Preface

The dynamic and expanding knowledge of environmental stresses and their effects on plants and crops has resulted in the compilation of a large volume of information since the first edition of the *Handbook of Plant and Crop Stress* was presented to scientists and professionals in the field of agriculture. This fact necessitated that this unique comprehensive source of information be revised and all the new findings in this field be included in the new expanded edition. Like the first edition, the new expanded edition is also a unique, comprehensive, and complete collection of the issues on stress imposed on plants/crops.

More than two-thirds of the material in this edition is new, and it has been included in this volume in 37 new chapters. The other one-third of the material (19 chapters) has been updated. Therefore, overall, about 80% of the book is new, and it seems that a totally new volume has emerged. This new edition contains 11 parts, four more than in the first edition.

Since the early 1900s, soil/plant scientists have observed that plant growth and crop yields decrease under salinity, drought, and/or other environmental stress conditions. Reduction in plant growth was reported as a result of modification in the physiological process and environmental conditions that control growth. Stresses imposed on plants by pollution or application of agrichemicals have recently attracted the attention of scientists, investigators, and environmentalists in the field of agriculture and related areas. The mechanisms by which salinity, drought, high/low temperatures or heat, high/low pH, high/low light, nutrient deficiency, pollution, agrichemicals, climatic changes, or any other stresses affect plant metabolism, thereby reducing growth and development, are still not completely understood. Among the plant physiological processes, the change in nutrient uptake and metabolism induced by salt, drought, and/or other stress factors is commonly accepted among scientists as one of the most important factors in abnormal plant metabolism, reduced growth, and decreased crop yield. The need for minimizing these stress effects as well as other environmental stresses on plant growth and crop yield is vital. Thus, a greater awareness of these stress factors and their related problems is essential to scientists, growers, and all others involved in the field of agriculture.

This handbook is a comprehensive, up-to-date reference book effectively addressing issues and concerns related to plant and crop stress. Although many reference books about soil salinity, sodicity, specific plant/crop salt and water stress, pollution, and other environmental stresses have been published, they all exist in relative isolation from one another, covering only one specific topic.

Efficiency and effectiveness in solving plant and crop stress problems are dependent on the accountability and coordination of all the factors and the interrelationships involved with plant/crop stress. Although previous authors have indeed competently covered the many areas separately, the areas are, nonetheless, interrelated and should be covered comprehensively in a single text. Thus, the purpose of this book is to fill this niche.

The updated and expanded edition of the *Handbook of Plant and Crop Stress* has been pre-

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

pared by over 100 contributors, who are among the most competent and knowledgeable scientists, specialists, and researchers in agriculture from 25 countries. It is intended to serve as a resource for both lecture and independent purposes. Scientists, agriculture researchers, agriculture practitioners, and students will benefit from this unique comprehensive guide, which covers plant stress problems from the soil to the atmosphere.

As with other fields, accessibility of knowledge is among the most critical factors involved with crop stress problems. Without due consideration of all the elements contributing to a specific crop stress problem, it is unlikely that a permanent solution will be achieved. For this reason, as many of the factors as possible are included in this handbook. To further facilitate the accessibility of the desired information in the areas of stress covered in this collection, the volume has been divided into 11 parts: Soil Salinity, Sodicity, Low/High pH, and Soil Nutrient Deficiency Problems; Plants, Crops, and Stressful Conditions; Plant and Crop Responses Under Salt, Drought, Heat, Temperature, Light, and Other Stressful Conditions; Plant and Crop Responses Under Pollution Stress; Plant and Crop Responses Under Agrichemical Stress Conditions; Molecular Biology and Microbiological Aspects of Plant Responses Under Salt, Drought, and Other Environmental Stress Conditions; Genetic Factors and Plant/Crop Stress; Examples of Empirical Investigations of Specific Plants and Crops Grown Under Salt, Drought, and Other Environmental Stress Conditions; Future Promises: Plant and Crop Adaptation and Cultivation Under Stressful Conditions; Climatic Changes, Elevated Carbon Dioxide, and Plant/Crop Responses; and Beneficial Aspects of Stress. Each of these parts comprises one or more chapters that, independently, discuss as many aspects of stress as possible.

Numerous figures and tables appear in this technical guide to facilitate comprehension of the presented materials. The volume also includes a comprehensive index to increase further the reader's accessibility to the desired information.

I would like to express my appreciation for the secretarial assistance that I received from Elenor R. Loya, College of Agriculture, University of Arizona, for the completion of this work.

In addition, my sincere gratitude is extended to Russell Dekker (Chief Publishing Officer, Marcel Dekker, Inc.), who supported this project from its initiation to its completion. Certainly, this job would not have been completed as smoothly and rapidly without his most valuable support and sincere efforts. Also, the patience shown by the Production Editor, Rod Learmonth, and his careful and professional handling of the material in this volume is greatly appreciated. The remarkable work of the copyeditor, Kitty McCullough, during the course of completion of this book is sincerely acknowledged.

The invaluable efforts of each and every one of the contributors who responded to my request for contributions to this volume are deeply appreciated. Their proficiency and knowledge in their area of expertise made this significant task possible.

Also, I thank my wife, Vinca, for her support in the completion of this work. Last, but not least, I would like to thank my son, Mahdi, who had great patience and understanding and let me take the time to complete this project that otherwise would have been spent with him.

Soil Salinity and Sodicity as Particular Plant/Crop Stress Factors

MOHAMMAD PESSARAKLI
University of Arizona
Tucson, Arizona

I. SZABOLCS
Research Institute for Soil Science and Agricultural Chemistry
of the Hungarian Academy of Science
Budapest, Hungary

INTRODUCTION

Salinity and sodicity problems are common in arid and semiarid regions, where rainfall is insufficient to leach salts and excess sodium ions out of the rhizosphere. In addition, these areas often have high evaporation rates, which can encourage an increase in salt concentration at the soil surface.

The presence of a cliche horizon and/or a cemented hardpan layer at varying depths plus insufficient precipitation for leaching often adds to the salt accumulation in these soils. Newly established irrigation projects, with improper planning and management practices, may also add salts to soils [1].

Soil salinity and sodicity problems are present in nearly every irrigated area of the world and also occur on nonirrigated croplands and rangelands. Thus, virtually no land is immune from salinization. Therefore, for sustaining life on earth, control of these problems and finding new ways to utilize these extensive saline and sodic soils and water resources, at least for agricultural purposes, are vital and urgent. Reclamation, or at least minimizing the effect of salinity and/or sodicity, is important and necessary. In this respect, proper utilization of water for both plant growth and soil salinity and sodicity control is probably of the greatest importance.

The main focus of this introductory chapter is to summarize general information on salt-affected (saline and sodic) soils and factors influencing their formation and reclamation.

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

SIGNIFICANCE OF SOILS IN RESPECT OF CROP STRESS

As far as all the crops are grown on soils, soil properties have substantial influence on the life conditions of plants and crops. In nature, usually particular plant species grow on specific soils. Thus, specific relationships exist between a particular soil and the vegetation cover of that specific soil. For example, Kreeb et al. [2] investigated soil and vegetation relationships associated with alkaline-saline soil surfaces.

Plant development and successful crop production require proper soil conditions, including adequate water and nutrient supply. Unfavorable soil conditions (environmental stress [3–5], salinity and/or sodicity [6,7], inadequate nutrient supply [8,9]) have an adverse effect on the life of the plants, sometimes seriously hindering their effective production.

Based on the above facts, we can speak of stress factors originating in the soil; that is, such unfavorable soil conditions which cause, or contribute to, the stress factors that plants and crops are exposed to.

It is impossible to list all or most of such factors in a short introductory chapter. Therefore, we limit the range of this chapter to a general description of soil behavior and its function in nature and production as well as to an outline of one of the most serious factors originating in salt-affected soils. For more in-depth information regarding salt-affected soils, the readers are referred to the more comprehensive available sources [10–31].

PLACE AND ROLE OF THE SOIL IN NATURE

It is generally accepted that the soil is a substantial part of the environment, comprising different substances and forming a special kind of ecosystem inside the given ecosystem, with various properties and attributes. It is also accepted that the soil of the continents is of high diversity, which is dealt with by several branches of soil science; for example, taxonomy, classification, survey, and mapping.

The soil, or the pedosphere, which is an environmental synonym of the soils of a given territory, has a specific place in nature. It is a natural body, similar to rocks, waters, or biota in the sense that they too have their own materials, mass and energy fluxes, development, and regularities. This fact should be mentioned because, not only in newspapers but also in technical literature, soils are frequently treated either as living substances or as nonbiological substances. Neither of these approaches is correct, because one of the characteristics of the soil is its complexity, the fact that it contains both living and nonliving substances, forming as a result of both biotic and abiotic processes.

The soil as a natural body is inseparable from the rocks and the crust of weathering on the surface of the continents from which it has developed, on the one hand, and from the biological processes on the other hand. The main characteristics that distinguishes the soil from the rocks is the result of biological processes: the production of organic matters by the activities of microorganisms, plants, invertebrates and other animals, and finally human beings which transforms the rocks into soils capable of supplying plants and crops with nutrients and water.

The processes of soil formation started concurrently with the appearance of life on the continents and continued during the billions of years of interactions between living substances and rocks under the influence of climatic conditions, with particular regard to the action of water, geomorphological patterns, and the time factor. As a result of their interactions, specific mass and energy fluxes formed the different soil types in various environmental conditions.

With the appearance of the human race on the face of the earth, even changes in the environment became different. Owing to human activities, the natural processes affected by biotic and abiotic factors accelerated and several others which were unknown or minimal before developed.

The role of soils in nature is complex and many sided, including biospheric, hydrospheric, and lithospheric functions. Their interaction is illustrated in Figure 1 [11], which clearly shows that

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

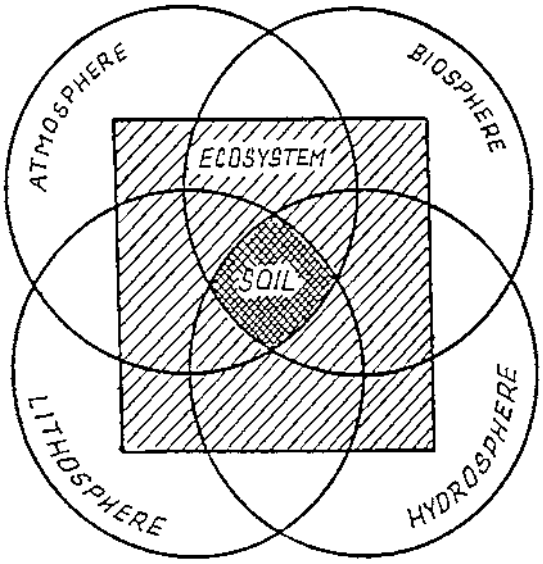

FIGURE 1 Schematic diagram of the interaction of lithosphere, atmosphere, biosphere, hydrosphere, ecosystems, and soils. (From Ref. 11.)

the soil is a specific body related to the ecosystem. Even the word *soil* is very often used as a synonym of ecosystem when characterizing the given ecological conditions in a certain place. If we want to be precise, we must agree that the ecosystem includes the pedon, in other words, the soils. However, the soil includes different phases (solid, liquid, gaseous), living and nonliving substances, plants, animals, and microbes and has its own energy and material fluxes. Therefore, it can be considered an ecosystem in itself. In this respect, when speaking of soils versus their plant cover, we can consider the soils of a given location as the basis, ladder, and foothold, for instance, in savannas, or in the tropical belt, a well-defined plant cover develops and very often the soil properties promote or limit the living conditions of certain plant species or associations.

Based on the above considerations, it can be accepted that certain soil types, when discussed as the habitat for certain plant associations, are often named as the ecosystem of the plant association concerned, as the pedon includes, apart from the plants, most of the components of the ecosystem.

Evidently the soil, as a specific natural entity, is far from being identical with the vegetation and, in spite of their close correlation, direct conversion between soil types and vegetation is hardly possible. Still there are soil types which, more or less, determine the ecological function for certain types of vegetation either by providing beneficial conditions for its development or by limiting the ecological conditions for other types of vegetation.

This is perhaps best demonstrated in the case of salt-affected soils where high electrolyte contents of extreme pH conditions limit the development of the majority of plants and serve as a habitat only for such species which can survive or tolerate the unfavorable conditions caused by the salinity and alkalinity of the soil. For example, the grass *Leptochloa fusca* that grows vigorously on the salt-affected soils can tolerate extremely saline and sodic (alkaline) conditions [25]. This species is also well adapted to the waterlogging encountered on saline and sodic (alkaline) soils. Other investigators [2,7,32,33] have also reported on the soil and vegetation relationships that specific plant types are adapted and growing on specific habitats. In such respects, salt-affected soils can be considered as habitat or ecosystems for halophytes and, if we agree on this, correlations can be found between the different types of salt-affected soils and their flora and fauna as components of the ecosystem.

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

In order to cast light on both the theoretical and practical aspects of such considerations, it is necessary to describe briefly the properties and grouping of salt-affected soils with regard to the possibilities of the occurrence and distribution of halophytes and xerophytes developing on them.

EXTENSION AND GLOBAL DISTRIBUTION OF SALT-AFFECTED SOILS

Nearly 10% of the total land surface is covered with different types of salt-affected soils. Table 1 demonstrates the distribution of salt-affected soils in the world [34], and it shows that no continent on our planet is free from salt-affected soils. They are distributed not only in deserts and semidesert regions, but also frequently occur in fertile alluvial plains, river valleys, and coastal areas close to densely populated areas and irrigation systems [11–14,16,17,26].

Figure 2 shows the distribution of salt-affected soils throughout the world [12,17].

TABLE 1 Salt-Affected Soils on the Continents and Subcontinents

Continent	Area (millions ha)
North America	15.7
Mexico and Central America	2.0
South America	129.2
Africa	80.5
South Asia	87.6
North and Central Asia	211.7
South-East Asia	20.0
Australasia	357.3
Europe	50.8
Total	954.8

DEVELOPMENT AND GROUPING OF SALT-AFFECTED SOILS

In spite of the fact that the properties and attributes of salt-affected soils have been well known for a long time, it is appropriate to give a brief definition of this group of soils right at the start, because the salinity and sodicity (alkalinity) as well as the acidity of soils are substantial stress factors seriously affecting the productivity of the land [3–9,12,17,29,35–38].

Salt-affected (i.e., saline, saline-sodic, and sodic) soils usually have low biological activity both because of osmotic and ionic effects of salts and due to limitation of carbonaceous substrates. Rao and Pathak [39] reported that microbial growth was depressed in sodic (alkali) soils due to, at least in part, limitation in carbon substrate (carbon stress) and in saline soils due to salt stress.

For detailed information on the formation of salt-affected soils, the readers are referred to Szabolcs [11,12] and Pessarakli [17].

Salt-affected soils can be characterized as soils formed under the dominant influence of different salts in their solid or liquid phases, which will then have a decisive influence on the development, characteristics, physical, chemical, and biological properties, and eventually the fertility of the soil. Whenever and wherever this phenomenon occurs, it produces specific formations of soils where the high electrolyte concentration and its consequences overshadow the former soil-forming processes or former soil properties and environmental conditions, often radically changing them.

High electrolyte concentration is the only common feature of all salt-affected soils. Their chemistry, morphology, pH, and many other properties may be different depending on the character of salinization and/or alkalization.

Salt-affected soils, in the broader sense, can be divided into the following groups:

1. Saline soils that develop under the influence of electrolytes of sodium salts with nearly neutral reaction (dominantly Na_2SO_4, NaCl, seldom $NaNO_3$). These soils occur mainly in arid and semiarid regions and form a major part of all the salt-affected soils of the world. High contents of soluble salts accumulated in these soils can significantly decrease their value and productivity.
2. Sodic (alkali) soils that develop under the influence of electrolytes capable of alkaline hydrolysis (mainly Na_2CO_3 and $NaHCO_3$ and seldom Na_2SiO_3 and $NaHSiO_3$). This group is well extended in practically all the climatic regions from the humid tropics to beyond the polar circles and their total salt content is usually lower than that of saline soils, sometimes even strongly sodic (alkaline). Virgin sodic (alkali) soils have a high pH and high exchangeable Na and are often barren. Sodic soils exhibit poor physical conditions that adversely influence water and air movement in the soils. Sodicity causes soil erodibility and impairs plant growth [27].
3. Salt-affected soils that mostly develop owing to the presence of $CaSO_4$ (gypsiferous soils) or, rarely, in the presence of $CaCl_2$. Gypsiferous soils can mainly be found in the arid and semiarid regions of North America, North Africa, the Near, Middle, and Far East, and also in Australia.
4. Salt-affected soils which develop under the influence of magnesium salts. This group occurs in arid, semiarid, and even semihumid regions and has a particular significance, especially those soils which have a heavy texture.
5. Acid-sulfate soils whose salt content is composed mainly of $Al_2(SO_4)_3$ and $Fe_2(SO_4)_3$. This type of salt-affected soils is broadly extended in the tidal marsh areas along the seashores of all the continents. These soils are particularly common in, for example, North Europe, the western and eastern coastlines of Africa, and along the coastline of Southeast India, and develop on sulfurous marine sediments.

Inland acid-sulfate soils can also be found in different areas of the world, such as the western territories of the United States, Asia Minor, and China. Such soils developed as a result of fluvial glacial processes and have had no connection with seashores in recent geological times.

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

Evidently the different groups of salt-affected soils have diverse physicochemical and biological properties besides the one they have in common; that is, a comparatively high electrolyte content.

The grouping of the salt-affected soils and their properties causing plant and crop stress are presented in Table 2. The five groups in Table 2 represent the formations of different salt-affected soils described above, indicating their chemical types, the environmental conditions where they dominate or occur, the pattern of their main adverse effect on production, and the basic methods of their reclamation. For detailed information on formation and reclamation of salt-affected soils see Szabolcs [11,12] and Pessarakli [17].

In Table 2, the adverse properties of different salt-affected soils causing crop stress are also included. From these, it is clear that, in various groups, different properties are responsible for hindering the development of plants and crops by causing stress.

In saline soils, it is the high salt concentration in the solid and liquid phases which results in high osmotic pressure, hindering the normal development of plants. the stress factor is the salinity with all its disadvantageous consequences of plant life. Apart from this, some compounds of the salt content of these soils, for example, chlorides as toxic elements, also act as one of the stress factors.

In sodic (alkali) soils, as a rule, not the high salt concentration but the sodic (alkaline) pH value is the stress factor, particularly in cases where there is a high concentration of sodium carbonate in the solid and liquid phases of the soil. The high pH hinders the life function of crops and limits their development.

In another group of sodic (alkali) soils, which sometimes does not have very alkaline pH value (solonetz type), the comparatively low concentration of sodium salts capable of sodic (alkaline) hydrolysis constitutes a stress factor through its action, resulting in poor water physical properties in the soil. As a consequence of this phenomenon, the wilting point in the soil increases and the plants suffer from water deficiency, even in wet soils, owing to the swelling of clay saturated with sodium ions.

In magnesium soils, which have not been adequately studied, the combination of toxic effect, calcium deficiency, and poor soil physical properties are the stress factors.

In gypsiferous soils, the acidic pH, and sometimes the toxic effect of the high gypsum content, contribute to the appearance of stress factors for plant and crop life in areas with large extensions of intensively gypsiferous soils.

In acid-sulfate soils, the very high acidity, with a pH sometimes below 2, poses stress with all the adverse effects of extreme acidity. Furthermore, the high aluminum content of the soil solution has an intensive toxic effect. Apart from this, the temporary or permanent waterlogging in such soils acts as a stress factor hindering the normal air and nutrient regimen necessary for plant life in these soils.

Besides the salt-affected soils developing as a result of natural soil-forming processes, the so-called secondary salt-affected soils have an increasing importance that is both scientific and practical. Secondary salt-affected soils are those which have been salinized owing to manmade factors, mainly as a consequence of improper methods of irrigation. The extension of secondary salt-affected soils is rather sizeable, and this adverse process is as old as irrigated agriculture itself. Ancient civilizations in Mesopotamia, China, and Pre-Columbian America fell as a consequence of the salinization of irrigated land. The process is also advancing vigorously at present, and more than half of all the irrigated lands in the world are under the influence of secondary salinization and/or alkalization.

When speaking of the manmade factors of salinization, we also have to mention potential salt-affected soils which are not salt-affected at present, but in case of the extension of irrigation, deforestation, overgrazing, and other manmade measures, can and will be salinized unless the necessary preventive procedures are undertaken in due time. No global records are available of the size of potential salt-affected soils; however, the area that they cover is larger than that of existing salt-affected soils.

Secondary salt-affected soils can be divided into the following two categories: secondary

Marcel Dekker, Inc.

TABLE 2 Grouping of Salt-Affected Soils and Their Properties Causing Plant and Crop Stress

Type of salt-affected soils	Electrolyte(s) causing salinity and/or alkalinity	Environment	Properties causing plant and crop stress	Methods for reclamation
Saline	Sodium chloride and sulfate (in extreme cases nitrate)	Arid and semiarid	High osmotic pressure of soil solution, toxic effect of chlorides	Removal of excess salt (leaching)
Alkali	Sodium ions capable of alkaline hydrolysis	Semiarid, semihumid, and humid	High (alkali) pH, poor water physical conditions	Lowering or neutralizing the high pH by chemical amendments
Magnesium	Magnesium ions	Semiarid and semihumid	Toxic effect, high osmotic pressure, Ca deficiency	Chemical amendments, leaching
Gypsiferous	Calcium ions (mainly $CaSO_4$)	Semiarid and arid	Low (acidic) pH toxic effect	Alkaline amendments
Acid sulphate	Ferric and aluminium ions (mainly sulfates)	Seashores and lagoons with heavy, sulfate-containing sediments, diluvial inland slopes and depressions	High acidity and the toxic effect of aluminium	Liming

formation of salt-affected soils caused by irrigation and secondary formation of salt-affected soils caused by human activities other than irrigation.

Secondary Formation of Salt-Affected Soils Caused by Irrigation

In spite of the negative experiences, the salinization of irrigated and surrounding areas has not diminished. On the contrary, it is still on the increase.

According to the estimates of the Food and Agriculture Organization (FAO) and the United Nations Educational, Scientific, and Cultural Organization (UNESCO), as much as half of all the existing irrigation systems of the world are, more or less, under the influence of secondary salinization, alkalization, and waterlogging. This phenomenon is very common not only in old irrigation systems but also in areas where irrigation has only recently begun.

According to the estimates of the above-mentioned agencies, 10 million hectares of irrigated lands are abandoned yearly because of the adverse effects of salinity due to irrigation, mainly secondary salinization and alkalinization.

The mentioned losses and damages are not evenly distributed among the irrigating countries. In some of them, the damage may be relatively small, whereas in others, it actually constitutes the major problem in agriculture or even in the national economy of the country in question. In this respect, unfortunately, there are countless sad examples. In Pakistan, Ahmad [40] carried out statistical analyses in respect of secondary salinized land. According to his data, out of 35 million acres (approximately 16 million ha) of total irrigated territory, salinized areas account for 5.3 million acres (approximately 2.4 million ha) after a few years of irrigation. He indicated among the causes of secondary salinization in Pakistan the joint effect of irrigation and ground water. According to Zavaleta [10], practically all irrigated alluvial soils in Peru show the features of salinity and sodicity (alkalinity). It is known from FAO reports and the papers of Kovda [41] that more than 40% of irrigated soils in Iraq and Iran is affected by secondary salinization. In a country report on salinity in Syria, the FAO [42] estimated the adverse effects of salinity as follows:

1. In more than 20,000 ha, salinity developed to a level where these soils had to be taken out of cultivation, and the loss is estimated at a total of 30,000 tons of cotton per year.
2. In about 30,000 ha, the yield decreased by 50%, and the total loss is estimated at 20,000 tons of cotton per year.
3. In about 60,000 ha, the yield decreased by 20%, and the total loss is estimated at about 18,000 tons of cotton per year.

At present, no continent is free from the occurrence of this very serious phenomenon. In Argentina, 50% of the 40,000 ha of land irrigated in the 19th century are now salinized. In Australia, secondary salinization and alkalization take place in the valley of the River Murray, and in Northern Victoria, 80,000 ha have been affected. The same phenomena can be observed in Alberta, Canada, and similar processes have been recorded in the northern states of the United States, where irrigation was introduced much later than in the dry western states. It is noteworthy that these last examples, and many other irrigated regions, are far from being arid areas, and the majority of salt accumulating is associated with the sodium salts capable of sodic (alkaline) hydrolysis and not with the neutral sodium salts that we are familiar with in desert and semidesert areas.

Secondary Formation of Salt-Affected Soils Caused by Human Activities Other Than Irrigation

When speaking of secondary salinization, most people have irrigation and drainage in mind. However, there are also other anthropogenic factors causing these adverse phenomenon. It is true that the majority of secondary salt-affected soils develop as a result of improper methods of irrigation,

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

but there are other human effects which more and more often trigger this process in many places both in arid and humid areas.

Some of these anthropogenic processes include, but are not limited to, the following:

Overgrazing

This process occurs mainly in arid and semiarid regions, where the natural soil cover is poor and scarcely satisfies the fodder requirement of rather extensive animal husbandry. If the natural vegetation is sparse or annihilated on account of overgrazing, progressive salinization develops and, step by step, the scarcity of the plant cover becomes increasingly pronounced. Sometimes the process ends in desertification, because even the poor pasture diminishes and no other fodder resources are available. According to Theunissen [43], the gradual decline in the ecological condition of natural pastures as a result of overgrazing and the application of insufficient management decisions, coupled with the detrimental effects of long-term drought, has left extensive areas of high-potential grazing land in southern Africa in urgent need of restoration. However, owing to the limited number of grasses currently available for rehabilitating and restoring the vast number of different habitats encountered, selecting indigenous grasses suitable for restoration of denuded areas in the arid and semiarid grasslands of southern Africa was initiated.

Deforestation in Semihumid and Semiarid Areas

Particularly in the past few decades, it has become evident in many tropical and subtropical countries that deforestation results in the salinization and alkalization of soils due to the effects of soil migration both in the upper and lower layers. In South East India, for example, vast territories of former forest land became intensely saline and sodic (alkaline) in a few years after the annihilation of the woods. Similar phenomena occurred in, for example, the forest steppe areas in Russia, Iran, East-Central Europe, and Latin America.

Salinization Caused by Contamination with Chemicals

In spite of the fact that the amount of chemicals applied in agriculture is practically negligible in comparison with the salt content of several soils, we have considered the fact that this kind of salinization more and more often occurs in modern intensive agricultural production, particularly in greenhouses and intensive farming systems. When production takes place in semiclosed systems (e.g., greenhouses), where the chemicals applied will not be removed regularly, the accumulation of salts or their components becomes possible in the upper layer of the soil, resulting in salinity and sodicity (alkalinity). In Japan, the Netherlands, and other countries with intensive agriculture, and particularly horticulture, such types of salinization more and more frequently appear, causing serious losses of crop yields.

Accumulation of Airborne or Waterborne Salts

Owing to the concentration of industrial plants, the emission of chemical compounds may accumulate in the soil and, if their concentration is high enough, they result in salt accumulation in the upper layer of the soil.

A similar phenomenon appears when, owing to water system regulations, sludge water disposal, and other hydrotechnical measures, water with considerable salt concentration contaminates the upper soil layer, causing salinization and/or alkalization.

RECLAMATION OF SALT-AFFECTED SOILS

Population growth and increasing demand for food and agricultural products necessitate using the salt-affected soils and marginal lands for food production. These soils are needed for the agricultural extension, and hence reclamation is required.

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

Reclamation is needed on the millions of hectares of slowly permeable salt-affected (i.e., saline-sodic and sodic) soils throughout the world [44].

Different techniques have been used for reclamation of salt-affected soils. Saline soils are usually reclaimed by leaching the salts out of the soil through irrigation and drainage systems. Whereas, reclamation of sodic (alkaline) soils requires application of chemical amendments followed by the leaching process.

Present recommendations for reclamation of the salt-affected soils are usually based only on relatively simple and often empirical relations. Various amendments and management strategies have been used for reclamation of the salt-affected soils. To evaluate particular reclamation strategies, some specific considerations should be noted as follows:

1. Quantity of water needed
2. Quality of water needed
3. Quantity of amendments to be used
4. Type(s) of amendment(s) to be used
5. Time required for reclamation to be completed

Chemical reactions such as cation exchange, precipitation, and dissolution of solid phases (reclamation amendments) and the soil hydraulic properties and corresponding changes in the water flow and solute transport rates must be considered [31].

Among the various reclamation practices, a combination of added gypsum amendment and crop rotation usually has been proven to be the best.

Since reclamation of salt-affected (saline-sodic and sodic) soils by chemical amendments has become cost effective and requires high capital investment, cultivation of salinity and sodicity-tolerant plants ''saline agriculture'' may be another alternative.

Cultivation of different salinity and sodicity-tolerant plant types and species has been used by several investigators (i.e., grasses [7,25,43], agronomic crops [45], forest species [38,46–48]) for reclamation purposes. These plants can mobilize the native lime (calcium carbonate, $CaCO_3$) in these soils through root action, a substitute for the chemical approach. Qadir et al. [7], studying the combination of chemical amendments and biological (using plants) reclamation technique, reported that the soil treated with gypsum at a high rate (100% GR) removed the greatest amount of Na^+ from the soil columns and resulted in a marked decrease in soil salinity (EC, electrical conductivity) and sodicity, sodium absorption ratio (SAR). The performance of grass treatment in enhancing the leaching of Na^+ was between the gypsum treatments.

According to Kumar [25], the grass *Leptochloa fusca* is very useful and effective in the reclamation of salt-affected soils. This plant can tolerate extremely saline and sodic (alkaline) conditions. Since its growth is not affected by gypsum application, planting with *Leptochloa* is an alternative biological rather than a chemical method for the reclamation of sodic (alkaline) soils. This plant is also well adapted to the waterlogging encountered on saline and sodic (alkaline) soils. The plant improves the soil physical, chemical, and biological properties so that within 2 or 3 years many commercial and forage crops can be grown on the soil [25]. *Leptochloa* excretes salts through specialized glands and is, therefore, reasonably palatable to farm animals. It must be noted that because of its vigorous growth on sodic (alkaline) soils, *Leptochloa* does not allow satisfactory growth of companion plant species, especially in the initial years of soil reclamation.

Subramaniam and Babu [48] also used a forest shrub species for reclamation of sodic soils. According to these investigators [48], *Sophora mollis*, which grows as a shrub to a medium-sized tree and is used for both fodder and firewood, can be used in the reclamation of sodic (alkaline) soils.

Although slow but definite improvement is achieved in the physicochemical properties of the salt-affected soils by encouraging the vegetation growth on such lands. The tree species in general are effective in improving the soil properties as reflected by the changes in physicochemical characteristics of the soil such as bulk density (BD), water-holding capacity (WHC), hydraulic conductivity (HC), and pH, EC, OC (organic carbon), N (nitrogen), and exchangeable cations (Na^+ and Ca^{2+}) [46].

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

Owing to the low biological activity and depressed microbial growth of salt-affected (i.e., saline, saline-sodic, and sodic) soils, there is a need for applying organic amendments (i.e., plant residue or manure) during sodic (alkali) soil reclamation. In reclamation of saline soils, organic amendments must be applied following the leaching process.

Kumar et al. [35] conducted a combination of biological and chemical reclamation studies on a highly sodic (alkaline) soil. These investigators [35] found that rice produced satisfactory yields in the first year of gypsum application, but sorghum and *Sesbania* yields were very poor. The yield of *Leptochloa* was not affected by gypsum application. In their crop rotation practice, Kumar et al. [35] reported that the green forage yield of sorghum was greatest when sorghum followed *Leptochloa* grown for 2 years and the harvested grass was left to be decomposed on the site.

In a biological reclamation study of saline soils, Helalia et al. [49] reported that amshot grass significantly reduced the soil salinity compared with either ponding or gypsum application, and this grass produced a higher fresh yield than clover cultivated in such soils.

The above findings indicate that biological reclamation with the salinity- or sodicity-tolerant plants (i.e., *Leptochloa*, grasses, shrubs, or trees) is a proper substitute for chemical reclamation with gypsum, and the former has an economic advantage over the latter.

Compost or any other organic materials is recommended to be used during the reclamation process of the salt-affected soils. The results of a field experiment conducted by Avnimelech et al. [24] verified that compost application improved both physical and chemical conditions of saline and sodic (alkaline) soils. Compost application to such soils is expected to release acids which would ultimately lead to the replacement of exchangeable sodium by calcium. In addition, compost application would stabilize soil structure and enhance plant growth. These investigators [24] found that the municipal solid-waste compost application was equivalent or even superior to the addition of gypsum, the most common amendment used to reclaim sodic (alkaline) soils. This was evident from the substantial increase in crop yields. The combined application of compost and gypsum raised yields to the levels equal to that of the commercial fields.

In a field experiment, Batra et al. [30] compared the microbiological and chemical amelioration of a highly deteriorated sodic (alkaline) soil using two reclamation technologies:

1. Growing Karnal grass (*Leptochloa fusca*) as a first crop with no chemical amendment (biological reclamation)
2. Gypsum application as a chemical amendment for different crop rotations

These investigators [30] reported that the microbiological properties changed more than the chemical properties of sodic (alkali) soil as the time period advanced.

