of 46%. They collected a total of 192 ovarian cases managed laparoscopically. Overall, 16% of borderline stage IA and 39% of malignant stage IA tumors (based on laparoscopy) had spread of disease identified at staging laparotomy. In 92% of cases, capsule rupture and tumor morcellation with intra-abdominal spillage occurred at laparoscopy. Endoscopy bags were used in only 7.4% of ovarian cancer cases. In patients staged more than 8 days after initial laparoscopy, nearly 75% of cases were upstaged (20% to stage IC and 53% to stages II-III). Most disturbing, trocar-site metastasis was identified in 52% of patients with stages IC-III at initial laparoscopy if definitive surgery was delayed more than 8 days.

Leminen and Lehtovirta (127) reported on eight patients who had their staging laparotomy after laparoscopic surgery within a mean of 17 days (range, 7 to 29). In four patients, the disease had spread from a localized to an advanced stage during the delay. The authors concluded that laparoscopic surgery of ovarian masses later found to be malignant can cause considerable and rapid spread of the disease. Hopkins et al. reported a similar experience with three young women who had laparoscopic removal of what appeared to be benign lesions. All three underwent re-exploration within 3 weeks, yet trocar site metastasis and intra-abdominal tumor spread had already occurred (77).

Lastly, Lehner et al. (117) sent a questionnaire to all gynecology departments in Austria regarding laparoscopic management of ovarian masses later found to be malignant. Of the 70 cancers identified, 48 patients underwent an immediate laparotomy to complete surgery, 24 had a laparotomy within 17 days (median, 9.9 days), and 24 patients had delays of more than 17 days (median, 47.7 days). The cutoff of 17 days was chosen arbitrarily. Only 10% of malignant tumors were reported using an endoscopy bag. They found that patients in whom definitive surgery was delayed more than 17 days were more likely to be upstaged (odds ratio of 5.3 for borderline tumors and 9.2 for invasive cancers). In a multivariate analysis, delay of more than 17 days was an independent prognostic factor for stage of disease in borderline cases. This was not statistically significant in the cases of invasive ovarian cancer. The study does not provide data as to whether survival was subsequently affected by the upstaging.

The above studies emphasize that poor surgical technique and delayed definitive surgery when managing ovarian masses by laparoscopy can have a very serious impact on patients' survival. It also underscores the fact that, because of the subsequent upstaging, a number of patients will likely be subjected to adjuvant chemotherapy, which they may not have otherwise needed.

Comprehensive Management of Suspicious Pelvic Masses

Recently, Dottino et al. (39) challenged the concept that patients with a suspicious pelvic mass should necessarily undergo laparotomy. In their study, they purposely approached all the

pelvic masses referred to their oncology unit by laparoscopy regardless of the suspicion of malignancy, except when there was evidence of gross metastatic disease (i.e., omental cake) or masses extending above the umbilicus. All masses were sent for immediate frozen-section analysis. Despite the fact that the majority of the masses were considered suspicious for malignancy preoperatively, 87% of the masses were in fact benign, and 88% were successfully managed by laparoscopy. Not surprisingly, compared with other series (Table 13.1) (39,94–109), a higher proportion of the masses turned out to be malignant (10.6%), but most of them were managed laparoscopically following oncologic standards. If debulking was deemed to be best performed by laparotomy, the laparoscopy was converted to an open case. In many instances, adequate surgery could be completed by laparoscopy. Long-term data on overall outcome and survival following laparoscopic surgery for ovarian cancer are not available. Canis et al. (121) also suggest performing a diagnostic laparoscopy regardless of the ultrasonographic appearance of the pelvic mass, although they then recommend an immediate laparotomy for staging of cancer cases. They also reiterate the importance of frozen-section analysis to appropriately decide definitive treatment. When indicated, they consider restaging of cancers as an “oncologic emergency.” Quinlan et al. (115) included complex masses and septated cysts in their selection criteria. Laparoscopy by trained laparoscopists can be used to evaluate adnexal masses in women with risk factors for ovarian cancer with a low complication rate and reduced hospital stay (128). A recent study of 313 patients comparing the performance of ultrasound findings, laparoscopy findings, and frozen-section analysis showed that laparoscopy correctly identified ovarian cancer and borderline tumors with a sensitivity and a specificity of 100% and 99%, respectively (129).

It would thus appear that even though suspicious masses have traditionally been managed by laparotomy, laparoscopic management of high-risk pelvic masses can be successfully performed in an oncology referral population if there is expertise in operative laparoscopy, availability of immediate and accurate pathologic evaluation, and appropriate further treatment where indicated. In many cases, having an oncologist skilled in advanced laparoscopic procedures allows laparoscopic completion of the staging procedure. However, when skilled assistance is unavailable, it is best to terminate the laparoscopic procedure after a cancer diagnosis and to promptly refer the patient for definitive surgery. As stated by Alvarez et al. (130), “accuracy is more important than immediacy.”

According to the literature, laparoscopy for the management of pelvic masses can eliminate the need for unnecessary laparotomy in most cases. Statistically, the majority of them will be benign and can be adequately managed laparoscopically, and most of the recent publications conclude that laparoscopy is a safe approach for the treatment of adnexal masses (Table 13.1) (39,94–109). However, the above data clearly demonstrate that delayed staging and definitive treatment can have a negative impact on patient outcome more than the laparoscopic procedure itself. When appropriate referral for a staging operation is made in a timely fashion, ideally within 2 weeks, it is unlikely that disease progression will occur (122,130). Moreover, until proven otherwise, ovarian masses should always be considered potentially malignant. Thus, surgeons should be technically meticulous in order to minimize the risk of ovarian cyst rupture and spillage, and specimens should always be retrieved intact through an endobag to reduce the risk of trocar-site metastasis. With advances in laparoscopic surgical technique, suspicious ovarian masses can be approached laparoscopically as long as a plan is in place for appropriate staging and treatment by laparotomy or laparoscopy (39).

Borderline Tumors

Borderline tumors often present as multilocular lesions on sonogram and may have elevated CA-125 levels. Darai et al. (131) reported a series of 43 borderline tumors of which 34 were approached by laparoscopy. Of those, 27 were completely managed by laparoscopy. There were four recurrences, three of which occurred in patients who had ovarian cystectomies only. The authors concluded that laparoscopic management of borderline tumors is feasible, but ovarian cystectomies are associated with a higher risk of recurrence. Two other recent French studies showed that the initial laparoscopic surgery in the management of borderline tumors is associated with a lower rate of complete staging, a higher rate of cyst rupture, and a higher recurrence rate following conservative treatment (132,133). However, despite an incomplete staging, there does not appear to be a detrimental effect on outcome in patients with apparent early borderline tumors (134). A Scandinavian group also retrospectively compared the short-term outcome of 107 patients with borderline tumors operated on by laparoscopy or laparotomy. The authors concluded that laparoscopic treatment of borderline tumors is feasible in moderate size tumors (<10 cm) and is associated with fewer complications and shorter hospital stay. However, in larger size tumors, cyst rupture was significantly more frequent in the laparoscopy group (135).

LAPAROSCOPIC RETROPERITONEAL STAGING: PELVIC AND AORTIC LYMPH NODE DISSECTIONS

Laparoscopy enables visual assessment, sampling, and systematic dissection of the lymph nodes located in the extraperitoneal space along the pelvic sidewall and in the para-aortic area. Both direct and indirect transumbilical approaches are discussed.

Transumbilical Transperitoneal Laparoscopic Lymphadenectomies

The transumbilical transperitoneal technique for laparoscopic lymphadenectomy remains the most popular approach employed by gynecologists. This in part has to do with the familiarity of gynecologists with this indirect approach. The setup is essentially the same as for routine laparoscopy. The ports are placed in a similar configuration as that used for traditional pelvic laparoscopy (Fig. 13.1). The size of the ports will depend on the instruments that are to be employed. When para-aortic lymphadenectomy is to be performed, it is helpful to place the lateral ports slightly more cephalad, avoiding the abdominal wall vasculature, and an additional port in the left upper quadrant may be required to assist with retraction of the intestines.

Pelvic Dissection

The surgeon intending to perform a pelvic dissection stands on the patient's left side. The video monitor is placed at the foot of the operating table. The peritoneum is divided along the pelvic brim between the round ligament and the infundibulopelvic (IP) ligament, which are best left undivided until the dissection is finished. Prior to opening the peritoneum, the umbilical ligament is located, which is seen as an oblique peritoneal fold on the posterior surface of the abdominal wall. By

FIGURE 13.1. Transperitoneal trocar placement for laparoscopic lymphadenectomy.

following this “Ariadne’s thread” from front to back, once the broad ligament is opened, it is easy to identify the superior vesical artery and its ventral continuation, the umbilical ligament. The superior vesical artery is the first surgical landmark in the pelvic dissection. Retracting it medially enables one to open the paravesical space and free the pelvic sidewall. This exposes the external iliac vessels at the point where they cross Cooper’s ligament. In obese patients whose anatomic structures are covered with fatty tissue, it is recommended to locate Cooper’s ligament first. This can be identified by palpation with a blunt instrument on the posterior surface of the pubis, lateral to the umbilical ligament—much the same way a blind person seeks the edge of the pavement with a cane.

Prior to dissection, one must identify the major vascular landmarks including the common, external, and internal iliac vessels. The dissection starts with grasping the tissues located anterior to the external iliac vessels and gently placing them on traction. A second instrument can then be used to dissect the connective fibers and lymphatic channels joining the node-bearing tissues to the surrounding structures (Fig. 13.2). In 20% of cases, an accessory obturator vein will be found in the obturator nodal tissue and inserted on the inferior surface of the external iliac vein; blunt dissection is generally enough to free the nodal tissue from this structure. Once the nodes are freed from beneath the vein and the obturator nerve is exposed, the external iliac vein is traced back to the bifurcation of the common iliac vessels.

The next step is to dissect the node-bearing tissues located between the external iliac vessels and the psoas muscle. One starts ventrally at the level of the origin of the circumflex artery and continues dorsally to the level of the common iliac artery. At that point, it is often necessary to make a lateral peritoneal incision in order to reflect the ileocecal junction upward on the right side and the sigmoid colon on the left side. The ureter is identified at the level at which it crosses the iliac vessels. If the IP ligament has not been divided and the posterior sheet of the broad ligament is intact, the ureter remains attached to its natural support. Both are pushed medially. The pararectal space is then opened. The node-bearing tissues alongside the inferior aspect of the common iliac artery and posterior aspect of the internal iliac artery are exposed.