In a biological reclamation study carried out on saline soils, Apte and Thomas [50] found that a brackish water, nitrogen-fixing cyanobacterium, *Anabaena torulosa*, could successfully grow and fix nitrogen on moderately saline soils (EC of 5.0–8.50 dS m^{-1}). These investigators [50] reported that cyanobacterium exhibited high rates of nitrogen fixation and substantially enriched the nitrogen status of saline soils. However, permanent removal of Na^+ from saline soils using cyanobacteria or any other microorganisms may not be possible, since Na^+ is released back into the soil subsequent to the death and decay of cyanobacteria or other microorganisms. Amelioration of soil salinity by simultaneous application of *Anabaena torulosa* during crop growth seems to be an attractive possibility for reclamation, especially since it can also supplement the nitrogen requirement of the crops growing on these soils.

Blue-green algae that tolerate excess Na and grow extensively on the soil surface in wet seasons was found to be effective in sodic soils reclamation [51]. However, a permanent reclamation of such soils by using only blue-green algae as a biological amendment to achieve sodic (alkali) soil reclamation is neither possible nor comparable with an effective chemical amendment such as gypsum.

In the reclamation process of the saline soils, De Villiers et al. [33] compared different annual and perennial species. Of the six species tested, the perennials seemed to be more effective and better suited for rehabilitation purposes under saline soil conditions.

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

The type of chemical compound being used also influences the reclamation process of salt-affected soils. Sharma and Upadhyay [52] reported that, among the up-to-date known chemical compounds, cyclohexathiazenium chloride (S-6N-4)-2+Cl-2 is the best and the most suitable chemical to reclaim the sodic (alkaline) soil at any pH of the soil.

When good-quality water is not available for leaching the salts out of the soil, low-quality water can be used for the initial stages of reclamation. In this regard, Singh and Bajwa [53] studied the effects of gypsum and sodic irrigation on the precipitations of Ca^{2+} and removal of Na^{+} from a sodic soil reclaimed with different levels of gypsum and growth of rice in a greenhouse experiment. Dubey and Mondal [22] also used low-quality saline water in conjunction with organic and inorganic amendments for the initial stages of reclamation of sodic soils. Using low-quality water, Joshi and Dhir [54] evaluated the rehabilitation of degraded sodic soils using residual sodium carbonate water (low-quality water) combined with gypsum treatment and found that the combination treatment was effective in lowering the soil SAR and improved the water infiltration rate. In the first year of gypsum treatment, it was possible to establish the crop. In the second year, a moderate production of wheat (2610 kg ha^{-1}) and raga (*Brassica* sp) (2000 kg ha^{-1}) was obtained [54].

Using the most common technique, irrigation water and drainage system, for reclamation of the salt-affected soils, the results of an investigation carried out by Millette et al. [23] demonstrated the ability of fall irrigation to leach salts from the surface soil during a period of low consumptive use, which could lead to reclamation. Long-term monitoring would be required to determine whether a further and permanent decline in salinity could be achieved.

Concerning other reclamation materials and techniques, results of Jones et al. [55] indicate that acid whey is effective in reclaiming sodic soil by lowering ESP (exchangeable sodium percentage), SAR, and pH and by improving the infiltration rate. Rao and Leeds Harrison [56] used simulation models for desalinization of a drained two-layered saline soil using surface irrigation for different water management practices to increase leaching efficiency. Based on image elements and their correlation with the ground features, Rao et al. [57] suggested categorizing sodic soils in moderately and strongly sodic groups. The delineation thus made would help the execution of a reclamation program for sodic soils at the study sites. Abdel-Hamid et al. [58] monitored soil salinity in the northern Nile delta of Egypt by using data collected via landsat and the geographical information system (GIS). The collected data were used in making recommendations for reclamation of the saline soils of the Nile delta area.

The vast areas of salt-affected soils still remain a burden for the affected societies, particularly the developing countries, where the adequate resources needed to reclaim them with the available technology involve initial heavy investments. The process of degradation, which has been due to reckless destruction of vegetation, can be reversed by reestablishment of vegetative cover which results in slow but definite improvement in such soils. This phenomenon has been very much demonstrated by various parameters influencing the soil welfare in several investigations which show a positive sign of improvement both in terms of physical and chemical properties of the salt-affected soils. Such soils should, therefore, be brought under any type of vegetation (i.e., sod, shrub, tree) cover, if not found to be economical for regular farming and growing agronomic crops [46].

Even by the execution of the reclamation processes, nutrient status and their behavior in salt-affected soils (i.e., saline-sodic and sodic) during reclamation by crop rotation and chemical amendments requires a comprehensive assessment. This is usually because some soil nutrients are also lost and leached out of the soil during the leaching process of the soluble salts and the exchangeable sodium. In this regard, several investigators [8,9,36–38] have studied nutrient status and behavior during the reclamation processes. Swarup et al. [36] reported the effect of gypsum on the behavior of soil phosphorus during the reclamation of a sodic soil. According to Bhojvaid et al. [38], soil nutrient status under the tree plantation was higher than that of the nonsodic farm soil. This finding confirms that successful tree plantation may restore the productivity and fertility of highly degraded sodic soils.

Regardless of the techniques used in reclamation of salt-affected soils, postreclamation management practices, that is, proper choice of crops, crop rotation, method of irrigation, quality and

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

quantity of water used for irrigation and reclamation, fertilization, and the economics of reclamation, must be taken into consideration and followed to achieve successful results.

CONCLUSIONS

In this chapter, information has been given on the important functions of the soil in relation to soil-originated stress factors for plant and crop development as well as a little more detailed information of particular problems related to salt-affected soils and their formation and reclamation.

The properties of the stress factors for plant and crop growth originating in soil are diverse and many sided. We know comparatively little about the status of salt-affected soils and, particularly, for finding methods to improve the situation of reclaiming these soils (salt-affected soils) and ensure better plant and crop development. Therefore, target-oriented studies of the different kinds of soil-originated stress factors for plant and crop growth are necessary so that the complex correlations and the actions in the soil-plant-water system can be understood for the purpose of a better characterization of stress factors on the one hand and improving the environmental and production conditions on the other hand.

Influence of Sodium on Soils of Humid Regions

V. P. EVANGELOU

Lexington, Kentucky

L. M. MCDONALD, JR.
West Virginia University
Morgantown, West Virginia

INTRODUCTION

A salt-affected soil is defined as one that has been adversely affected to the extent that it is no longer suitable for the growth of most crops by the presence or action of soluble salts. This group of soils includes both saline and sodic soils. James et al. [1] defined a saline soil as one that contains a quantity of soluble salts sufficient to interfere with the growth of most crops. On the other hand, a sodic soil possesses enough exchangeable sodium (ExNa) also to have an adverse effect on the growth of most plants. A saline-sodic soil contains both soluble and exchangeable Na at levels that impose stress on plant growth.

Salt-affected soils are a common feature of arid and semiarid landscapes. In humid regions, soils may become salt affected when they are irrigated with brackish water or treated sewage effluent, intruded by sea water, or contaminated with oil well brines. Some differences exist between salt-affected soils found in arid and semiarid regions and those found in humid and tropical regions. Sodic soils found in arid and semiarid regions are usually associated with high pH and dominated by the 2:1–type clay minerals. Salt-affected soils in humid or tropical regions generally have low pH, and they are often, but not always, dominated by 1:1–type clay minerals.

The loss of plant productivity from the excess of salinity is a worldwide problem. Where salinity is a problem, an effective use of soil and water resources dictate the production of agricultural crops. Numerous laboratory and field experiments have been conducted in order to determine the plant growth and yield response to various levels of soil salinity. For example, Shalhevet et al. [2] found that the yield of peanuts grown in artificially salinized plots was reduced to 50% at EC_e (EC_e = specific electrical conductance of saturated extract) of 4.7 dS m^{-1} and by 20% at EC_e of 3.8 dS m^{-1}. Additionally, these investigators reported that salt tolerance was much higher during germina-

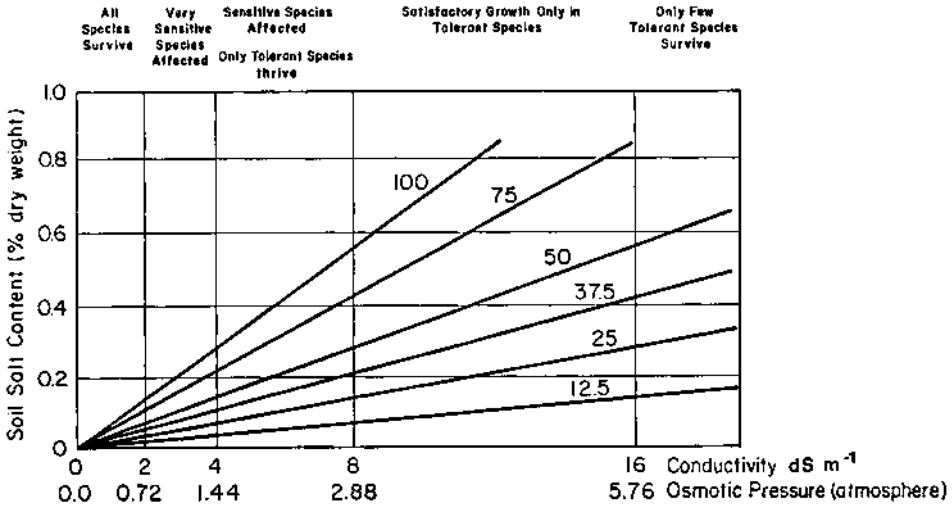

FIGURE 1 Relationship between electrical conductivity (EC) of soil solution and salt content. The numbers in the plot represent grams water needed to saturate 100 g soil. (It takes 12.5 g water to saturate 100 g sand, 100 g water to saturate 100 g clay, and about 50 g water to saturate 100 g of most Kentucky soils.) (From Ref. 6.)

tion than during subsequent growth. A 50% reduction in germination occurred at $EC_e = 13$ dS m^{-1}. Shalhevet and Yaron [3] reported a 10% yield reduction in tomatoes for every 1.5 dS^{-1} increase in EC_e above 2 dS m^{-1}. The adverse effects of soil salinity on plant growth and productivity vary with the type of plant being grown. A summary of the general response of plants to salinity is presented in Figure 1.

The presence of salinity in the soil solution resulting from either indigenous salt or that through irrigation can affect plant growth in three ways: (a) It can increase the osmotic potential and hence decrease water potential, thereby reducing water availability, the *osmotic effect*. (b) It can increase the concentration of certain ions that have an inhibitory effect on plant metabolism, a process known as the *specific-ion effect* [1]. (c) It can adversely affect soil structure such that water permeability and soil aeration are diminished [4], the *physicochemical effect*.

Osmotic Effect

The osmotic effect on plant growth is related to water availability or soil-water potential. Under normal field conditions, the soil-water potential, U_w, is determined by the osmotic potential, U_s, the matrix potential, U_m, and the gravitational potential, U_p. Mathematically, U_w is described by the equation

$$U_w = U_m + U_s + U_p \tag{1}$$

At any given matrix potential and a fixed gravitational potential, an increase in salinity is manifested by a reduction in U_w [1]. Bresler et al. [5] pointed out that physicochemically it can be shown that U_s of a solution is directly related to total dissolved solids (TDS). The relationship between U_s and TDS can be expressed by the following equation [6]:

$$U_s \text{ (bar)} = -5.6 \times 10^{-4} \times \text{TDS (ppm)} \tag{2}$$

Another way to express the above relationship is through the specific conductance of a soil's solution. The EC measurement is based on the principle that the amount of electrical current transmitted by a salt solution will increase as salt concentration in the solution increases. The U.S. Salinity Laboratory Staff [6] described the relationship as

$$U_s \text{ (bar)} = -0.36 \times \text{EC (dS m}^{-1}\text{)} \tag{3}$$

Specific Ion Effect

An excess of Na ions in the soil solution can be inhibitory to various plant physiological processes. Hausenbuiller [7] and Donahue et al. [8] reported that the sensitivity of plants to various Na levels in the soil solution and/or exchanger phase is highly dependent on plant species as well as the stage of plant development. Symptoms of Na toxicity can be easily seen when the leaves of sensitive plants contain approximately 0.25% Na on a dry-weight basis [1,5]. The Na^+ toxicity is characterized by leaf tip burn, necrotic spots, and limited leaf expansion, which in turn directly reduces plant photosynthesis and yield [9,10].

Obvious specific effects of Na^+ on plant physiological processes are observed when plants are grown in high-Na environments. High sodium concentrations have been shown to increase K^+ leakage and decrease root elongation [11]. Meire and Poljakoff-Mayber [12] reported that, when Na^+ is present in high concentration in the solution, transpiration rate of peas was reduced in proportion to salinity. Porath and Poljakoff-Mayber [13] found that Na^+ also affected the respiratory pathway of pea roots. High Na^+ in soil solution also has an antagonistic effect on Ca^{2+} and Mg^{2+} uptake [9]. Geraldson pointed out that salinity caused Ca deficiency symptoms in tomato, pepper, and celery plants. This is most likely caused by Na^+ displacing Ca^{2+} from membranes of root cells [15].

Physicochemical Effect

An excess of exchangeable Na is harmful to plants principally because it induces undesirable physical and chemical conditions in soils. The dispersion effect of exchangeable Na on clays is related to the highly hydrated nature of this ion. Soils disperse only when they are in equilibrium with an electrolyte solution under the ''flocculation value.'' The flocculation value depends on solution composition (sodium adsorption ratio, SAR), solution ionic strength, clay mineralogy [16–18], and pH [19,20]. For example, flocculation values for Na/Ca–montmorillonite are 3, 4, and 7 $mmol_c\ L^{-1}$ and 6, 10, and 18 $mmol_c$ L-1 for Na/Ca–illite with exchangeable sodium percentage (ESP) values of 5, 10, and 20, respectively [21].

Clay dispersion causes modification of soil pore distribution, which in turn affects soil hydraulic conductivity. An increase in Na levels in the soil solution or on the exchange phase (ESP) causes soil-saturated hydraulic conductivity to decrease [22–24].

The magnitude of ESP is related to the relative ratio of Na to Ca in the solution phase, also known as sodium adsorption ratio. An empirical relationship between ESP and SAR representing soils of the arid West was developed by the U.S. Salinity Laboratory Staff [6]. This ESP-SAR relationship is as follows:

$$\text{ESP} = \frac{100(-0.0126 + 0.014575\ \text{SAR})}{1 + (-0.0126 + 0.01475\ \text{SAR})} \tag{4}$$

where SAR in $(\text{mmol L}^{-1})^{1/2}$. When SAR is approximately in the range of 10–15, the ESP is also in the range of 10–15. In this ESP range, soils of the arid West will undergo dispersion. However, this relationship does not apply to all soils.

General Information on Saline-Sodic Soils

The removal of sodium from the soil profile of any given salt-affected soil is necessary, because Na is one of the most pronounced ions that influences plant growth and yield in salt-affected soils

[25]. Sodium is not only toxic to most plants because of its specific ion effect but it also influences certain soil properties. The major concern is the eventual deterioration of soil structure, resulting in decreased water infiltration and gas exchangeability [5].

Management and reclamation of salt-affected soils are necessary to maintain, or increase, their productivity. At least three processes take place during reclamation of a sodic soil: (a) the Na^+ on the exchange complex is replaced by Ca^{2+}; (b) the soil-saturated hydraulic conductivity is improved following Ca application; and (c) sodium salts are removed from the soil profile through leaching [1]. Thus, reclamation of salt-affected soils often requires the removal of excess soluble salts as well as reduction of the soil ESP (see Ref. 26 and references therein). The only proven method to reduce the soluble salt concentration in the root zone is through leaching. Reduction of the ESP is more difficult, because sodium ions adsorbed on exchange sites must first be replaced with divalent cations and then be leached from the root zone. According to Hoffman et al. [25], the amount of leaching required is dependent on the salt content of irrigation water, salt tolerance of the crops, climatic conditions, and soil and water management practices.

Imhoff Cone

In reclaiming salt-affected soils, the dispersion and hydraulic conductivity properties should be considered along with their exchange behavior. In this chapter, clay dispersion is based on the Imhoff cone technique. This Imhoff cone is commonly used by engineers to determine settleable solids. Settleable solids are the particles that settle in the bottom of an Imhoff cone during 1 h of settling [27].

In this chapter, the utility of Imhoff cone test results in predicting relative suppression in soil hydraulic conductivity is demonstrated. Such predictive potential–based Imhoff cone results (an engineering standardized test for evaluating settleable solids) will allow us to classify sodic soils with respect to their potential to undergo dispersion and/or restrict water movement. The results of this evaluation are presented in the latter portion of this chapter.

General Objectives

The effect of clay dispersion on saturated hydraulic conductivity in a soil is well established. However, there is a need for information on the influence of saturated hydraulic conductivity by various combinations of ionic strength, SAR, and pH for soils that have developed under temperate climatic regimes.

The U.S. Salinity Laboratory Staff [6] reported that an ESP of 15 is considered as the critical value above which most crop plants will not grow well because of adverse soil physicochemical effects induced by the presence of sodium salts. However, this threshold ESP value represents soils of the arid West and may not be universally applied to all soils. There is a great deal of information on the behavior of sodium chloride in soils and in soil solution suspensions [6,21]. However, most of this research pertains to soils of the arid West, which are often alkaline and consist mostly of 2:1 clay minerals. In the temperate regions of the United States, soils are often acid, their mineralogy is highly mixed (1:1 plus 2:1 clay minerals), and the 2:1 minerals are highly interlayered.

There is a need to understand sodicity and reclaimability of soils with a mixed type of charged site mineralogy (permanent plus variable charge), because (a) the ESP-SAR relationship has not been extensively investigated for these soils, which are present in the temperate region of the United States, and (b) brine discharges from oil wells have become a problem in the temperate regions of the United States.

Oil production often occurs in geographical locations where oil is not in abundant supply and environmental safeguards are not in place. Such oil wells, also known as ''stripper wells,'' are producing a large quantity of brine. This brine is often discharged into agricultural lands and/or into natural water supplies. In the state of Kentucky, it has been estimated that more than 375,000 L of brine per day is discharged onto land and surface waters. These brines contain approximately

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

0.5 mol L^{-1} sodium chloride. Similar brine problems exist in many other southeastern and northeastern states. In the state of Ohio, for example, approximately 16 million L of brine per day is produced from such wells [28].

Information is needed on temperate region soils regarding their reactions with Na^+, the critical Na^+ loads under which these soils undergo dispersion, and to predict such critical Na^+ loads. This information is needed by farmers to reclaim brine-contaminated farmlands and/or irrigate lands with brackish water and is also needed by state, federal, and oil company personnel to develop guidelines for brine discharge management.

THERMODYNAMICS OF SODIUM-CALCIUM EXCHANGE IN SOILS

Soils are multicomponent systems consisting of solid (inorganic and organic components), liquid (soil solution), and gaseous phases. These three dynamic phases are to some extent in a constant state of flux, trying to maintain a state of equilibrium. The change in one phase will influence the other two phases until a new equilibrium state is approached. Cation exchange is one type of equilibrium interaction. This involves interexchange between cations in the solid phase with other cations in the solution phase.

Cation exchange reactions result primarily from the excess of negative charge of soil colloids. There are mainly two types of negative charge found in soil systems: permanent negative charge and variable or pH-dependent negative charge [29,30]. A permanent negative charge is generated because of isomorphic substitution of elements of smaller positive charge for those of higher positive charge in the crystal structure of clay minerals. Variable negative charge on mineral surfaces results from organic matter functional groups, such as carboxyls, and/or surface hydroxyls of inorganic minerals [31]. The magnitude of the variable negative charge is influenced by pH as well as ionic strength. An increase in pH and/or ionic strength is followed by an increase in negative charge [32]. In soil systems of temperate regions, these two types of negative charges are always present, but in some soils, one type of negative charge is more dominant than the other.

Because soils contain a mixture of various types of clay minerals and because more than two cations are present in such soil systems (Ca, Mg, K, Na, NH_4), a rigorous theoretical description of ionic distribution is difficult. Several theoretical approaches have been used in deriving binary exchange equations. Those most often mentioned in the literature are the thermodynamic and the double-layer approaches. The formal thermodynamic approach, based on the mass action principle, gives no direct information about the molecular mechanisms and the forces operating in such systems. On the other hand, the diffuse double-layer approach provides a description of Coulombic forces operating on ion exchange processes [21].

Bohn et al. [33] summarized the limitations of most cation exchange equations: (a) Binary cation exchange is frequently considered but rarely the simultaneous presence of additional cations is acknowledged even for highly acidic systems. (b) The cation exchanger is assumed to possess constant cation exchange capacity, but often cation exchange capacity varies with the nature of the exchanging ions, solution concentration, and pH. (c) Simple stoichiometric (1:1) ion exchange is generally assumed, but apparent deviations from 1:1 stoichiometry are usually explained in terms of simultaneous adsorption of molecules or in terms of the formation of complex ions. (d) Complete reversibility is usually taken for granted.

A large number of studies involving Na-Ca exchange have been conducted with respect to influence of ionic strength and solution composition. A few studies, however, have dealt with the role of pH on Na-Ca exchange reactions. This omission could be due to the fact that most salt-affected soils in the arid West exhibit pH values in the neutral range. Salt-affected soils in the temperate regions of the United States are often acid in nature and of mixed type of charge site mineralogy. That is, they are composed of minerals that contribute significant quantities of variable

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

and permanent charge. It is not known how brine affects the Na-Ca exchange reactions in such soils.

Sodium-Calcium Exchange Theory: Mass Action

A binary exchange reaction at equilibrium involving Na^+ and Ca^{2+} on a soil system can be written as

$$\frac{1}{2}\,Ex_2Ca + Na^+ \Leftrightarrow ExNa + \frac{1}{2}\,Ca^{2+} \tag{5}$$

where Ex is an exchanger phase taken to have a charge of negative one (-1) and Na^+ and Ca^{2+} denote solution species. A criterion of chemical reaction equilibrium is [34]:

$$\sum \nu_i \mu_i = 0 \tag{6}$$

where ν_i is the stoichiometric coefficient in chemical reaction for species i and μ_i is the chemical potential for species i.

The chemical potential μ_i of species i in solution is identical to the partial molar Gibbs energy, G_i, and at constant T

$$d\mu_i = dG_i = RTd \ln f_i \tag{7}$$

relates these quantities to the fugacity, f_i, in solution. Integration of Equation (7) from the standard state of species i to a state of species i in solution gives

$$\mu_i - G_i^o = RT \ln\left(\frac{f_i}{f_i^o}\right) \tag{8}$$

where G_i^o is the molar Gibbs energy for species i, R is the gas constant, and T is the system temperature. The ratio f_i/f_i^o is defined as the activity, a_i, in solution. For a gas, the standard state, f_i^o, is the ideal gas state of pure i at a pressure of 1 bar (or 1 atm). Thus for gas phase reactions, $a_i = f_i/f_i^o = f_i$. For solids and liquids, the usual standard state is the pure solid or liquid at 1 bar (or 1 atm) and the system temperature.

From the preceding equations and definitions,

$$\mu_i = G_i^o + RT \ln a_i \tag{9}$$

and at thermodynamic equilibrium for a chemical reaction,

$$\sum \nu_i (G_i^o + RT \ln a_i) = 0 \tag{10}$$

from which it follows that

$$\Pi(a_i)_i^{\nu} = \exp\left(-\frac{\sum \nu_i G_i^o}{RT}\right) = K_{eq} \tag{11}$$

where Π signifies the product over all species i in the chemical reaction and K_{eq} is the equilibrium constant for the reaction. The pure component Gibbs energy, G_i^o, is a property of pure species i in its standard state and fixed pressure. It depends only on temperature. It follows from Equation (11) that K_{eq} is also only a function of temperature and ΔG^o is the standard Gibbs energy change of reaction. Furthermore, activities, a_i, are not completely defined without also defining the pure component reference states f_i^o and G_i^o.

The thermodynamic exchange equilibrium constant K_{eq} for reaction (5) at room temperature (22°C) and 1 atm pressure is thus represented by

$$K_{eq} = \frac{a_{Ca}^{1/2}\, a_{ExNa}}{a_{Na}\, a_{Ex_2Ca}^{1/2}} \tag{12}$$

where a_{Na} and a_{Ca} are the activities of solution phase Na^+ or Ca^{2+} and a_{ExNa} and a_{ExCa} are the activities of exchange phases Na^+ and Ca^{2+}. Activity, a_i, is defined by the equation

$$a_i = f_i \chi_i \tag{13}$$

where f_i = activity coefficient of species i and χ_i = concentration of species i. For mixed electrolyte solutions, the single ion activity concept introduced by Davies [35] is employed to estimate f_i [36].

The activity component of the adsorbed or solid phase is defined by employing the mole fraction concept introduced by Vanselow [37]. According to Vanselow [37], for a heterovalent binary exchange reaction such as Na^+-Ca^{2+}, assuming that the system obeys ideal solid-solution theory, the activity term (a_{Exi}) is defined by

$$a_{ExNa} \approx X_{Na} = \frac{ExNa}{ExNa + Ex_2Ca} \tag{14}$$

and

$$a_{Ex_2Ca} \approx X_{Ca} = \frac{Ex_2Ca}{ExNa + Ex_2Ca} \tag{15}$$

where X_{Na} and X_{Ca} are mole fractions of Na^+ or Ca^{2+} and Ex denotes exchange phase with a valence of -1. For a system where ideal solid-solution behavior is not obeyed,

$$a_{Exi} = f_i \chi_i \tag{16}$$

where f_i is the adsorbed ion activity coefficient. Note that in the mole fraction concept, the sum of exchangeable Na^+ (ExNa) and exchangeable Ca^{2+} (Ex_2Ca) is expressed in moles per kilogram soil. Because of this, the denominator of Equations (14) and (15) is not a constant even though the sum of exchangeable Na^+ and exchangeable Ca^{2+} when expressed in units of charge equivalents is a constant. Equivalent fractions E_i for Na^+ and Ca^{2+} are defined by

$$E_{Na} = \frac{ExNa}{ExNa + 2Ex_2Ca} \tag{17}$$

and

$$E_{Ca} = \frac{2Ex_2Ca}{ExNa + 2Ex_2Ca} \tag{18}$$

Equation (17) is used to estimate exchangeable sodium percentage simply by multiplying E_{Na} by 100. This above binary systems cation exchange capacity (CEC) of the soil is taken to be

$$CEC = ExNa + 2Ex_2Ca \tag{19}$$

Based on this concept, an equilibrium exchange expression for reaction (5) can be given as

$$K_v = \frac{X_{Na} a_{Ca}^{1/2}}{X_{Ca}^{1/2}\, a_{Na}} \tag{20}$$

where $a_{Na}/a_{Ca}^{1/2}$ is known as the sodium adsorption ratio and K_v is the Vanselow exchange selectivity coefficient.

Commonly, the magnitude of K_v is taken to represent relative affinity of Na^+ with respect to Ca^{2+} by the clay surface [38,39]. When K_v equals 1 at a given level of exchangeable Na^+, the

exchanger at that level of Na load shows no preference for either Na^+ or Ca^{2+}. On the other hand, a $K_v > 1$ at any given level of exchangeable Na^+ signifies exchanger preference for Na^+ and a $K_v < 1$ at any given level of exchangeable Na^+ signifies preference for Ca^{2+}.

Upon making the proper substitutions and rearranging Equation (20) to the form of a quadratic equation

$$(\text{ExNa})^2 = \frac{(K_v\ \text{SAR}\ \text{CEC})^2}{(K_v\ \text{SAR})^2 + 4} \tag{21}$$

If one takes the positive root of Equation (21) and redefines the left hand term of this equation as exchangeable sodium percentage (ESP)

$$\text{ESP} = \frac{\text{ExNa}}{\text{CEC}}\,100 = \frac{K_v\ \text{SAR}}{[4 + (K_v\ \text{SAR})^2]^{1/2}}\,100 \tag{22}$$

Taking limits of Equation (22) as SAR approaches zero and SAR approaches infinity,

$$\lim_{\text{SAR}\to 0}\ \text{ESP} = 0 \tag{23}$$

and

$$\lim_{\text{SAR}\to \infty}\ \text{ESP} = 100 \tag{24}$$

In Equation (22), it is assumed that CEC and K_v are constant for the entire N^+-Ca^{2+} exchange isotherm. The plot of this equation in terms of ESP versus SAR gives a curvilinear function asymptotically approaching 100 [40]. Note that the shape of this plot is K_v dependent.

A variable K_v with respect to the exchangeable Na^+ load on the soil can be transformed to the thermodynamic exchange constant K_{eq} as follows:

$$K_{eq} = K_v \frac{f_{Na}}{f_{Ca}^{1/2}} \tag{25}$$

where f_{Na} and f_{Ca} are adsorbed ion activity coefficient for Na^+ and Ca^{2+}. Argersinger et al. [41] noted that any variation in K_v with respect to exchange-phase composition is followed by a variation in the solid-phase activity coefficients f_i. Furthermore, any variation in E_{Na} must be compensated for by a variation in E_{Ca}.

Based on this, Argersinger et al. [41] generated two equations that give values for $\ln f_{Na}$ and $\ln f_{Ca}$ at any value of E_{Ca}:

$$\ln f_{Na} = (1 - E_{Na})\ln K_v - \int_{E_{Na}}^{1} \ln K_v dE_{Na} \tag{26}$$

and

$$\frac{1}{2}\ln f_{Ca} = -E_{Na}\ln K_v + \int_0^{E_{Na}} \ln K_v\, dE_{Na} \tag{27}$$

where E_{Na} is the equivalent charge fraction of adsorbed Na^+. The equation for E_{Na} is given by Equation (17). For a detailed discussion of Equations (26) and (27), refer to Evangelou and Phillips (42) and references therein.

A number of researchers have carried out various studies involving binary heterovalent exchange on various clay minerals. For example, Sposito and Mattigod [43] showed that for the exchange reactions of Na^+ with trace metal cations (Cd^{2+}, Co^{2+}, Cu^{2+}, Ni^{2+}, and Zn^{2+}) on Camp Berteau montmorillonite, K_v was constant and independent of exchanger composition up to an equivalent fraction of trace metal cations of 0.70. These observations indicate that the cationic mixture on the

exchanger phase up to an equivalent fraction of trace metal cations of 0.70 behaves as an ideal mixture. However, Van Bladel et al. [44] studied Na^+-Ca^{2+} exchange reaction on the same kind of mineral and found that there is a more pronounced selectivity of clay for Ca^{2+} ions at the calcium-rich end of the isotherm. Levy and Hillel [45] reached the same conclusions studying Na^+-Ca^{2+} exchange on montmorillonitic soils.

Based on these Na^+-Ca^{2+} exchange studies, the magnitude of K_v is variable in nature and detailed and meticulous experiments are required in order to quantify it. In general, it can be said that the selectivity coefficient K_v of a binary exchange reaction depends primarily on the ionic strength and on two dimensionless parameters, one a measure of the proportion of cations in the soil absorbing complex and the other a measure of their proportions in the soil solution phase [39,46].

Sodium-Calcium Exchange Theory: Diffuse Double Layer

The diffuse double layer is the swarm of ions accumulating near a charged surface, balancing the charge of that surface. The distribution of ions in that swarm is assumed to follow a Boltzmann distribution (see Ref. 47 and references therein):

$$n_c = n_c^{\infty} \exp\left(\frac{-z_c e\varphi}{kT}\right)$$
$$n_a = n_a^{\infty} \exp\left(\frac{z_a e\varphi}{kT}\right) \tag{28}$$

where n and z are the electrolyte concentration and valence for the cation (c) and anion (a) as a function of distance from the surface, n_c^{∞} and n_a^{∞} are the cation and anion concentrations in the bulk solution, e is the electronic charge, φ is the electrical potential as a function of distance from the surface, k is Boltzmann's constant and T is temperature. At any point in the system, the local net charge density (ρ) is given by

$$\rho = [\Sigma(z_c e n_c) - \Sigma(z_a e n_a)] \tag{29}$$

For symmetrical electrolytes of the form NaCl or $CaSO_4$,

$$\rho = \left[z_c e n_c^{\infty} \exp\left(\frac{-z_c e\varphi}{kT}\right) - z_a e n_a^{\infty} \exp\left(\frac{z_a e\varphi}{kT}\right) \right] \tag{30}$$

where Equation (28) has been substituted into Equation (29). Given that

$$\sinh(x) = \frac{e^x - e^{-x}}{2} \tag{31}$$

and, recognizing that electroneutrality requires

$$n_c^{\infty} = n_a^{\infty} \tag{32}$$

Equation (30) can be written as

$$\rho = -2 e n_c^{\infty} \sinh\left(\frac{ze\varphi}{kT}\right) \tag{33}$$

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

For mixtures of symmetric electrolytes of the form NaCl and $CaSO_4$, again recognizing that electroneutrality requires

$$n^{\infty}_{Na} = n^{\infty}_{Cl} \text{ and } n^{\infty}_{Ca} = n^{\infty}_{SO_4} \tag{34}$$

Equation (30) can be written as

$$\rho = -2e\left[n_1^{\infty} \sinh\left(\frac{e\varphi}{kT}\right) + 2n_2^{\infty} \sinh\left(\frac{2e\varphi}{kT}\right)\right] \tag{35}$$

where subscripts 1 and 2 refer to the univalent and divalent salt respectively and the ion valences have been included explicitly. Equations (33) and (35) then describe the net charge density, at any point (x) in the solution, as a function of the electrical potential at that point. When the point x is taken to be very far from the charged surface (x^{∞}), the electrical potential = 0 and hence $\rho = 0$. To describe the variation in electrical potential as a function of distance from the surface, one makes use of the Poisson equation, which in one dimension reads

$$\frac{d^2\varphi}{dx^2} = -\frac{\rho}{\varepsilon} \tag{36}$$

where ε is the dielectric constant. Substituting Equation (35) into Equation (36) yields

$$\frac{d^2\varphi}{dx^2} = \frac{2e\left[n_1^{\infty} \sinh\left(\frac{e\varphi}{kT}\right) + 2n_2^{\infty} \sinh\left(\frac{2e\varphi}{kT}\right)\right]}{\varepsilon} \tag{37}$$

It is customary to let

$$y = \frac{e\varphi}{kT} \tag{38}$$

so that Equation (37) can be simplified to

$$\frac{d^2y}{dx^2} = \frac{2ze}{\varepsilon kT}\left[n_1^{\infty} \sinh(y) + 2n_2^{\infty} \sinh(2y)\right] \tag{39}$$

Considering the interaction between two flat plates separated by a distance, 2d, Equation (39) can be integrated once [48], with the appropriate boundary conditions ($dy/dx = 0$ for $x = d$ when $y = y_d$) to yield,

$$\frac{dy}{dx} = -\frac{\sqrt{4e^2}}{\varepsilon kT}\left[n_1^{\infty}(\cosh y - \cosh y_d) + 2n_2^{\infty}(\cosh^2 y - \cosh^2 y_d)\right]^{0.5} \tag{40}$$

Letting

$$\beta = \frac{\sqrt{4e^2}}{\varepsilon kT} \tag{41}$$

Equation (40) reads

$$\frac{dy}{dx} = -\beta\left[n_1^{\infty}(\cosh y - \cosh y_d) + 2n_2^{\infty}(\cosh^2 y - \cosh^2 y_d)\right]^{0.5} \tag{42}$$

Erickson [48] made an elegant observation in that Equation (42) need not be further integrated

to determine the fraction of monovalent ion in the diffuse double layer. Electroneutrality requires that the charge on the particle be balanced by the charge in the diffuse double layer. Therefore, the particle surface charge density, σ_0, can be expressed as

$$\sigma_0 = -\int_0^d \rho dx = \varepsilon \int_0^d \frac{d^2\varphi}{dx^2} = -\varepsilon\left(\frac{d\varphi}{dx}\right)_{x=0} = -\frac{\varepsilon kT}{e}\left(\frac{dy}{dx}\right)_{x=0} \tag{43}$$

Substituting Equation (42) into Equation (43) yields

$$\sigma_0 = \left(\frac{\varepsilon kT}{e}\beta\right)[n_1^\infty(\cosh y - \cosh y_d) + 2n_2^\infty(\cosh^2 y - \cosh^2 y_d)] \tag{44}$$

In the same way, the concentration of monovalent ions in the diffuse double layer is given by

$$\sigma_1 = -2n_1^\infty e \int_0^d \sinh y \, dx \tag{45}$$

where Equation (33) was used. By substituting Equation (42) into Equation (45),

$$\sigma_1 = \frac{2n_1^\infty e}{\beta}\int_{Y_d}^{y_0} \frac{\sinh y \, dy}{[n_1^\infty(\cosh y - \cosh y_d) + 2n_2^\infty(\cosh^2 y - \cosh^2 y_d)]^{0.5}} \tag{46}$$

integrating Equation (45), the fraction of the surface charge neutralized by the monovalent ions (σ_1/σ_0) is given as [48,49]

$$\frac{\sigma_1}{\sigma_0} = \frac{n_1^\infty}{\sigma_0\sqrt{n_2^\infty}\sqrt{\beta}} \sinh^{-1}\frac{\sigma_0\sqrt{\beta}}{\frac{n_1^\infty}{\sqrt{n_1^\infty}} + 4u_d\sqrt{n_2^\infty}} \tag{47}$$

where

$$u_d = \cosh\frac{e\varphi_d}{kT} \tag{48}$$

and φ_d = potential in the plane midway between the clay plates. Since

$$SAR = \frac{n_1^\infty}{\sqrt{n_2^\infty}}\sqrt{1000} \tag{49}$$

where n_1^∞ = Na and n_2^∞ = Ca, Equation (20) can be written

$$\frac{\sigma_1}{\sigma_0} = \frac{SAR}{31.6\sigma_0\sqrt{\beta}} \sinh^{-1}\frac{31.6\sigma_0\sqrt{\beta}}{SAR + 126.4u_d\sqrt{Ca}} \tag{50}$$

In the above derivation, it was assumed that the surface charge is a constant. Although derived for symmetrical electrolytes, Equation (47) has been shown to work reasonably well for the Na-Ca-Cl system [49,39].

From Equations (47) and (50), and recognizing the shape of the function $y = \sinh^{-1}(x)$, the following observations can be made. First, increasing SAR increases σ_1/σ_0, although not linearly. Second, increasing ionic strength, which is accounted for by the $\sqrt{Ca}$ term, decreases σ_1/σ_0 [50]. And third, increasing CEC ($\sim \sigma_0$) increases σ_1 but decreases σ_1/σ_0 [50]. All of these observations are consistent with the results of Evangelou and Phillips [40]. Typically, it has been assumed that the soil particles were sufficiently far apart so that $\varphi_d = 0$ and $u_d = 1$ [49,51]. Shainberg et al. [39] have shown that in systems where tactoids are formed such that $\varphi_d \neq 0$, increasing ionic strength

increases σ_1 for the internal tactoid surfaces but decrease σ_1 for the external clay surfaces. This suggests that montmorillonitic soils will behave differently than soils with mixed mineralogy [39,52].

Note that if an approach similar to Erickson's [48] were used to calculate ion accumulation in the diffuse double layer for a homovalent exchange system, Equation (47) would read [51]

$$\frac{\sigma_1}{\sigma_0} = \frac{n_1^\infty}{n_1^\infty + n_2^\infty} \tag{51}$$

where here the subscripts 1 and 2 refer to two monovalent ions (e.g., 1 = Na^+ and 2 = K^+). That is, the unmodified diffuse double layer theory does not predict ion selectivity: the fractional concentration of ion 1 in the diffuse double layer is equal to the fractional concentration of ion 1 in the bulk solution. Bolt [53] has shown that the effects of dielectric saturation, ion polarization and ionic interactions are small if $\sigma_0 < 160$ $cmol_c$ kg^{-1}. Shainberg and Kemper [54] have shown that incorporating ion hydration energies into the Stern-modified diffuse double layer theory, the observed ion affinity sequence $K^+ > Na^+ > Li^+$ can be rationalized. Because the hydration energies of ions has implications for ion exchange reactions on soils and ion selectivity at the plasmalemma level, the results of Shainberg and Kemper [54] are reviewed here.

The Stern modifications to the diffuse double layer theory are (a) ions can get no closer to a surface than the radius of that ion and (b) some ions may specifically sorb to the surface (i.e., without the hydration waters). The diffuse double layer is then separated into two parts, a layer of specifically sorbed ions (Stern layer) and the ordinary diffuse double layer. The equations for the diffuse double layer are modified such that φ is the potential at the Stern layer instead of at the particle surface. Following this, Shainberg and Kemper [54] outline the following. The total surface charge density, σ_T, is divided into two components, one for the Stern layer (σ_s) and one for the diffuse double layer, σ_{ddl},

$$\sigma_T = \sigma_S + \sigma_{ddl} \tag{52}$$

The concentration of cations in the diffuse double layer, n_C^{ddl} is given, following Equation (28) as

$$n_C^{ddl} = n_C^\infty \exp\left(\frac{-ze\varphi_s}{kT}\right) \tag{53}$$

where φ_S is the electrical potential at the Stern layer. The concentration of cations in the Stern layer, n_C^S, is given as

$$n_C^S = n_C^{ddl} \exp\left(\frac{E_S - E_{ddl}}{kT}\right) \tag{54}$$

where E_S is the potential energy of an ion in the Stern layer and E_{ddl} is the potential energy of an ion in the diffuse double layer. The charge density of cations in the Stern layer is given as

$$\sigma_S = ze\delta\, n_C^S \tag{55}$$

where δ is the thickness of the Stern layer, or combining Equations (53), (54), and (55)

$$\sigma_S = ze\delta\, n_C^\infty \exp\left(\frac{-ze\varphi_s}{kT}\right)\exp\left(\frac{E_S - E_{ddl}}{kT}\right) \tag{56}$$

An approximate form of the surface charge density in the diffuse double layer [55] is given as

$$\sigma_{ddl} = \sqrt{\varepsilon kT\, n_C^\infty}\exp\left(\frac{-ze\varphi_S}{kT}\right) \tag{57}$$

Combining Equations (52), (56), and (57) and setting

$$B = \sqrt{\varepsilon k T n_C^{\infty}}$$

$$H = ze\delta n_C^{\infty} \exp\left(\frac{E_S - E_{ddl}}{kT}\right), \text{ and} \tag{58}$$

$$Y_S = \frac{-ze\varphi_S}{2kT}$$

yields

$$H \exp(2Y_S) + B \exp(Y_S) - \sigma_T = 0 \tag{59}$$

The positive root of Equation (59) is

$$\exp(Y_S) = \frac{-B + \sqrt{B^2 + 4H\sigma_T}}{2H} \tag{60}$$

That is, the Stern layer potential (Y_S) can be written as a function of the fundamental constants k, e, E_S and E_{ddl}, and the experimental variables ε, T, and n_C^{∞}. Shainberg and Kemper [54] provide the detail for determining E_S-E_{ddl}. Once Y_S is known, n_C^{ddl} can be determined from Equation (53) and σ_S and σ_{ddl} from Equations (56) and (52). The results for Li^+, Na^+, and K^+ are that 16% of the Li^+, 36% of the Na^+, and 49% of the K^+ is in the Stern layer (Fig. 2A) [54]. That is, when comparing monovalent ions, the higher the ion hydration enthalpy, the less likely it is that the ion will be located in the Stern layer.

The above equations have implications for ion uptake by plants as well as ion exchange reactions on soil surfaces. Because cell membranes are negatively charged, the presence of an aqueous solution establishes an electric double layer. In many, but not all, cases ion toxicity effects are more closely correlated with ion (concentrations) activities at the membrane surface that with bulk solution ion (concentrations) activities [56]. In these instances, it is possible to rationalize the effects of ion interactions on ion uptake without invoking the presence of specific ion carriers, multiple sites, or other metabolic explanations. For example, Maas [57] evaluated the effect of increasing concentrations of Li, Na, and K on the uptake of Li, Na, K, and Ca into excised maize roots (see Fig. 2B). The results (see Fig. 2B) are entirely consistent with the preceding equations. In Equation (47), increasing r (the relative monovalent ion concentration) increases σ_1/σ_0 and hence the monovalent ion concentration in the double layer. Accepting that for an ion to move into a cell it must first move to the surface of the cell membrane, increasing the relative monovalent ion concentration in the solution phase necessarily increases ion uptake. When comparing Li, Na, and K, the extent ion uptake increases should be proportional to the ability of the ion to move into the Stern layer. That is, increasing the solution phase Li concentration has a modest effect on Li uptake, whereas increasing the solution K concentration has a large effect on K uptake. The effects of monovalent ion concentration on Ca uptake can be explained similarly. To suppress Ca uptake, the monovalent ion has to compete at the Stern layer level. Therefore, from Shainberg and Kemper's analysis [54], one would predict that K would be more effective at suppressing Ca uptake than Li (see Fig. 2B).

SALT CONCENTRATION AND pH INFLUENCE ON SODIUM-CALCIUM EXCHANGE

In order to demonstrate the influence of salt concentration and soil pH on Na^+-Ca^{2+} exchange on soils representative of humid regions, data on two such soils are given here. These two soils are the Pembroke (fine silty, mixed, mesic, Mollic Paleudalf) from Hardin County, Kentucky and the Uniontown (fine silty, mixed, mesic, Typic Hapludalf) from Union County, Kentucky [36]. The

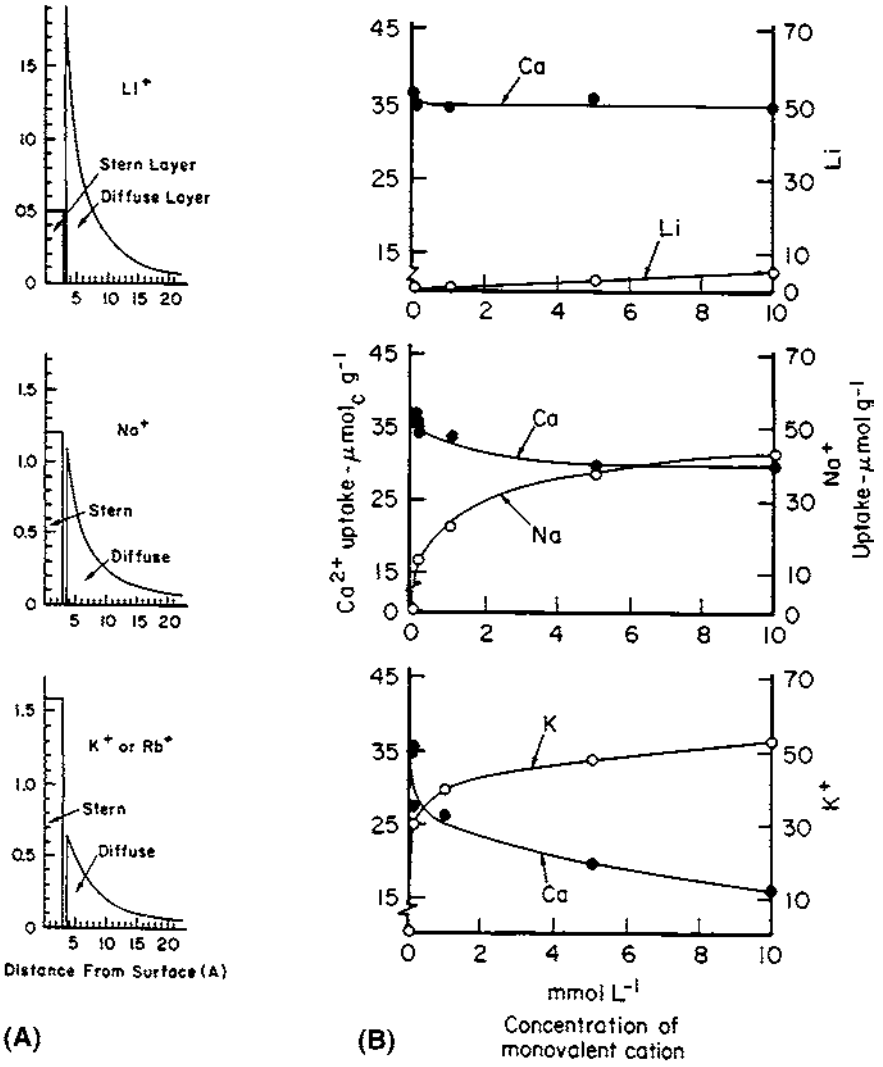

FIGURE 2 (A) The effect of increasing K^+, Na^+, and Li^+ concentration on the uptake of Ca^{2+}, K^+, Na^+, and Li^+ in 24 h. The concentration of Ca^{2+} was 10 $mmol_c\ L^{-1}$ and the pH was 6 (after Ref. 57). (B) Calculated cation concentrations near a charged surface (after Ref. 54).

Pembroke soil is much higher in clay content than the Uniontown soil. The Pembroke soil is dominated by kaolinite and to a lesser extent by mica, vermiculite, and hydroxy-interlayered vermiculite and smectite. The Uniontown soil is dominated by vermiculite and to a lesser extent by mica, kaolinite, and hydroxy-interlayered vermiculite and smectite. Another important difference is the much greater iron content of the Pembroke soil.

The data in Table 1 show the mean value of the summation of exchangeable Na^+ and exchangeable Ca^{2+} as a function of pH and chloride concentration for the Pembroke and the Uniontown soils, respectively. Each mean value reported is represented by 15 different ExNa or ExCa loads. The plus or minus value associated with each mean value represents the difference in metal adsorption when one of the metals (Na^+ or Ca^{2+}) on the exchange phase approaches zero. Thus, for any

TABLE 1 Mean-Sum *M* of Exchangeable Na and Ca of Pembroke and Uniontown Soils as a Function of pH and Chloride Concentration[a]

	Pembroke ($cmol_c\ kg^{-1}$)			Uniontown ($cmol_c\ kg^{-1}$)		
Cl ($mmol\ L^{-1}$)	pH 4.3	pH 6.1	pH 7.5	pH 4.3	pH 6.3	pH 7.7

Source: From Ref. 36.

mean value plus the deviation from the mean, the sum signifies the effective charge (EC_g) of the soil when the latter is loaded with Ca^{2+}, and for any mean value minus the deviation from the mean, the difference signifies the EC_g of the soil when the latter is loaded with Na^+. The data in Table 1 clearly demonstrate that the EC_g of these two soils is highly ionic strength dependent, specific ion dependent, and to a lesser degree pH dependent. The variation in effective soil charge as a function of the type of metal was previously reported by Fletcher et al. [58], Hutcheon [59], and Faucher and Thomas [60].

The ESP versus sodium adsorption ratio SAR plots of the Pembroke soil are presented in Figures 3 and 4. These two figures demonstrate that the ESP-SAR relationship of the Pembroke soil is independent of pH and ionic strength. The data also imply that the K_v for this soil should be independent of pH and ionic strength [40]. This is demonstrated in Figures 5 and 6. These two figures show that there are at least two classes of exchange sites with respect to Na^+-Ca^{2+} exchange on the Pembroke soil. These data also point out that at low ESP values (ESP $<$20) the soil exhibits a high affinity for Na^+, perhaps because of steric processes. At ESP $>$20, however, the magnitude of K_v remains constant, approximately 1, which suggests no ion preference [61]. Furthermore, it appears that the Pembroke soil behaves as an ideal exchanger between ESP of about 20 and 100. These observations are consistent with the information presented by van Bladel et al. [44] and Levy and Hillel [45].

The apparent lack of influence of pH and ionic strength on the K_v of such soils could be related to a number of processes that take place on a clay surface as pH and/or ionic strength increases. For example, Pratt et al. [62] have demonstrated on a number of soils that as pH decreases the exchange selectivity coefficient of Na^+-Ca^{2+} exchange increases. This increase signifies increase in affinity of the Na^+ by the clay surface through decreasing surface charge density. The Pratt group's [62] data tend to support this conclusion. Additionally, Shainberg et al. [39] have shown that for Na^+-Ca^{2+} exchange, as ionic strength increases the affinity for the Na^+ by the illite surface also increases. The latter observation, however, depends on whether one deals with an external surface or internal surface. For example, an increase in ionic strength on an external surface (low electrical potential surface) could increase the affinity for the Ca^{2+}. However, an increase in ionic strength on an internal surface (high electrical potential surface) could increase the affinity for the Na^+. Considering that mix mineralogy soils are made up of external and internal surfaces, a canceling effect on the magnitude of K_v due to an increase in ionic strength could be obtained.

The ESP versus SAR plots for the Uniontown soil are also shown in Figures 3 and 4. That pH and ionic strength have a strong influence on K_v is strongly supported by these figures. This is substantiated in Figures 5 and 6. The K_v data in Figure 5 show that as pH increases K_v also increases; consequently, Na^+ is preferred by the solid phase. Furthermore, as ESP increased K_v also increased. Stumm and Bilinski [63] showed that deprotonating clay edge surfaces have greater affinity for a monovalent cation than a divalent cation, because the former (monovalent cation) requires much less free energy to desolvate and thus come closer to the adsorbing surface. On the other hand,

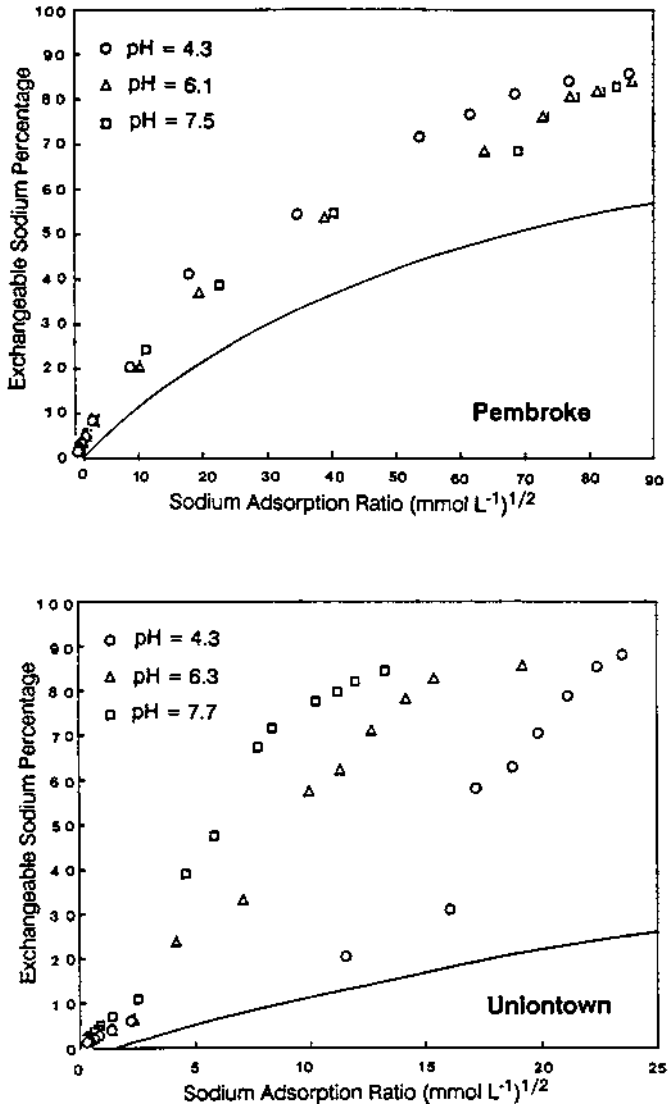

FIGURE 3 Relationship between exchangeable sodium percentage (ESP) and sodium adsorption ratio (SAR) at a chloride (Cl) concentration of 5 mmol L^{-1} of Pembroke and Uniontown soils at three pH values. The solid line without data represents most salt-affected soils in the western United States. (From Refs. 6 and 36.)

according to the data shown in Figure 6, as ionic strength increases, K_v decreases. This indicates that under high ionic strength the soil prefers Ca^{2+}. This also implies that under high ionic strength the divalent cations are most likely to carry out the soil deprotonation process. Finally, the data in Figures 3 and 4 clearly demonstrate that the two humid region soils exhibit a much higher affinity for Na^+ than the average salt-affected soil in the western United States. Note the difference in the Na^+ adsorption isotherms exhibited by the humid region soil and the western U.S. soils. This implies

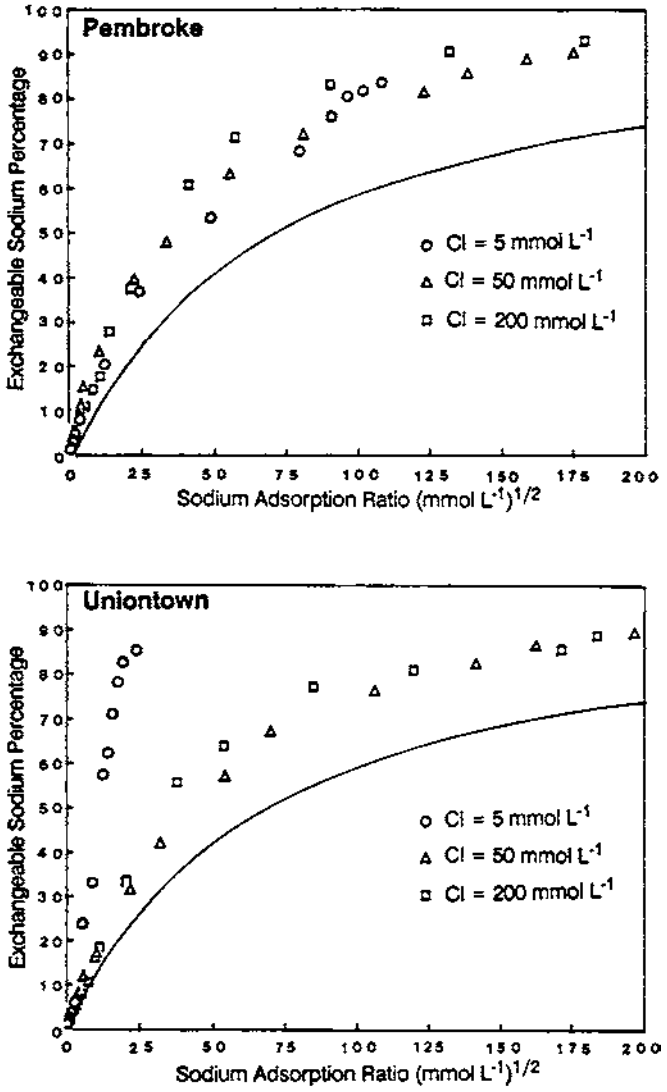

FIGURE 4 Relationship between exchangeable sodium percentage (ESP) and sodium adsorption ratio (SAR) at three chloride (Cl) concentrations of the Pembroke and Uniontown soils at pH 4.3. The solid line without data represents most salt-affected soils in the western United States. (From Refs. 6 and 36.)

that physical behavior and reclamation practices for these two groups of soils are expected to be different.

Values of f_{Na} and f_{Ca} for the Pembroke and Uniontown soils are plotted as a function of ESP in Figure 7. These data represent the two soils, at pH 6.1 for the Pembroke soil and 6.3 for the Uniontown soil, in all three chloride levels. These treatments were chosen because the two soils show the largest differences in K_v as a function of ionic strength as well as when the pH is near neutral. The data show that for the Pembroke soil Ca^{2+} is tightly bound to the charged surface (f_{Ca}

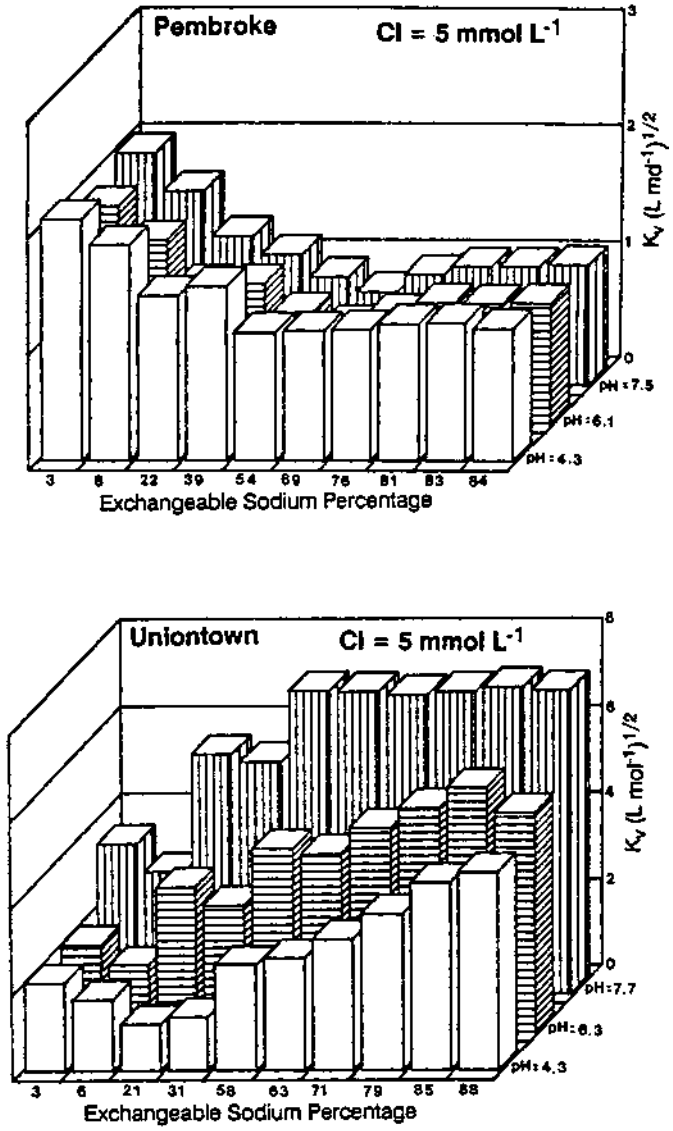

FIGURE 5 Influence of exchangeable sodium percentage (ESP) on the Vanselow exchange coefficient of Pembroke and Uniontown soils at a chloride (Cl) concentration of 5 mmol L^{-1} and at three pH values. (From Ref. 36.)

< 1). This adsorption strength increases as ESP increases. Also at low ESP values, f_{Na} is less than 1, which signifies that the Na ion is specifically interacting with the surface. Furthermore, as ESP increases, f_{Na} increases and becomes approximately 1. Ionic strength also appears to have influence on the magnitude of f_{Ca}. The data show that f_{Ca} at 200 mmol L^{-1} Cl concentration is larger than f_{Ca} at 5 and 50 mmol L^{-1} Cl. This could be because the Pembroke soil is dominated by external adsorption sites [42].

The findings demonstrated in Figure 7 for the Pembroke soil are not in full agreement with

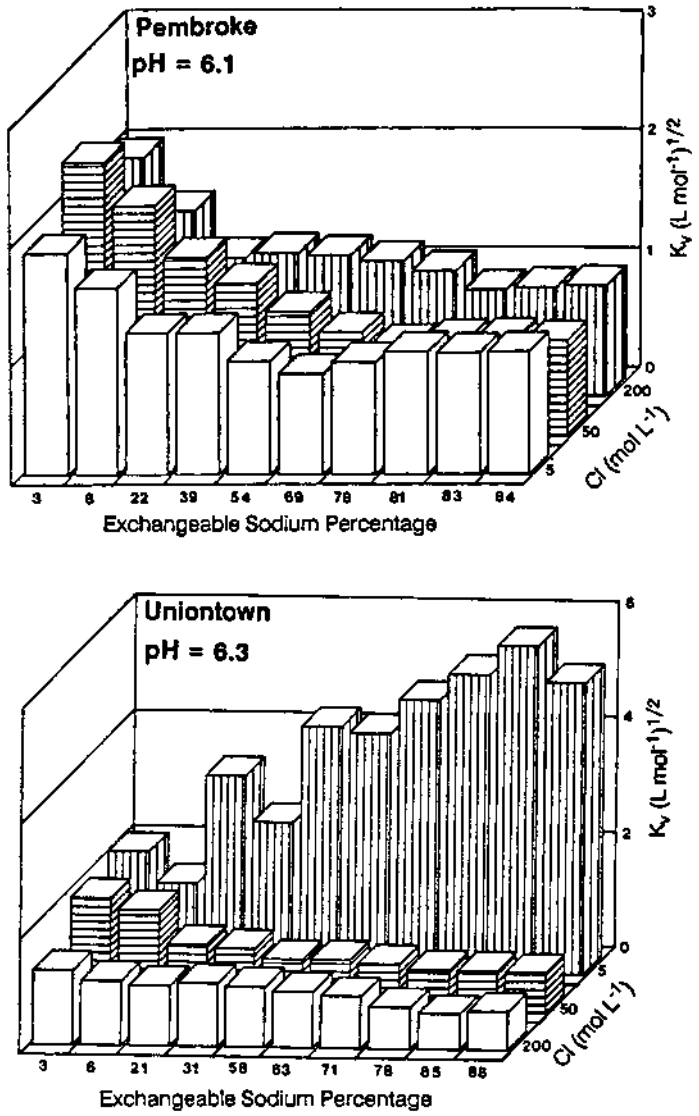

FIGURE 6 Influence of exchangeable sodium percentage (ESP) on the Vanselow exchange coefficient of the Pembroke and Uniontown soils near pH 6 and at three chloride (Cl) concentrations. (From Ref. 36.)

the findings also shown in Figure 7 for the Uniontown soil. This is especially true for f_{Na}. These differences could be attributed to the mineralogical differences of these two soils. The Pembroke soil, because of its high kaolinite content, is dominated by external surface area; therefore, it is expected to exhibit high specificity for Na^+ [42]. On the other hand, the Uniontown soil, because of high vermiculite content (large internal surface area), is expected to exhibit low specificity for the Na^+, especially at low ionic strength [42]. It is important to keep in mind that temperate region soils are of mixed mineralogy and much of the Na^+-Ca^{2+} exchange behavior is also subject to the interactions between fixed- and variable-charge components.

SODIUM INFLUENCE ON SOIL DISPERSION AND SATURATED HYDRAULIC CONDUCTIVITY

The classic theory of colloidal stability developed by Derjaguin and Landau [64] and Verwey and Overbeek [65] (DLVO theory) generally accounts for the influences of ion valence and concentration on suspended colloid interactions. According to the DLVO theory, the long-range repulsive potential (μ) resulting from diffuse double layers (DDLs) of like charged colloids retards the coagulation or flocculation rate of clay colloids.

Colloidal stability (maximum dispersion) depends on maximum Φ (Φ_{max}), which describes the maximum repulsive energy between two planar colloidal surfaces. Furthermore Φ_{max} is controlled by surface electric potential (Ψ) and ionic strength. The component, Ψ, is controlled by the pH of the colloidal suspension, assuming that the colloids involved exhibit pH-dependent charge [66]. Generally, in clay colloids on increasing pH, Ψ becomes more negative and thus Φ_{max} increases. Conversely, on decreasing pH, Ψ becomes less negative. When Ψ approaches zero, Φ_{max} approaches zero. This leads to colloid coagulation or flocculation [19,20,67,68]. Increasing I in a colloidal suspension decreases Φ_{max}, which enhances colloid flocculation rate [69].

In addition to these components (Ψ, I) controlling colloidal flocculation or stability [21,69,70], additional components in the case of clay colloids are also involved. These additional components include relative proportion of monovalent to divalent cations in the bulk solution [21], type of cations, shape of particles and initial particle concentration in suspension [71], type of clay minerals present, and relative proportion of clay minerals [47].

The above observations of the effect of clay mineral type and their relative proportion on dispersion and flocculation behavior suggest that certain interactions between the various colloids change their dispersive behavior or colloidal stability. Based on these observations, soils of mixed mineralogy and with various proportions of different clay minerals are expected to have unique dispersive properties.