Dissection techniques and the sequence in which the landmarks are identified vary from surgeon to surgeon. The most basic technique of dissection is recommended, that is, grasping

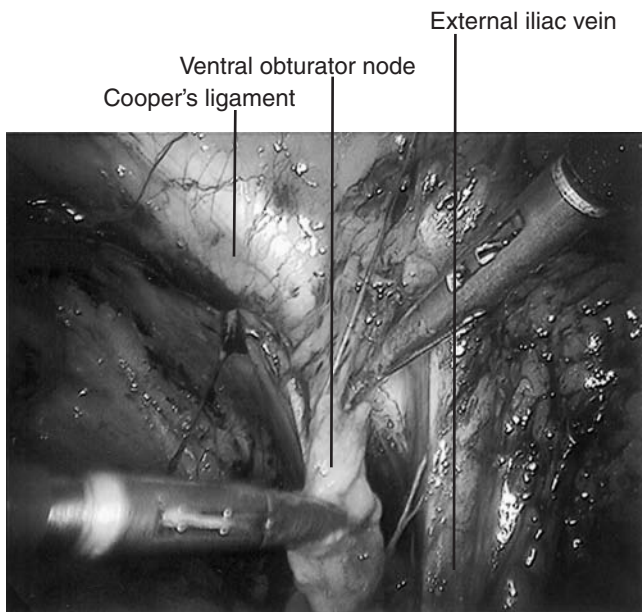

FIGURE 13.2. (See color plate section.) Pelvic laparoscopic lymphadenectomy. The pelvic lymphadenectomy is initiated. Picture of the ventral part of the right pelvic sidewall.

the nodes with grasping forceps and employing blunt dissection to separate the node-bearing tissue from the underlying structures. Such a technique (Fig. 13.2) requires skill, but once this skill is acquired, less blood loss is involved. Only the resistant structures, that is, the blood vessels, must be controlled before being divided, and these are few if the dissection is performed in the correct tissue planes. Needless to say, other techniques exist that can yield comparable results.

Removal of the nodes can be accomplished by (a) gathering them (e.g., in the uterovesical space) and extracting them at the end of the procedure using an extracting bag, or (b) using a specialized nodal extractor such as the Coelio-Extractor (Groupe Lepine, Lyon, France) to deliver the nodes without contaminating the abdominal wall.

Querleu et al. (7) were the first to provide data describing the feasibility and safety of transumbilical transperitoneal laparoscopic pelvic dissection. There were 39 procedures performed on patients with cancer of the cervix, stage IB to IIB, and the mean duration of the procedure was 80 minutes. No conversion to laparotomy was required. The mean node count was 8.7 (range, 3 to 22). Positive nodes were found in 5 patients who were subsequently treated with radiotherapy, and the remaining 34 patients underwent either an abdominal radical hysterectomy or a VRH. All patients were followed for 5 years (136), and the 5-year survival rate was similar to the survival of a historical group of patients who underwent standard abdominal radical hysterectomy. Patients were matched for age, stage, and therapy. Childers et al. (9) reported the experience from 18 patients with cervical cancer who were initially managed with laparoscopy. Five patients had immediate abdominal radical hysterectomy and 13 were subsequently treated with radiotherapy. No complications were observed. The duration of the staging procedure was 75 to 175 minutes for the patients assessed prior to radiotherapy. The mean number of lymph nodes was 31.4 (range, 17 to 37) for patients submitted to abdominal radical hysterectomy. One year later, Childers et al. (137) provided data for 53 patients with endometrial cancer. All the patients underwent laparoscopic assessment, and 29 underwent pelvic lymphadenectomy plus

aortic sampling. Three intraoperative complications occurred (one pneumothorax, one transection of the ureter, and one bladder injury) and three postoperative complications (two patients had a postoperative ileus and one patient had significant atelectasis). The issue was addressed again 5 years later (138) in 125 patients. The rate of complications did not vary. However, the rate of conversion to laparotomy dropped from 8% (2 of 25) to 0% (0 of 100), whereas the operative time decreased from 196 minutes to 128 minutes ($p < 0.02$) and the hospital stay from 3.2 days to 1.8 days ($p < 0.0001$).

Aortic Dissection

Two techniques have been described for performing an aortic dissection with the laparoscope. In the first (9), the setup is the same as the one used for the pelvic dissection. Two details differ: The video monitor is put on the side of the patient opposite the side where the surgeon stands, and the video camera is turned clockwise 90 degrees, so that the axis of the aorta appears to be horizontal. The intestines are pushed under the diaphragmatic areas. The dorsal peritoneum is opened longitudinally alongside the axis of the aorta. The upper peritoneal flap is developed upward. The right ovarian vessels and the right ureter are identified and pushed laterally. The nodal tissue on the ventral aspect of the vena cava is removed followed by that in the interaorticocaval space. Finally, the nodes from the anterior aspect of the aorta are removed. The origin of the inferior mesenteric artery is identified, and the nodes lying on the left side of the aorta are mobilized and delivered.

In the second technique (18), the surgeon stands between the patient's legs with the monitor at the head of the bed. The dorsal peritoneum is opened transversely alongside the axis of the right common iliac vessels. The upper peritoneal flap is pushed cranially at the same time as the last ileal loop. The right gonadal vessels are identified at the level of the third portion of the duodenum. After having mobilized and divided the ovarian vessels, one finds the left renal vein and begins the dissection that is performed alongside the anterior aspect of the vena cava and then continued in the interaorticocaval space, alongside the ventral aspect of the aorta, and, finally, alongside the left aspect of the aorta. Gaining access to the retroaortic and retrocaval spaces necessitates mobilizing the vessels laterally and medially in order to clear out each of the spaces in two steps. The lumbar arteries and veins represent major danger during this final part of the dissection.

Since 1993, many series have appeared in the literature describing laparoscopic lymphadenectomy (11,12,17,127–136). Most have included data from an inframesenteric dissection as well. Summarizing the larger series (Table 13.2) (7,11,12,17,27, 139–149), one can assume that the mean number of pelvic nodes retrieved laparoscopically was 21 and the mean number of aortic nodes was eight. This number is close to the number of nodes retrieved by laparotomy (150). Comparative studies confirm that the numbers are approximately the same (29,151). Fowler et al. (152) addressed the fact that 25% of the pelvic nodes were still present at laparotomy after the patient underwent a laparoscopic lymphadenectomy; however, no patients with negative nodes at laparoscopy had positive nodes at laparotomy.

The thoroughness of laparoscopic lymphadenectomy has been demonstrated by the recent Gynecologic Oncology Group (GOG) study (149). In this series in which laparoscopic pelvic and para-aortic lymphadenectomy was immediately followed by laparotomy, the mean number of retrieved pelvic nodes was 32.1 (16.6 on the left side and 15.5 on the right side). In spite of this large number, the results were judged to be incomplete in 6 of the 40 patients who subsequently underwent laparotomy after laparoscopic lymphadenectomy. The objective

Note: Gyn: cervical, endometrial, and ovarian tumors.

of laparoscopic lymphadenectomy should be to remove the nodes at risk for spread of disease. The rarity of pelvic sidewall recurrences in node-negative patients managed without a complete lymphadenectomy suggests that laparoscopy enables us to remove the significant nodes. If a criterion to judge the adequacy of the procedure had to be selected, photographic records taken at the end of the laparoscopic procedure would provide the best means to this end. In the GOG study, the

result was judged to be inadequate in three of the patients whose photographic records were reviewed by two independent observers. If clearly identifying the dorsal part of the obturator nerve and lumbosacral nerve is required (Figs. 13.3 to 13.5), the risk of missing positive pelvic nodes is very low, at least in cases of cervical and endometrial cancer.

Lymphadenectomy is one of the cornerstone procedures in gynecologic oncology. The development of the laparoscopic

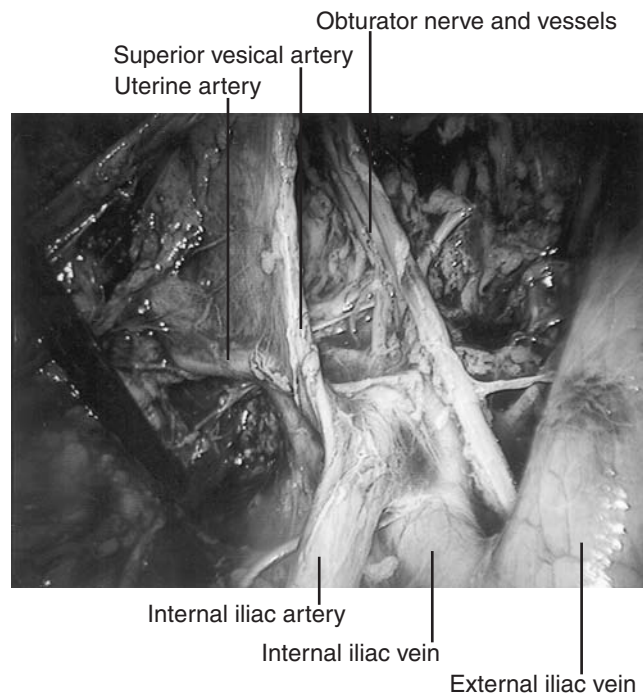

FIGURE 13.3. (See color plate section.) Pelvic laparoscopic lymphadenectomy. The pelvic lymphadenectomy is complete. Picture of the dorsal part of the right pelvic sidewall.

Lumbosacral nerve

FIGURE 13.5. (See color plate section.) Pelvic laparoscopic lymphadenectomy. The pelvic lymphadenectomy is complete. Same view as Figure 13.3, but the external iliac vein and the obturator nerve have been pushed medially. The lumbosacral nerve is visible; this, more than the lymph node count, is proof that the pelvic lymphadenectomy has been done thoroughly.

lymphadenectomy has opened the door for the use of minimally invasive surgery in the management of gynecologic malignancies. The benefits of the procedure alone are difficult to assess since in most of the reported series the procedure is combined with additional operations. This makes it difficult to assess the role of laparoscopic lymphadenectomy either in duration of surgery, appraising intraoperative or postoperative complications, and duration of hospital stay. In the inaugural series by Querleu et al. (7), the procedure was discontinued in 1 of 14 patients owing to an anesthetic problem. One case of intraoperative bleeding was controlled laparoscopically, and all patients except one were discharged the day after the procedure. Possover et al. (138) reported that ten major vessel injuries were registered among 150 procedures (four vena cava, two right renal vein, two external iliac vein, one internal iliac vein, and one internal iliac artery). A conversion to laparotomy was necessary in four of these cases. The mean hospital stay for the 26 patients submitted to lymphadenectomy for pure staging was 3.2 days. Dottino et al. (140) reviewed 94 cases of laparoscopic lymphadenectomies of which 3 required conversion. There was one vascular injury, one case of densely adherent nodal tissue that was felt to be laparoscopically unresectable, and one case of a bulky cervical tumor making laparoscopy difficult. Thirty patients had laparoscopic lymphadenectomy alone and the mean hospital stay was 3.6 days; however, this number included a group of patients who received postoperative chemotherapy. Patients who did not receive chemotherapy were discharged in 1.7 days. Scribner et al. (141) reviewed their first 103 laparoscopic lymphadenectomies. Laparoscopy was completed in 70.9% of patients, with obesity, adhesions, and intraperitoneal disease being the main reasons for not being able to complete the laparoscopic procedure. Three procedural complications included a bladder laceration, a ureteral injury, and one vessel injury at trocar insertion. Other operative procedures were performed and direct correlation with the lymphadenectomy was not mentioned. These studies provided evidence that laparoscopic lymphadenectomy is feasible with an acceptable complication rate.