Many processes and/or conditions in the soil environment are highly dependent on colloid dispersion or flocculation. Such processes and/or conditions include erosion, water suspension of solids, soil structure, and hydraulic conductivity, among many others. A number of studies involving sodic soils have been carried out in order to relate soil dispersive properties to saturated hydraulic conductivity. For example, Suarez et al. [72] was able to link soil dispersion in suspensions measured spectrophotometrically to saturated hydraulic conductivity. Other researchers measured the percentage of clay in suspension during a given settling period and then established relationships between percentage of clay in suspension (dispersion index) versus saturated hydraulic conductivity. The purpose in establishing clay dispersion–saturated hydraulic conductivity relationships is to develop rapid tests for predicting hydraulic conductivity of salt-affected soils and/or to evaluate mechanisms that are involved in regulating saturated hydraulic conductivity.

The data in Figure 8 show that the potential of the soils to undergo dispersion is related to ESP. This is true only at low ionic strengths. When ionic strength was adjusted to 200 mmol L^{-1}, there appeared to be no effect of ESP on soil dispersion due to suppression of the double-layer repulsive forces. These data are consistent with qualitative predictions of clay dispersion equations [73]. The data in Figure 9 also show that, even at pH 4.3, both soils exhibit dispersion at low ionic strength. This observation suggests that at pH 4.3 both of these soils will likely exhibit a net negative charge.

It can be summarized from Figures 8 and 9 that the Uniontown soil was more sensitive to dispersion under decreasing electrolyte concentration and increasing ESP but less sensitive to pH changes than the Pembroke soil. The data also demonstrate that for any given electrolyte concentration, pH and ESP, the dispersion index of the Uniontown soil was always greater than that of the Pembroke soil. This appeared to be in agreement with the thermodynamic exchange parameter of these soils. The magnitude of adsorbed ion activity coefficient f_{Na} [36] for the Uniontown soil is greater than 1. Considering that $f_{Na} > 1$ could signify that Na^+ ''reside'' in the diffuse layer, one expects the Uniontown soil to be highly dispersive. On the other hand, the magnitude of f_{Na} for the

Pembroke soil is less than 1. Assuming this signifies that Na^+ forms outer-sphere complexes with the clay surfaces, this soil would be expected to be less dispersive than the Uniontown.

The presence of exchangeable Na^+ significantly decreases soil permeability [74–76]. The mechanism(s) responsible for decreasing soil permeability in the presence of Na^+ can be demonstrated by looking into the components controlling water or soil solution movement potential under saturating conditions.

Soil-saturated hydraulic conductivity is described by Lagerwerff et al. [77].

$$K = \frac{kg}{\eta} \tag{61}$$

where k = permeability of the soil
g = gravitational constant
η = kinematic viscosity or the ratio of solution viscosity to fluid density

For soil systems contaminated with brackish solutions, kinematic viscosity is not significantly affected [77] and thus the components controlling water flow velocity are the hydraulic gradient (H) and soil permeability (k). The latter component (k) is influenced by clay dispersion and migration and clay swelling. These processes may cause considerable alteration to soil matrix characteristics, such as porosity, pore-size distribution, tortuosity, and void shape [78]. Detailed description of the physicochemical mechanisms influencing clay dispersion and/or clay swelling are given in Marsi and Evangelou [73].

The deterioration of soil physical properties influencing k is accelerated directly or indirectly by the presence of high Na^+ on the soil's exchange complex and the electrolyte composition and concentration of the soil solution [74,79–82]. To improve soil physical properties of Na-affected soils, Ca^{2+} is usually added to replace Na^+ on the exchange sites. Calcium reduces clay swelling and enhances clay flocculation [83].

Additional components influencing the effect of Na^+ on saturated hydraulic conductivity of soil include clay mineralogy, clay content, soil bulk density, Fe and Al oxide content, organic matter content, salt concentration, and Na^+/Ca^{2+} ratio [78,84–90]. The hydraulic properties of soils dominated by 1:1–type clay mineralogy (i.e., kaolinite) and Fe or Al oxides are relatively insensitive to variation in soil solution composition and concentration in contrast to those dominated by 2:1–type clay minerals (i.e., montmorillonite). McNeal and Coleman [79] stated that each soil has a unique saturated hydraulic conductivity response threshold because of its unique properties.

Martin et al. [91] studied the importance of pH on saturated hydraulic conductivity (SHC) and found that the same total quantity of Na^+ on a soil will reduce SHC more effectively at a lower pH than at a higher pH. These investigators [91] concluded that the reduction in soil CEC as pH decreased was responsible for decreasing soil SHC, since the same amount of Na^+ represents a greater ESP at a lower soil pH. Suarez et al. [72] reported that for the same ESP or SAR value, the SHC decreased as pH increased. The pH effect on hydraulic conductivity is pronounced only when the soil contains a high quantity of variable-charge minerals and organic matter.

In contrast to the studies on the effect of the electrolyte concentration and composition on saturated hydraulic conductivity, fewer studies have examined the influence of pH, solution composition and salt concentration on SHC. It seems necessary to understand the influence of pH on soil hydraulic conductivity, because in humid region soils contaminated with oil well brine are often associated with low pH, either the pH drifts downward as extensive leaching is taking place or the pH rises when alkaline brines are discharged onto the soil.

Reductions in the relative saturated hydraulic conductivity (RSHC) as a function of pH and chloride concentration are summarized in Table 2. These data show ''threshold'' ESP or SAR values which are defined as 20% relative reduction in RSHC. It is clearly shown that the ESP-SAR critical threshold is highly dependent on pH and Cl concentrations. It varies from an SAR of approximately 0.30 to an SAR of approximately 90. These values strongly indicate that the critical SAR threshold reported by U.S. Salinity Laboratory Staff [6], in the range of 10–15, applies to the 50 mmol L^{-1}

TABLE 2 Sodium Adsorption Ratio (SAR)[a] and Exchangeable Sodium Percentage (ESP) Values Associated with 20% Reduction in Relative Saturated Hydraulic Conductivity (RSHC) for Pembroke and Uniontown Soils at Three pH Values

	Pembroke						Uniontown

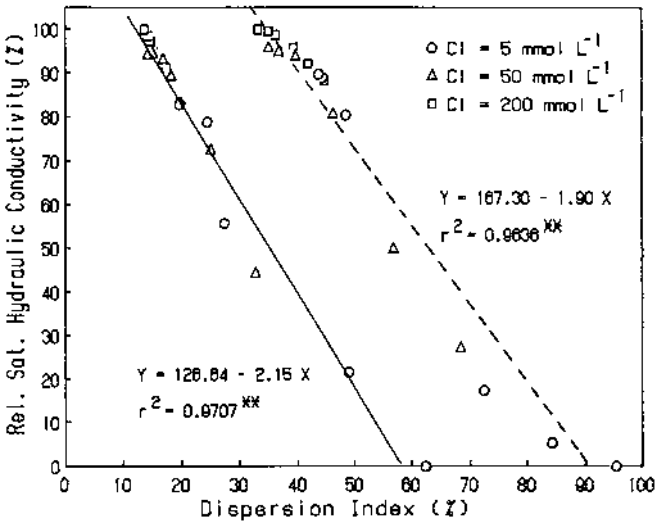

FIGURE 10 Relationship between relative saturated hydraulic conductivity (RSHC) and dispersion index (DI) of the Pembroke (solid line) and Uniontown (dashed line) soils at pH 4.3 with three chloride (Cl) concentrations. (From Ref. 92.)

Cl concentration of the Uniontown soil only. The Pembroke soil (Table 2) at the 50 mmol L^{-1} Cl concentration exhibits a much greater critical threshold.

The data presented in Table 2 show that the RSHC of the Uniontown soil is more sensitive to ionic strength and solution composition than that of the Pembroke soil. These sensitivity differences are probably a result of the differences in mineralogy between the two soils. The effect of clay mineralogy on the critical SAR was also reported by McNeal and Coleman [79].

Imhoff Cone–Saturated Hydraulic Conductivity

Values of relative saturated hydraulic conductivity correlated with Imhoff cone results, expressed as dispersion index (DI) to predict the RSHC for the soils, when salt affected, are shown in Figures 10 through 14.

The data in Figure 10 show that near pH 4, the RSHC-DI relationship was independent of Cl concentrations, but at pH of approximately 7.5, the soils (Fig. 11) exhibited two unique RSHC-DI relationships. The first RSHC-DI relationship belongs to the 50 and 200 mmol L^{-1} Cl system and the second belongs to the 5 mmol L^{-1} Cl system.

The data in Figure 12a revealed that the Pembroke soil, at 5 mmol L^{-1} Cl solution, showed two unique RHSC-DI relationships. One occurred at pH 4.3 and the other occurred at pH 6.1 and 7.5. The Uniontown soil (Fig. 12) showed a unique RSHC-DI relationship for each of the pH values tested. When the Cl concentration was raised to 200 mmol L^{-1}, the RSHC-DI relationship became independent of pH for both soils (Fig. 13).

In all of the data displayed in Figures 10 through 13, one piece of specific information stands out. Generally, the slope of the RSHC-DI relationship was greater for the Pembroke soil than the Uniontown soil. This is also shown in Figure 14. This suggested that the SHC of Uniontown soil was less affected by changes in DI than was the Pembroke soil. Moreover, these data also show that to attain similar relative suppression in SHC, a greater DI was needed for the Uniontown soil than the Pembroke soil. This is probably due to soil texture. The Pembroke soil contained 59% clay; the Uniontown contained only 28%. Hamid and Mustafa [81] reported that RSHC-DI relationships are highly affected by soil texture as well as pore size distribution.

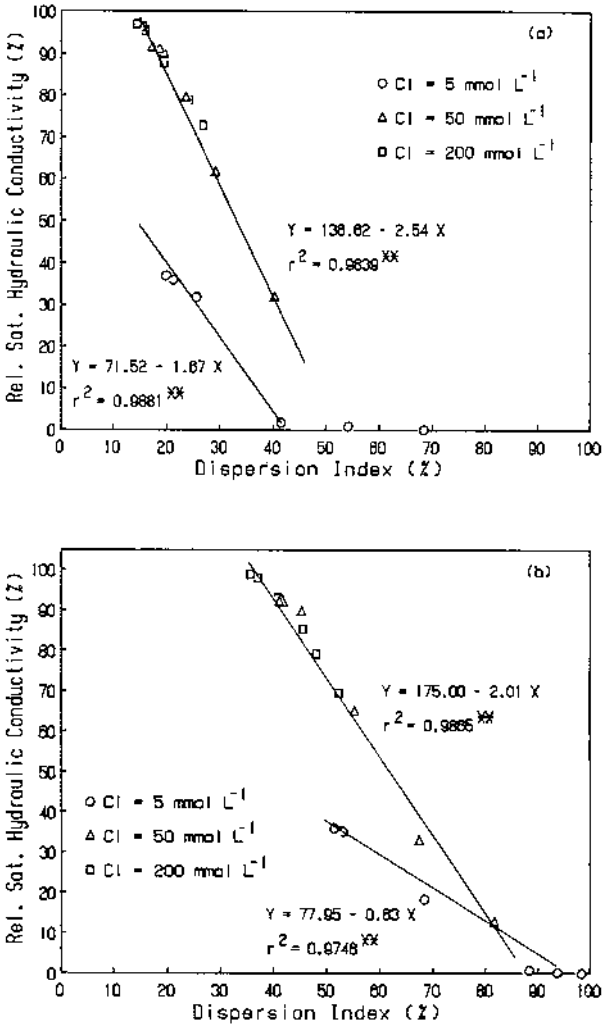

FIGURE 11 Relationship between relative saturated hydraulic conductivity (RSHC) and dispersion index (DI) of the Pembroke soil at pH 7.5 (a) and Uniontown soil at pH 7.7 (b) with three chloride (Cl) concentrations. (From Ref. 92.)

Figure 11 shows that for each of the two soils there was a unique RSHC-DI relationship at the 5 mmol L^{-1} chloride concentration. More importantly, at this Cl concentration a lower DI was needed than with the higher Cl concentrations to suppress to a large degree the SCH. This suggests that at the lower salt concentration, clay swelling is also implicated in reducing SHC [20,74, 79,80,93].

A swelling effect could therefore be implicated in the results shown in Figure 12. As pH increases, a small DI imposes a large suppression in the SHC. The increase in pH could be implicated in increasing swelling potential. This is likely because of the removal of Al-OH polymers from the interlayer (Fig. 15). The presence of Al-OH polymers at the lower pH values may limit interlayer swelling [94]. Clays that have the basic 2:1 mineral structure may exhibit limited expansion because of the presence of hydroxy-Al islands which block their interlayer spaces (see Fig. 3). It is well

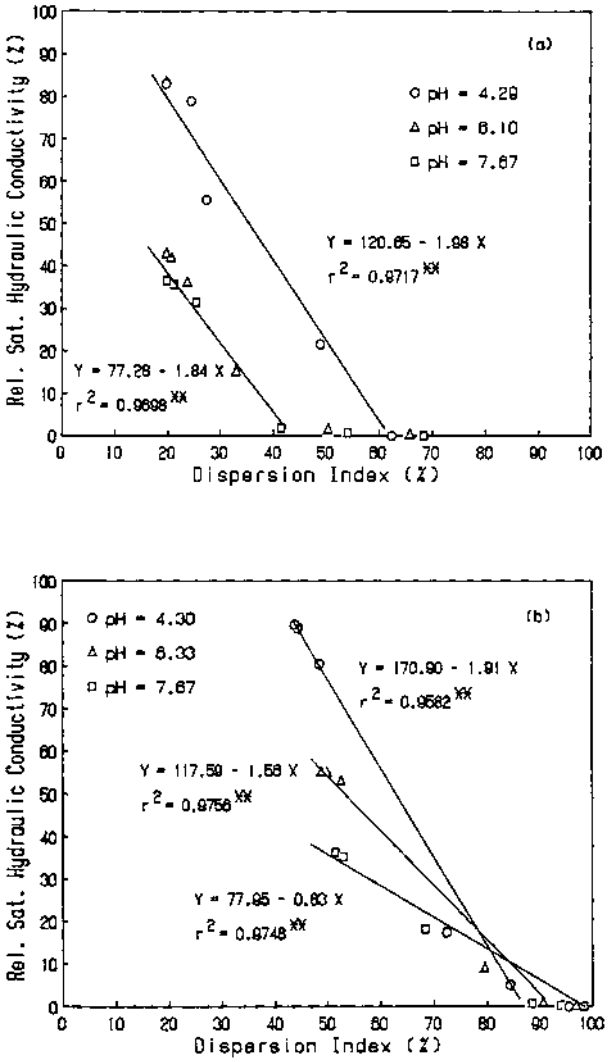

FIGURE 12 Relationship between relative saturated hydraulic conductivity (RSHC) and dispersion index (DI) of the Pembroke (a) and Uniontown (b) soils equilibrated with solutions of 5 mmol L^{-1} of chloride (Cl) at three pH values (DI = amount of dispersed clay divided by the amount of clay in 1 g soil). (From Ref. 92.)

known that these Al interlayer components are completely removed at pH values 9.0–10.0 through dissolution mechanisms [95]. This interlayer removal is expected to increase the dispersion potential of the mineral by allowing free expansion. Similar phenomena of hydroxy-Al interlayer removal have been demonstrated to be the cause for failed septic systems [96] under a far less dramatic chemical regimen than that often encountered in salt brine–contaminated systems. In addition to increased swelling, dispersion can also be enhanced in such systems as a result of the increased mineral surface charge following removal of Al-hydroxy from the interlayer. When removed from interlayer positions, these positively charged hydroxy-Al components would increase the effective

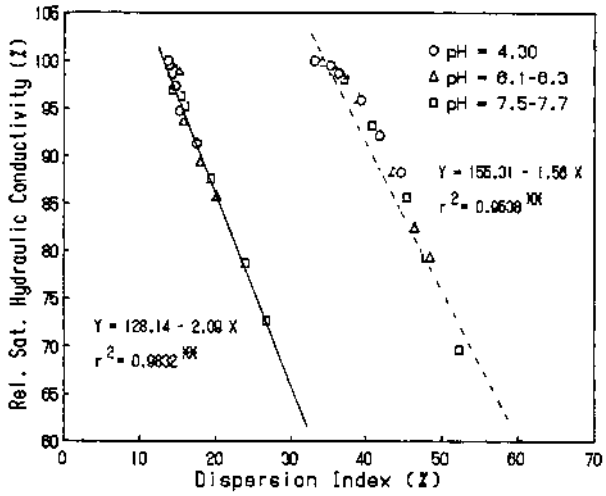

FIGURE 13 Relationship between relative saturated hydraulic conductivity (RSHC) and dispersion index (DI) of the Pembroke (solid line) and Uniontown (dashed line) soils equilibrated with solutions of 200 mmol L^{-1} of chloride (Cl) at three pH values (DI = amount of dispersed clay divided by the amount of clay in 1 g soil). surface charge available for Na adsorption, thus increasing the probability of soil structural destabilization.

CONCLUSIONS

The dispersion index could predict RSHC. The relationship between RSHC and DI is not universal; however, it is unique to a particular soil under a given set of leaching conditions. The properties that appear to influence the RSHC-DI relationship of soils in humid regions are soil mineralogy, soil texture, soil pH, ionic strength, and solution composition. Information on humid region soils clearly demonstrates the following points: (a) the RSHC is related to the clay dispersion index, (b) the relationship between RSHC and DI is dependent upon ionic strength and pH, and (c) soils exhibit different RSHC-DI relationships. Furthermore, soils of the humid regions appear to behave differently with respect to Na^+-Ca^{2+} exchange and physical stability in relationship to soils of arid regions.

Impact of Soil pH on Nutrient Uptake by Crop Plants

Syed Manzoor Alam, Syed Shamshad Mehdi Naqvi, and Raziuddin Ansari
Nuclear Institute of Agriculture
Tando Jam, Sindh, Pakistan

INTRODUCTION

Soil pH is one of the most indicative measurements of the chemical properties of a soil, which exerts far-reaching and potentially favorable or adverse effects on the growth and nutrient uptake by crop plants.

SOIL pH–INDUCED STRESS

The pH of the growth medium has significant effects on the properties of soils and consequently on the nutrient uptake by crop plants. Soil pH is one of the most indicative measurements of the chemical properties of a soil. Whether a soil is acidic, neutral, or basic has much to do with the solubility of various compounds, the relative bonding of ions to exchange sites, and the activity of various microorganisms in the soil systems. Thomas [1] noted that three soil pH ranges are particularly informative: a pH less than 4 indicates the presence of free acids generally from oxidation of sulfides; a pH less than 5.5 suggests the likely occurrence of exchangeable Al; and a pH from 7.8 to 8.2 indicates the presence of calcium carbonate, an important agent of calcareous soil.

Soils with pH values ranging from 4 to 7 [2] are extensively distributed throughout the tropical and subtropical regions of the world. Soils with pH values less than 4 also exist and are commonly found as acid sulfate soils and in mine soils. Plant growth in acid soils may be limited by a variety of factors, including the direct effect of pH (excess H ion concentration) as well as pH-induced toxicities (e.g., Al, Mn) and/or insufficiencies (e.g., Ca, Mg, P, Mo) [3]. Increase in the hydrogen-ion concentration of the medium generally causes a decrease in the rate of absorption of cations, probably as a result of competition between the similarly charged ions for binding and carrier sites. Similarly, the role of high pH has often been considered to be detrimental in causing deficient nutrient availability and ionic imbalance.

Depending on the predominant clay-type soil, pH can indicate the percentage base saturation. It also can indicate something about the degree of dissociation of H^+ from cation exchange sites or the extent of H^+ formation by hydrolysis of Al. Since the availability of most plant essential elements depends on soil pH, it is an indication of the relative availability of plant nutrients. Thus, soil pH is generally an indicator of both the soil condition and of the reactions that occur in the soil.

Soil pH is an important factor influencing the growth of most crops and pastures and the distribution of native plant species [4,5]. Often the effects of pH on the growth of plants are complex and it is difficult to separate direct effects of excess hydrogen (H^+) or hydroxyl (OH^-) ions from indirect effects associated with numerous chemical changes in the solubility and availability of various biologically important plant nutrients [6,7].

Among the various plant parts, the roots are directly affected by the pH of the growth medium. Low pH injury or H^+ injury is one of the factors responsible for growth retardation in acid soils. Hydrogen ions (H^+) increase the solubility of Al, Mn, and Fe in acid soils [8]. The presence of hydrogen ions in the growth medium generally inhibits root elongation, and this phenomenon is observed at extremely low pH [9,10]. It has generally been considered that H^+ injury is negligible in a medium at a pH above 4. However, even in this case, the contents of mineral nutrients in plants decrease with the decrease of the pH [11], and, in some cases, mineral ions flow out of the roots [12]. Excess H^+ in the growth medium affects plant growth by two processes: (a) Nonspecific inhibition of root elongation, lateral branching, and water absorption; and (b) specific effects on root ion fluxes via H^+ competition with base cations for uptake and H^+ damage to the ion-selective carrier in root membranes.

It is generally recognized that poor growth in acid soils is not caused by the Ca deficiency of the soils but by other factors such as Al or Mn excess, because plant growth does not improve by the addition of calcium sulfate to the acid soils. In acid soils, it may be difficult to observe the ameliorating effect of Ca, because Al injury is predominant [13]. In solution culture, however, a high Ca concentration in the growth medium alleviates Al injury or low-pH injury [10] and prevents K loss associated with H^+ injury [12].

Calcium plays an important role in raising the pH of the growth medium. It is required to sustain cell membrane integrity plus facilitate the active uptake of otherwise competitive cations. This ''Viets'' effect of Ca can be demonstrated with other polyvalent cations (including Al) [14], and it has been shown to alleviate the toxic effects of high H^+ activities. At pH levels of less than 4, H^+ may out compete Ca^{2+}, preventing their absorption, and even displacing Ca present in the root apoplast. Once Ca absorption is repressed, cell membranes lose integrity and the selective ion carrier mechanism dysfunctions resulting in reduced base cation absorption and efflux of cations. Loss of root membrane integrity can also produce the wilting symptoms of low turgor pressure observed with H toxicity.

The important role of Al in acid soil chemistry has been reviewed, as have Al effects on plant growth in predominantly horticultural and agronomic species. Three general processes by which Al affects plant growth in acid soils are: (a) reduced divalent cation (especially, Ca) uptake by plant roots due to the presence of excess Al in the rhizosphere or in the root apoplast; (b) dysfunction of cell division in the root meristematic tissue due to penetration of Al into the root protoplasm and the production of abnormal root morphology; and (c) decreased anion (SO_4^{2-}, PO_4^{3-}, Cl^-) adsorption by roots due to increased positive adsorption sites in the rhizosphere and root apoplast. Aluminium activity is critical in the above processes, because at low activities, a synergistic response with plant growth can occur. Aluminium is believed to facilitate monovalent cation uptake (especially K uptake via the Viets effect), and increased P sorption, as hydroxy-Al-P-complexes of low positive charge density have been proposed [15].

Several studies have shown that solution pH greatly affects the absorption of inorganic nutrients by plants [4,5,16]. Short-term studies have shown that, at low pH, ion transport may be impaired, especially at low Ca concentrations, and sufficient membrane damage may occur to allow the loss of previously absorbed solutes. Similarly, long-term studies on several plant species have shown

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

that prolonged exposure of roots to low pH leads to suppression of lateral root development and, in extreme cases, to death of the root tips [17].

The solubility and plant availability of micronutrient cations in soils generally decreases with increasing pH owing to adsorption-precipitation reactions. The pH of the nutrient solution will affect the availability of certain elements, particularly the micronutrients, stimulating excessive uptake at a low pH, and resulting in removal from the nutrient solution by precipitation at high pH. The pH of the nutrient solution is thought to be best when kept between 6.0 and 6.5, although most nutrient solutions when constituted will have a pH between 5.0 and 6.0. In their experiments, Islam et al. [5] have found that tissue concentrations of all essential elements were adequate for healthy plant growth at pH 5.5.

In a solution culture experiment, the concentrations of N, P, K, Ca, Mg, and Mn generally increased in rice leaves with increasing pH values [6] and were higher with NO_3-N than with NH_4-N, whereas Fe content decreased in rice shoots but increased in roots with high pH. The result suggests that a pH of 5–6 is reasonably good for normal growth and nutrient uptake by rice plants with these N sources.

Nitrogen concentration in plant tops decreased with decreasing pH over the range of 5.5–3.3, and in tomato, the concentrations at pH 3.3–4.0 (1.2 and 1.3%, respectively) were clearly in the deficient range [5]. Nitrogen concentrations in cassava (*Manihot esculenta* Crantz.) tops at pH 3.3 and 4.0 (2.3 and 2.6%, respectively) were also well below the critical N concentration of 5.1% in the fourth and fifth fully expanded leaves of cv. Llanera [18] and the normal N concentrations ranging from 4.5 to 6.5% in young fully opened leaves. No satisfactory explanation can be given for the decline in plant N concentrations at low pH. Bassioni [19] observed that NO^-_3 uptake by excised barley roots was less at pH 4 than at pH 6. However, this result is somewhat suspicious, as the test solution apparently did not contain Ca. Rao and Rains [20] reported higher rates of NO_3^- absorption in short-term uptake experiments with barley roots at pH 4.0 than at pH 5.7 or 8.5. Similarly, in flowing solution culture experiment, Forno [21] found that mean rates of N uptake by cassava (as NO^-_3) per unit root weight were either higher at pH 4.4 than at pH 6.8 (Cassava cv. M. Aus. 3) or approximately the same (Cassava cvs. Nina and Ceiba). In the roots of sunflower (*Helianthus annuus* L.) and flax, the total N concentrations were strongly reduced at pH 4 [22]. In soils with pH 7 or below, high concentrations of NH_4^+ can be toxic to raddish (*Raphanus sativus* L.) [23], and NH_4^+ toxicity is particularly deleterious to young seedlings, limiting plant yields.

Ammonium absorption by plants can rapidly depress solution pH to injurious levels in noncalcareous soils (NH_4^+ and Al^{3+} toxicities), because NH_4NO_3 contributes to soil acidity. Ammonium toxicity occurs in many plant species, but it is not considered a problem when the plants are grown in calcareous soils (free $CaCO_3$). Barker and Mills [24] noted that even when all of the N is ammonical, near-normal growth can be obtained if the pH of the medium is buffered to near neutrality (e.g., calcareous soil). Less N plant tissue was found at pH 5.5 under all redox potential conditions in the soil, with the highest pH being 7.5 [25].

Nitrification of NH_4-N based N fertilizers is known to increase soil acidity. Legumes increase soil acidity, because they absorb more cations than anions from soil [26]. Nitrogen, in the NO_3^- form, seems almost universally to lead to an increase in pH. The observed effect of pH on NO_3^- uptake suggests that both H^+ and OH^- are involved in the absorption process. At low pH values, H^+ may cause injury to the root tissue, whereas at higher pH values, competition with OH^- reduces NO_3^- uptake.

Breemen et al. [27] have indicated that nitrification of NH_4^+ and accompanying soil acidification can occur even at a pH of less than 4. Lowering of pH has been found to be associated with the uptake of N as NH_4^+ [28]. Uptake of NH_4^+ by the roots results in a release of H^+. The rhizosphere (or nutrient solution) becomes acidified and root integrity is impaired. This type of NH_4^+ toxicity can be avoided by pH control of the rooting medium. In their experiment with Kentucky bluegrass (*Poa pratensis* L.) and using N sources, Davis and Dernoeden [29] observed that soil pH was affected by N sources. In the years 1987 and 1988, the $NaNO_3$-treated plots had the highest pH, whereas SCU- (sulfur-coated urea) and NH_4Cl-treated plots had the lowest pH. Acidification was greatest

(pH 5.3) in NH_4Cl-treated turf, whereas pH was highest (pH 6.0) in plots subjected to NaCl. They further stated that NH_4Cl-treated plots generally exhibited severe disease injury. Sodium nitrate-treated plots which had the highest soil pH were associated with more disease injury when compared with SCU-treated turf. The data provide no clear evidence for a relationship between disease and soil reaction as influenced by the N sources.

The concentration of H^+ in the growth medium has an especially important effect on phosphate absorption, because over the physiological range of pH values, the predominant ionic form shifts from univalent ($H_2PO_4^-$) to bivalent ($HPO_4^=$), and finally to trivalent ($PO_4^{\equiv}$) as the medium becomes more alkaline.

Decreases in rate of phosphate absorption with increasing pH are well documented [30]. Arnon and Johnson [10] considered that P deficiency contributed to the poor growth of their plants at higher pH values. However, Islam et al. [5] reported that tissue phosphate concentrations were adequate in their plants at pH 8.5. Khalid et al. [31] reported that the availability rates of P depended on the differential sorption under the influences of changing pH. The increase in pH of the test solution from 5.3 to 7.4 may increase P absorption. Arnon et al. [11] found that for tomato, maximum absorption of P occurred at pH 7 and decreased toward pH 3 and 9. Ponnamperuma [32] reported that the increase in pH of acid soils due to submergence is beneficial to plants, as it increases the P availability.

The shifting of pH from acidity to neutrality increases the P mineralization. Several essential elements become limiting to plant growth at alkaline soil pH. For example, the availability of phosphate, Fe, B, Zn, and Mn has been shown to decrease at high pH. Precipitation of phosphate by Ca and the cations by carbonate, hydroxide, or phosphate is responsible for decreased availability of these elements. Hagen and Hopkins [30] observed that excised barley roots absorbed both univalent and bivalent phosphate from the growth medium. This may be due to the fact that roots absorbing more anions than cations excrete OH^- rather than H^+, leading to an increase in solution pH [33].

Soil pH can indirectly reflect the P distribution pattern of soils to a certain degree but not perfectly. The pH of the soil solution determines the form of P absorbed by plants, however, P is absorbed mainly as the inorganic dihydrogen ion ($H_2PO_4^-$). It is known that Ca-P is found in large amounts in alkaline soils, and Al-P and Fe-P are found in acid soils. Therefore, the concentration of phosphorus in the soil solution depends mainly on soil pH, and a decrease in pH can reduce P concentration by causing precipitation of Al-phosphate or Fe-phosphate as amorphous polynuclear complexes with high surface area.

Addition of NH_4^+ rather than NO_3^- increases P uptake from the neutral soils [28]. Generally, absorption of the NH_4^+ tends to lower the pH in the rhizosphere, and in the soil studies, there was a corresponding increase in the concentration of phosphate in the solution. At 1 mM $NaNO_3$ and lower pH [4], the ion uptake (N, P, K, and S) and growth of wheat and rice were severely affected [34]. There was a great decrease in the P concentration with the increase in $CaCO_3$, which was mostly due to the transformation of available P to di- and tricalcium phosphates and also to apatites owing to formation of ferric phosphate/hydroxy phosphate.

Decreases in the K content of plants were observed under low pH conditions [12], and the movement of K in roots was symplastic. It is assumed that in the plants which exhibit a low K content in a medium with a low pH, the function of the plasma membrane is impeded by H^+. One of the main physiological roles of K is to maintain the osmotic pressure of cells (maintenance of turgor). As the roots elongate rapidly by the successive production and thickening of new cells, they must absorb a large amount of K in order to maintain the K concentration of these newly formed cells at a suitable level [7]. Therefore, it is assumed that H^+ decreases the function of the plasma membrane and promotes K loss or the inhibition of K uptake, and consequently brings about poor root growth.

Potassium loss associated with a low pH can be alleviated by the increase Ca concentration in the growth medium [12]. In gramineous crops, the index of the K content tended to increase with the increase of the Ca concentration in the medium. Many experimental results have been published on the stimulation of K absorption by Ca in plant roots [35].

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

Large decreases in the rate of absorption of Ca with decreasing pH have been reported. The availability of Ca has been limited at low pH; this is because as the amount of H^+ increases, the amount of Ca decreases. A strong antagonism between H^+ and Ca^{2+} in legume nodulation has been documented [36], and calcium accumulation in maize has been associated with soil pH. In their experiments, Inoue et al. [7] observed that under both conditions of low pH and low Ca concentration, the Ca uptake was strongly inhibited by H^+, and consequently the corn shoots suffered Ca deficiency, leading secondarily to poor root growth of several gramineous crops. This inhibition of Ca uptake appears to be caused by the antagonism between H^+ and Ca^{2+} at the position of the substitution radical of the cell wall and/or of plasma membrane. Both the contents of K and Ca in barley, wheat, and rye were low in medium with a low pH. It is, thus, considered that since the functions of the plasma membrane and Ca uptake were inhibited by H^+, the root growth was considerably poor. The roots of gramineous crops generally display a low ability to absorb Ca and to transfer Ca to the top. Calcium plays an important role in the strengthening or maintenance of the cell wall and plasma membrane. Assuming that H^+ and Ca^{2+} antagonize each other at the position of the substitution radical of the cell wall or plasma membrane, the increase of the Ca concentration in the medium may alleviate the H^+ injury.

Calcium concentrations in maize at pH 3.3 and 4.0 (0.39 and 0.37%, respectively) were below the concentration normally considered adequate for healthy growth [5]. However, Loneragan and Snowball [37] obtained maximum yield of young maize plants in flowing solution culture when the Ca concentration in the tops was only 0.12%. In the same experiment, tomato and the wheat cultivars Gabo and Wongoondy achieved maximum yield, with Ca concentrations in the plant tops of 1.29, 0.15, and 0.32%, respectively. These Ca concentrations are well below those obtained in the tops of tomato and wheat cv. Gatcher in the experiment carried out by Islam et al. [5] at low pH with different plant species.

Arnon and Johnson [10] attributed much of their growth reduction below pH 5 to inadequate Ca absorption. In a subsidiary experiment with lettuce (*Lactuca sativa* L.) and tomato, these investigators showed that raising the initial Ca concentration in the nutrient solution from 2000 to 7000 μM increased yields at both pH 4 and 5, whereas lowering the initial Ca concentration to 500 μM lowered plant yields. Further evidence of the interation between effects of low pH and Ca concentration comes from studies in legume nutrition. Lucerne (*Medicago sativa* L.) plants supplied with combined N grew equally well at pH 4 and 5, with a Ca concentration of 5000 μM, but that growth was poorer at pH 4 when lower Ca concentrations were used.

In an unsuitable environment, limitation in Ca supply to the plant roots caused disturbance in the growth and metabolic processes in plants. Deficiency of Ca reduces the absorption and accumulation of monovalent cations and increases the uptake of divalent cations [38]. Accumulation of P, K, and Na decreases in all part of Ca-deficient potato plants. This view strengthens the argument that the absence of Ca in the growth medium will cause a decrease in the uptake of K and Na and increases in the accumulation of Mg in plants. Calcium deficiency causes accumulation of oxalic acid in such a quantity as to become injurious to the plants. Calcium helps in the precipitation of oxalic acid and soluble oxalates in the form of Ca-oxalate and protects plants from being affected by more H^+ concentrations. Large decreases in the rate of Mg absorption by different crop plants have been reported with decreasing pH [11]. Magnesium concentrations in the tops of plant species at pH 3.3 and 4.0 (0.03–0.16%) were sufficiently low to be either deficient or marginally limiting for plant growth [6].

The solubility of Fe salts in soils are reported to be governed by the pH of the system, which affects the availability of Fe to the plants. The increase in pH of acid soils is due mainly to reduction of ferric-Fe to ferrous-Fe. The decrease in pH of sodic and calcareous soils and the check on the pH rise of acid soils are the result of the accumulation of CO_2, soil reduction, and organic acid production. Increased Fe availability on calcareous soils can also be achieved by lowering the pH of the bulk soil with the application of S and sulfuric acid. In a short-term experiment, increasing the solution pH from 3.5 to 8.5 decreased the concentration of Fe by the tops of rice plants, whereas in roots, the Fe content increased [4]. At a high-solution pH, the new leaves become chlorotic. The

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

appearance of Fe deficiency in rice plants at high pH may be explained by the low solubility of Fe in the rooting medium by the fast oxidation of ferrous-Fe and by immobilization in the roots. The action of rice roots in oxidizing Fe^{2+} to Fe^{3+} is believed to be responsible for the oxidation of H_2S by the roots, suggesting that chlorosis at high pH may be related to a more rapid oxidation of ferrous-Fe to higher forms [9].

When the pH of the growth medium is high, Fe phosphate is precipitated in the stem and both high phosphate and increased pH are known to enhance Fe chlorosis. High levels of P and Al in the growth medium often have been found to reduce Fe absorption and utilization, especially under neutral or alkaline condition [13]. Rice plants given excess P in the growth medium progressively accumulated Fe [39]. The activity of iron is affected by P in the plant tissue or nutrient media. Poor Fe nutrition depressed the growth of maize and wheat at pH 7.5 and 8.5 despite the use of Fe N,N-dihydroxyethylethylene-diamineacetic acid (HEDDA) (Sequestrene 138) as an Fe source. This compound is reported to be stable over the pH range of 4–9 [40]. Iron concentration in the tops of maize grown at pH 8.5 (85 μg/g) is in the range that has been considered deficient for this species. This observation is confirmed by the development of severe symptoms of Fe chlorosis [41].

The high hydroxyl and bicarbonate ion concentrations associated with the alkaline soil solution in a calcareous soil keep available Fe^{2+} concentrations too low to supply sufficient Fe for normal plant uptake. Similarly, bicarbonate induced Fe stress for plants grown in nutrient solution and in alkaline soils. Some studies have indicated a combination of bicarbonate and high P–induced Fe chlorosis. Iron chlorosis is also enhanced under conditions of increased soil moisture and high Fe to P ratio.

When large amounts of NO_3^- are taken up, more hydroxyl ions are released by roots resulting in decreased availability of soil Fe [42]. The availability of Fe, Mn, Zn, and Cu was low in calcareous soils, and added P antagonized micronutrient deficiencies more under high pH conditions. Therefore, under conditions where Fe is highly insoluble and immobile, the main mechanism of Fe uptake may be by direct contact between insoluble Fe compounds and plant roots. Inhibition of lateral root development would have detrimental effects on the ability of the roots to reduce Fe^{2+}, since the iron-reducing activity occurs at or near the surface of young lateral roots.

Soil pH is often the determining factor in whether a soil will respond to Mn fertilization. Liming coastal plain soils from pH 6.0 to 6.5 intensified Mn deficiency symptoms on soybeans [43,44]. Fitts et al. [45] observed yield responses to Mn only where the soil pH was neutral or alkaline. These investigators found that liming above pH 6 reduced leaching of Mn and decreased plant Mn. The decrease in soil pH from 6.8 to 6.0 during the course of a greenhouse experiment prevented Mn deficiencies from developing in soybeans. Jones and Nelson [46] reported that liming soils to a pH 5.5 or above reduced extractable soil Mn, decreased foliar Mn concentration, eliminated toxic effects, and increased soybean yields. Manganese availability is inversely related to soil pH and its oxidation-reduction potential. Plants take up the divalent form of Mn for their normal growth. The oxidation of divalent Mn to less soluble forms occur in the pH range of 7–8, primarily as a result of microbial activity. At soil pH less than 7, Mn was sufficiently available for normal turf appearance and growth of Bermuda grass (*Cynodon dactylon* L.), and Mn deficiencies observed were pH induced rather than attributable to insufficient total Mn in the soil [43]. A soil pH of 5.3 resulted in highest concentration of Mn in the soybean leaf, whereas pH 7.0 showed the lowest Mn concentration in the leaf [47]. Higher concentration of Mn in the leaf tissue at pH 5.3 was due to the greater solubility of Mn under the strongly acid solution of the soil and consequently absorption by the soybean.

With decreasing pH, the concentration of Mn decreased in crop plants. Similarly, decreasing the solution pH from 7.0 to 5.4 resulted in decreased Mn concentration in the tops of two *Medicago* species. Apparently, in the poorly buffered solution, high Ca levels ameliorated the adverse effects of an acidic pH on Mn uptake. Manganese concentrations in tops of maize (*Zea mays* L.) plants at pH 3.3 and 4.0 (12 and 14 μg/g, respectively) decreased [5] and were in the range that is considered to be inadequate for healthy growth.

Zinc deficiency is prevalent in acid, leached sandy soils having a low Zn content and in neutral

and alkaline soils having high levels of available P and organic matter. Availability of Zn in soils may become critical at soil pH values as low as 5.3. Zinc uptake by corn was significantly correlated with soil pH between 4.3 and 7.5. Lime reduced Zn uptake by red clover (*Trifolium pratense* L.), timothy, and bromegrass (*Bromus marginatus* L.). The N fertilizers affect the availability of Zn, and these effects were attributed to changes in soil pH, and $NaNO_3$ decreased the Zn uptake and $(NH_4)_2SO_4$ increased it [48]. Severe Zn deficiency in subterranean clover with increasing N supply is due to formation of a Zn-protein complex in the roots. The addition of $CaCO_3$ generally decreased the Zn content of sorghum at soil pH levels between 5.7 and 6.6 [49]. The reduction in Zn uptake induced by $CaCO_3$ was attributed to the increased soil pH and not the Ca added. Similarly, the addition of lime to sandy Alabama soils to a pH near 6.5 produced Zn deficiency in corn.

Reducing the pH of the test solution from 5.5 to 4.5 decreased Zn absorption rates by factors of 1000 and 10000 in the rice cultivars IR6 and Basmati-370 [50]. Similarly, reducing the solution pH from 5 to 3 reduced zinc absorption by a factor of about 100 in wheat seedlings [51]. Zinc absorption by plants usually decreases as the concentration of H^+ increases, presumbly because of the direct effect of H^+ toxicity and because of an indirect effect of competition between Zn^{2+} and H^+ ions from uptake sites on the root surface. At low pH in presence of citrate (pH 4.0 and 4.6), when the toxicity effect of H^+ ions was greatest, the roots did not respond to an increasing concentration of Zn [52]. Soil pH, organic matter content, and the presence of other cations affect the availability of Cu to plants in soils. At a pH value above 4.7, Cu is probably precipitated as $Cu(OH)_2$ in the presence of organic matter. Increasing the soil pH decreases the solubility and availability of Cu to plants [53]. However, the pH at which Cu availability is highest appears to vary with the orgnic matter content and the presence of other ions.

The chemistry of boron (B) in the soil is still poorly understood. It is probably present in the soil solution as boric acid, $B(OH)_3$. Liming of acid soils to a pH of 7 and above has often resulted in B deficiencies. The fixation of applied B in soils was much greater at pH 7 and above. The work of Sims and Bingham [54] indicates that hydroxy Al and Fe materials are responsible for B fixation when acid soils are limed. Retention of B by hydroxy Al and Fe compounds was pH dependent. According to Sims and Bingham [55], retention of B was maximum at pH 7 with hydroxy Al compounds and at pH 8.5 with hydroxy Fe compounds. These investigators postulated that the retention of B is due to anion exchange reactions in which borate ions replace hydroxyl ions.

Soil pH also had an effect on the availability of water-soluble B. As the pH was increased from 5.2 or 6.3 to 7.4, the concentration of B in the plant decreased [56]. Boron absorption by plants decreased much more when both pH and Ca concentrations were increased. The uptake of B has been shown to decrease as the Ca uptake has increased. Availability and plant uptake of native or added B was generally lower in calcareous soils than in noncalcareous soils. A high pH and high Ca concentrations of the nutrient solution decreased B uptake by cotton. Neither high pH nor high Ca alone had any effect on the absorption rate of B. It was suggested that the presence of a high concentration of Ca^{2+} and OH^- affected the B adsorption mechanism. Therefore, pH appeared to have a physiological effect on B absorption by plants when the supply of Ca was high.

The S requirements of crops are very similar to their P requirements. Sulfur deficiency is most widely found in leguminous crops. The atmosphere contains S compounds, partly as aerosols and partly as gaseous SO_2. In an experiment, Kamprath et al. [57] observed that there was a marked decrease in the amount of sulfate adsorbed when the pH of a soil was increased from 5 to 6. The effects of pH on sulfate adsorption were much more pronounced on soils that contained appreciable amounts of Al oxides and hydrous Fe. Chang and Thomas [58] have suggested that sulfate adsorption increases when the pH is lowered, because the replaced hydroxyl ions are more effectively neutralized by H^+ resulting from the hydrolysis of Al replaced by the cations added with the sulfate in the soil. The adsorption of sulfate was greater from a solution of $CaSO_4$ than from K_2SO_4. However, the soil pH had a greater effect on sulfate adsorption than did the nature of the cation.

It is well known that acid soils and those rich in Fe stone can strongly fix Mo. In a review on factors affecting availability of Mo, Davis [59] stated that many investigators have shown that Mo availability increases as the pH of the acid soil is increased. Stephens and Oertel [60] suggested

that this might be due to hydroxyl ion replacing adsorbed molybdate ions. The amount of Mo sorbed by soils and the amount of hydrous oxides increased as the pH was decreased. Molybdate ions replaced surface hydroxyls of hydrous oxides of Fe and Al in acid soils. Water-soluble Mo increased sixfold as the pH increased from 4.7 to 7.5. Generally, replacement of tightly adsorbed Mo by OH^- ions is responsible for the increase in the water-soluble Mo as the pH is increased.

CONCLUSIONS

As natural stress, soil pH has far-reaching effects on the growth and nutrient uptake by crop plants. It is difficult to minimize the abnormal effects of pH exerting on the growth of crop plants. However, efforts should be made to reduce the ill effects of pH in order to maintain the normal growth of plants in a growing medium.

INTRODUCTION

The world population has increased during this century from about 1.5 to over 5.5 billion people. Every year, approximately 90 million more people are added to the global population, which is expected to reach 8.5 billion by the year 2025. Since the total area of arable land is stable or declining, the average area of cropable land per person must decrease as population grows. During the recent past, the successful implementation of several technologies that form the basis of modern agriculture has contributed to the production of enough food today, on a global scale, to meet the basic requirements of every person in the world. Mechanization of agricultural production, developments in irrigation systems, cost-effective crop protection chemicals and fertilizers, and genetic enhancement of crops are the major contributors. Yet one-fifth of the developing world's population remains chronically hungry owing to inequalities in availability and distribution. Equitable food distribution is restricted by lack of purchasing power among poor countries and within countries. The threat of famine is greatest in rural areas where approximately two-thirds of the population of developing nations live. Predictions of population growth in developing countries give cause to anticipate further disparities.

Despite the advances of modern agriculture, current average yields of our major crops are only a small fraction of the record yields realized with best management practices (Table 1). The major causes for the shortfall can be separated and attributed, directly or indirectly, to biotic and abiotic factors. Biotic factors, including insects, diseases, and weeds, are responsible for losses representing less than 20% of the record yields of most crop species [1–3]. Abiotic factors, including edaphic and climatic constraints, account for the major portion of the yield losses. Among the edaphic factors, low availability of phosphorus (P) is a major constraint to crop production in the tropics.

Crops grow by acquiring resources from their environment: nutrients and water from soil, oxygen, carbon dioxide, and light from the atmosphere. Agriculture is concerned with making conditions favorable for the acquisition of these resources, so as to produce crops profitably and with minimal environmental damage. Agriculture is also concerned with improving genetic adaptation of crops to abiotic and biotic constraints. Increasing demand for food and fiber requires new approaches to further enhance crop yields and quality. There is also a need to reduce the energy inputs in modern intensive crop production by improving the acquisition and utilization of native and applied nutrients in soil.

Soil and agriculture are the foundation for sustaining human societies through production of food and renewable forms of energy [4–6]. Soils exert production, filtering, and biological functions. Therefore, soils not only produce food, feed, fiber, and fuel but also play a central role in determining the quality of our environment. Land productivity is viewed as decreasing when withdrawals of nutrients exceed their inputs. Maintaining long-term land productivity, therefore, requires that agricultural system management activities minimize exportation of soil resources and, when necessary, replenish depleted resources with inputs.

Global soil maps show that poor soils dominate the tropical latitudes, whereas the most fertile soils are found in certain areas of the Temperate Zone [5]. The inherent infertility of many tropical soils is a consequence of their formation on geological parent materials that were low in essential mineral elements coupled with the intense rates of weathering they have experienced under warm humid tropical conditions. Under these conditions, accelerated chemical and biological processes and high rainfall have resulted in the loss of most nutrients by leaching and the development of a highly acidic solum dominated by the endproducts of mineral weathering: kaolinite and the oxides and hydrous oxides of iron and aluminum [7]. Geological stability and the lack of glaciation have reduced the input of fresh, mineral-rich substrate for soil formation so that highly fertile soils in the tropics are generally limited to areas of active volcanism or alluvial sediments from young mountain ranges [8].

The latitudinal gradient of soil fertility has global economic significance, because most developing countries are located in the tropical latitudes. One tragic consequence of this is that rural poverty is likely to be much more severe in tropical than temperate countries. Economies of Third World countries in the tropics are based disproportionately on agriculture. Owing to their potential

Table 1 Record Yields, Average Yields, and Causes of the Yield Losses of Major Crops

	Mg ha^{-1} (% of record yield)			
Crop	Record yield	Average yield	Yield loss due to biotic factors	Yield loss due to abiotic factors
Corn	19.3	6.6 (34)	2.2 (11)	10.5 (54)
Wheat	14.5	1.9 (13)	0.7 (5)	11.9 (82)
Sorghum	20.1	3.6 (18)	1.0 (5)	16.3 (81)
Soybean	7.4	1.6 (22)	1.3 (17)	5.1 (69)
Cotton	4.0	0.7 (17)	0.9 (22)	2.4 (60)
Sugarbeet	121.0	42.6 (35)	17.1 (14)	61.3 (51)

to increase yields, the use of nutrient inputs has benefited countless individual farmers as well as the economies of these countries, contributing to agricultural development in general. However, weak economies coupled with inherently low soil fertility often are unable to support the investment needed to improve agricultural productivity.

Phosphorus deficiency is one of the most widespread nutrient constraints to agricultural productivity in soils of the tropics [9]. In a sample of 500 soils collected from 42 countries in the tropics, the World Phosphate Institute classified 65% as acutely deficient in P, whereas only 8% were classified as not deficient [10]. Amelioration of P deficiency with fertilizers is not a viable option for many resource-poor farmers. Moreover, as a nonrenewable resource with relatively low concentrations in the biosphere, the use of fertilizer P inputs in any agricultural system must be carefully rationalized [11]. Crop and forage genotypes that can acquire and utilize scarce P resources more efficiently from low-P tropical soils could both improve and stabilize agricultural production.

One advantage of applied P over other nutrients is that once applied it is adsorbed and retained in the soil-plant system and is not subject to the large losses by leaching that occur with N and K fertilizers. Genotypes which can better exploit the residues of fertilizer P would substantially improve the returns on strategic P inputs as well as ''capital investments'' in large basal or corrective P fertilizer applications. The sustained agricultural productivity of low P tropical soils, therefore, requires that crops and forages make the most efficient use of available soil P in order to reduce the demand for P applications.

The genetic potentials of tropical crop and forage cultivars and the environments in which they are grown influence growth and productivity. Adaptation of crop and forage plants to low P-supplying soils could be due to plant mechanisms which contribute to a high P uptake ability at low P concentrations and/or more efficient internal use of P for increased crop/forage yield (Fig. 1). Genetic variability in the ability of plants to absorb, translocate, distribute, accumulate, and use P is important in adapting plants to low P-supplying tropical soils. However, only recently has this

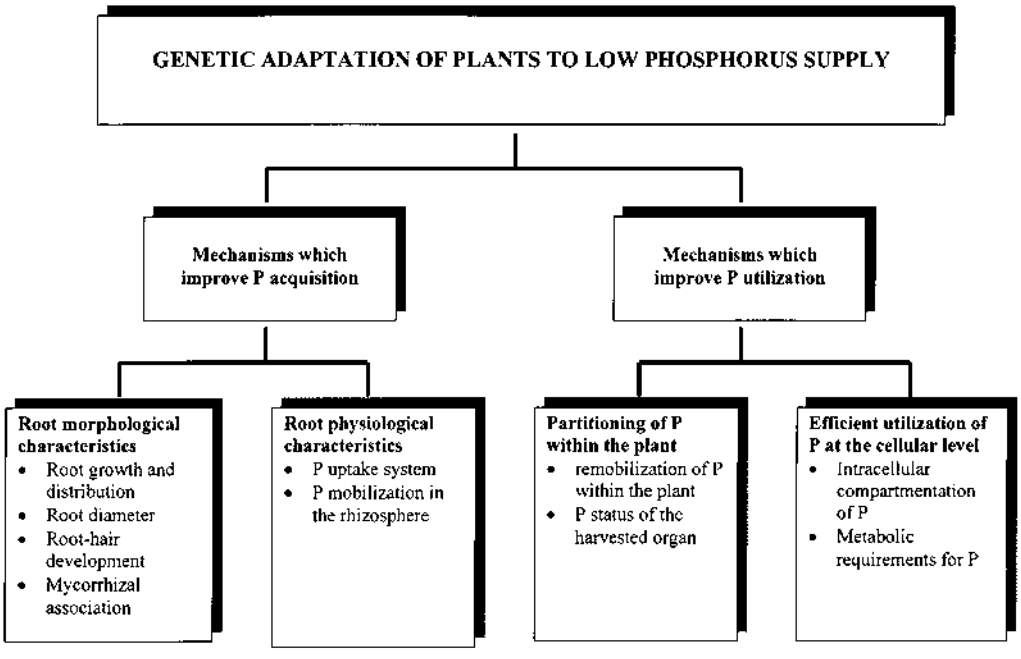

FIGURE 1 Mechanisms which improve genetic adaptation of plants to phosphorus-limited tropical soils.

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

variability been conscientiously considered for the purpose of adapting plants to low-P soil conditions [12]. Although inter- and intraspecies differences in P uptake, accumulation and use are well known [13,14], the mechanisms responsible for the differential abilities of tropical crop and forage species to grow at low or high P supply are not completely understood and few have been described to any extent [12,15]. Understanding these mechanisms is a prerequisite to the identification, selection, and improvement of adapted germplasm for low-P soils.

PHOSPHORUS AVAILABILITY IN TROPICAL SOILS

Tropical soils have been broadly defined as those soils which have an ''iso-'' soil temperature regimen (i.e., mean annual variation of $<5°C$). Approximately 40% of the earth's land surface occurs within the intertropical zone (below 23½° latitude) and more than one-third of world soils are classified as tropical soils [16]. Because they have developed under immense environmental and ecological diversity on both very old and recent land surfaces, soils of the tropics are extremely diverse and variable. All 11 Orders of the U.S. Soil Taxonomy are represented in the tropics. Some 36% (1.7 billion ha) of tropical soils have low nutrient reserves (defined as containing $<10\%$ weatherable minerals in the sand + silt fraction), whereas 23% (1.1 billion ha) have a high P fixation capacity [17]. Phosphorus is probably the major limiting nutrient on the vast majority of these soils [18], particularly the acid savanna soils in South America which are primarily classified as Oxisols [19,20].

Phosphorus-limited soils in the tropics generally fall within the soil taxonomy orders of Oxisols and Ultisols (43% of tropical soils), whereas relatively minor but demographically important areas (in Latin America, cultivated by the poorest sector of the rural population) occur under the Andisol and Spodosol orders (2% of tropical soils). (Approximately 7 and 6%, respectively, of temperate region soils also belong to these orders.) Soils belonging to other soil orders, notably rhodic or oxic subgroups of Alfisols and Inceptisols, also suffer from limited P availability owing to the mineralogical composition; clayey phases may also be high P-fixers [21]. Other less weathered soils of the tropics may also have P limitations for crops because of overexploitation during centuries of cultivation with low inputs.

Characteristics of P-Limited Tropical Soils

Oxisols and Ultisols are characterized by their low content of weatherable minerals and high content of low-activity clays and oxides of iron (Fe) and aluminum (Al), with these minerals being the endproducts of chemical weathering in which primary P in the form of calcium phosphate minerals is hydrolyzed and moves through the soil solution to various adsorbed, precipitated, and organically immobilized forms [22,23]. Weathering results also in the loss of basic cations, the desilication of clay minerals and the generation of iron and aluminum hydrous oxides onto which phosphates adsorb or precipitate. With time the more labile adsorbed phosphate and amorphous precipitates are occluded with fresh coatings of oxides or become more crystalline, reducing P solubility and the concentration in soil solution [24,25]. Through geological time, P is also lost from the system and total P content declines stabilizing typically in the range of 200–400 $\mu g\text{-}P\ g^{-1}$ soil depending on soil texture [26]. Organic P (Po) forms between 20 and 80% of the total P content and constitutes an increasingly important fraction of the total P content of soils as they weather [26–29].

Oxisols and Ultisols also have a moderate to high P-''fixation'' capacity owing to the large surface area for phosphate adsorption presented by the significant contents of amorphous and microcrystalline iron and aluminum oxyhydroxides. An estimated 110–450 mg P/kg soil are required to obtain 0.1 mg P/L in equilibrium soil solution in these soils [30–32], a level considered adequate for crop growth.

Andisols, in contrast to Oxisols and Ultisols, are relatively young soils that most usually developed on volcanic parent materials [23]. Although they often contain high total amounts of P,

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

it usually occurs in highly stabilized inorganic and organic forms in highly amorphous associations with the allophane, imogolite, ferrihydrite, and/or Al-humus complexes which dominate the clay fraction [33,34], and is virtually unavailable to crops. The allophanic materials also impart to these soils a P-fixation capacity which requires even greater amounts of applied P than is usually necessary in Oxisols and Ultisols to attain the required equilibrium solution concentration to support adequate crop growth [21].

Although young soils often show a relatively uniform distribution of total P in the profile, pedogenesis brings about a redistribution in which calcium (Ca)–phosphates are gradually depleted, beginning in the surface horizons, and replaced by organic P [22]. This is the result of biogeochemical cycling of P by deep rooted plant species and the deposition of this P on the soil surface through litterfall and decomposition. Hence, the profile gradient in P concentration increases with increasing age of the soil and is greatest in highly weathered soils. The gradient is also increased by fertilizer applications to the plow layer [35,36]. Phosphorus deposited at the soil surface moves exceedingly slowly in inorganic form into the soil profile, especially in medium to heavier textured soils, owing to the strong adsorption reactions which bind phosphate onto clay colloids [37]. Organic P forms are similarly bound in the surface horizons of allophanic soils [33]. As a result of this significant P gradient with soil depth and the fact that P applications remain close to where they are applied in soil, plant root architecture can markedly affect the accessibility of soil P. Although deeper rooting plants may exploit a greater volume of the soil profile, it is pertinent to ask whether they might better invest their photosynthate in developing roots in the more P-enriched soil layers.

Plants take up P as orthophosphate ions (Pi) from soil solution. Soil solution Pi is in dynamic equilibrium with labile Pi forms adsorbed onto mineral surfaces, and it is replenished as solution concentration is depleted by plant uptake. As labile Pi itself is depleted, less soluble (primary or secondary) Pi forms control the Pi concentration in soil solution [38–40]. Soil solution Pi is also replenished by mineralization of labile organic P forms in processes mediated largely by inter- and extracellular phosphatase enzymes [41,42]. The role of extracellular enzymes in Po mineralization led McGill and Cole [43] to hypothesize that the process is driven more by Pi availability than the need for energy. Thus, microbial activity is controlled both by availability of substrate (e.g., litter and crop residues) and solution Pi concentration (i.e., demand). The availability and contribution of labile Po forms to plant P nutrition, therefore, depends on microbial activity.

As soils weather, an increasingly greater proportion of their labile P content is derived from organic P forms Tiessen et al. [44] showed that, in Mollisols, 86% of the labile P is associated with inorganic P (Pi) forms, whereas in Ultisols, 80% of the labile P is associated with organic P forms. Similarly, Sharpley et al. [28] found an increasing proportion of total P as organic P in more highly weathered soils. This implies that Ultisols and Oxisols rely much more on organic P forms to resupply Pi removed from soil solution by plants. Logically, as shown by Sharpley [45], available P (by Bray P) is correlated with soil Pi content in fertilized soils but with Po content in depleted unfertilized soils.

Availability and Fate of P Inputs

There is an extensive literature (reviewed by Sample et al. [24]) on the reactions and fate of P fertilizers applied to soils. Reaction products differ among soluble and insoluble as well as between inorganic and organic P sources. The nature of the products also depends on the mineralogy of the soil with which they react.

Soluble P fertilizers hydrolyze in soil to produce an acidic, supersaturated solution which diffuses outward from the point of application, dissolving soil mineral constituents as it does so [24]. For Ca-phosphate fertilizers (''superphosphates''), an insoluble Ca-P product (dicalcium phosphate) is initially precipitated at the dissolution site, whereas other secondary phosphates precipitate from the diffusing solution. In calcareous soils, these will mainly be Ca-phosphates, whereas in acidic soils, the main products will be Fe- and Al-phosphates. As the solution radiates outward and insoluble P compounds precipitate, solution P concentration declines eventually to the point where

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

dissolution/precipitation reactions are no longer possible and chemisorption and surface adsorption reactions dominate. These initial reactions occur within a very short time after P fertilizer application (approximately 1–3 weeks) and within a very short distance (<25 mm) from the point of P placement. Because of their amorphous nature, these reaction products are highly labile in soil. With time, however, the amorphous and more soluble products are gradually converted to less soluble more crystalline compounds which, in acid soils, are predominantly variscite and strengite-like compounds.

The availability of insoluble P fertilizers such as phosphate rocks (PR) depends largely on the solubility product of the mineral which is controlled by its mineralogical characteristics [46]. Since the products of PR dissolution are Ca and phosphate ions, and since dissolution involves an acid reaction, Ca and Pi concentration in soil solution and soil pH are important external factors governing PR availability [47]. Of these three, Ca sink size seems to be the strongest factor driving dissolution [48,49]. This suggests that a plant with strong Ca acquisition characteristics may encourage PR dissolution and efficient use of P from these sources. Because it forms a very dilute equilibrium solution, Pi derived from PR dissolution enters primarily into adsorption reactions with soil mineral constituents. Thereafter it may be expected to undergo slow transformations similar to those described above which render it less available with time to plants. Since the PR dissolution rate is slow, it has been argued that release would be more in synchrony with plant demand enabling roots to capture a greater proportion of the Pi before fixation. To the contrary, however, there is strong evidence that soluble P sources are less affected by increased fixation capacity than PR sources [50].

As with soil organic P forms, release of organically bound P from organic inputs (crop residues, green manures, animal manures) is mediated by soil microbial activity (these sources may also contain significant amounts of Pi) [51]. Although not fully understood, there is evidence that the rate of P release from residues is influenced by nitrogen (N) mineralization rates which in turn are affected by substrate composition (C/N ratio, lignin and polyphenol contents) as well as by the C/P ratio [52]. Pi immobilization during residue decomposition has been reported under tropical conditions [53]. On the other hand, the half-lives of P release from residues have generally been observed in the range of 3–18 weeks [52,54,55]. Pi released from organic sources, as with PR dissolution, is either adsorbed onto mineral surfaces or enters into the organic P cycle through plant or microbial absorption. Radioisotopic tracer studies with ^{32}P indicate that mineral surfaces compete very strongly with plants for P released from residues [56].

Forms of P in Low-P Soils and Implications for Improved Adaptation

Phosphorus-limited tropical soils range from highly weathered soils, containing low total (and hence low available) P, to young soils derived from or influenced by volcanic ash, containing large but highly stabilized total P contents. The chemical forms of P in these soils differ widely and organic P pools constitute a significant, indeed often a substantial, fraction of the total P content. Plant adaptation to low-P soils may depend on how the plant can influence the availability of P in the various soil P pools. As will be discussed in more detail below, this can occur in a number of ways, including rhizosphere influences on Pi sorption, dissolution of precipitated Ca-, Al-, and Fe-phosphate forms, and mineralization of organic P forms. This influence occurs primarily through root exudation of protons to maintain internal charge balance or organic acids [57].

Phosphate sorption on Fe and Al oxide surfaces depends on pH, although the literature reports contradictory effects [58–60]. According to Barrow [60], these can be explained by the confounding effects of solution electrolyte composition, the variable charge properties of the oxide surfaces, the form (monobasic or dibasic) of the phosphate ion, and the direction of Pi movement—onto the surface or from the surface. In the absence of cation interferences, increasing pH reduces Pi adsorption owing to increased negative charge on the variable charge oxide surfaces [60]. Paradoxically, and more importantly from the point of view of rhizosphere influence on P availability, decreasing

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

pH results in increased desorption of labile Pi. Phosphate sorption may also be reduced by organic anions such as citrate, malate, oxalate, and phytate which compete for adsorption sites on oxide surfaces (recently reviewed by Iyamuremye and Dick [61]). The effectiveness of anion competition depends on the anion, the nature of the mineral surface, and pH. Similarly, organic acids may release Pi from adsorption sites on Fe and Al hydrous oxide surfaces by ligand exchange reactions [62].

Dissolution-precipitation equilibria of Ca-, Al-, and Fe-phosphate minerals involve H^+ and OH^- ions [63]. As illustrated in phase diagrams [63], the solubility of these minerals (and their amorphous precursors) depends on pH; Al- and Fe-phosphate solubility increases with increasing pH, whereas the solubility of Ca-phosphates, including phosphate rocks, decreases [64]. Changes in pH in the root rhizosphere can therefore influence the dissolution of secondary P forms in soils, although the rates of dissolution may be too slow to have significant impact on plant growth. On the other hand, decreasing pH in the root rhizosphere of legumes as a result of an alkaline uptake pattern has been shown to increase the availability of PR fertilizers [65]. Organic anions may also enhance dissolution of mineral phosphates by forming complexes with metallic ions such as Al and Fe [61,66–69]. Complexation lowers the activity of metal ions in solutions shifting the dissolution equilibrium to the right and bringing more phosphate into solution.

Mineralization of P from organic pools may be stimulated by exudation of organic acids which become substrates for microbial and enzymatic processes in the rhizosphere [41,70]. A large part of soil organic P is in the form of phosphate esters. Phosphate is cleaved from these esters by enzymes such as phosphatase which is produced by roots of higher plants [71]. Helal and Sauerbeck [41] showed that phosphatase activity was much greater in the rhizosphere of maize roots than in bulk soil.

IMPORTANCE OF PHOSPHORUS SUPPLY TO PLANT GROWTH

No soil can sustain high yields if it is deficient in P. As an essential plant nutrient, P is involved in a wide range of plant processes from permitting cell division to the development of a good root system to ensuring timely and uniform ripening of the crop. P is needed most by young, fast-growing tissues, and performs a number of functions related to growth, development, photosynthesis, and utilization of carbohydrates [72–76]. P is a constituent of adenosine diphosphate (ADP) and adenosine triphosphate (ATP), two of the most important substances in life processes. Because of the importance of P for plant growth and yield, many compound fertilizers (NPK) used to correct major deficiencies in soil contain P as a major element [11].

Optimal plant growth requires P in the range of 0.3–0.5% of dry matter during the vegetative growth stage. Dry-matter P contents in excess of 1% may be toxic for most crops. However, many tropical food legumes are more sensitive to excess P, and toxicity may occur at much lower shoot P contents, for example, 0.3–0.4% in pigeonpea and 0.6–0.7% in black gram [77]. The partial productive efficiency of P for grain or seed is higher at early growth stages than at later stages, because P is needed for tillering or branching. If sufficient P is absorbed at early growth stages, it will be redistributed to other growing organs.