Childers initially limited the surgical effort to the right inframesenteric area. Consequently, the mean lymph node yield was about eight (Table 13.2) (7,11,12,17,27,139–149). This number is not much different from the number reported for the same dissection at laparotomy (150). It is now known from studies like those published by Benedetti-Panici et al. (153) that the actual number of nodes is around 20 if the dissection is continued to the level of the left renal vein. Michel et al. (154) report that, in cervical cancer involving aortic nodes, the involvement on the left side of the aorta is 72% (23 of 32) and involves the supramesenteric level in 25% of cases (8 of 32). Because of these findings, the aortic dissection must be extended to the left side and to the level of the left renal vein. The feasibility of such an extensive dissection has been demonstrated since the early report by Querleu and Leblanc in 1992 (15), and the yield of 20 nodes, with acceptable morbidity, has been reached in a large series of patients (155).

As the need to perform a systematic infrarenal dissection became more evident, data regarding this procedure under transumbilical transperitoneal laparoscopic guidance began to appear for adnexal cancers (15). Possover et al. (139) also performed such operations in selected cases (ovarian cancer and uterine cancer with high risk of metastasis). When comparing the infrarenal lymphadenectomy to the inframesenteric lymphadenectomy, Kohler et al. (156) confirmed that this could be performed safely. This extended para-aortic lymphadenectomy only took an additional 31 minutes on average and significantly increased the mean node counts from 9.0 to 19.6. A report from the same group (157) indicates that the greatest dangers are not in the higher part of the dissection, but they are lower where tributaries to the anterior aspect of the vena cava are found in the area of the bifurcation of the vena cava in 58.0% of cases, versus 19.6% in the area between the bifurcation and the inferior mesenteric artery, and 0.9% of cases in the area between the inferior mesenteric artery and the right ovarian vein. Furthermore, it appears that if need be, dissection higher than the left renal vein is feasible. Possover et al. (19) attempted this in patients with stage IIIB cervical cancer, transecting at first the left paracolic peritoneum and the left phrenicocolic ligament and mobilizing medially the colonic flexure, left kidney and adrenal gland, tail of pancreas, and spleen. The median number of retrieved nodes was ten. No intraoperative or postoperative complications occurred.

Extraperitoneal Laparoscopic Pelvic Lymphadenectomy

Laparoscopic pelvic lymphadenectomy can be performed using the direct extraperitoneal approach. Historically, this approach was the first method described. Although it is no longer routinely used, one remaining application may be laparoscopic preparation for vaginal radical trachelectomy. The direct extraperitoneal approach had the advantage of completely avoiding the “other surface” of the peritoneum and thus minimizing the risk of postoperative adhesions potentially impairing fertility. This risk, however, appears to be low with the indirect transumbilical approach, and the direct approach does have two drawbacks: (a) loss of time (approximately 15 minutes) and (b) potential for postoperative collections, that is, hematomas, abscesses, lymphoceles (which may be preventable by creating a peritoneotomy at the end of the dissection).

In spite of the above disadvantages to the direct approach to the pelvic extraperitoneal spaces, this approach may be useful in cases where the pelvic cavity is not accessible or not easily accessible such as in pregnancy more than 16 weeks or when severe postoperative adhesions are present. This

approach starts with a blind digital preparation of the preperitoneal space. It is also possible to obtain access to the correct space under direct optical guidance through a 10-mm incision thanks to the new laparoscopic trocars that have a cutting tip (Endotip, Storz, Tuttingen, Germany) or accommodate a cutting and transparent punch (Visiport, Tyco; Optiview, Ethicon, Cincinnati, Ohio, USA).

Midline Suprapubic Access

Midline suprapubic access is obtained through an incision made 3 to 4 cm above the pubis. The surgeon stands across from the pelvic sidewall to be dissected and handles the trocar obliquely in order to get access directly to the iliopubic bone at an equal distance from the midline and the external iliac vessels. Once the bone is located, the extraperitoneal space is insufflated and the ancillary trocars can be placed (at 5 to 6 cm from each other on a vertical line running perpendicular to the pubis at 3 to 4 cm lateral to the midline). Cooper's ligament leads to the external iliac vessels that can be traced in ideal conditions from the femoral ring to the bifurcation of the common iliac artery.

Transumbilical Access

Direct access to the extraperitoneal spaces while using a transumbilical microincision (Fig. 13.6) can be obtained using the same technique one uses for routine transumbilical laparoscopy. One only has to use the previously mentioned dissecting trocars (see above) and stop the sharp dissection once the fascia parietalis is opened, that is, before entering the peritoneal serosa. Once the fascia is opened, the CO₂ insufflation begins, and one proceeds to use the laparoscope as a blunt dissector until the symphysis pubis is reached. After using a fine-needle puncture to check the retroperitoneal channel one has created on the midline (Fig. 13.7), a 10- to 20-mm trocar is introduced in the midline that will accommodate the laparoscopic scissors that are used to prepare the posterior surface of the abdominal wall up to the level of McBurney's point. Care must be taken not to dissect too close to the muscle (staying posterior to the inferior epigastric vessels) and not too close to the serosa (accidental peritoneotomy makes the continuation

FIGURE 13.7. (See color plate section.) Umbilical extraperitoneal laparoscopic approach. A spinal needle is introduced in the midline in the extraperitoneal space before the ancillary instruments are put in place.

of the surgery very difficult if not impossible). Having prepared the posterior surface of the abdominal wall on both sides, the setup is exactly the same as that used for routine laparoscopy (Fig. 13.8). The access to the retroperitoneal space is ideal, but access to the iliac vessels is limited by the adherent nature of the peritoneum to the abdominal wall, particularly at the level of the inguinal canals. In order to mobilize this, division of the round ligaments is required at the most distal point where they disappear into the inguinal canals (Fig. 13.9). Once the ligaments are divided and the peritoneum developed dorsally, the view obtained of the pelvic sidewall is similar to that seen in the transumbilical transperitoneal approach. The only difference is the superior vesical arteries and umbilical ligaments now run dorsally since the bladder has been detached from the abdominal wall and reflected dorsally.

Sentinel Node Biopsy

The use of the sentinel node (SN) concept in the clinical management of epithelial malignancies started in the 1970s. The urologist Cabanas (158) proposed replacement of full inguinofemoral dissection that was traditionally combined with radical surgery for penile cancer with only a biopsy of the so-called sentinel node. The use of the new technique spread rapidly beginning in the early 1990s. In gynecologic oncology, the first application was in vulvar cancer (159), but this was soon followed by its application in cervical cancer (20,160–175) and endometrial cancer (175,175). Numerous opinions about techniques of injection, methods of dissection, modality of pathologic assessment, and, even more, the practical use of the end results have been put forth. The only point that gives rise to quasiunanimity is that the laparoscope is a tool perfectly suitable for SN biopsy technique in the field of cervical cancer. Table 13.3 (20,160–166,167–171,173,176,177) summarizes the early literature concerning the use of SN biopsy in early cervical carcinoma. The data should be interpreted carefully because of the different techniques employed among the teams. A recent systematic review by van de Lande et al. (178) reported on a pooling of carefully selected publications. Only 23 out of 98 articles met the selection criteria. Ultimately, 12 studies used the combined technique with a sensitivity of 92% (95% CI, 84% to 98%). Five studies used (99m)Tc-colloid, with a pooled sensitivity of 92% (95% CI, 79% to 98%; $p = 0.71$ vs. combined technique), and four used blue dye with a pooled sensitivity of 81% (95% CI, 67% to 92%, $p = 0.17$ vs. combined technique). The SN detection rate was highest for the combined technique: 97% (95% CI, 95% to 98%) vs. 84% for blue dye (95% CI, 79% to 89%; $p < 0.0001$), and 88% (95% CI, 82% to 92%; $p = 0.0018$) for (99m)Tc colloid. The authors concluded that SN biopsy has the highest SN detection rate when (99m)Tc is used in combination with blue dye (97%), and a sensitivity of 92%.

The SN injection is started by injecting the normal tissues surrounding the tumor. The size of the needle is ideally 21 gauge.

The injection must not be too deep and not too superficial (Fig. 13.10). A “learning curve effect” does exist with this technique. Many factors may contribute to the discrepancies in the literature such as the nature of the injected medium: either a blue dye (Lymphazurin or Patent Blue Violet) or radioisotopic colloidal particles. The blue dyes have to be used at an appropriate dilution and in appropriate quantity. The isotope used for the radioisotopic technique is generally technetium 99m, but the colloidal particles vary in nature and size (2 to 80 nm), which contributes to variability in the transit time and number of detected nodes. No matter what the radioisotopic colloid used, the detection rate is generally higher and the number of detected nodes greater with the radioisotopic technique. It appears that the combination of blue dye and isotopes is the most accurate. The result of the radioisotopic injection can be assessed 3 hours after a lymphoscintigraphy (Fig. 13.11). The result of the blue dye injection is assessed at the time of surgery, which is performed soon after injection.

The surgery is performed in the usual fashion for laparoscopic pelvic surgery, usually within 12 hours of injection of the colloidal radioisotope and immediately after the injection of the blue dye. The procedure starts with the transperitoneal assessment. If the injection has been done correctly, the blue channels are located through the dorsal leaf of the broad ligament and traced from the center of the pelvis to the pelvic sidewall. The isotopic detection probe demonstrates where the injected nodes are situated (level of radioactivity ten or more times higher than the basic level). In order to dissect the nodes, the pelvic peritoneum is opened alongside the external iliac vessel axis, and the broad ligament is opened. Some surgeons, in particular those who use an isotope, immediately search for the SNs, whereas others first identify the blue channels and trace them to the SNs. Technique plays a major role in the chances for success, and may explain the variations in the “SN detection rate.” It also may explain the great variations in the number and the topography of the detected nodes.

The use of blue dye will demarcate one or more lymphatic channels at the base of broad ligament. They run parallel to the uterine artery, cross the obliterated obturator artery, and end in a node situated in the so-called interiliac area, that is, at the bifurcation to the common iliac artery either medial or dorsal to the external iliac vein (Fig. 13.12) or between it and the external iliac artery. One node is usually found (or two or three juxtaposed micronodes). However, in 5% of the cases, injected nodes are found in two distant basins. At least one node should be found on each pelvic sidewall. In approximately 15% of cases (Fig. 13.13), the SN is located either in the region of the internal iliac artery or in the common iliac and/or low aortic area. Such results are usually observed when the dissection is performed by first identifying the blue lymphatic channels.