The most striking effects of P deficiency are reduction in leaf expansion and leaf surface area as well as total number of leaves [78–81]. The reduction in leaf expansion in low-P leaves is strongly related to the extension of leaf epidermal cells, which may be attributed to their low P content [82]. The reduction in leaf expansion was found to be related to a decrease in root hydraulic conductivity [83]. Reduced leaf expansion, auxillary bud growth, and, therefore, shoot canopy reduce the plant's photosynthetic surface area and carbohydrate utilization [75,76]. Since cell and leaf expansion are more retarded than chloroplast and chlorophyll formation [84], a low P supply increases the soluble protein and chlorophyll content per unit leaf area, resulting in small and darker green leaves [79]. Nevertheless, an inadequate supply of Pi limits the rate of photosynthesis owing to both the short- and long-term effects of Pi on the development of photosynthetic machinery and metabolism [76].

In the short term, low Pi might restrict photophosphorylation which should lead to increased energization of the thylakoid membrane, decreased electron flow, and associated inhibition of photosynthesis. In contrast to the short-term effects, inadequate Pi supply over the long term decreases the rate of photosynthesis by limiting the capacity for regeneration of ribulose 1,5-bisphosphate in the photosynthetic carbon reduction cycle. However, the long-term effects of Pi deprivation on photosynthesis are reversible [85].

Often P deficiency is not easily recognized, because plants may not show symptoms or the symptoms may be confused with those of other nutrients. The effects of P deficiency, for example, may resemble those of N deficiency. Stunted growth, suppression of tillering (in monocots) or branching (in dicots), shorter and more erect leaves, and delayed flowering are common effects of P deficiency in many crops. As indicated above, older leaves may be darker green or, in more extreme deficiency, may turn purple.

Root growth in P-deficient plants is relatively less inhibited than shoot growth, leading to an increase in root to shoot dry weight ratio [85–88]. In the forage legume, *Stylosanthes hamata*, shoot growth declines rapidly, but roots continue to grow under low P supply, not only because most P is retained but also because there is additional net translocation of P from the shoot to the root [89]. The maintenance of root growth at the expense of shoot growth is correlated with an increase in partitioning of carbohydrates toward the roots of P-deficient maize [90] and beans [91], which is indicated particularly by a steep increase in the sucrose content of the roots. The greater assimilate importation and sugar accumulation in the roots appears to be an early plant response to P deficiency [92]. The increase in dry weight and carbohydrate status in P-deficient bean roots was also associated with an increase in alternative respiration (cyanide-resistant pathway) which can be reversed within a few hours after P resupply to low-P plants [93]. The absence of chlorosis and maintenance of a high level of root growth in P-deficient bean plants was attributed to stimulated sucrose transport to roots due to unimpaired phloem loading [94]. This stimulation is probably related to the repressed sink activity in shoots; that is, reduced leaf expansion and shoot growth rate [85,95,96]. There is also evidence for an enhanced elongation rate of individual root cells and roots of low-P plants [97]. In certain plant species, a low P supply results in the formation of ''proteoid roots'' which are clusters of determinate lateral roots [98].

In addition to the aforementioned effects on vegetative growth, a low P supply also limits the formation of reproductive organs. Premature leaf senescence, delayed flower initiation [99], decreased number of flowers [100], and restricted seed formation [101] all contribute to yield reductions under P-limited conditions.

PHOSPHORUS REQUIREMENTS OF TROPICAL CROPS

The P requirements of plants are defined both in terms of their ''internal'' requirements and their ''external'' requirements for plant growth and yield. Genetic variation in plant adaptation to low-P soils may be related to external and internal P requirements. The internal requirement is the minimum uptake by a plant associated with a specific yield, usually near maximum growth [38]. It may also be expressed in terms of concentration; hence the term *critical concentration* for optimal crop growth or yield. Plants take up P as phosphate ions from soil solution and, hence, the external P requirement of plants is the P concentration in soil solution associated with adequate nutrition or growth [38].

Concentration of P in soil solution is very dilute (in the order of 0.01–0.6μg P mL^{-1}) [40,102] and is rapidly depleted by growing roots in soil. Depletion of Pi in the soil solution at the root surface results in the establishment of a concentration gradient between the root surface and the bulk soil solution, a short distance away from the surface. As solution Pi falls below its equilibrium concentration, it is replenished by labile Pi desorbed from clay mineral surfaces adjacent to the roots [38]. Pi thus moves from the adsorbed forms on clay surfaces into solution and along a concentration gradient to the root where the concentration is lowest. The depletion of P observed at the root surface

shows that plants are able to create almost the maximum possible P concentration gradient between bulk soil and the root surface [103]. This is important for the movement of P toward the root surface, because gradient is the driving force of diffusive flux. On the other hand, P depletion may imply severe restriction of P influx into plants, because P influx depends on the concentration at the root surface.

Although the external P requirement for a particular plant varies little between soils, the amount of labile Pi needed to provide a certain Pi concentration in soil solution depends on soil mineralogy and texture [38,104]. In P-limited tropical soils, the quantity of labile P may be insufficient to maintain Pi solution concentration against depletion by plant roots. Adsorption isotherms have been used to establish the relationship between adsorbed (labile) Pi and solution Pi concentration for a wide variety of soils [38]. Based on these, P fertilizer applications are used to adjust solution Pi to the desired concentration for adequate crop nutrition. With their capacity to adsorb large quantities of P from solution, P-limited tropical soils often require much higher applications than Temperate Zone soils.

The P concentration in soil solution (external P requirement) necessary to achieve maximum growth differs widely among crops. Using flowing solution cultures, Asher and Longeragan [105] showed a 25-fold difference in external P requirements among 8 plant species and Asher [106] reported a 200-fold difference for 18 species ranging from *Stylosanthes guianensis* to cassava. External P requirements of a range of crops and vegetables estimated in the field on Hawaiian Oxisols using adsorption isotherms were equally variable [38]. Kamprath and Watson [102] summarized external P requirements for several temperate and tropical crop species in the range of 0.06–0.68 μg P mL^{-1}. Requirements summarized by Föhse et al [107] also demonstrate wide variation in external P requirements as well as internal requirements (Table 2). There was no correlation between internal and external P requirements (e.g., wheat vs onion). These data indicate that the differences were mainly due to differences in the P-acquisition efficiency of the root systems.

MECHANISMS WHICH IMPROVE PHOSPHORUS ACQUISITION

Phosphorus acquisition by plants depends on the morphological and physiological characteristics of the root system, because the relative immobility of P in soil makes P acquisition by the plant very dependent on soil exploration in time and space [14,103,108,109]. Research in germplasm development for the past 20 years has resulted in the identification of superior tropical crop and forage germplasm adapted to low P soils [9,15,110–120]. Crops and forages that are genetically adapted to low P–supplying tropical soils are often characterized by a low P requirement and/or

increased efficiency in absorbing P from soils of low P status, and in utilizing P for plant growth. Identification of plant attributes and mechanisms that contribute to the P efficiency of these crop and forage genotypes, however, remains a major research challenge. Below we consider both root morphological and physiological characteristics implicated in improved P acquisition.

Root Morphological Characteristics

The roots of annual crops have a volume that is usually less than 1% of the soil volume they occupy [103]. Therefore, crop roots contact less than 1% of the total available P in the soil, an amount which is usually only a small fraction of the crop's requirement. Several root morphological characteristics including length, diameter, number, and duration and length of root hairs, as well as mycorrhizal associations, are very important in determining the efficiency of P acquisition from low-P soils.

Root Growth and Distribution

Efficiency in P acquisition depends markedly on rooting density and root distribution in the soil profile. Both parameters depend on plant genotype, soil chemical and physical properties, and cropping system (e.g., rotation). The rooting depth of most annual crops increases as the growing season progresses, although it is rare for it to increase much after anthesis in determinate crops such as the cereals. Indeterminate legume crops continue to allocate assimilate to the root system during early pod filling. Consequently, the total size of the root system continues to increase, although usually at a lower rate than before flowering. Compared with annual crops, perennial forage species, particularly grasses, develop more vigorous root systems as an adaptive feature to low P availability in tropical soils [55,121]. Differences in root growth and distribution to a large extent explain the differences among cultivars in P acquisition [122–124] or the competitive advantages of grasses over nongrasses at low P supply [121,125].

The importance of root size in P acquisition was convincingly demonstrated using maize isolines differing in the ''rootless'' gene [126,127]. A monofactorial inherited mutation caused a drastic reduction in the growth of crown roots of the ''rootless'' isoline [128]. Under limited P–supply conditions, total dry matter production of the ''normal'' line significantly exceeded that of the ''rootless'' line and P acquisition was strongly correlated with root dry weight for both isolines. However, the advantage of the ''normal'' line vanished with the increase in P supply. Otani and Ae [129] found the opposite effect in their examination of the relationships between P uptake and root length, as affected by soil volume and soil P status, in field and pot experiments for several crops, including buckwheat, castor, peanut, pigeonpea, sorghum, and soybean. P uptake by crops was strongly correlated with root length in soils where P availability was high, but not in soils with low P availability or where volume is limited. These results suggest that additional mechanisms besides root length are involved in P acquisition.

Root Diameter

The fineness of the root system (root diameter) is an important attribute that determines P acquisition from low-P soils [103,130]. This is because root diameter defines the maximum volume of soil which can be exploited with a given amount of photosynthate. If a fixed proportion of photoassimilates is used for root growth, a much greater root length can be achieved by reducing root diameter; that is, specific root length (length of root per unit root weight) increases [131]. Root diameter varies between species and cultivars and changes as plants age [132,133]. There are large variations between monocotyledonous and dicotyledonous species [134,135] (Table 3). The greater root diameter of dicots than monocots could be due to (a) a need for a greater surface for symplastic loading and (b) a greater need for basic cations. The variation in root diameter among closely related species was found to be greatest when plant growth is limited by P supply [131]. A comparative study of two wheat cultivars, a modern (''Cosir'') and a traditional (''Peragis''), indicated that the larger specific root length of the modern cultivar contributed to the greater P-acquisition efficiency [136].

Root-hair Development

The formation of root-hairs is one of the most efficient ways to increase P acquisition. Jungk and Claassen [137] found the influx of P per unit root length greatly enhanced by root-hairs. This can be explained by the enlargement of the root surface area and because root-hairs penetrate the soil perpendicular to the root axis, giving access to a larger volume of soil per unit root length. Consequently, P-depletion profiles are found to differ in their radial extension depending on root-hair length [138]. Assuming a frequency of 100 mm^{-1}, a radius of 0.005 mm, and a dry matter content of 5%, Clarkson [139] calculated a threefold increase in surface area could be achieved at an expense of less than 2% of root dry matter.

There is marked variation among crops in the number and surface area of root-hairs per unit root cylinder (see Table 3). Differences in P acquisition among several crops may be explained by differences in root-hair length [140,141]. Root-hair length was 0.28 mm in cotton and 0.77 mm in rape, so that 1-cm length of cotton root would utilize a volume of 19 mm^3, whereas an equal length of rape root would utilize 41 mm^3 [141]. Thus, for cotton, the soil would be completely explored by a root length density of 52 $cm\text{-}cm^{-3}$ but rape would require a density of only 24 $cm\text{-}cm^{-3}$. The major benefit of root hairs in P acquisition seems to be that they enable the root system to operate effectively with low P concentrations in the soil solution. This demonstrates the importance of root diameter and the peculiar geometrical arrangement of root hairs in soil.

Plant breeding for low-P soils could involve selection for root-hair length. Selection for root-hair length improved P-acquisition efficiency of white clover [142]. In the case of wheat, the P-efficient variety had longer root-hairs (1.37 mm) than the less efficient variety (1.19 mm). However, a major limitation for using root-hair length as a selection criterion could be the high environmental variability of this trait [143,144].

Mycorrhizal Association

Mycorrhizae colonize the root systems of most plants and serve as an extended link between plant roots and soil [145]. These links are very important in increasing the efficiency with which root systems can acquire P, since the external hyphal system enables the roots to exploit a larger soil volume. When root exploration of the soil is restricted by low P supply, up to 80% of the plant P can be delivered to the host plant by the external arbuscular-mycorrhizal (AM) hyphae which explore soil to a distance of more than 10 cm from the root surface [146].

Associations of AM fungi are almost universal in the roots of plants in the tropics. Although

roots of most crops are colonized with AM fungi, the mycorrhizal efficiency of P acquisition probably varies markedly among crop species. Cassava has a higher AM dependence than *Stylosanthes guianensis*, cowpea, beans, *Andropogon gayanus*, maize, or rice [110]. Because of its thick roots and poorly branched root system, cassava will not grow without AM infection except in soils with extremely high available P [147–149]. Many other important tropical crops in addition to cassava are also highly dependent on mycorrhizal associations for adequate supplies of P when no P fertilizer is applied [110].

The impact of crop management (e.g., rotations and green manures versus monocultures) on P acquisition may be an indirect way of affecting mycorrhizal infection potential in the soil and root colonization with AM. In natural ecosystems, significant associations between roots, mycorrhizal fungi, and decomposing organic materials can be observed [150]. By this means, plants can achieve very close contact with sites where nutrients are being released by the processes of decomposition. Thus, systems which promote mycorrhizal associations may well be used to influence P acquisition by components and directly reduce P-fixation processes and increase P cycling.

Soil and crop management practices (crop sequence, tillage, fertilizers, pesticides) can influence the total quantity of AM development [151]. Thus, changes in cropping systems and fertilizer applications that affect the soil environment should affect both roots and AM colonization [152]. In continuous monocultures of corn or soybeans, detrimental species in the mycorrhizal fungal community increase relative to beneficial species [153]. In time, crop vigor declines under monoculture, because populations of beneficial AM fungal species decrease. Using different plant hosts, different populations of AM can be built up in the soil around the root system [154].

Mycorrhizal association could reduce the overall retention of carbon in the plant-fungus symbiosis by increasing carbon in roots and belowground respiration, and reducing its retention and release aboveground [155]. A shift in allocation of carbon in mycorrhizal plants to pools that are rapidly turned over (primarily to fine roots and fungal hyphae) could alter the size of belowground carbon pools as well as the quality and, therefore, the retention time of carbon belowground. Should this occur, mycorrhizal associations could significantly increase the rate of cycling of N, P, and S through organic pools in litter and soil organic matter. There is some evidence that mycorrhizal fungi, in certain cases, may directly recycle P from litter [156]. In addition, there is evidence that roots influence decay rates. It is therefore important to define both the magnitude of these effects and the circumstances under which they operate.

In view of the various possible effects of mycorrhizae on plant growth [145,157], a better understanding of the host-mycorrhizal interactions is necessary to be able to predict the capacity of external mycelium to acquire P for the host under various conditions. There is also a need to characterize the conditions at the hyphae-soil interface which may influence P availability in soil.

Root Physiological Characteristics

Phosphorus-Uptake System

The uptake of Pi across the plasma membrane of a plant cell proceeds via $2H^+/H_2PO_4$-cotransport driven by an electrochemical proton gradient [158]. This proton-cotransport mechanism has been found in the Pi-uptake system of *Lemna gibba* [158], corn [159], and *Catharanthus roseus* [160]. Recent studies on phosphate transporters of different species indicate that the mechanism of P uptake at the cellular level is remarkably similar among organisms [161–164].

Under conditions of P deficiency, an enhanced P-uptake system may be induced [165]. This enhanced P-uptake system causes a rapid accumulation of P in leaves once the availability of Pi to roots is improved [85,166]. Under conditions in which the rate-determining step in P uptake is located in the root, P uptake will increase if root length per unit plant weight and maximal net influx per centimeter of root length (I_{max}) increase and the Michaelis-Menten constant (K_m) and minimum concentration (C_{min}) decrease [167].

Large genotypic differences in the efficiency and kinetics of P uptake from soil have been

reported [168]. However, the assessment of the kinetic parameters (I_{max}, K_m, and C_{min}) characterizing the uptake system of a genotype is complicated by at least three factors [136]: (a) the plasticity of the system in response to the P status of the plant [137,169], (b) the differences in P uptake along roots [170,171], and (3) the dependence of P uptake on plant growth rate [172]. Thus there is general agreement that the efficiency of the uptake system is of minor importance for P acquisition from soils, because transport of P to the root surface rather than the uptake is the limiting step [103]. Therefore, it is less likely that selection for an efficient P-uptake system will contribute to more efficient P acquisition from low-P soils.

Phosphorus Mobilization in the Rhizosphere

In low-P soils, root-induced changes in the rhizosphere may be particularly important in P acquisition. There is increasing evidence that root release of organic acids (especially malic acid, citric acid, and perhaps oxalic acid) are key components in this respect. Organic acids differ markedly in their capacity to complex Fe and Al and thus solubilize the respective P compounds in soil bound by these ions. An example of this high specificity was seen in pigeonpea which releases a particular acid (piscidic acid) that complexes Fe but not Ca [111]. Accordingly, pigeonpea is highly P efficient on Alfisols where P is bound predominantly as Fe-phosphates but not on Vertisols where P occurs predominantly as Ca-phosphates. The release of organic acids is enhanced under conditions of P deficiency [173–175]. Aluminum tolerance in certain crop species is associated with the release of organic acids stimulated by monomeric Al species in soil solution [176]. It is expected that both mechanisms are important in mobilizing P from sparingly soluble sources in the root rhizosphere in low P-supplying tropical soils. In addition to these two mechanisms, Ae et al. [177] proposed that cell walls of plant roots are involved in P-solubilizing activity. Their results indicated that groundnut root cell walls had a higher P-solubilizing activity than those of soybean or sorghum. Thus, there is a need to further examine ''direct contact reactions'' between the root surface and P minerals.

Organic P forms in infertile tropical soils probably contribute significantly to plant P nutrition, particularly in natural ecosystems [178]. Root exudation of acid phosphatases (ectoenzymes) is common in plants and is usually enhanced under P deficiency [179]. The kinetic constants of secreted acid phosphatase enzymes from roots may be used as an indicator of the P stress tolerance of plants [180]. Secretory acid phosphatase can liberate bound P from soil [181] and have been shown to deplete organic P in the rhizosphere of lupin roots within about 2.5 mm of the root surface [182].

A comparative study using 16 plant species indicated a marked variation in the secretion of phytase from roots of P-deficient plants [183]. Secretion of phytase was highest in *Brachiaria decumbens* CIAT 606, *Stylosanthes guianensis* CIAT 184, and tomato. It is speculated that the secretory phytase could provide an efficient mechanism for wide adaptation of the tropical forage grass *B. decumbens* CIAT 606 (planted on over 40 million ha) to the low P–supplying tropical soils of Latin America. Studies of enzyme activity at the soil-root interface [180,184] may help to identify genotypes which are more efficient in mobilizing organic P sources in soil.

At least some species of AM fungi also show acid phosphatase activity at the external hyphae, effectively utilizing organic P (Po) (e.g., Na phytate) and supplying it to the host plant [185]. There is a need to evaluate the capacity of hyphae, roots, and mycorrhizal roots to utilize these various forms of Po using compartmented pots [185,186].

MECHANISMS WHICH IMPROVE PHOSPHORUS UTILIZATION

In addition to possible genotypic differences in P acquisition, plant adaptation to P-limited tropical soils can be partially attributed to inherent genotypic differences in P use efficiency (PUE). From the agronomic point of view, the amount of total biomass and/or economic yield produced per unit of acquired P indicates PUE [187–189]. As defined, such efficiency is controlled directly or indi-

rectly by plant traits and mechanisms related to basic metabolism [190], by patterns of partitioning and remobilization of P among different organs and tissues [12], and perhaps mostly by the capacity of the plant to accumulate dry matter owing to efficient utilization of P in plant metabolic processes. A comparison of the amount of P taken up by various crops to produce 1 ton of yield is shown in Table 4 [149,191–193]. Beans and soybeans stand out as the most P-demanding crops.

PUE is sometimes considered to be the inverse of P concentration [194–197]. This definition may be more useful in describing the current dynamics of P acquisition in relation to P utilization. PUE can also be defined as a response (measured in dry weight) for a given increase in P content during a given increment of time [14]. All plants exhibit an increase in PUE under conditions of P deficiency [86,198–200], because (a) a larger proportion of plant biomass is allocated to tissues with low P concentration (e.g., roots as contrasted with leaves or reproductive organs); and (b) P storage in vacuoles declines [201] and structural and nonstructural carbohydrates increase [76,86,202].

Efficient utilization of P acquired from low-P soils is dependent on a number of plant attributes [12,15], including (a) high–dry matter yield per unit of P acquired, (b) growth duration and plant type, (c) partitioning of P between different pools within the plant, (d) translocation and partitioning of P within the plant, (e) redistribution of previously assimilated P, (f) leaf death rate, and (g) partitioning of a greater proportion of biomass to harvestable yield. When the P supply limits plant growth, higher plants undergo changes in a number of shoot and root attributes [86,121,201,203]. Among them are a marked reduction in leaf area production [78,79], an increase in P-uptake capacity per unit root length [204–208], an increase in root to shoot ratio [79,209,210], changes in the morphology of the root system [107,118,211], and an increase in the proportion of total P partitioned to roots [209,212,213]. Several studies indicate that P-efficient species have a high ability to retranslocate P from inactive to active tissues [201,214–216]. Several of these plant attributes may be significantly affected by association with AM fungi [14,150].

Table 4 Comparison of P Uptake and P Taken Up per Unit of Economic Yield by Various Crops

Crop	Plant part	Yield (kg ha^{-1})	Total P uptake and removal (kg P ha^{-1})	Total P uptake per unit yield (kg P t^{-1} yield)
Maize	Grain	9,416	26	4.67
	Total	19,496	44	
Rice	Grain	5,380	10	2.97
	Total	10,990	16

When the P supply is limiting in soil, plants have to make most efficient use of the P that they have acquired. Improvements in P use efficiency can be achieved by at least two major mechanisms: (a) changing the partitioning of P among plant parts and (b) increasing the metabolic efficiency of P at the cellular level. These are discussed in the following sections.

Partitioning of Phosphorus Within the Plant

Remobilization of Phosphorus Within the Plant

The ability of crop plants to remobilize P from vegetative to reproductive organs and forage plants from senescing to growing points may form an important mechanism that allows plants to improve the utilization of acquired P [15]. Any factor that affects plant growth (and therefore P demand) will alter PUE. For example, the degree of P remobilization from leaves increases when there are P sinks such as reproductive organs present; this results in reduced leaf P concentration (i.e., increased PUE). On average, about 50–75% of the P contents are retranslocated from a leaf before it is shed [217,218]. Comparison of two white clover cultivars has shown that the more P-responsive cultivar was better able to remobilize P from senescing tissue to growing points than the less P-responsive cultivar [219]. Populations of white clover collected from low-P soils had a lower proportion of dead leaf to total leaf than populations from high-P soils when grown in solution culture [220]. Several researchers found that species adapted to low-P soils generate a lower proportion of dead leaf to total leaf material when under P stress than species from high-P soils [221–224].

Based on nutrient harvest indices in soybean, it has been suggested that more seed P than N is derived from remobilization [225,226]. From these studies, it appeared that P nutrition and the remobilization of vegetative P to reproductive structures may be closely associated with leaf senescence and productivity. But subsequent studies using soil P treatments showed that P nutrition, in general, and specifically P remobilization from leaves, does not exert any regulatory control on the process of leaf senescence [227], and seed development in soybean may occur independently of net P remobilization [228].

Snapp and Lynch [229] measured P remobilization from roots and leaves and examined the influence of P nutrition on remobilization patterns and tissue longevity in the common bean cultivar, ''Calima.'' Using a split-root system and ^{32}P tracer, they demonstrated that low-P roots successfully competed with reproductive tissues for available P. Retention of P in low-P roots was in contrast to remobilization of P from leaf and stem to grain in both low-and high-P plants. They suggested that root P retention may allow roots to sustain nutrient and water uptake late in the ontogeny.

Common bean lines with low P concentration in shoot tissue retained more P in roots and older leaves under P-deficient conditions than lines with a high P concentration [230]. The greater remobilization of P in bean lines with a high P concentration could be attributed to greater P requirement to maintain normal metabolic activity in growing tissues. But in the case of a forage legume, white clover, there was no evidence that populations from low-P soils were more effective in remobilizing P from senescing leaves than populations adapted to high-P soils [220]. When both populations were grown in low-P soils, the P concentration in dead leaves did not differ, indicating that differences in remobilization of P from leaves prior to senescence or abscission were not a significant adaptive feature of white clover populations growing on low-P soils [231]. Thus, the contrasting patterns of P remobilization from older leaves between common bean and white clover may indicate the importance of maintaining greater P concentration in the grain of crop plants.

Phosphorus Status of the Harvested Organ

The concentration of P in the harvested organ (grain) is important, because (a) it indicates the amount of P used to produce a kilogram of harvested organ; (b) high-yielding genotypes with low grain P concentration would remove less P from the soil and therefore reduce the cost to produce each ton of grain; and (c) reduction of grain P concentration would also lower the concentration of phytic acid, an antinutritional factor [232,233]. However, high grain P concentration may have some bene-

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

fits, including greater seedling vigor and higher grain yield if the seed is used to grow the following crop [234,235].

Glasshouse and field studies using a genetically diverse range of wheats indicated that the concentration of P in grain was negatively correlated to the harvest index (grain dry weight/grain + straw dry weight) [236,237]. However, the strength of this relationship varied between seasons and the level of fertilizer P application [237]. Based on these data, it appears that, if adequate selection pressure is applied, higher or lower grain P concentrations can be achieved. However, attempts to retain P in vegetative tissues may be counterproductive, because a reduction in the supply of P to developing grains could result in smaller grain size [238].

Efficient Utilization of Phosphorus at the Cellular Level

A number of tropical crop and forage species can grow normally with low tissue P concentrations owing to efficient utilization of P among the major biochemical fractions. Several studies have indicated that the differences in utilization of P fractions (soluble P, Lipid P, and residue P) may form the basis for the identification of plants tolerant to low-P environments [73,196,210,239]. Comparative studies between lotus and white clover suggested that changes in the pi concentration in tissues may affect the ability of species to survive under low-P environments [240]. Lotus, which maintained relatively low tissue Pi concentrations, was found to be more tolerant to low-P conditions than white clover, which exhibited high-Pi concentrations in the tissues. Leaf Pi concentrations are also known to regulate plant growth, photosynthesis, and carbon partitioning [76,85]. Leaf Pi values correlated most closely with relative grain yields ($R^2 = 0.89$) of pot-grown barley in mineral soils [241].

It is possible that species which have a relatively small ''pool size'' of Pi would be able to maintain high metabolic activities at the low external Pi supply and therefore be adaptable to low-P soils. On the other hand, Chisholm and Blair [196] concluded in their experiment with white clover and stylo that differences between species or cultivars in lipid P stability may form the basis for the selection of plants tolerant to low-P conditions. Adu-Gyamfi et al. [242] compared the degree of P tolerance in soybean and pigeonpea based on the utilization of P fractions, especially at low-P conditions. They found that pigeonpea is more tolerant to low-P conditions compared with soybean, because it maintains relatively low tissue concentration of Pi owing to the efficient incorporation of the external Pi into residue P. The importance of intracellular compartmentation of P and metabolic utilization of P for plant adaptation is discussed below.

Intracellular Compartmentation of P

The pioneering work of Bieleski and his associates [73], using radioisotopes, showed that the cytoplasm and vacuole work as distinct compartments for Pi at the cellular level in plants. Intracellular Pi compartmentation studies using ^{31}P-NMR (nuclear magnetic resonance) indicate that, under Pi deficiency, the vacuole acts as a Pi reservoir to maintain a constant cytoplasmic Pi concentration [76,243,244]. Measurements of in vivo changes in intracellular distribution of Pi in soybean leaves as affected by P nutrition, using ^{31}P-NMR, indicated that the cytoplasmic P pool, and the leaf carbon metabolism dependent on it, are buffered by the vacuolar P pool until the late stages of reproductive growth [245]. Using ^{32}P-labeled Pi, and an autoradiographic measuring system highly sensitive to beta irradiation, Mimura et al. [246] visualized and measured the retranslocation of Pi in the same plantlet. Under Pi deficiency, the cytoplasmic Pi concentration of the first leaf remained constant until 16 days after sowing whereas vacuolar Pi was completely exhausted after 8–10 days. The exhaustion of vacuolar Pi in the first leaf coincided with the appearance of the second leaf. They suggested that various membrane-transport systems, that is, the plasma membrane and the tonoplast, play important roles in Pi homeostasis and translocation. Further research is needed to measure the changes in the Pi-transport activities of these membranes during plant growth with a limited Pi supply.

Metabolic Requirements of P

Differences in the utilization of leaf P fractions (soluble P, lipid P, and residue P) may form the basis for genetic differences in plant adaptation to a low P supply in soil [15]. Species with a low leaf Pi ''pool size'' may be able to maintain high metabolic activity at a low external Pi supply and therefore be adapted to low-P soils. Jeschke et al. [247] compared, for the first time, complete inventories of uptake, transport, and utilization of C, N, and H_2O between and within organs of intact castor bean plants deprived of P at a given growth state. Despite much lower intakes under P deficiency, the general patterns of flows and partitioning of C, N, and H_2O, in comparison with the P-sufficient plants, appear to be well coordinated and well adapted toward allowing the plants to withstand the disadvantageous P deficient conditions. They suggested that the formation of a proportionally larger root system in P-starved plants would clearly offer a means of adaptation to a deficiency of P supply.

GENETIC ADAPTATION TO LOW PHOSPHORUS SUPPLY IN SOIL

Several physiological attributes of plants can exhibit considerable genotypic variability in their expression, a high degree of stability in genotype ranking across environments, and in some cases a high narrow sense heritability so that improvement through recombination and selection may be both effective and relatively straightforward [248]. Genetic variability for the trait or traits in question and the ability to manipulate this genetic variability for improvement of desirable traits are two essential components for enhanced genetic adaptation of crop and forage species and cultivars to a low P supply in tropical soils. However, plant breeders are aware of the fact that selection for a single desirable trait can often have deleterious effects such as (a) poor field adaptation as a result of ignoring the general agronomy of the crop and (b) concomitant changes in other desirable traits which are of adaptive significance. Genotypic variation in plant traits related to P acquisition and utilization has been observed in a number of crop and forage species [112,115,123,168,188,233,249–265] (Table 5). Since a number of shoot and root traits contribute to P acquisition and utilization, determining the genetic control of these traits becomes a major research objective [13,266].

Shoot Traits

Reciprocal grafting experiments indicate that shoot factors rather than root factors regulate P uptake per unit root size [267]. This is because removing a part of the shoot, by cutting, reduced P uptake per unit root weight. But removal of half of the root system from the P supply, either by splitting root systems or root pruning alone for approximately 3 days, had no effect on P uptake per unit root weight [268]. It may be that the rate of P absorption is quite strictly regulated by biochemical factors which vary with the rate at which P is utilized for plant growth [269]. There is evidence that P uptake is regulated primarily by Pi concentration of the root cell [270] which largely reflects the P status of the shoot [271]. Increase in the root Pi concentration improved P-acquisition efficiency of the tropical forage legume *Arachis pintoi* [265].

Screening of several hundred accessions of wheat for tolerance to a low P supply in soil showed that lines with a higher harvest index had greater and more consistent grain yields compared with lines with a low harvest index [272]. High P efficiency in other wheat genotypes was also associated with high harvest indices [233].

Field and pot studies were conducted to evaluate genetic variation in diverse bean germplasm for P efficiency on soil types with contrasting P chemistry and to assess possible relationships between dry matter distribution, P partitioning, and yield [254,255]. They found no evidence for specific adaptation to low P availability in volcanic or mineral soils. They also showed that vegetative and reproductive responses to low P availability are not correlated.

TABLE 5 Summary of Studies Identifying Genotypic Differences in P Acquisition and Utilization in a Range of Crop and Forage Species

Species	No. of genotypes	Shoot and root traits measured	Reference
Crops			
wheat	23	Grain yield, P uptake, root dry weight, P harvest index	188
	20	Harvest index, grain P concentration	233
	9	P uptake, root length	123
corn	9 inbreds	Dry matter yield, P uptake, root to shoot ratio	112
rice (upland)	20	Dry matter yield, root length, P uptake, P use efficiency	249
barley	7	Dry matter yield, P uptake, net P influx rate	168
sorghum	8 parents and 16 hybrids	Dry matter yield, P uptake	250
	2	Dry matter distribution, P distribution, P uptake	251
pearl millet	12	Grain yield, dry matter, P uptake, P use efficiency	252
cassava	4	Root yield, root length density, P uptake, P use efficiency	115
bean	26	Shoot growth, P distribution	253
	16	Shoot growth, root growth, P accumulation	254
	12	Grain yield, yield components, P distribution	255
	6	Shoot biomass, root biomass, P accumulation	256
cowpea	20	Grain yield, root dry weight, P use efficiency	257
	5	Shoot dry matter, P uptake	258
pigeonpea	2	Dry matter yield, root length, root surface area, P translocation, P distribution	259
soybean	2	Root carbohydrates, P uptake	260
mungbean	3	Shoot dry matter, nodulation, N_2 fixation	261
Forages			
white clover	98	Shoot dry wt., root dry weight, shoot P, root P	262
	6	Shoot dry wt., root dry weight, root hairs, P uptake	263
lucerne	2	Shoot dry wt., root dry weight, P uptake, P use efficiency	264
stylosanthes	4	Shoot dry wt., root dry weight, P uptake, P use efficiency	265
centrosema	4	Shoot dry wt., root dry weight, P uptake, P use efficiency	265
brachiaria	4	Shoot dry wt., root dry weight, P uptake, P use efficiency	265

Root Traits

Evaluation of the root system as a selection criterion can help to increase productivity and yield stability [273]. A special synthetic variety of lucerne (*Medicago sativa*) with a large root system has been developed which is notable for performance, stability, and persistence [274]. A recent review [266] summarized the extent of genotypic variation in a number of root traits. Traits that reflect root system size include root weight, root length, root number, and root volume. Traits that reflect root morphology include root diameter, primary root length, number of adventitious roots, root branching, root length density, and root-hair length. In addition to these traits, those that increase the solubility of sparingly soluble soil P such as, root exudates, root exocellular phosphatases and phytases, and root-induced pH changes are also important. At low levels of available P, total root length, root weight, and extensiveness (mass and surface area) of all roots and root-hairs were found to be important traits in genetic adaptation of tomato [275] and white clover [142] to a low P supply. However, these traits were not important when plants were grown with adequate levels of available P or with mycorrhizal association at low P.

Genetic Manipulation of Traits

The existence of, or potential to create adequate genetic variability in important shoot and root traits, is a prerequisite to favorable genetic manipulation. Classic plant breeding techniques and/or modern molecular and cellular biological techniques for gene transfer can be employed to improve plant adaptation to P-limited environments [13,118,119,276,277], as discussed below.

Use of Classic Plant Breeding Techniques

Coltman et al. [275] used yield at a low P supply as a selection criterion to identify strains of tomato that are adapted to P deficiency. They found that broad-sense heritability for yield at a low P supply varied from 0.61 to 0.67 depending on generation. In the expression of low-P tolerance, dominance effects were more important than additive genetic variance. Additive gene effects indicate that a genetic trait is altered by each additional allele whereas dominant gene effects indicate gene action deviating from an additive condition, such that the heterozygote is more like one parent than like another.

A study of P-efficiency traits in wheat indicated that P uptake in shoots per unit root dry weight, which describes the ability of the plant to obtain P from the soil, is a far more beneficial measure for use in breeding programs than either grain yield per unit P uptake or grain P content as a percentage of total P uptake [188]. Selection for shoot P concentration has been successful with realized heritabilities for increased P concentration of up to 0.36 for alfalfa [278] and narrow-sense heritabilities of 0.42 for wheat [279]. Three major genes [280], probably located on chromosome 9 [281], seem to control P concentration of the ear leaf of maize. In sorghum, dominant effects were found to be more important [250], whereas in wheat, additive genes were responsible for P utilization (the inverse of P concentration) differences [279]. In common bean, epistatic effects (i.e., gene interactions where one gene interferes with the phenotypic expression of another nonallelic gene[s]) were important [282]. Genetic component analysis in rice suggested that both additive and dominance gene effects are involved in the inheritance of P-deficiency tolerance [283].

Selections for extremes of root system size have been successful in alfalfa [284], ryegrass [285], white clover [286], maize [287], spring wheat [288], peas [289], and rice [290,291]. Heritabilities for root weight have been estimated frequently for a number of crop and forage species by several researchers [266], with a median narrow-sense heritability of 0.53 (mean 0.52 $\pm$ 0.05). Heritabilities increased with depth of rooting for root number and root surface area of creeping bentgrass [292]. For root to shoot ratio and root growth rate, the median narrow sense heritabilities were 0.52 and less than 0.4, respectively [292].

There has been some inconsistency among studies in determining the importance of additive and dominance effects on root system size [266]. Both additive and dominance components of

genetic variation were important for root number in maize [287], root length and weight in spring wheat [288], root weight and root volume in peas [289], and root length, root number, root to shoot ratio, and root volume in rice [290,291]. However, only additive gene effects were important for root length and diameter in rice [293].

Genotypic variation in responsiveness to P application (i.e., growth rate per unit of P applied) was observed in rice [249,294,295], maize [294], sorghum [12,250], beans [296], and white clover [297]. In white clover, superior genotypes were identified that combined both tolerance to low P (i.e., high yield at low P) and an ability to respond to added P [298]. Genetic studies indicated that high P response (higher dry weight increase per unit of P applied) was dominant over low P response, and that narrow-sense heritabilities for P response were moderate (0.33–0.66) [299]. The ratio of dominant to recessive genes in all white clover parents was approximately 2 for P response. Moreover, it was estimated that at least four individual or groups of genes are involved in the P response [299].

In a breeding program to improve dry bean performance under P deficiency, Schettini et al. [300] successfully employed one accession of an exotic snap bean germplasm and demonstrated that quantitative traits such as P efficiency can be transferred into an agriculturally useful genetic background using the inbred backcross line method. They found, in general, that the lines which performed well in nutrient solution culture also performed well in a field test in soil moderately deficient in P.

Use of Molecular and Cellular Biological Techniques

During the past decade, much progress has been made in the use of molecular and cellular biological techniques to improve plant adaptation to biotic and abiotic constraints. Many of the agronomically and economically important crops have been transformed so that genes for pest and disease resistance, improved grain or fruit quality, herbicide resistance and more recently aluminum tolerance from a variety of sources can be and are being inserted [301,302,303,304]. Molecular markers and associated technologies can assist in map construction and the analysis of the molecular and genetic basis of quantitative and qualitative traits [305]. Rapid progress in this field has enabled high-density genetic maps to be made and the location of the genes regulating the expression of physiological and agronomic characteristics that are inherited in a quantitative manner to be determined using a combination of statistical analysis, multiple regression, and maximum likelihood techniques [306,307]. By analyzing these quantitative trait loci (QTL) for coincidence among traits, it is now possible to test whether the characteristics are causally related.

The molecular maps produced by restriction fragment length polymorphisms (RFLP) and random amplified polymorphic DNA (RAPD) have excellent potential for use as tools for gene mapping of root and shoot traits associated with plant adaptation to a low P supply in soil. QTL analysis has been used to identify the number of loci in a maize population segregating for tolerance to low-P stress, their approximate location, and the magnitude of their effect [308]. Six RFLP marker loci were found to be significantly associated with performance under low-P stress. One marker locus accounted for 25% of the total phenotypic variation. Additive gene action was predominant for all of the QTL identified.

Further progress in the use of molecular and cellular biological techniques is dependent on finding common ground among molecular/cell biologists, breeders, physiologists, and agronomists to test genes for low-P adaptation and to identify genes that will be useful for yield improvement under low P availability in soil.

SUMMARY AND CONCLUSIONS

The supply of P to plant roots depends on soil properties such as P content, chemical form of P compounds, and the mobility of this P in soil. These parameters constitute the P availability of a soil. The amount of P that a plant can acquire from this available P depends on its root length and

on several other morphological and physiological properties of the root, including association with AM fungi. Furthermore, availability and acquisition of P are markedly affected by root-induced changes in the rhizosphere such as P mobilization by root exudates. Different crops and forages differ in their ability to extract P from soil, presumably owing to differences in rooting characteristics and root-AM symbiosis and to differences in their ability to influence and modify the rhizosphere soil.

When the P supply limits plant growth, higher plants undergo changes in a number of shoot and root attributes. Among them are a marked reduction in leaf area production, an increase in P uptake capacity per unit root length, an increase in root to shoot ratio, changes in the morphology of the root system, and an increase in the proportion of total P partitioned to roots. Several studies indicate that P-efficient species have a high ability to retranslocate P from inactive to active tissues. Several of these plant attributes may be significantly affected by association with AM fungi.

Poor adaptation of plants to a low P supply in soil is mostly the result of the inability of roots to absorb P from soil solution that is low in P supply and then to function metabolically and physiologically because of the low available P concentration in the plant. Plant adaptation to low-P soils can be maximized by manipulating the genetic characteristics related to P acquisition and utilization, by enhancing the symbiosis with mycorrhizal fungi that may increase the soil volume from which P can be acquired, and by increasing the P supply of the soil through application of P-containing fertilizers or adjustment in soil pH.

It must be recognized that strategic P inputs are essential components to increased and sustained agricultural production in any agricultural system and in infertile tropical soils in particular. Resource-poor farmers in the tropics, however, often cannot afford fertilizer inputs. Their best short-term option for increased production is therefore to use germplasm adapted to poor soils. This situation conflicts with the demand for a higher food supply to support increasing populations and the need to protect the resource base against nutrient mining and further degradation. However, more efficient genotypes may also extract the greatest benefit from applied P and thereby provide farmers with a greater incentive to apply P fertilizer. Since P acquisition by even the most efficient genotypes is unlikely to exceed much more than 20% of the total fertilizer P applied to low-P soils, small strategic P applications based on soil P availability and reduced crop P requirements will gradually build up the level of available P in the soil. Consequently, the frequency and amounts of P applications required to sustain production will decrease with time. The challenge, however, will be to provide farmers with the incentive to begin the process of strategic P application. This is more likely to succeed if the fertilizer requirements needed to produce an economic return can be reduced through the use of more efficient crop and forage germplasm.

FUTURE RESEARCH PRIORITIES

Approaches to improve P nutrition of plants involve either manipulation of the plant to improve its ability to acquire and utilize P or manipulation of the plant's environment to improve the physical and chemical availability of P in soil [309]. The former approach involves both the identification of plant attributes and traits which confer greater efficiency in P acquisition and the selection of species and genotypes that have a greater capacity to utilize P for maximizing crop/forage yield within the plant (that is, greater internal P use efficiency). Greater efficiency in P acquisition may also be achieved by manipulating the symbiosis between plants and AM fungi in soil to maximize P uptake. Manipulation of the plant's environment to enable greater acquisition of P may involve removal of physical and chemical limitations to root growth or activity (such as improving soil tilth and penetrability and reducing toxicities such as Al). It may also involve increasing the availability of soil and applied P by reducing the rate of fixation and increasing P cycling in crop-livestock production systems [55]. There exists a great potential for genetic manipulation of plant efficiency in P acquisition and utilization.

In view of the various possible effects of mycorrhizae on plant growth [145,157], a better

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

understanding of the host-mycorrhizal interactions is necessary to be able to predict the capacity of external mycelium to acquire P for the host under various conditions. There is also a need to characterize the conditions at the hyphae-soil interface which may influence P availability.

It is essential to identify differences in P acquisition among crop and forage components from different P sources and soil P pools in P-limited tropical soils in order to design crop/pasture production systems that optimize the use of strategic P inputs. Introduction of forage/cover legume components with crop components could stimulate soil P transformations and P cycling that improve the profitability of P applications to P-limited tropical soils. Economically viable and ecologically sound P management in tropical soils can contribute not only to sustained crop/animal production but also to reduced soil degradation.

Mechanisms Involved in Salt Tolerance of Plants

BENJAMIN JACOBY
The Hebrew University of Jerusalem
Rehovot, Israel

INTRODUCTION

A large part (about 70%) of the surface of the earth is covered by oceans that comprise a salt solution with an osmotic potential of about −2.0 MP, derived primarily from sodium and chloride—about 0.5 and 0.6 M, respectively [1]. It is further estimated that a third of the world's irrigated land has been salinized to various degrees. This salinization results from an accumulation of salts dissolved in the irrigation water. Many wild as well as cultivated plants have thus to deal with saline environments.

A saline environment imposes two principal kinds of stress on plants: an osmotic stress and a toxicity stress.

OSMOTIC STRESS

The water potential of plant cells generally equilibrates with that of their environment. The water relations of plant cells and their environment are given by Equation (1) [2]:

$$\Psi_w^o = \Psi_w^i = \Psi_\pi^i + \Psi_p \tag{1}$$

where Ψ_w = water potential, Ψ_π = osmotic (or solute) potential, Ψ_p = turgor, o = outside and i = inside. The water potential of the saline environment, Ψ_w^o, is primarily determined by its salt concentration (Ψ_π). Exposure of wall-encased plant cells to the low Ψ_w^o of a saline environment results in equilibration of Ψ_w, by cell-water loss and an accompanying decreases of Ψ_π^i and turgor (Ψ_p), according to Equation 1. In wall-less cells, such as those of some microalgae, turgor is almost nonexistent and $\Psi_w^i = \Psi_\pi^i$. In such cells, the lowering of Ψ_w^o, the consequent water loss, and the decrease of Ψ_w^i, are accompanied by a decrease of Ψ_w^i and of cell volume.

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

Turgor is a prerequisite for plant cell expansion and growth. A simplified description of the growth in relation to turgor is given in Equation (2) [3]:

$$G = m\ (\Psi_p - y) \tag{2}$$

where G = growth rate, m = plasticity of cell walls, and y = threshold turgor for cell enlargement. In a saline environment, growth should, hence, cease if turgor is not regulated. Salt-resistant plants are able to regulate their turgor within the range of their salt resistance, or they are able to adjust cell-wall plasticity and threshold values.

Turgor Regulation

Bisson and Gutknecht [4] described the sequence of events occurring in plant cells on external salinization and decrease of Ψ_w^o (Fig. 1): Water exits from the cell, turgor decreases, and water potentials equilibrate. The turgor decrease is sensed by a ''turgor sensor,'' apparently in the plasma membrane. The sensor emits an ''error signal'' that is transduced to the activation of some biochemical processes, such as increased solute accumulation or synthesis. Changes in the physical tension of the cytoskeleton during water stress might be involved in triggering the responses [5]. Enhanced accumulation and synthesis results in an increase of the amount of solutes in the cell, a transient decrease of Ψ_π^i and Ψ_w^i water influx, and eventually recovery of the original (regular) turgor pressure. During the recovery phase, Ψ_w^i and Ψ_π^i do not change, but the amount of solutes in the cell and turgor increase concurrently. In wall-less cells, a similar sequence of events regulates volume instead of turgor.

Some initial error signals resulting from turgor decrease have been investigated. In the salt-resistant Characean *Lamprothamnium* [6], a hypertonic salt shock induced a hyperpolarization of the plasma membrane potential. Concordantly, in red beet tissue slices and some plant roots, a nonplasmolysing hypertonic DASW, (dilute artificial sea water −0.5 MPa) shock induced an enhancement of plasma membrane (PM) adenosine triphosphatase (ATPase) activity; in response to

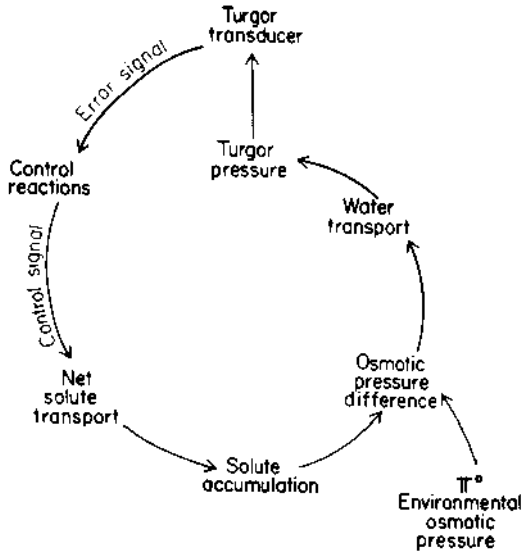

FIGURE 1 Basic elements of turgor regulation system based on solute and water transport. Input of system is random fluctuations in environmental water potential and output is turgor pressure. (From, Ref. 4.)

a similar (−0.5 Mpa) mannitol shock, enhanced K^+ uptake could be measured as well. The DASW shock also induced an increase of the inositol-1,4,5-trisphosphate (1,4,5-IP_3) content in the cells [7] (Table 1), a decrease in PM phosphatidylinositol-4,5-bisphosphate ($PtdInsP_2$) (Table 1), and phosphorylation of some PM membrane proteins [7] (Table 1). The effects of a DASW shock on ATPase activity, 1,4,5-IP_3 and $PtdInsP_2$ were observed 1 min after shock application and before enhancement of protein phosphorylation was evident [8] (Table 1). This sequence of events implied that protein phosphorylation was not a prerequisite for DASW-induced enhancement of ATPase activity. All the cited effects of DASW were inhibited by neomycin, an inhibitor phospholipid interconversion and hydrolysis in animals [9] and plants [10]. These cited DASW effects could be induced by secondary butanol in the absence of a DASW shock (Table 1); the latter compound artificially activates G-proteins [11]. These results indicated that the initial, turgor loss–induced, *error* signal involves G-proteins and the phosphoinositide cascade [12]. Changes in PM phosphoinositide composition may activate the PM ATPase [9,12,13]. Protein phosphorylation may be involved in subsequent activation of processes responsible for long-term turgor regulation, such as synthesis of osmoprotective compounds. For example, osmotic stress increased the phosphorylation of spinach leaf sucrosephosphate synthase, catylized by a Ca^{2+}-dependent protein kinase [14]. In yeast the protein phosphatase calcineurin was essential for salt tolerance. The latter data indicated that NaCl adaptation in yeast depended on signal transduction involving Ca^{2+} and protein phosphorylation/dephosphorylation.

Calcium ions also seem to be involved as a second messenger in transduction of the error signal in the unicellular, wall-less alga *Poterioochromonas*. In response to an osmotic shock, this alga regulates volume first by enhanced K^+ uptake and later by isofloridozide synthesis. The synthesis depends on Ca^{2+}-mediated activation of the enzyme isofloridozidephosphate synthase [15]. Volume regulation was not hinged on the presence of external Ca^{2+}. The Ca^{2+} needed for activation of isofloridozide synthesis should, hence, have originated from an internal compartment, apparently the vacuole. Calcium release from the vacuoles of plant cells is induced by elevation of cytosolic 1,4,5 -IP_3 [16]. Increased cytosolic Ca^{2+} concentration seems to induce the release of a membrane-bound protease in *Poterioochromonas* cells. The protease, in turn, activates isofloridosidephosphate synthase [15].

Joset et al. [17] distinguish between immediate responses to salt stress, such as those cited above and long-term adaptations that are protein synthesis dependent. The latter kind of adaptations reported for higher plants include synthesis of neutral organic compounds; induction of salt stress–associated proteins, such as osmotin [18] and gluthatione peroxidase [19]; and upregulation of PM [20] and tonoplast [21] H^+-ATPases. Some of the stress-inducible genes that encode proteins, such as Δ^1-pyrroline 5-carboxylate synthetase, a key enzyme for proline biosynthesis, were overexpressed in transgenic plants to produce a salt-tolerant phenotype of the plants [22]; the latter results indicated that the gene products really function in stress tolerance.

Genes induced during water- and salt-stress conditions are thought to function not only in protecting cells by the production of important metabolic proteins but also in the regulation of genes for factors involved in the signal transduction cascades of the stress response [23]. The latter include such factors as protein kinases and phosphlipase C [5,24].

Solutes Employed for Turgor Regulation in Plants

Various organic solutes, as well as mineral ions, in particular Na^+, K^+, and Cl^-, are accumulated in plants during turgor or volume regulation. Some halophytes, the native flora of saline environments [25], adjust their solute content mainly with inorganic ions. *Suaeda maritima* plants grown in 370 mM NaCl (−1.76 MPa) maintained the Ψ_π of their leaves at −2.5 MPa and NaCl accounted for 93% of the accumulated salt [26]. In other plants, such as the marine alga (*Porphyra purpurea* L.) [27], sodium is excluded or excreted, and KCl is the major solute accumulated for turgor regulation. Potassium chloride also comprises most of the solute accumulated in the extremely halophylic bacteria *Halobacterium halobium* grown in 3 M NaCl, whereas Na^+ is excreted and maintained at a low

internal concentration [28]. In other plants, a larger part of the solutes comprise organic compounds. Thus, in mature leaves of *Thinopyrum bessarabicum*, a salt-tolerant perennial grass [29], K^+ and Na^+ salts accounted for only 50–60% of the sap Ψ_π in both control and salt-treated plants. In control plants, the K^+/Na^+ ratio was 60, and it changed to 1.0 in plants treated with 0.37 mM NaCl in the medium. A survey of salt marsh plants [30] showed low K^+/Na^+ ratios in dicotyledonous halophytes and high ratios for monocotyledons. The range of K^+/Na^+ ratios for dicotyledons was 0.06–1.19 with a mean of 0.38 ± 0.3, and for monocotyledons, it was 0.27–14.2 with a mean of 2.4 ± 0.6.

Neutral organic solutes make major contributions to turgor regulation in unicellular, slightly vacuolated algae [31]. A large part of the biomass of plants would have to be diverted to turgor regulation if organic solutes were the main compound employed for this in highly vacuolated plant cells. Greenway [32] calculated that for adaptation to 100 mM external NaCl with hexoses, 20–30% of the total biomass would be needed. Raven [33] analyzed the cost benefit of turgor regulation with different solutes. These calculations show that 2–4 mol photons of light energy are needed for the accumulation of 1 osmol KCl or NaCl, whereas 68–78 mol photons are needed for the synthesis of 1 osmol sorbitol or mannitol, 70–93 mol photons for 1 osmol proline, and 78–101 mol photons for 1 osmol glycinebetain. The exact amount of mol photons needed in each case depends on whether the solutes are accumulated in the roots or shoots, and for proline and glycinebetain, also on the N source—NH_4^+ or NO_3^-.

Energy inexpensive turgor regulation with mineral ions, seems to be limited by the inhibitory effects of high salt concentrations on various metabolic processes in the cytoplasm. Hence, adjustment to low Ψ_w^o with mineral salts is limited in the cytoplasm and largely confined to the vacuoles. Slightly vacuolated organisms, such as *Chlorella, Ochromonas*, and *Dunaliella*, have to use compatible organic compounds for a large part of the adjustment. The same seems to be true for the cytoplasmic compartment of vacuolated cells.

Cytoplasmic Compartmentation of Organic Solutes

Various lines of evidence indicate that, in response to salt stress, organic solute accumulation in vacuolated plant cells is primarily restricted to the cytoplasmic compartment (cytosol and cytoplasmic organells). As the cytoplasm constitutes only 5–10% of the osmotic volume [34] of vacuolated cells [35], relatively small amounts of solute can account for the adjustment therein to high external salt concentrations.

Cytoplasmic confinement of digeneaside (2-D-glyceric acid α-D-mannopyranoside) accumulated under saline conditions is indicated for the marine red alga *Griffithia monilis* L. [36]. Digeneaside concentration decreased in the cells of this alga with cell size and concomittant vacuolization. The digeneaside/chlorophyll *a* ratio of the cells however did not change (Table 2). These relations indicated that digeneaside accumulation was restricted to the cytoplasm that also contains the chlorophyll. Confinement of organic solutes to the cytoplasm was also shown for *Mesembryanthemum crystallinum*. Exposure of this plant to 0.4 M NaCl was accompanied by pinitol (1-D-3-O-methyl-

TABLE 2 Variation of Digeneaside Concentration with Size of *Griffithia monilis* Cells[a]

Cell size	Digeneaside (μmol g^{-1} FW)	Chlorophyll a (mg g^{-1} FW)	Digeneaside (μmol g^{-1}/Chlorophylla *a*)
Large	1.97	0.097	20.3
Small	5.87	0.280	20.9

chiro-inositol) accumulation in the leaves to 10–14 mmol (kg frwt)$^{-1}$ [37]. Leaf-cell protoplasts, chloroplasts, and vacuoles were separated and analyzed. Calculations indicated a pinitol concentration of 230 mM in the chloroplasts and of 100 mM in the cytosol; none was detected in the vacuoles.

Transmission electron microscopy and x-ray microanalysis were employed by Hall et al. [38] to localize glycinebetaine in shoot cells of *Suaeda maritima*. Glycinebetaine was shown to be accumulated under saline conditions and to be restricted to the cytoplasm (Fig. 2).

Adjustment of Cell Wall Characteristics

Equation (2) [$G = m(\Psi_p - y)$] shows that the growth rate (G) of plant cells depends on cell wall plasticity (m) and on the turgor above a threshold value (y). Hence, in order to maintain growth under saline conditions, plants may either increase the amounts of solutes in the cells and regulate turgor or adjust plasticity and/or threshold turgor. Adjustment of threshold turgor can indeed be considered as regulation of the effective turgor ($\Psi_p - y$). Plasticity and threshold turgor are both cell wall characteristics.

Munns et al. [39] found only partial turgor regulation in the unicellular microalga *Chlorella emersonii* L. when exposed to low external Ψ_w. However, growth decreased much less than turgor (Table 3). They found a large decrease in the volumetric elastic modulus ε of the cells. This modulus is the relation between turgor change ($\Delta\Psi_p$) and relative volume change (ΔV) during variations in water content of plant cells ($\varepsilon = \Delta\Psi_p \times V_{\text{initial}}/\Delta V$). The decrease of ε was not related to a decrease in wall thickness; the latter, indeed, increased with water stress. The investigators concluded that the decrease of ε indicates a change of cell wall properties that also effects plasticity and threshold turgor. The latter changes would explain the relatively small effect of turgor decrease on the growth rate of *Chlorella emersoni*.

SALT TOXICITY

Sodium chloride is the most important constituent of saline environments. The accumulation of NaCl by plant cells for turgor regulation is limited by the toxicity of a high salt concentration. Such cytoplasmic Na^+ toxicity is ubiquitous in all eucaryotes and bacteria. Even the ancient halophilic *Halobacteria* [40] accumulate K^+ and Cl^- to concentrations of several mols L^{-1}, but not Na^+. The accumulated K^+ and Cl^- ions are located in the cytoplasm of these bacteria and the enzymes are adapted to the high KCl concentration. Enzymes extracted from salt-adapted halophytes are NaCl sensitive. These enzymes are severely inhibited in vitro at salt concentrations similar to those that are optimal in the medium for growth of these plants [41,42]. The in vitro salt sensitivity of amino acid incorporation into proteins by microsomes from salt-adapted halophytes (Fig. 3) did indeed not differ from that of microsomes obtained from glycophytes [43].

The specific harmful effect of NaCl, in addition to its osmotic effect, was elegantly demonstrated by Cramer et al. [44]. They monitored the growth of maize roots in the presence of mannitol

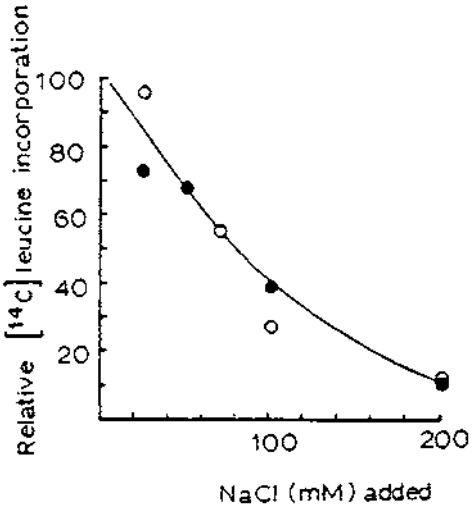

FIGURE 3 The effect of NaCl on the incorporation of leucine into protein by microsomal fractions prepared from *Suaeda* grown in the presence (open circles) and absence (closed circles) of salt. (From, Ref. 43.)

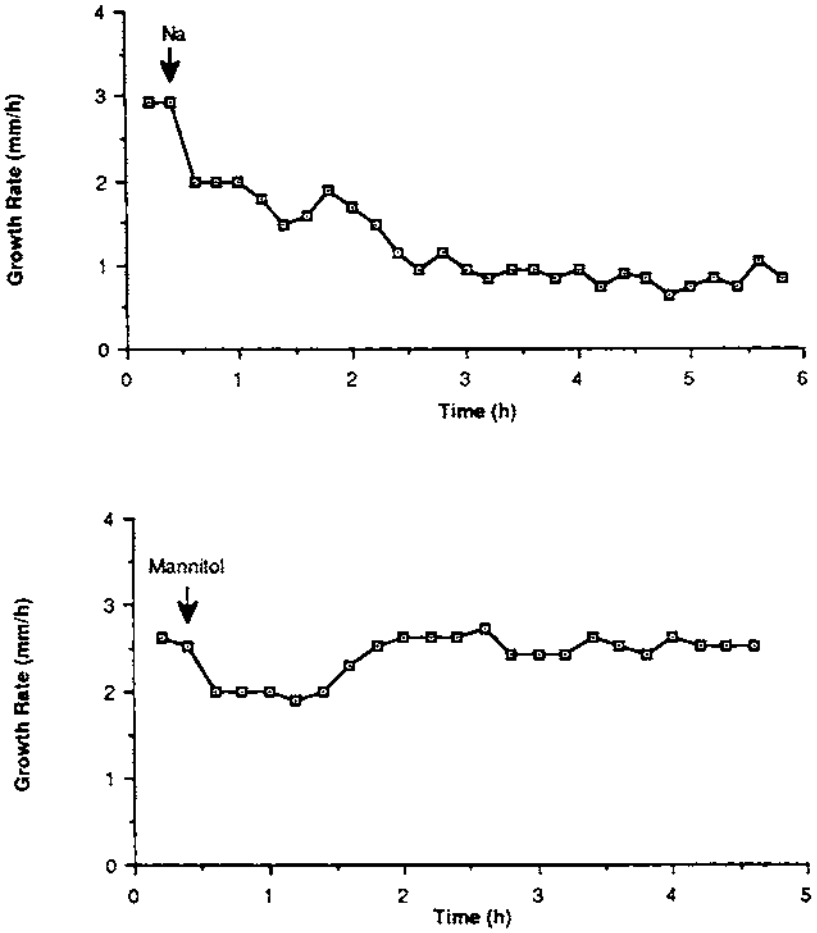

FIGURE 4 The effects of NaCl (above) and mannitol (below) on root elongation over time. At the time indicated by the arrow, 75 mM NaCl or 138 mM (isotonic) mannitol were added. (From, Ref. 44.)

and isotonic NaCl (Fig. 4). In mannitol, an initial decrease of growth rate occurred followed by gradual recovery. In NaCl, the growth rate declined to 20% of that before salt addition and did not recover.

Plant Strategies for Sodium Avoidance

Plants have apparently evolved two principal strategies for avoiding high sodium concentrations in the cytoplasm: compartmentation and exclusion.

Sodium Compartmentation and Compatible Solutes

Many halophytes regulate turgor by NaCl accumulation to a concentration higher than that in the saline medium. Numerous essential enzymes are severely inhibited in vitro at such Na^+ concentrations. Flowers et al. [45] compiled a list of enzymes that are 50% inhibited when exposed in vitro

to the salt concentration found in their source tissue. Wyn Jones et al. [46] suggested compartmentation of salts in plant cells. Thus, in plants, such as the halophilic grass *Distichis spicata* L. [47] that accumulate large amounts of sodium salts in their cells, these salts seem to be occluded in the vacuole, where they serve for turgor regulation. Organic solutes that are compatible with enzyme function apparently have a large share in turgor regulation in the cytoplasmic compartment of the plant cells.

Compatible osmolytes found in higher plants comprise a relatively small number of low molecular weight organic compounds, mainly proline [47–55], glycinebetaine [29,38,51,55–57], some sugars [29,58–60], polyols [37,60], and malate [60]. A larger variety of such compounds is found in lower plants [31,47]. Compatible solutes are supposed to provide an environment that is compatible with macromolecular structure and function [61]. It was proposed that these solutes are preferentially excluded from the surface of proteins and their immediate hydration sphere. Thus, the addition of these solutes to a protein suspension creates a thermodynamically unfavorable situation, since the chemical potentials of both the protein and the additive are increased. This situation stabilizes the native conformation of the proteins, because denaturation would lead to a greater contact surface between the protein and the solvent, thus augmenting the unfavorable effect [62]. Steward and Lee [50] demonstrated the compatibility of proline with glutamate dehydrogenase extracted from the halophyte *Triglochin maritima*. The enzyme was not inhibited in vitro by proline up to a concentration of 0.6 M. Similar results were obtained for barley leaf malate dehydrogenase and barley-embryo pyruvate kinase [63]. These enzymes were not inhibited in vitro by up to 0.5 M glycinebetaine. In addition, glycinebetaine, and to a lesser extent dimethylglycine, partially restored malate dehydrogenase activity in the presence of NaCl. The enzyme was 70% inhibited in the presence of 0.3 M NaCl alone. The inhibition decreased linearly with addition of glycinebetaine to 50% at 0.5 M glycinebetaine (Fig. 5).

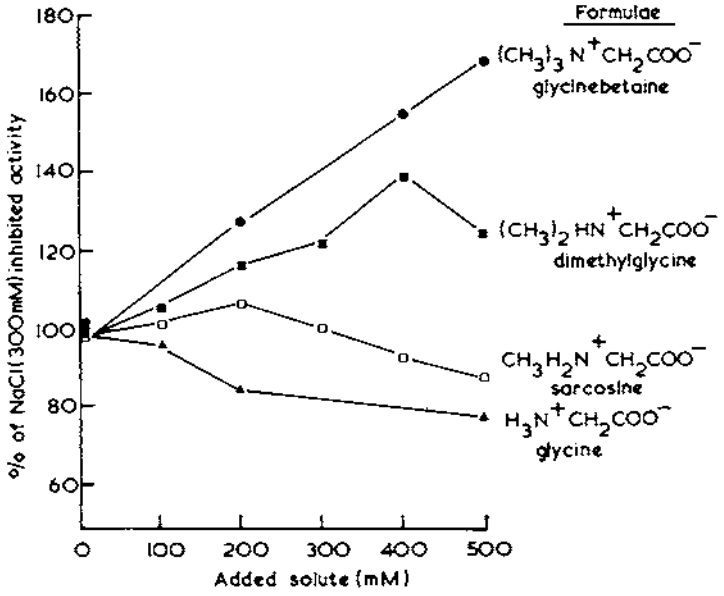

FIGURE 5 Comparative effects of successively methylated derivatives of glycine on inhibition of barley leaf malate dehydrogenase (decarboxylating) by 0.3 M NaCl. Activity was 70% inhibited by 0.3 M NaCl alone. (From, Ref. 63.)