The results may be different when isotopes are used. Detected nodes are found in distant basins. This means that the sensitivity of the isotopic technique is higher than the sensitivity of the blue dye technique. But this questions the specificity and even challenges the concept itself. Since SN dissection with a radioisotope may include multiple anatomic areas, it may tend to resemble a systematic dissection more than a true “sentinel node” biopsy.

Pathologic assessment of the SN can be performed by various techniques. Frozen section has been criticized because of the higher rate of false negatives. It does have the advantage of immediate answers in patients with metastasis to the SN (no false positive). The classic unilevel sectioning after paraffin embedment and the hematoxylin and eosin (H&E) staining are the most widely used techniques. Micrometastasis, however, can be missed. Multilevel sectioning may help minimize this problem. The literature concerning the topic is very

confusing. Ideally, the best technique is serial sectioning of the entire node with all slides being stained and assessed, but this is unrealistic. The semiserial sectioning entails examining slides at 40- to 200- μm (depending on institutional protocol) intervals. Even the so-called micrometastasis can thus be identified. Using immunostains can improve the sensitivity. The most common antibodies used in current practice are

those directed toward the cytokeratins. Very small clusters of epithelial cells (Fig. 13.14) and isolated epithelial cells can be identified that were previously impossible to identify after the standard H&E staining. However, if true serial sectioning is not employed, these epithelial cells can be missed as well. Molecular biology analysis for cytokeratins or human papillomavirus (HPV) may provide the highest sensitivity. Each group has its own personal technique, and this explains the great variability of the rate of positive and false-negative SNs reported in the literature. With the unilevel sectioning and classic H&E staining, the rate of SN positives is, in cervical cancer stage IB1, approximately 15%, and the rate of false negatives varies between 0% and 17%. Both rates are much

higher if semiserial sectioning and immunostaining are used both for the assessment of the SN and the non-SN. In the series by Marchiolo et al. (179), the rate of SN positivity increased from 10.3% (3 of 29) to 27.5% (5 of 29) using semiserial sectioning and cytokeratin AE1 and AE3 immunostaining. However, the rate of false negatives was also increased to 37% as three of the five micrometastases were discovered in non-SNs with the SNs being uninvolved. This questions the role of SN biopsy in the clinical management of early cervical cancer.

The goal of the SN concept is avoiding systematic dissection in patients who do not have node metastasis. This goal is reached if one does not consider micrometastasis as being clinically relevant. However, in spite of the fact that the clinical significance of micrometastasis is not clearly established, it seems oncologically safer to remove nodes that could be involved. On the other hand, laparoscopy makes systematic dissection a relatively safe and acceptable procedure that may be no more morbid than a laparoscopic SN biopsy. A reasonable strategy may include (a) laparoscopy with SN biopsy, (b) frozen sections of the SN, and (c) systematic dissection if the frozen section is negative. In the cases where either the SN biopsy or other nodes have metastasis, chemoradiation can be given. The risk for radiation enteritis is minimized by the decreased adhesion formation after laparoscopy.

The concept of SN biopsy has been tested in advanced cervical carcinoma. The detection rate is low, and the clinical value is only theoretical. In endometrial cancer, several publications (175,180,181) demonstrate similarities with the early cervical cancer model. Injections of the cervix give better results than injections of the fundus (180), which give rise to a larger amount of diffusion and result in a higher false-negative rate (50% in one of the published series) (175). Laparoscopy can also be used with SN biopsy in endometrial cancer. However, SN biopsy may not have the impact on the current management of endometrial cancer as it does with cervical cancer. In ovarian, tubal, and peritoneal cancers, the application of the SN concept is not likely to be applicable.

Extraperitoneal Laparoscopic Aortic Lymphadenectomy

Unlike pelvic lymphadenectomy, the use of the extraperitoneal approach to laparoscopically remove the aortic nodes followed the introduction of the transperitoneal technique. Transperitoneal laparoscopic aortic lymphadenectomy still remains the more common approach employed by the majority of gynecologic oncologists. However, this innovative extraperitoneal approach does have several advantages when compared to the transperitoneal technique and has gained increasing popularity.

An extraperitoneal approach to the aorta is begun by using a 3-cm incision made at McBurney's point (or at the point exactly opposite on the left side of the patient). The contralateral nodes can be removed using a one-sided approach. The left-sided approach is preferred for several reasons, which will be illustrated below. The successive layers of the abdominal wall are transected, including the parietal fascia, leaving the parietal peritoneum intact. Insertion of a transperitoneal laparoscopic trocar is recommended so that the area where the extraperitoneal dissection starts can be visualized to prevent entry into the peritoneal cavity. Once the parietal fascia is opened, the surgeon's forefinger is introduced into the extraperitoneal space and develops the retroperitoneal space along the psoas muscle and common iliac artery. With gentle blunt dissection, the peritoneal sac is elevated off the underlying structures. The second landmark is the iliac crest, which is followed laterally in order to open the inferior part of the side. At this time, a laparoscopic trocar with a pneumostatic tool (Blunt Tip Auto Suture, Norwalk, Connecticut, USA) is introduced.

Once the extraperitoneal space has been adequately developed, insufflation begins, the gas from the peritoneal cavity is drained, and the extraperitoneal laparoscopic assessment can begin. This trocar accommodates one laparoscopic forceps, which is used to develop the extraperitoneal spaces to the level of the lower ribs. A second ancillary trocar is introduced in the infracostal area in the midaxillary line.

The video monitor is placed on the opposite side of the table from the surgeon as he or she seeks the first landmark (Fig. 13.15): the fascia of the psoas muscle. Detaching the

FIGURE 13.15. (See color plate section.) Left-sided extraperitoneal laparoscopic approach. Position of laparoscopic trocar and ancillary trocars (the extraperitoneal approach is preceded by a transumbilical transperitoneal approach; the umbilical trocar is left in place after exsufflation).

FIGURE 13.16. (See color plate section.) Left-sided extraperitoneal laparoscopic approach. The left ureter is pushed ventrally. The left common iliac artery is visible.

peritoneum from the muscle reveals the second landmark, the ureter (Fig. 13.16), and then the third landmark, the ovarian vein, a fragile structure that must be handled carefully. After pushing the peritoneum medially, the common iliac vessels can be identified and the aortic dissection can begin. The lower aspect of the dissection is shown in Figure 13.17.

The lateral aspect of the aorta is approached in a caudal-to-cranial direction. At the level of the origin of the inferior mesenteric artery, the dissection becomes more difficult owing to the presence of the lower mesenteric autonomic nervous plexus. There are no drawbacks in dividing this plexus in a woman. Once the nervous plexus is divided and

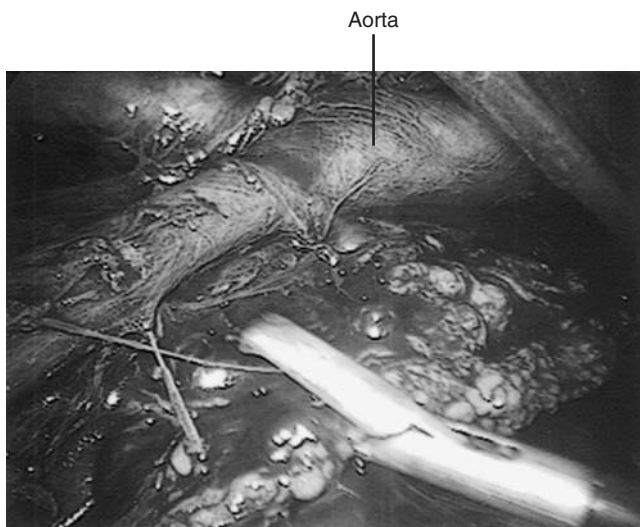

FIGURE 13.17. (See color plate section.) Left-sided extraperitoneal laparoscopic approach. Picture taken at the end of the common iliac and lower aortic dissection.

FIGURE 13.18. (See color plate section.) Left-sided extraperitoneal laparoscopic approach. Picture taken at the end of the aortic dissection.

the ventrolateral aspect of the aorta is freed up, the dissection is continued cranially up to the level of the left renal vein. This is the superior limit of the dissection of the left para-aortic lymph nodes. The anterior aspect of the completed dissection is shown in Figure 13.18.

If one starts with the right-sided dissection, it is easy to remove the nodal tissue on the anterior aspect of the vena cava and the interaorticocaval space where the right lateroaortic nodes lie. However, the difficulty lies in reaching the left lateral aspect of the aorta. This is largely due to the noncompressible nature of the aorta. Conversely, if dissection is started on the left side, exposing the right lateral aspect of the aorta can be simplified by dissecting from beneath the aorta. Hence, it is recommended to start with the left side and move to the right side only if difficulties arise. When comparing the unilateral to the bilateral approach, the total node counts of a unilateral left-sided approach have been shown to be comparable to those from a bilateral extraperitoneal approach and a transperitoneal approach; however, the right-sided node counts are significantly decreased compared to the bilateral approach (182).

During the unilateral left-sided technique, the separation of the left aortic nodes is performed either cranially to caudally or vice versa. The nodes are located between the artery and the psoas muscle. Separating these structures reveals the lumbar sympathetic chain and the vertebral vessels. Once the left aortic lymph nodes have been retrieved, attention now moves to the retroaortic space. The aorta is separated from the common ventral vertebral ligament. The aim of this maneuver is to remove the few nodes lying in the retroaortic space while exposing the nodes on the right side of the aorta and the interaorticocaval space. This dissection can be made in the spaces located between the successive lumbar arteries (Fig. 13.19) but access to the interaorticocaval space is limited. It is better to divide the collaterals of the aorta: the fifth lumbar arteries in all cases and the fourth if needed. Division of these lumbar vessels opens the retroaortic space and simplifies the removal of the right aortic nodes (Fig. 13.20). The additional exposure allows the right laterocaval nodes to be removed via the retrocaval or

FIGURE 13.19. (See color plate section.) Left-sided extraperitoneal laparoscopic approach. Picture taken at the beginning of the retroaortic dissection: the lumbar arteries and veins are visible.

the precaval route. Dissection of these nodes is usually only performed for a right ovarian tumor. Thus, except for cases of ovarian cancer, there is no need to proceed this far if the caval dissection appears from the left side to be dangerous (owing to the distribution of the vertebral veins).

Reports on this particular approach are relatively sparse in the gynecologic oncology literature and have been limited to patients with cervical cancer. Vasilev and McGonigle (183) were the first to publish data on laparoscopic extraperitoneal para-aortic lymphadenectomy using a left-sided approach in

FIGURE 13.20. (See color plate section.) Left-sided extraperitoneal laparoscopic approach. Picture taken after the lumbar arteries and veins have been divided and the interaorticocaval space appeared: the junction of the left renal vein and inferior vena cava is visible.

humans. They reported an average of five nodes in four cases; the dissection was limited to the inframesenteric area. In a larger series, Querleu et al. used this technique to perform an infrarenal aortic dissection, and by doing such, the mean node count rose to 20.7 (184).

Sonoda et al. (185) reported on 111 patients with locally advanced cervical cancer who underwent surgical staging. This comprises the largest series to date using this novel approach for the management of locally advanced cervical cancer. In this study, 30 patients were found to have positive nodes. The mean duration of the procedure was 157 ± 46 minutes and the average number of nodes was 19. The mean postoperative stay was 2 days. Perioperative complications occurred in 14 patients. The majority of these complications were symptomatic lymphoceles that occurred in 11 patients: Eight of these lymphoceles were drained under radiologic guidance, two required a catheter placed under anesthesia, and one required laparoscopic drainage. In the final 37 patients, marsupialization of the peritoneum was performed to drain the retroperitoneal fluid into the peritoneal cavity. No further symptomatic lymphoceles were observed after adopting this maneuver. There were two retroperitoneal hematomas and one bowel obstruction from a trocar-site hernia. Only two patients in the series required a reoperation for a complication. Of the 30 patients with positive nodes, only the patient who had a trocar-site hernia that required small bowel resection developed radiation enteritis. This is consistent with the finding that the laparoscopic extraperitoneal approach is associated with less adhesion formation in the radiation field (186). The benefits of surgical staging of locally advanced cervical cancer remain controversial, and procedure-related morbidity must be taken into consideration. Thirty (27%) of 111 patients in this series were found to have positive lymph nodes in spite of negative imaging studies and received extended field radiation with or without chemotherapy. However, the overall survival was still significantly worse in this group of patients with positive aortic nodes.

The subject of surgical staging for locally advanced cervical cancer remains controversial and has been prospectively studied in only one small, randomized trial (32). The primary objective of this study was to determine percentage of improvement in detection of para-aortic node metastasis with survival being secondary. Unfortunately, the study was closed prematurely because both a significantly worse progression-free and overall survival were identified in the group undergoing surgical staging. Treatment after the staging procedure was inconsistent and biased, thus tainting the conclusions on survival. Additionally, there was a background of unfavorable characteristics facing the surgically staged group. In general, the surgically staged patients were of higher stage, had larger tumor size, and fewer received concurrent chemoradiation as compared to the patients who were clinically staged. These differences in variables did not reach statistical significance, but this was most likely due to the small sample size.

In spite of this randomized prospective trial, the option on surgical staging for locally advanced cervical cancer is still adopted in a growing number of centers, on the basis of acceptable morbidity and the evidence of an acceptable oncologic outcome in aortic node-negative patients managed without aortic radiation therapy (187). In addition, the same study from France found that the outcome for patients with laparoscopically removed nodal micrometastases in the aortic area is similar to the outcome of node-negative patients, suggesting a therapeutic role of aortic node dissection.

Until definitive conclusions on the optimal management of locally advanced cervical cancer are reached, extraperitoneal laparoscopic aortic lymphadenectomy appears to be a reasonable approach for these patients when surgical staging is employed.

LAPAROSCOPIC ASSISTANCE TO RADICAL SURGERY AND LAPAROSCOPIC RADICAL SURGERY

Laparoscopy can be used to assist extirpative transvaginal surgery or it can be used to perform the entire operation, after which the specimen is removed transvaginally.

Laparoscopically Assisted Vaginal Hysterectomy and Laparoscopic Hysterectomy

The concept of laparoscopic assistance to vaginal hysterectomy emerged in 1984 (21) as a procedure for the management of benign conditions. Its use for the management of endometrial cancer was naturally foreseeable. The main contraindication to the vaginal approach in endometrial cancer was the inability to assess the ovaries and tubes, the peritoneal serosa, and the retroperitoneal spaces. This was made possible by using laparoscopic assessment of the pelvis before undertaking the hysterectomy. Laparoscopically assisted vaginal hysterectomy (LAVH) includes five types, which are listed here, and whose descriptions can be found elsewhere (188):

Type 0: Laparoscopy is only used to assess the pelvic cavity and the organs it includes.

Type 1: Laparoscopic management of inflammatory peritoneal adhesions and control of the round ligaments and infundibulopelvic ligaments.

Type 2: Laparoscopic preparation and division of the uterine arteries.

Type 3: Laparoscopic management of the paracervical ligaments.

Type 4: Laparoscopic transection of the vagina, transvaginal extraction of the specimen, and laparoscopic closure of the vagina.

Type 4 LAVH corresponds to the total laparoscopic hysterectomy first described by Reich et al. (189). This technique as well as others has been used in the field of endometrial cancer. Childers and Surwit (8) were the first to report on the combined use of laparoscopy with vaginal hysterectomy for the treatment of early-stage endometrial cancer. This group later reported on a series of 59 patients with clinical stage I endometrial cancer who were staged by this new procedure (136). Their technique included an inspection of the intraperitoneal cavity, intraperitoneal washings, and LAVH. Patients with preoperative grade 2 or 3 tumors or grade 1 tumors with greater than 50% myometrial invasion underwent laparoscopic pelvic and para-aortic lymphadenectomy. Six patients had intraperitoneal disease. Two patients could not undergo laparoscopic lymphadenectomy secondary to obesity, and two patients required conversion to laparotomy for intraoperative complications. These reports stimulated the interest in laparoscopic management of endometrial cancer.

Laparoscopically Assisted Vaginal Radical Hysterectomy

The introduction of laparoscopy into the realm of gynecologic oncology was first proposed as a means of expanding the use of VRH for the management of cervical cancer. The laparoscope was to perform the lymphadenectomy before the radical hysterectomy, which was entirely done through the vaginal

approach. Subsequently, the concept of laparoscopically assisted vaginal radical hysterectomy (LAVRH) appeared with variations in the degree of laparoscopic preparation for the vaginal part of the surgery with the ultimate development being the total laparoscopic radical hysterectomy.

Vaginal Radical Hysterectomy After Laparoscopic Staging

Type 0 LAVRH, although not discussed here, combines pelvic lymphadenectomy as previously described and a VRH whose description can be found elsewhere (190).

The first large series of LAVRH (5) reported on type 0 LAVRH. The technique was used until June 1992. At that time (unpublished data), the series included 95 cases. The mean duration of the laparoscopic staging was 60.4 ± 25.8 minutes. The Schauta-Stoeckel technique (less radical) was used in 28 cases and the Schauta-Amreich technique (more radical) was used in 67 cases. The mean duration of the surgery was 74 ± 31 minutes and 89 ± 26 minutes, respectively. No perioperative complication was observed with the Schauta-Stoeckel technique, whereas six complications were observed with the Schauta-Amreich technique: one cystotomy, four ureterotomies, and one proctotomy (all repaired immediately with no postoperative complications). Only one patient required reoperation for postoperative bleeding after a Schauta-Amreich procedure. Only 14 patients received transfusions. Among the 28 patients who underwent the Schauta-Stoeckel operation, 8 suffered from urinary bladder problems but only 1 had persistent dysuria after 6 months. Among the 67 patients who underwent the Schauta-Amreich procedure, 27 suffered the same bladder problems and 10 had persistent dysuria after 6 months.

Laparoscopic Vaginal Radical Hysterectomy

As with LAVH, there are different techniques between the two extremes of the spectrum, that is, laparoscopy for staging purposes only and laparoscopy for the entire procedure. The techniques first described were highly radical comparable to types 3 and 4 abdominal radical hysterectomy (ARH). A less radical approach appears to be possible leading to surgery like type 2 ARH. Laparoscopically assisted vaginal radical trachelectomy (LVRT) is a conservative modification of this less radical LAVRH.

Supraradical Laparoscopically Assisted Vaginal Radical Hysterectomy. Since 1992 a series (12,22,25,26,176) of reports have been published describing a variety of techniques of LAVRH that could be designated as type 3, and that involved preparation of the parametrium during the laparoscopic step. The common feature of these techniques was the quest for radicalness that was made possible by the laparoscope. In fact, one of the technical difficulties of the radical vaginal approach is the clamping of the parametrium close to the pelvic sidewall due to the obliquity of the latter to the former; this is in contrast to the oblique angle along which the "vaginal" surgeon naturally works. Alternatively, using an ipsilateral iliac laparoscopic port, one can operate in the plane of the pelvic sidewall, and using endoscopic staplers, bipolar cauterization, the argon-beam coagulator, or other devices, the surgeon can divide the parametrium at its lateral insertion. As a consequence, the operative specimen (Fig. 13.21) is very large, that is, identical to type 3 ARH. It can even be extended (26) by the addition of a piece of the "posterior parametrium," that is, uterosacral ligaments, which are easily divided during laparoscopy.

In 1993, Kadar and Reich (191) reported an operative time of 10 hours. However, the postoperative course was uneventful and the patient went back to work after 3 weeks. The operative time for the second patient was 8 hours. The blood loss was 2 L, and the postoperative pyelogram revealed a transection of the

FIGURE 13.21. (See color plate section.) Specimen of supraradical LAVRH (distal celio-Schauta).

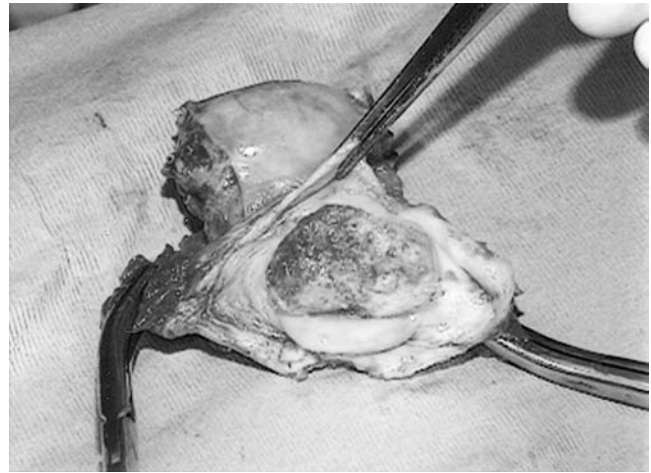

FIGURE 13.22. (See color plate section.) Specimen of modified LAVRH (proximal celio-Schauta).

left ureter, which was reimplanted by laparotomy. Pulmonary embolism and vesicovaginal fistula occurred after the reoperation. Roy et al. (25) reported on 25 cases with a mean duration of the operation of 270 minutes. Two conversions to laparotomy occurred, one for an external iliac vein injury and the second for a cystotomy. One other cystotomy was repaired transvaginally. Five patients received a transfusion. These data were similar to those collected in a comparative group of 27 patients who underwent ARH. In the series of 37 cases reported by Hatch et al. (12), the mean operative time was 225 minutes. Two intraoperative bladder injuries and one large bowel injury occurred. Two postoperative ureterovaginal fistulas developed. Four patients required blood transfusion. When compared to a matched series of 30 patients treated by ARH, the mean operative time was significantly longer for LAVRH, but blood loss, rate of transfusion, and mean hospital stay were significantly lower for LAVRH. Martin (192) reported on Dargent's experience in 28 patients from June 1992 to June 1994. The mean duration of the operation was 204 minutes. Four complications occurred during the transvaginal portion of the surgery: one bladder injury, two ureteral injuries, and one internal iliac vein collateral injury. The first three injuries were repaired transvaginally. The bleeding complication was managed by laparoscopic re-exploration, and eight patients received blood transfusions. During the postoperative course, a surgical re-exploration was necessary in three instances: one for bleeding, one for incisional dehiscence, and one for intestinal obstruction. Fourteen patients suffered from bladder problems, and one had persistent dysuria after 6 months. Schneider et al. (26) reported a series of 33 patients. The mean operative time was 295 minutes. Three patients sustained injury to the bladder, one patient had injury to the left ureter, and another patient had an injury to the left internal iliac vein. Blood transfusions were necessary in four women.

Since 1999 a larger series has been compiled demonstrating that the oncologic outcomes are at an acceptable level. Operative complications are less frequent, which may be due to the "learning curve effect" as well as the trend toward less radical surgery. The standard operation of today ends up with an operative specimen that is similar to type 2 ARH (Fig. 13.22), but this is combined with laparoscopic paracervical lymphadenectomy to preserve the radical nature.

Modified Laparoscopically Assisted Vaginal Radical Hysterectomy.

Laparoscopic Step. The route used for introducing the laparoscope can be either transperitoneal or extraperitoneal. Pelvic lymphadenectomy is performed first and then

"paracervical cellulolymphadenectomy." Paracervical cellulolymphadenectomy consists of removing all the lymph node-bearing tissues located in the vasculonervous web making up the lateral part of the paracervical ligament. It is a multistep procedure.

First, the "deep obturator nodes" (nodes located underneath the obturator nerve) are removed, which completely opens up the paravesical space, reveals the origin of the obturator vessels, and exposes the ventral surface of the paracervical ligament.

The dorsal aspect of the paracervix is exposed in the second step. The pararectal space opens when pushing the posterior sheet of the broad ligament, to which the ureter is attached, medially. Following the ureter ventrally, one arrives at the point where the ureter crosses the uterine artery. Starting from this point, the pararectal space is developed as far as the sacrospinous muscle. The fatty tissues lying between the ventral aspect of the sacrum, the lateral aspect of the rectum, and the medial aspect of the pelvic sidewall are removed. During this part of the procedure, one must proceed carefully owing to the confined nature of the pararectal space, especially on the left side where the presence of the left common iliac vein poses an added obstacle.

Once the two aspects of the paracervical ligament are exposed, the fatty tissue among the paracervical vascular network must be removed. This can be done by using the grasping and dissecting forceps similar to the technique that is recommended for pelvic dissection. This technique is better suited to paracervical dissection for which the use of scissors is dangerous. Another solution could be using a vacuum curette as recommended by Hockel et al. (193) for open dissection. It is perfectly possible to adapt this technique to laparoscopic dissection, but with the disadvantage of working in a gasless environment.

The last step of the paracervical dissection is cleaning out the retrovascular area (i.e., the space located lateral to the common iliac vessels and medial to the psoas muscle). The lymph node-bearing tissues located in this space are quite abundant. One must take care not to injure the collateral vasculature from the common iliac vessels to the psoas muscle. Once the deepest part of the obturator nerve and the lumbosacral nerve crossing the sacroiliac joint have been identified, the procedure is completed (Figs. 13.2 to 13.4).

Since paracervical cellulolymphadenectomy has been performed, there is no need to divide the cardinal ligament at the level of its origin. The division can be performed in the mid part and is easiest when performed transvaginally. This is the rationale of the technique of LVRH recommended by Dargent and Querleu.

FIGURE 13.23. (See color plate section.) Technique of modified LAVRH (proximal celio-Schauta). Incision of the vagina.

Transvaginal Step. The transvaginal portion of the Dargent and Querleu LAVRH simulates the modified VRH described by Stoeckel. In both, the paracervical ligaments are divided at an intermediate level. However, the technique differs in that no paravaginal incisions are used in the Dargent and Querleu LAVRH. Stoeckel made two incisions: one on each side of the patient.

The first step of the transvaginal operation is the formation of the vaginal cuff. A series of Kocher forceps is put onto the vaginal mucosa following a circular line located at the level of the junction between the upper and the middle thirds. Traction is exerted on the forceps, creating an internal vaginal prolapse. The two sheets of the vaginal fold raised by the traction are separated from each other by injection with saline midway between each traction forceps. The outside sheet of the fold is then divided. The division is gradually made outside a line drawn by exerting appropriate traction on each pair of forceps. The pressure on the scalpel blade must be released as soon as the saline drop appears, so as not to enter the opposite sheet of the fold. This full-thickness incision (incision of the three layers of the vaginal wall) is made only on the anterior and posterior aspects of the developed vaginal cuff (Fig. 13.23). Only the skin is incised on the dorsolateral aspects (between three and four o'clock and between eight and nine o'clock), so that the relationship between the vaginal cuff and the paracervical ligaments is maintained.

FIGURE 13.24. (See color plate section.) Technique of modified LAVRH. Closing the vaginal cuff with Chrobak forceps.

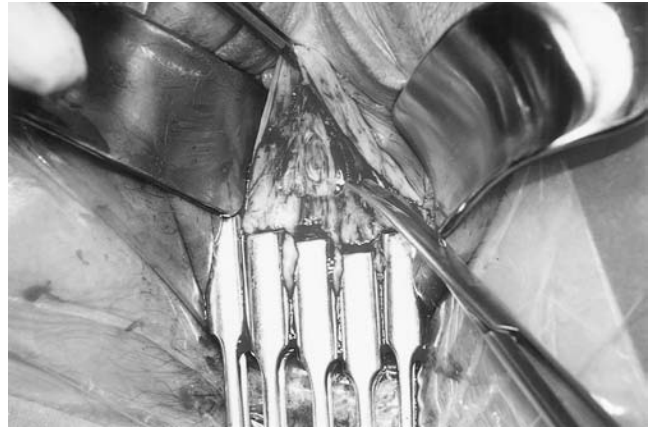

FIGURE 13.25. (See color plate section.) Technique of modified LAVRH. Opening the vesicovaginal space.

Once separated from the remainder of the vagina, the cuff is taken into strong grasping forceps that are aligned in a frontal plane (Fig. 13.24). It is retracted dorsally in order to free the ventral aspect of the vaginal cuff at the same time as the ventral aspect of the uterus and surrounding tissues (i.e., paracervical and parametrial ligaments). The bladder floor and terminal ureter are attached to these structures and must be separated from them. The vesicovaginal space is carefully developed in the midline so as not to injure the bladder, which is very close to the tips of the grasping forceps. Caution must be taken because of the condensation of the cellular tissue joining the bladder floor to the vagina. This condensation raises a pseudoaponeurotic coronal structure named the supravaginal septum, which must be perforated (Fig. 13.25) to reach the appropriate space. Once the midline interspersal space has been opened, the bladder pillars can be approached.

The bladder pillars are divided in two steps. Initially, the pillar is separated into the lateral and medial parts by opening the caudal brim of the pillar at an equal distance from its two sides and two extremities. After opening, the scissors are pushed laterally (Fig. 13.26). One ensures that the instrument is placed lateral to the ureter by palpating and feeling the "plop." These fibers are divided after stapling or bipolar cauterization (Fig. 13.27), making the paravesical space wider. A bigger retractor is put in place and the knee of the ureter appears in the deepest part. Once the knee of the ureter has

FIGURE 13.26. (See color plate section.) Technique of modified LAVRH. Opening the paravesical space on the left side of the patient.

FIGURE 13.27. (See color plate section.) Technique of modified LAVRH. Dividing the lateral fibers of the bladder pillar on the left side of the patient.

been identified, the medial fibers (Fig. 13.28) of the pillar can be divided. This division exposes the ventral aspect of the juxtatauterine part of the paracervical ligament. The paraisthmic window (the inferior brim of which is the superior brim of the paracervical ligament) is identified by palpation. The arch of the uterine artery is located inside it. The afferent branch of the arch is isolated (Fig. 13.29) and dissected upward as far as the level of the knee of the ureter. Then the dissection is pushed further laterally inside the knee of the ureter and the artery is cut close to its origin.

Freeing the dorsal aspect of the vaginal cuff is easier than freeing its ventral aspect. The grasping forceps are retracted ventrally. The pouch of Douglas is opened in the midline and the rectal pillars are divided, that is, the sacrouterine ligaments or, more precisely, the medial part of them (i.e., the rectouterine peritoneal folds). Once these ligaments have been divided, the dorsal aspect of the paraisthmic windows is palpated. Their inferior brim corresponds to the superior brim of the paracervical ligaments.

FIGURE 13.28. (See color plate section.) Technique of modified LAVRH. The location where the ureter enters the bladder floor is visible. The medial fibers of the bladder pillar can be cut.

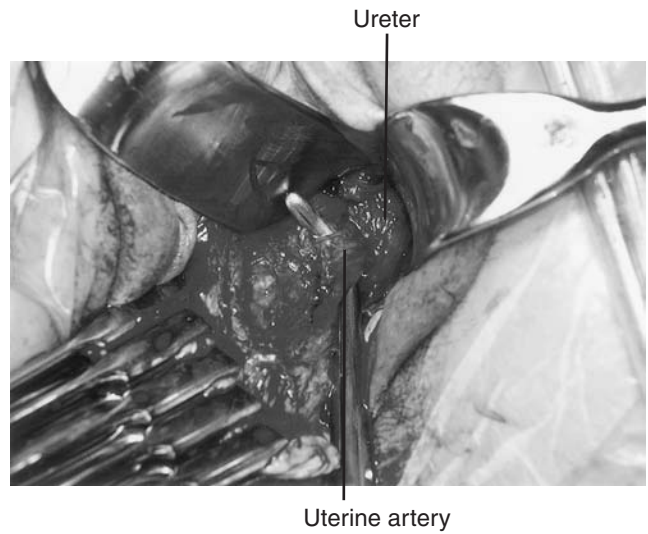

FIGURE 13.29. (See color plate section.) Technique of modified LAVRH. The medial fibers of the bladder pillar have been divided; the arch of the uterine artery is demonstrated.

A right-angle dissector is pushed from back to front through the parauterine ligament. Opening the dissector frees the upper brim of the paracervical ligament. This is done while dividing the paracolpos, that is, the expansion that the paracervix sends to the vagina. This division is done by deepening the dorsolateral incision in the vagina and pushing it laterally while controlling the bleeders encountered during this action.

Now that the dorsal and ventral aspects of the paracervical ligaments are both exposed with the superior and inferior brims, they can be divided. Two clamps are placed on each ligament, the most lateral being just at the contact of the tip of the knee of the ureter (Fig. 13.30).

Once the two paracervical ligaments have been divided, the operation can be completed without difficulty.

Sardi et al. (194) reported on 47 patients who underwent a procedure closer to type 0 LAVRH than to type 3. After 4 years, the overall survival was 100% for stage IA, 88% for stage IB1, and 85% for stage IB2. Sardi et al. suggested that 20 cases were needed to obtain the minimum skill to perform

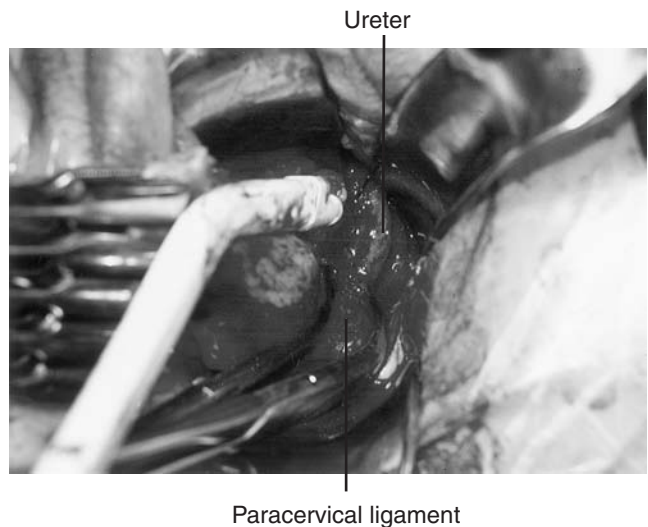

FIGURE 13.30. (See color plate section.) Technique of modified LAVRH. Two clamps are put on the paracervical ligament, the distal one being just underneath the tip of the knee of the ureter.

LAVRH. Renaud et al. (145) reviewed the charts of 102 patients affected by cervical cancer who had laparoscopic lymphadenectomy followed by VRH or trachelectomy in 91 of them (stage IA in 77%, IB1 in 17%, and IIA in 6%). There were two intraoperative complications due to laparoscopy and four due to VRH; however, only one postoperative complication was considered to be major (an abscess which required surgical drainage). With a median follow-up of 36 months, there were four recurrences in 91 patients. Three of the intraoperative and postoperative complications occurred in the first 25 cases compared to four in the following 77 cases. Querleu et al. (195) used personal interview and a standardized questionnaire in 60 of 95 patients who underwent LAVRH in order to assess the impact of the paracervical lymphadenectomy on late urinary bladder dysfunction. No difference was found between the patients operated before and after introduction of the new procedure. However, the paracervical dissection apparently failed to prevent the pelvic recurrences observed in the patients who had cancers 2 cm or greater. Six of 14 patients with tumors 2 cm or greater recurred with no difference being observed between those who underwent paracervical lymphadenectomy and those who did not. Conversely, only one recurrence was observed in the group of 81 patients affected by a tumor less than 2 cm. The uselessness of a very large surgery in small tumors is demonstrated in Dargent's series (unpublished data). Among 216 patients affected by cervical cancer stages pIA2 and pIB1 who underwent LAVRH between December 1986 and May 2002, the actuarial 5-year disease-free survival was 94.2%. No recurrence was observed in the 144 patients with stage pIA and stage pIB1 <2 cm large cancers. Conversely, among the 72 patients affected by stage pIB1 \geq 2 cm, the addition of a paracervical dissection was likely to decrease the risk of recurrence, which was as high as 18.9% during the first 3 years. Among the 53 patients followed during 3 years or more, the number of early recurrences was 3 of 11 after a proximal radical hysterectomy, 4 of 23 with a distal radical hysterectomy, and 3 of 19 with a proximal radical hysterectomy combined with a laparoscopic paracervical dissection. Hertel et al. (196) reported on 200 patients with cervical cancer stages IA to IIIA treated in Jena using LAVRH, and confirmed that the incidence of complications decreased significantly when comparing the first half with the second half of the series (65% of the complications in the first half vs. 35% in the second). This decrease could be linked to improvement in the technique (197,198). It could also be due to a change in the surgical radicality. In the reported series, the VRH was either performed according to the Schauta-Stoekel technique that is similar to type 2 radical hysterectomy (102 cases) or according to a more extensive original technique (98 cases) described by Possover et al. (199). At the time of the report, no change in the indications was formally introduced, but after having identified three independent risk factors for recurrence (tumor node metastasis (TNM) stage IB2 or greater, lymph node metastasis, and lymphovascular space involvement), the investigators decided not to use LAVRH for high-risk cases and to reserve it only for low-risk cases. This resulted in a projected 98% 5-year overall survival rate, even when the more patient-friendly Schauta-Stoekel technique was used (average duration of the surgery 298 minutes vs. 371; $p = 0.0001$).

Laparoscopic Vaginal Radical Trachelectomy

Radical trachelectomy is a conservative variant of radical hysterectomy for young patients affected by early invasive cancer on the superficial aspect of the cervix. This operation was devised by the Romanian gynecologist Aburel using a laparotomy. None of his patients ever became pregnant. Postoperative

adhesions, excessive tissue removal, and inaccurate isthmovaginal suturing were the probable causes for the lack of pregnancies in his patients. Using the laparoscopic vaginal approach allows successful outcomes.

The operation proceeds the same way as LAVRH. The arch of the uterine artery is identified, and the uterine artery must be preserved. Once the arch is identified, the afferent branch is followed laterally, ensuring that no lymph node is located along its course (if so, this node is removed). Once this dissection has been completed, the dorsal aspect of the paracervical ligament and its superior and inferior brims are cleared. The paracervical ligament is then divided at the same level that it is divided in LAVRH. The clamps are put in place taking care not to compromise the uterine artery. The uterine artery collaterals going to the lateral fornix and to the cervix (cervicovaginal arteries) are controlled and divided. At this stage, the most important difference from LAVRH occurs: The uterus is divided 5 mm below the isthmus (Fig. 13.31), which is generally easy to locate owing to the previous dissections that have freed its anterior, posterior, and lateral aspects. The specimen is sent to the laboratory for assessment of its superior margin by frozen section. The cavity is sounded and a dilator is inserted to widen the canal and facilitate the reconstruction.

Once the results of the frozen section determine negative margins, the reconstruction is undertaken. Initially, the pouch of Douglas is closed with a circular running suture, including the posterior aspect of the supraisthmic part of the uterus and taking the stumps of the paracervical ligaments that reattach the uterus to its natural support. Isthmic cerclage, using the same suture used for the conventional prophylaxis of miscarriage, is then performed. Finally, the isthmovaginal suturing is performed using two Sturmdorf stitches approximating the vaginal mucosa and the isthmic mucosa with great care—the previous dilation facilitates this crucial step of the operation. The reconstruction is completed by three interrupted stitches in each lateral part and eventually results in a new os (Fig. 13.32).

The data on laparoscopic vaginal radical trachelectomy are sparse. After the first presentation made by Dargent et al. (200) in 1996, Schneider et al. (201) published two cases and then Shepherd et al. (202) reported ten cases. The patients all had invasive cancer stage IB1 <2 cm in diameter. No complications were reported. Six pregnancies occurred after surgery and three live infants were delivered. One septic abortion occurred at 18 weeks and there were no recurrences. Roy and Plante (203) reviewed their first 31 cases in 1998. Most of the

FIGURE 13.31. Specimen of LVRT. The radicality is the same as in the modified LAVRH. The transected uterine isthmus is visible.

FIGURE 13.32. Postoperative picture after LVRT. The contour of the cervix has disappeared but the uterine orifice remains patent.

patients were stage IA and stage IB1 <2 cm in diameter. Only two patients had lesions >2 cm. Four complications required laparotomy: two external iliac vessel injuries during the laparoscopic step of the operation, one episode of intraoperative bleeding, and one bladder injury during the transvaginal step. Seven pregnancies occurred and four births were registered, one of them at 25 weeks of gestation. One recurrence was observed among the 26 patients followed for more than 6 months (median follow-up 25 months). The patient had a stage IIA 3-cm squamous cancer. Covens et al. (204) compared 31 patients treated with laparoscopic vaginal radical trachelectomy for stage IB1 cervical cancer <2 cm with two control groups, one matched and the other one unmatched (541 patients). The 2-year actuarial recurrence-free survival rates were 95%, 100%, and 98%, respectively. The cumulative actuarial conception rate at 12 months was 40%.

Dargent's experience was reviewed in May 2002 (205). Of the 96 patients with a follow-up of 1 to 15 years, one secondary cancer was observed (bilateral suprarenal gland cancer in a patient treated for neuroendocrine cancer of the cervix) as well as four recurrences. The retrospective univariate analysis demonstrated that the maximal tumor diameter (≥ 2 cm) and the depth of infiltration (≥ 1 cm) were the only two significant factors of risk. The chance of recurrence was zero for the small tumors, 19% for the tumors ≥ 2 cm ($n = 21$), and 25% for the tumors ≥ 2 cm with a depth of infiltration ≥ 1 cm ($n = 19$). The obstetric outcomes (unpublished data) were assessed at the same time. Forty-seven patients attempted to become pregnant, of which 36 succeeded and 11 did not (3 because of male factors). The 55 pregnancies ended with 11 early miscarriages, eight late miscarriages, and 36 live births. No recurrences were reported in the 61 patients from Shepherd et al. (206), Schlaerth et al. (207), and Burnett et al. (208). However, Picone et al. (209) reported the first central pelvic recurrence after radical trachelectomy. The tumor was 21 mm large, and the proximal tumor-free margin was only 4 mm. The recurrence developed on the isthmus 26 months after the surgery. Bernardini et al. (210) reported on the obstetric outcomes of 30 patients attempting to become pregnant after radical trachelectomy, of which 18 succeeded and 12 did not. Among the 22 registered pregnancies, 3 resulted in first-trimester abortion and 1 in an induced 17-week abortion after rupture of the membranes. Of the 18 pregnancies lasting past the seventeenth week, all resulted in a viable birth, but six occurred at or before 36 weeks of gestation.

One might assume, from summarized data, that laparoscopic vaginal radical trachelectomy provides the same chances for survival as either VRH or ARH. The question remains, however, as to whether the operation is acceptable for tumors

>2 cm in which the risk of recurrence is significant. There is no question about the absolute contraindication when the proximal tumor-free margin is too short (less than 10 mm). With regard to reproductive outcome, the main problem is miscarriage. Dargent's early experience suggests that cervical closure performed by the Saling method (211) at the end of the first trimester of pregnancy could improve the efficacy of the cerclage placed at the time of the initial procedure.

Laparoscopic Radical Hysterectomy

Laparoscopic radical hysterectomy was first introduced by Canis et al. (27) and shortly thereafter by Nezhat et al. (1992) (10). These two early cases were limited to stage IA2 tumors; however, as experience grew, the procedure was applied to larger tumors (212).

Sirtos et al. described a standardized technique to perform what was termed a laparoscopic type 3 radical hysterectomy (213). He separated this operation into eight components: (a) right and left aortic lymphadenectomy, (b) right and left pelvic lymphadenectomy, (c) development of the paravesical and pararectal spaces, (d) ureteral dissection, (e) ligation and dissection of the uterine artery, (f) development of the vesicouterine and rectovaginal spaces, (g) resection of the parametria, and (h) resection of the upper vagina. All the steps are carried out with the laparoscope, including the vaginal closure. Sirtos et al. use staplers for transecting the parametria and an argon-beam coagulator for dissection of the uterine artery, ureter, and paravaginal tissue and to open the vagina. Other American surgeons have found this technique to be successful (29). However, the procedure can be performed with basic bipolar coagulation (214) as well as ultrasonic energy (215).

As more surgeons began mastering the techniques of advanced laparoscopy, additional reports demonstrating the feasibility of this procedure began to appear in the literature. Ramirez et al. (216) reported the M. D. Anderson experience on 20 patients who underwent the laparoscopic radical hysterectomy. The procedure was completed laparoscopically in all patients with a median operative time of 332.5 minutes (range, 275 to 442) despite nine of the patients having additional procedures performed. The median hospital stay was only 1 day (range, 1 to 5). There were three perioperative and two long-term complications in this series. Others have reported a high level of success with the procedures. Gil-Moreno et al. (217) were able to complete the procedure laparoscopically in 26 of the 27 patients with no reported intraoperative complications. The one conversion reported was due to technical considerations. In a large series of over 300 patients, Xu et al. (218) reported an intraoperative complication rate of 4.4%. Vascular injury was the most common intraoperative complication. However, the majority of intraoperative complications were managed laparoscopically and the conversion rate was only 1.3%. There was a 5.1% postoperative complication rate with fistula being the most common complication.

When compared to abdominal radical hysterectomy, total laparoscopic radical hysterectomy has been shown to be feasible, safe, and associated with low morbidity. Abu-Rustum et al. (29) compared a group of patients who underwent a laparoscopic radical hysterectomy with pelvic lymphadenectomy to a group of patients managed with laparotomy. Patient age, body mass index, stage, histology, and mean pelvic lymph node counts were similar in both groups. Although the median operative time for the laparoscopic procedure was significantly longer (360 vs. 285, $p < 0.01$), the estimated blood loss and hospital stay were significantly less. Similarly, Frumovitz et al. (219) reported on a comparison between 35 patients who underwent total laparoscopic radical hysterectomy and 54 patients who underwent

an abdominal radical hysterectomy. Patient demographics and tumor factors were comparable in both groups. Although operative time was longer for the laparoscopic group, hospital stay, mean blood loss, and infectious morbidity were significantly less. Mean pelvic lymph node counts of patients undergoing laparoscopic procedure were less in this report; however, other larger comparative series have demonstrated that pelvic node counts are the same irrespective of the approach (219). Such a technically demanding procedure can be taught to trainees without compromising adequacy. In a recent case-controlled study specifically examining the use of total laparoscopic radical hysterectomy in a fellowship program, Zakashansky et al. (220) demonstrated that greater node counts, decreased hospital stay, and less blood loss are possible without increased morbidity in a training program.

Recently, follow-up data on the oncologic outcomes have been reported. In the largest series to date, Spirtos et al. (221) reported on 78 consecutive patients who underwent laparoscopic radical hysterectomy with aortic and pelvic lymphadenectomy. The average operative time was 205 minutes (150 to 430 minutes) and the average blood loss was 225 mL (range, 50 to 700 mL). With a mean follow-up of 66.8 months (\pm 1.78 months), the estimated 5-year disease-free survival was 89.7% and the estimated 5-year overall survival was 93.6%. Similar survival data have been reported by other groups performing laparoscopic radical hysterectomy (222). Pomel et al. reported a 5-year survival rate of 96% in 50 patients with stages IA2 and IB1 cervical cancers treated with laparoscopic radical hysterectomy (222). Several groups have compared the oncologic outcomes of laparoscopic radical hysterectomy with those of abdominal radical hysterectomy. In one of the larger series published to date, Li et al. (223) compared 90 patients treated with laparoscopic radical hysterectomy to 35 patients treated with traditional open surgery. Although the median follow-up was only 26 months, the recurrence rates for the laparoscopic and laparotomy groups were similar.

Since laparoscopic radical hysterectomy is a technically demanding procedure, some have implemented robotic-assisted surgery to perform the surgery. Sert and Abeler (224) recently published a case report on robotic-assisted radical hysterectomy with bilateral pelvic node dissection for a stage IB1 cervical cancer. In a larger series, Boggess et al. (225) reported on seven type III radical hysterectomies with pelvic node dissection for stage IB1 cervical cancers. The mean blood loss was 143 mL (range, 25 to 300) and mean operative time was 252 minutes (range, 187 to 290). The mean node count was 35 (range, 25 to 55) and all patients were discharged on postoperative day 1. The authors recently compared their experience in obese patients using a robotically assisted approach to an open approach. Those obese patients undergoing a robotically assisted approach had a superior node count, shorter hospital stay, and lower blood loss, which the authors reasoned may all contribute to reduced morbidity in this group of patients (226).

Laparoscopic radical hysterectomy appears to be a reasonable option for patients with early-stage cervical cancer. It can be performed with an acceptable morbidity and outcomes appear comparable to patients who undergo traditional open surgery. The application of robotic assistance may allow a greater number of surgeons to perform the laparoscopic radical hysterectomy without requiring them to acquire advanced laparoscopic skills.

Laparoscopic Pelvic Exenteration

Using the laparoscope to assess the feasibility of pelvic exenteration was addressed for the first time by Plante and Roy (227) and subsequently reported by Köhler et al. (228). Pomel et al. (31) extended the procedure by actually performing a

total laparoscopic pelvic exenteration with a small incision to create an ileal conduit and the diverting ileostomy. The operative time was 9 hours, and the postoperative course was uneventful. One can imagine that the complementary reconstruction will eventually be performed with a closed abdomen as well!

LAPAROSCOPY AND CANCER OF THE CERVIX

Although more than a century has passed since the first radical hysterectomy was performed by Clark (229), the role of surgery in the management of cervical cancer still remains a matter for debate. It is generally accepted that early cases can be managed using surgery or radiotherapy. Advanced cases must be treated using radiotherapy. The controversy arises from the many discrepancies existing among the definition of early and advanced cases. For some experts, the concept of ruling out surgery in the management of bulky but resectable tumors appears to be inappropriate considering that these tumors are less likely to be cured by radiotherapy. What should be the place of laparoscopic surgery in this controversial area of management? For simplification, the question will be addressed separating tumors <4 cm from tumors \geq 4 cm.

Early Stages

Surgery and radiotherapy produce comparable survival in the treatment of early cervical cancer (230). Even if the question of cost-effectiveness is not clearly settled, the majority of gynecologic oncologists have a preference for surgery, especially in young patients whose ovarian function can be preserved. Data obtained from the extensive use of radical surgery have demonstrated that the chances for cure depend in large part on the state of regional lymph nodes (231,232). For tumors <4 cm in diameter, the 5-year disease-free survival is approximately 90% as long as the nodes are negative, and approximately 60% if one or two nodes are involved. Disease-free survival drops to 15% if three or more nodes are involved. The opportunity to identify nodal spread is one of the advantages of a surgical versus a radiotherapeutic approach. However, when nodal spread is discovered after surgery is completed, it only serves to help adjust adjuvant therapy that has a low efficacy (63,233–235). Knowledge of lymph node status before the onset of radiotherapy is obviously better. Here lies the first indication for laparoscopy—the assessment of the regional lymph nodes to help decide on treatment modalities.

Staging

If accepted, the concept of pretherapeutic laparoscopic staging raises a series of practical questions, which we will try to answer in the order in which they appear in daily practice.

Prelaparoscopic Imaging

The sensitivity and specificity of computed tomographic (CT) scanning are approximately 60% and 85%, respectively (236). Lymphangiography has a slightly better accuracy, but it cannot be easily obtained in many centers. CT scanning (and/or magnetic resonance imaging [MRI]) must be performed in every case, and if enlarged nodes are detected, they must be assessed by guided biopsy. If the biopsy reveals metastatic involvement, there is no point in performing a

laparoscopy. If the biopsy is negative, laparoscopy should be undertaken.

Sentinel Node Biopsy. Although SN biopsy does not replace systematic lymphadenectomy, it deserves to be implemented in all cases. The first reason is that there are no false positives. Since involved lymph nodes can lead to altered therapy, the information is priceless. For the pathologist, identification of the node(s) at greatest risk for metastasis may help minimize the false-negative rate. The final (and possibly the best) reason for performing SN biopsy is that the scientific community needs more data and should encourage surgicopathologic studies regarding this matter.

Management of Bulky Nodes. Even if prelaparoscopic imaging does not suggest suspicious lymph nodes, it is still possible to encounter an obviously metastatic node. Freeing such a node laparoscopically is technically possible (139) even if vascular adhesions exist. One should, however, refrain from undertaking this dissection because of the hazard of tumor dissemination from nodal rupture. Two options for management are suggested: (a) referring the patient to the radiotherapist after having documented the metastatic involvement by fine-needle aspiration, or (b) opening the abdomen and performing nodal debulking.

Pelvic Versus Pelvic and Aortic Lymphadenectomy

In cases where the pelvic lymph nodes appear to be uninvolved whether at prelaparoscopic imaging, laparoscopic assessment, or at frozen section (frozen sections done on the SN and on the other pelvic nodes), the question is whether an aortic dissection has to be added. The risk of involvement of the aortic nodes is small if the pelvic nodes are negative (237). Therefore, we assume that aortic dissection is not indicated. If pelvic node involvement is found at the time of the initial laparoscopic staging, one should perform a para-aortic dissection using the same approach—the transumbilical transperitoneal one. If the pelvic node involvement is discovered at final pathology (no frozen sections during the initial procedure or a false negative of the frozen section: 20% to 40% of the cases), aortic dissection is performed at a second surgery. We recommend using the left-side extraperitoneal approach to do this. The dissection has to be extended up to the level of the left renal vein because isolated supramesenteric metastasis can exist (154).