Mechanisms of Sodium Compartmentation

Various lines of evidence show that Na^+ is occluded in the cell vacuoles of many plants, particularly in halophytes, and is excluded from the cytoplasm of all plants. Indirect evidence for such compartmentation comes from measurements of longitudinal profiles of Na^+ and K^+ concentrations in roots. In such experiments with *Hordeum distichum* grown in the presence of 1 M NaCl [64], Na^+ concentration in meristemic, nonvacuolated, cells at the root tip was 10 mM. Sodium concentration increased rapidly with distance from the root tip and with cell vacuolization to 65 mM at 2 mm from the tip. Potassium concentration changed in the opposite direction; that is, it decreased with distance from the root tip. Comparable results were obtained for *Atriplex hortensis* and *Plantago maritima* roots [65].

More direct evidence for compartmentation was obtained with electron probe x-ray microanalysis. Harvey et al. [66] examined compartmentation of the major mineral ions in leaf cells of *Suaeda maritima* grown in the presence of 350 mM NaCl (Table 4). They found a large accumulation of Na^+ and Cl^- in the vacuoles and relatively low concentrations in the cytoplasm; the K^+ concentration was similar in both compartments. The data for glycinebetaine presented in Table 4 were taken by the authors from their earlier work, where the concentration [67] and cytoplasmic localization of this solute [38] were established. Glycinebetaine accounted for more than 75% of the osmolality of the cytoplasm. Hijibagheri and Flowers [68] found similar Na^+ compartmentation in the roots of *S. maritima* 118 mM in the cytoplasm and 432 mM in the vacuoles.

Mechanisms of Na^+ Transport

Sodium transport from the environment into the cytoplasm of plant cells is a passive process. It depends on the electrochemical-potential gradient of Na^+ and the presence of Na-permeable channels in the plasma membrane. In principle, Na^+ could accumulate in the cytoplasm to a few hundred times of its concentration in the environment. For steady-state conditions and 30°C, the relation is $E_M/60 = \log [Na^+]^\circ/[Na^+]^i$, where E_M = membrane potential [69]. Thus, at an E_M of −120 mV (cytoplasm negative), Na^+ could accumulate in the cytoplasm to 100 times the external concentration. Such accumulation is prevented in salt-tolerant plants by control of influx (channel gating) and/or by active export from the cytoplasm to the vacuoles and also back to the environment.

Active sodium transport in plant cells is performed by Na^+/H^+ antiport [70] that is ordinarily driven by an ATPase-activity derived protonmotive force [71]. Such antiport has been documented at plasma membranes and tonoplasts of some plants [72]. In yeast, gene amplification at a locus encoding a putative Na^+/H^+ antiporter conferred Na^+ tolerance [73].

A survey of 16 crop plants [72], however, showed that the presence of a Na^+/H^+ antiporter is not ubiquitous in plants. It could not be demonstrated in 10 of the 16 surveyed plants, including *Zea mays*, *Phaseolus vulgaris*, and *Gossipium hirsutum*. In *Chara longifolia*, a salt-tolerant charophyte, Na^+/H^+ antiport at the PM was induced by 24 h preculture in artificial sea water [74].

The presence of a Na^+/H^+ antiporter would be expected in the tonoplasts of plant cells that

tolerate Na^+ by its excretion to and occlusion in the vacuoles. Plants that have not conserved this antiporter during their phylogenesis should have to regulate cytoplasmic Na^+ concentration by Na^+ exclusion.

Ion Channels and Sodium Exclusion

The sodium permeability of biological membranes is 10^2–10^6 times higher than that of artificial phospholipid bilayers [75]. This permeability is facilitated by intrinsic proteins that constitute ion channels in the phospholipid bilayer [76]. Sodium-specific channels have hitherto not been demonstrated in the plasma membranes of plant cells. Sodium apparently moves through a general cation channel with different permeabilities for the various ions [77]. Calculations for cells of the Characean alga (*Nitella obtusa* L.) [78] indicated that the measured permeability and density of such channels could quantitatively account for Na^+ influx in salt-stressed cells. Regulation of gating and selectivity of such channels seem to be responsible for sodium exclusion in many salt tolerant crop plants. The presence of K^+ and in particular Ca^{2+} ions has been shown to decrease Na^+ influx to plant cells (Fig. 6) [79–85], and consequently to decrease Na^+ damage [80] and yield reduction [83,84].

The existence of two kinds of channels that allow Na^+ permeation has been reported for the plasma membrane of plant cells. One is an inward rectified channel (closes on membrane depolarization) with P_K/P_{Na} (K^+/Na^+ permeability ratio) of 5–10 [86] and an outward rectified one (opens on depolarization) with P_K/P_{Na} of 20–60 [74]. The latter channel may serve as a possible route for Na^+ entry and K^+ loss under high salt conditions [87]. Schachtman et al. [77] suggested that depolarization opens the outward rectified channel allowing Na^+ influx and K^+ efflux under saline conditions and increasing conductivity. Indeed, Katsuhara and Tazawa [82] showed that 0.1 M NaCl depolarized the plasma membrane of *N. obtusa*, increased its electrical conductivity (EC), increased Na^+ content of the cells, and decreased their K^+ content.

Regulation of the inward rectified cation chanel seems to be involved in salt adaptation [87]. Adaptation of tobacco cells to 50 or 100 mM NaCl resulted in an about twofold reduction of the PM outward rectifying cation-channel permeability. Such reduction in the permeability to K^+ and Na^+ of the PM cation channels, caused by adaptation to salt stress, would decrease the entry of

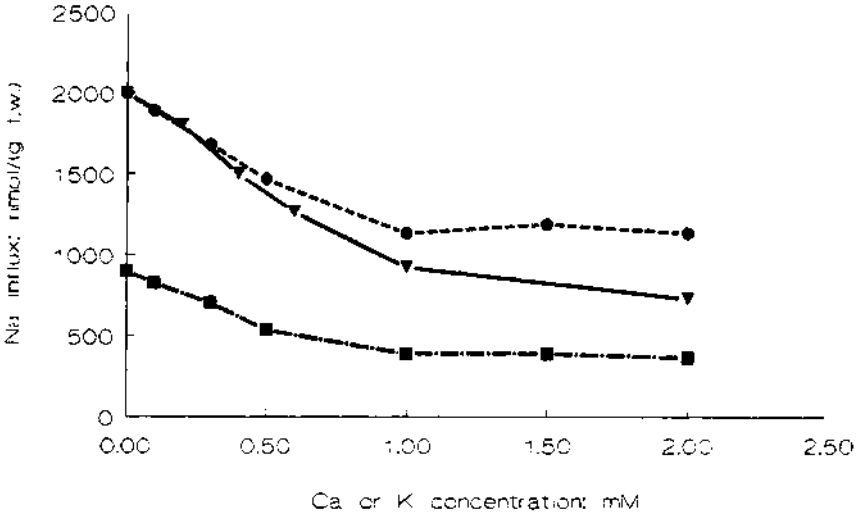

FIGURE 6 Effects of Ca^{2+} (triangles), K^+ (circles), and K^+ in the presence of 10 mM $CaSO_4$ (squares) on Na^+ influx from 10 mM NaCl for 30 min into corn root segments. (Compiled from Ref. 81.)

Na^+ ions into cells and the leakage of K^+ ions out of cells under high salt conditions. The latter study revealed no significant difference between NaCl–adapted and NaCl–unadapted cells in the K^+/Na^+ permeability ratio (P_K/P_{Na}). Similar results were reported for the P_K/P_{Na} of the outward rectfying PM channels of root cells from a NaCl-tolerant and a NaCl-sensitve species of wheat [80]. The investigators concluded that salt-induced reduction of conductivity should be ascribed to a reduction in the frequency of channel opening and/or in the number of channels. A different situation was reported for yeast (see Ref. 88 and references therein). Yeast cells absorb Na^+ by the K^+ uptake system, and the ratio between K^+ and Na^+ K_M values (affinities; low K_M = high affinity) varies depending on the growth conditions. When this system was in the low-affinity state, the ratio between K_M values for Na^+ and K^+ was approximately 15; in the high-affinity state, this ratio increased to 300. Under Na^+ stress, the uptake system converted to the high-affinity system, thus increasing the discrimination between K^+ and Na^+. *TRK1* is *a gene* required for the expression of the high-K– affinity mode of transport. The salt tolerance of a yeast strain carrying a disruption in *TRK1* was 125 mM NaCl, whereas that of the wild type was 400 mM.

Membrane potential–dependent Na^+ influx to corn root was abolished in the presence of K^+ [81] and Ca^{2+} [82]. These cations thus seem to prevent Na^+ movement across the inward rectified channel.

Katsuhara and Tazawa [82] investigated the effect of Ca^{2+} on the salt tolerance of *N. obtusa*. They showed that Ca^{2+} inhibits the Na^+-induced depolarization of the plasma membrane, its increase in electrical conductivity, the increase of Na^+ content of the cells, and the decrease of their K^+ content. Investigations by Hoffmann et al. [89] with *Chara* showed that addition of Ca^{2+} drastically decreased P_{Na} and, hence, Na^+ fluxes at all concentrations.

The sites of Na^+ action and its prevention by Ca^{2+} as well as the sequence of these events are still not clear. Cramer et al. [90] speculated that displacement of Ca^{2+} by Na^+ from the surface of the plasma membrane may be the primary event, and that this is prevented by increased external Ca^{2+} concentration. The investigations further suggested that the opening of K^+ channels and K^+ leakage may either be a direct result of Ca^{2+} displacement from membrane surfaces or from membrane depolarization and a rise of intracellular Ca^{2+}. Either way, potassium leakage should probably be preceded by a change in the direction of the electrochemical K^+ gradient. Such a change would be induced by membrane depolarization, and it should also open the outward rectified K^+ channel.

Evidence for a possible intracellular action of Ca^{2+} is provided by Lynch et al. [91] for maize root protoplasts showing an increase of cytosolic Ca^{2+} concentration in the presence of external 120—150 mM NaCl. The investigations proposed that this Ca^{2+} originated from an internal compartment. However, the possibility that Ca^{2+} may have permeated from the outside, where the Ca^{2+} concentration was 0.1 mM, can not be excluded. Membrane depolarization has been shown to increase Ca^{2+} influx [92], apparently due to Ca^{2+} channel opening [93].

Sodium-induced membrane depolarization may indeed, be activated by Ca^{2+} displacement from membrane surfaces [90,94], or alternatively by Na^+ influx and increased cytoplasmic Na^+ concentration. In *N. obtusa* cells, the protective effect of externally supplied Ca^{2+} depended on the concurrent intracellular presence of ATP or ADP [95]. The presence of the adenine nucleotides decreased the opening frequency of a Na^+-permeable channel [78]. The data for *N. obtusa* [95] further indicate that Ca^{2+} does partially prevent Na^+-induced membrane depolarization (Fig. 7). In the absence of Ca^{2+}, externally supplied Na^+induced a complete depolarization of the plasma membrane. In the presence of Ca^{2+}, only partial and transient depolarization was induced by Na^+; E_M then recovered and receded to -116 mV instead of -131 mV in the absence of Na^+. A transient depolarization induced by Na^+ influx could cause Ca^{2+} channel opening and Ca^{2+} influx. Elevated cytosolic Ca^{2+} concentration may then regulate Na^+ permeability in concert with adenine nucleotides and prevent further Na^+-dependent malfunction of the cells.

Effect of Salinity on Potassium Content

The deleterious effects of salt, reported for *N. obtusa*, included excess Na^+ accumulation as well as K^+ leakage [82]. Both are prevented by Ca^{2+}. Thus, the presence of Ca^{2+} seems to increase K^+/

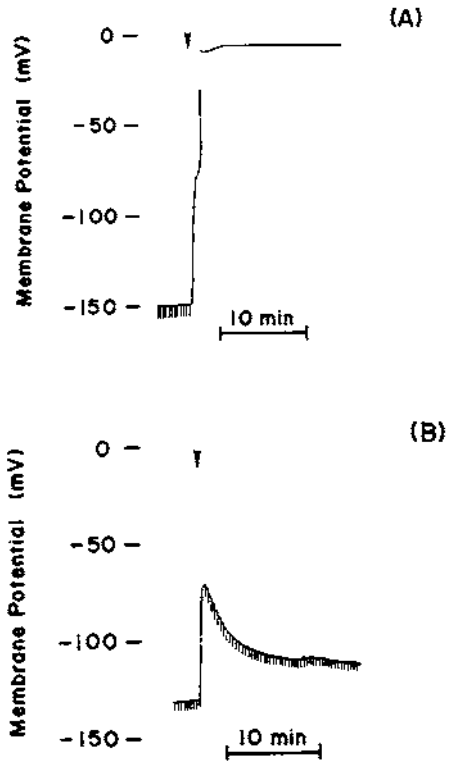

FIGURE 7 Changes in membrane potential of tonoplast free *Nitellopsis* cells perfused with a medium containing 1 mM ATP. Cells were first incubated in APW (artificial pond water) and then treated with APW + 0.1 M NaCl (A) or APW + 0.1 M NaCL + 10 mM $CaCl_2$ (B) at the time indicated. (From, Ref. 95.)

Na^+ selectivity [79] and to be necessary for the maintenance of an appropriate K^+ concentration in plant cells. The importance of Ca^{2+} for adequate K^+ absorption and growth under saline conditions was demonstrated in *Citrus* cell cultures grown on a range of NaCl concentrations in the presence of various $CaCl_2$ concentrations [84]. The growth rate of these cell cultures was related to their K^+ content. The capability of plants to maintain an adequate K^+ content under saline conditions is also enhanced by ample K^+ supply. Thus, salt-adapted *Sorghum* plants [96] were able to grow on 0.3 M NaCl in the presence of a full-strength Hoagland solution or half-strength Hoagland solution supplemented with K^+ to its concentration in full-strength Hoagland solution. The plants did not grow in 0.3 M NaCl with unsupplemented half-strength Hoagland solution.

The response of K^+ content in different plants to external Na^+ increments is not uniform, as shown in Table 5. Many plants, in particular relatively salt-tolerant glycophytes such as *Atylosia sericea* and *Glycine max* cv. Lee, maintain K^+ content constant or even increase it in the presence of salt. More sensitive glycophytes fail to maintain K^+ content in the presence of a high salt concentration. Such decrease of K^+ content may indicate damage [97]. This is demonstrated by two *Atylosia* species [98] and two *G. max* cultivars [99] differing in salt tolerance. The tolerant plants, *A. sericea* and *G. max* cv. Lee, are capable of increasing leaf K^+ content in the presence of salt as well as excluding Na^+ more efficiently than the sensitive ones, *A. acutifolia* and *G. max* cv. Jackson (Table 5). On the other hand, halophytes such as *Suaeda maritima* and *Simondsia chinensis*, as well as tolerant glycophytes that accumulate Na^+ such as *Lycopersicum peruvium, Solanum pennellii* [100], and *Sorghum bicolor* (Table 5), decrease their K^+ content with increasing external salt concentration

TABLE 5 Effect of Na^+ Concentration in the Medium on Na^+ and K^+ Concentration in Some Plant Species and Cultivars

without concomitant damage. This decrease seems to be related to the replacement of vacuolar K^+ with Na^+ [101]. The maintenance of adequate K^+ content under saline conditions seems to depend on selective K^+ uptake as well as selective K^+ and Na^+ compartmentation in the cells and distribution in the shoots.

Sodium Distribution in the Plant

Most plants, when grown in the presence of salt, accumulate some Na^+ in their roots even when it is excluded from the shoots. Collander [102] distinguished between Na^+ accumulator plants and nonaccumulators. The former plants, transport large amounts of Na^+ to their shoots, whereas the latter exclude Na^+ from their shoots and retain it in their roots. Dicotyledonous halophytes are the most prominent Na^+ accumulators, but some salt-resistant glycophytes, such as barley, also belong to that group. Generally, salt-sensitive plants, such as beans and corn, are the most prominent Na^+ excluders. Table 6 compares Na^+ distribution in corn and barley.

Sodium retention in the roots of bean (*Phaseolus vulgaris L.*) plants was shown to result from metabolic energy–dependent depletion of Na^+ in the ascending xylem sap and in roots as well as stems [103,104]. Derooted bean plants retained Na^+ at the base of the stem. Absorption from the xylem was Na^+ specific as compared with K^+ and Cl^-. Sodium depletion of the xylem sap is accomplished by stelar cells lining the xylem [105,106]; transfer cells also have been implicated in this process [107]. Sodium that is removed from the xylem is transferred to the phloem and retransported to the roots [108,109]. Preferential removal of Na^+ from the xylem sap and recirculation to the roots occurs also in petioles [110] and veins of mature leaves [111,112]. In the absence of an inward directed electrochemical Na^+ gradient in the roots, Na^+ leaks to the medium [109,113]; otherwise, it is recirculated.

Sodium recirculation is a mechanism for Na^+ exclusion from the shoots employed by relatively salt-sensitive plants. It breaks down at high salt concentrations [103,104]. Cell membranes of sodium nonaccumulators, such as beans and apparently many other crop plants, seem not to comprise a Na^+/H^+ antiporter at the tonoplast [72] and, hence, cannot excrete Na^+ from the cytoplasm to the vacuoles. Sodium influx to the root and xylem is passive uniport via channels and also possibly by apoplastic bypass flow [114]. The latter flow bypasses the Casparian strips of endodermal cell walls. It is suggested to occur at sites of secondary root emergence [115,116] or through the apical region of the roots [117]. Bypass flow seems to increase under conditions of stress damage. Under saline conditions, bypass flow contributed substantially to the total quantity of Na^+ reaching the xylem of rice plants [114].

The mechanism of selective Na^+ absorption from the xylem is still being explored. It is inhibited by anoxia and depends on energy metabolism [104,118]. It cannot be envisioned as simple

Na^+/H^+ antiport, because stelar cell plasma membrane ATPases secrete protons into the xylem [119], and the proton gradient is in the wrong direction—as evidenced by the relative acidity of the xylem sap. Lacan and Duran [120] suggested that the absorption of Na^+ from the ascending sap is primarily accomplished by indirect K^+-Na^+ exchange; namely, reverse H^+/Na^+ antiport (against the proton gradient) linked to K^+/H^+ antiport (with the proton gradient) and anion-proton symport to the symplast of cells bordering the xylem. They hypothesize that the process is primarily driven by a proton gradient resulting from proton pumping into the xylem by adjacent cells. This proton gradient is then utilized for K^+ transport to the xylem by H^+/K^+ antiport and for H^+-anion symport. The latter proton movements decrease the cytosolic pH of stellar cells lining the xylem and facilitate H^+/Na^+ antiport and Na^+ depletion of the xylem. The assumption of indirect Na^+-K^+ exchange was supported by the absence of a fixed stoichiometry between K^+ and Na^+ transport [121] and by the pH sensitivity of the Na^+/K^+ exchange. Also, increased xylem K^+ concentration resulted in decreased K^+ extrusion but not in decreased Na^+ uptake. The investigators do not provide direct evidence for reversed H^+/Na^+ antiport. Indeed, the proposed indirect Na^+/K^+ exchange could be sustained by K^+/H^+ antiport, as suggested, and electrophoretic Na^+ transport via cation channels (uniport). Such Na^+ transport would depend on the negative E_M of the living cells sorrounding the xylem, and hence on proton pumping as suggested in Lacan and Durand's [120] model. A previous proposal for reversed H^+/Na^+ antiport [122], cited by Lacan and Duran [120], concerns cells acidified by propionic acid.

Sodium recirculation has been found to contribute to salt resistance in many plants such as reed [123], the relatively salt tolerant soybean variety Lee [124], castor bean [125], trifoliate orange [126], *Trifolium alexandrinum* [127], *Atylosia albicans*, and *A. platicarpa* [98].

Chloride Toxicity

Chloride is the prevalent anion accompanying Na^+ and K^+, hence its concentration in vacuoles, as well as cytoplasm, is usually in the same range as the sum of Na^+ and K^+. This concurrence of Na^+ and Cl^- complicates the evaluation of Cl^--specific toxicity. Only a small number of experiments have been published that attempt to determine the direct toxicity of Cl^-, and their interpretation is not straightforward. Leopold and Willing [128] exposed soybean cotyledonary leaf slices to different salts and determined their effect on membrane integrity by measuring the subsequent leakage of organic solutes into water. They found a 28% increase of leakage when 133 mM Na_2SO_4 was replaced with near-isotonic (200 mM) NaCl. These results may be explained as a specific Cl^- toxicity, but Cl^- concentration was higher than that of SO_4^{2-}, and absorption as well as subsequent internal Cl^- concentration may have been much larger than that of SO_4^{2-}. In other experiments by Meiri et al. [129], 96 mM NaCl was less detrimental to the growth of bean plants than 72 mM (isotonic) Na_2SO_4.

Greenway and Munns [130] compared Na^+ and Cl^- contents in the leaves of seven salt-tolerant and salt-sensitive varieties or subspecies. In four of these plants, tolerance was related to lower contents of Na^+ as well as Cl^-. In two cases, there was little difference in concentration of either ion, or there was some increase in the concentration of both ions in the tolerant plants. In one case (avocado), a large decrease of Na^+ concentration was found in the tolerant variety but no difference in Cl^- concentration. In summary, these data do not indicate, that high Cl^- concentration in the leaves may have been related to sensitivity in any of the cases. A similar conclusion may be drawn from the comparison of Na^+ and Cl^- contents in salt-tolerant and salt-sensitive corn varieties [131] and *Atylosia* species [98]. In both cases, Na^+ and Cl^- were excluded from the leaves of the tolerant varieties and species, but exclusion was much more efficient for Na^+ than it was for Cl^-. Furthermore, in some salt-sensitive species, such as *Phaseolus coccineus* [107] and *P. vulgaris* [104,105], Na^+ was found to be excluded from the shoots but not Cl^-.

The growth rate of castor bean at different salinities [125] was not related to Cl^- content of the leaves but rather to Na^+ content. The growth rate was not affected by external NaCl up to 70 mM and decreased by about 80% at concentrations between 80 and 160 mM. Chloride

content of the leaves increased linearly with external NaCl concentration, whereas Na^+ was excluded from the leaves (up to 70 mM NaCl outside), and its leaf content was correlated with growth inhibition.

Although the cited experiments indicate that many salt-tolerant species can deal with higher Cl^- than Na^+ contents in the shoots, a greater Na^+ than Cl^- toxicity in the cytoplasm cannot be deduced. The apparently greater Cl^- than Na^+ tolerance may result from different capabilities for compartmentation of these ions in the vacuoles. All plants seem to be able to accumulate Cl^- in the vacuoles of their cells, whereas many are deficient in the Na^+/H^+ antiporter needed for Na^+ occlusion in the vacuoles [72].

SALT SECRETION

The transpiration stream continuously carries salts to plant shoots. Large amounts of salt should hence be delivered to the leaves of plants growing in a saline environment if the salts are not excluded from the shoots. Even in halophytes that accumulate Na^+ and Cl^- in their leaf cells, the amount of salt carried to the shoot is much in excess of that needed for turgor regulation. Secretion by special salt glands is one important mechanism for the removal of excess mineral ions from the leaves [132].

Structure of Salt Glands

The structural details of various kinds of plant salt glands (Fig. 8) were recently reviewed [133,134]. Based on their structure, three principal types of salt glands may be distinguished: two-celled glands of the grasses, multicellular glands of various dicotyledonous plants, and bladder hairs of the *Chenopodiacea*. The glands eliminate salts to the leaf surface, whereas bladder hairs eliminate them to the central vacuole of the bladder hair.

Some unifying principles in the structure of the different kinds of salt glands may be summarized. They all contain one or more subtending cells that are in apoplastic as well as symplastic continuum with both the adjacent mesophyll and the distal, secreting gland cells. These subtending cells are the basal cells in the two-celled glands, the inermost secretory cells in multicellular glands, and the stalk cells in bladders (see Fig. 8). The exterior walls of secretory cells in all salt glands are covered by a cuticle. The cuticle extends inward along the lateral walls of the external gland cells but not into the walls between the secretory and basal cells. In glands that excrete to the leaf surface, the cuticle is continuous with that of the epidermal cells and partially detached from the exterior walls of the secretory cells. The space formed between the detached cuticle and the walls forms a collecting compartment for the excreted solution. Small pores occur in the detached portion of the cuticle in all glands examined except those of *Aegiceras corniculatum* [135].

Pathway of Salts

As pointed out, structural investigations reveal the existence of an apoplastic continuum from the mesophyll to the subtending gland cells in all three types of glands. The availability of this route to solute transport was shown with the aid of La^{3+} [136,137]. This ion is able to move in the apoplast with the transpiration stream but is unable to penetrate into the symplast. The ion is visible as a precipitate in the electron microscope [138].

The existence of a symplastic continuum between the mesophyll and the gland cells suggests that symplastic flow can also occur. Cytochemical studies utilizing silver precipitates of Cl^- show the presence of Cl^- in plasmodesmata connecting the mesophyll and proximal gland cells of *Limonium* [139] and *Tamarix* [140]. Campbell and Thomson [140] concluded that salt moves to the salt glands apoplastically as well as symplastically, but the predominant route was probably the apoplast.

Function of Salt Glands

The qualitative composition of salts secreted by glands was usually found to be similar to that of the native environment [141] or the culture solution [142]. However, the proportions and concentrations of the various ions are different. Selectivity, therefore, occurs at some site in the path from the roots to the glands. Different orders of mineral-ion selectivity have been reported for different plants [143–145].

Ionic concentration and Ψ_π of solution secreted by salt glands were found to be higher than those of the root medium or the challenging solution in experiments with excised leaves or leaf tissues [146–149]. Similarly, Mozafar and Goodin [150] found higher NaCl concentrations in the bladder hairs of *Atriplex* than in the medium. The salt concentration of the secreted solution was also found to be higher than that in the xylem sap [141,143]. These concentration gradients indicate the involvement of a metabolic energy–dependent process in secretion. This was explicitly demonstrated by Arisz et al. [146], who measured the effect of light and inhibitors of energy metabolism on

salt secretion by *Limonium* leaf disks. The requirement for a metabolic energy source [147,151,152] and the involvement of the PM H^+-ATPase [153] were confirmed by other investigators.

Thomson et al. [133] proposed two possible mechanisms for secretion by salt glands. One proposal assumes symplastic transport to the secreting cells and metabolic energy–dependent secretion of the respective ions to the collecting chamber or vacuole in bladder hairs. Water movement should follow this salt secretion and expand the collecting chamber. This expansion is supposed to open the cuticular pores and enable outflow of the solution. The second proposal assumes apoplastic flow of solution to the subtending gland cells and metabolic energy–dependent accumulation of the respective ions by the latter cells. The ions are then supposed to move down their electrochemical potential gradient to the secreting cells.

The passive permeation of an accumulated salt solution from secreting cells to the collecting chamber could be regarded as a special case of turgor downregulation as described for the charophyte *Lamprothamnium* [93,154–156]. In this series of publications, turgor downregulation, in response to a hypotonic shock, was shown to be accompanied by depolarization and increased EC (electrical conductivity) of the plasma membrane in the involved cells. The presence of Ca^{2+} in the medium was needed for EC increase but not for depolarization. The proposed sequence of events is water influx from the hypotonic medium and turgor elevation; membrane depolarization; Ca^{2+} influx, apparently consequent to opening of Ca^{2+} channels; increased PM conductivity; and ion efflux accompanied by water. In the special case of salt glands, the initial water influx and turgor elevation would be induced by salt accumulation in the subtending gland cells.

SALT ADAPTATION

Suspension cultures and calli of plant cells have been adapted to NaCl by stepwise transfer to increasing salt concentrations. With this procedure, cell lines evincing enhanced resistance to salt have been isolated from various plants [45,52,157–163]. Dry weight production of some of the adapted cell lines, in the presence of salt, was similar to that of the wild lines in the absence of salt (Fig. 9) [158,161,164,165]. Such adapted cell lines may retain their resistance for many generations even after growth in the absence of salt [157,161,162,164].

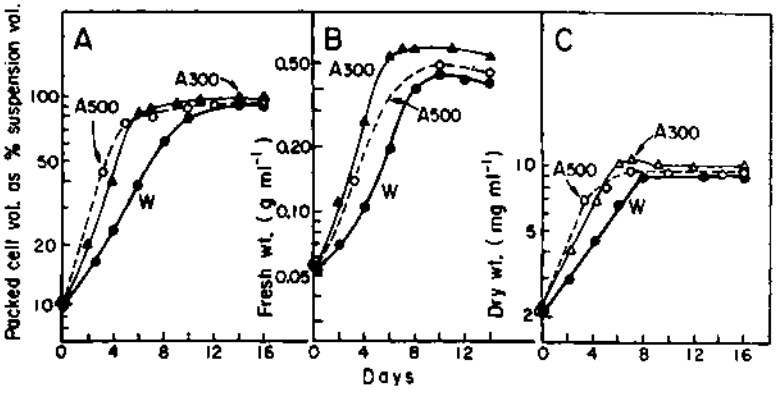

FIGURE 9 Growth curve (dry weight) for various NaCl adapted lines of *Nicotiana* cells growing in media to which they were adapted; also for wild-type cells growing in standard medium and in 0.3 M NaCl (closed circles), wild-type cells in standard medium and (open circles) in 0.3 M NaCl; (closed triangles), cells adapted to 0.3 M NaCl in 0.3 M NaCl; (open triangles) cells adapted to 0.4 M NaCl in 0.4 M NaCl; (open squares) cells adapted to 0.5 M NaCl in 0.5 M NaCL. Growth measured as packed cell volume (A); fresh weight (B); and dry weight (C) (From Ref. 164.)

Increased salt tolerance of salt-adapted cultured cells has rarely led to increased salt tolerance in normal regenerated plants [160,165,166]. Selected cultures, however, are systems where nearly isogenic cells differ, at least in theory, only in the desired tolerance trait [167]. Cell cultures and stress-adapted cell lines from such cultures provide a convenient tool for elucidating salt-resistance mechanisms at the cellular level.

Both of the strategies employed by intact salt-resistant plants can be found in salt-adapted cell lines. Thus, in the presence of salt, tolerant cell lines of *Citrus* [162] and potato [163] more efficiently excluded Na^+ and prevented the decrease of K^+ content than unadapted lines. In cultured *Citrus sinensis* cell lines, the most pronounced characteristic of adapted cells was indeed their capability for larger accumulation of K^+ [168]. A similar trait was reported for NaCl-selected alfalfa cell lines [160]. On the other hand, in tobacco cell lines, salt tolerance was associated with a decrease in K^+ content in concert with increasing salinity [159,169], and an increase of Na^+ [159,169] as well as Cl^- [169], as principle solutes for turgor regulation. Organic compounds also accumulated with salinity, in particular, proline [159,169] and sucrose [169]. Sodium and Cl^- were occluded in the vacuoles of adapted tobacco cells. In cells adapted to 428 mM NaCl, the vacuolar contents of Na^+ and Cl^- were 780 and 624 mM, respectively, whereas cytoplasmic concentrations were maintained at 96 mM [170].

Abscisic acid (ABA) accelerated the adaptation of cultured tobacco cells to high salt concentrations [171]. Abscisic acid, as well as exposure to salt, enhanced the synthesis of a number of proteins [172]. The most striking effect of both treatments on previously unadapted cells was induction of the synthesis of a cross-reactive 26-kDa protein. This protein appeared to be associated with adaptation. When induced by ABA, it was transient unless the cells were simultaneously exposed to salt. Salt-induced changes in the amounts of several proteins were also reported for salt adapted *Citrus* and tomato cell lines [167].

Salt adaptation was also accomplished with whole plants. Eight-day-old *Sorghum* seedlings could be adapted to high salinity by growth in 150 mM NaCl for 20 days [173]. At that time, NaCl could be increased to 300 mM without an effect on the relative growth rate and dry weight produced. The adaptative treatment (150 mM NaCl), however, decreased shoot dry weight production by about 70% as compared with unsalinized control plants. The salt adaptation of *Sorghum* plants was accompanied by an increased capability to exclude Na^+ [173] and an increase in phosphoenolpyruvate carboxylase activity [174]. Treatments with 40 mM ABA increased the growth of salt-treated *Sorghum* seedlings and inhibited the growth of the controls. Abscisic acid also accelerated the adaptation of *Sorghum* plants [174] similar to its effect on the salt adaptation of cultured tobacco cells [171]. The time needed for adaptation of *Sorghum* plants in the presence of 150 mM NaCl was decreased by ABA from 20 to 10 days [174].

CONCLUSIONS

Salt-resistant plants have to maintain growth in the presence of an osmotic stress and, concomitantly, avoid high salt concentration in their cytoplasm. Growth is primarily maintained by an increase of the amount of solutes in the cells and by subsequent turgor regulation. This mechanism may be supplemented by increased cell wall plasticity and decreased threshold turgor. The turgor decrease is sensed by a ''turgor sensor'' apparently in the plasma membrane. The sensor emits an ''error signal'' that is transduced to the activation of adaptive processes.

Salt toxicity is avoided by employing compatible solutes for osmotic cytoplasm adjustment and by confining salt, in particular Na^+, to the vacuoles. Some plants excrete Na^+ from the cytoplasm by active Na^+/H^+ antiport into the vacuole and also to the apoplast. The leaves of such plants may also contain salt glands. These glands accumulate excess salts and subsequently excrete it. This excretion may be explained as a special case of turgor downregulation. Other plants that apparently lack the Na^+/H^+ antiporter accumulate organic solutes and K^+ salts; they prevent Na^+ influx to the roots and its translocation to the more sensitive shoots. The latter is accomplished by selective Na^+ absorption from the ascending xylem sap and its recirculation to the roots via the phloem.

Sodium ions permeate into plant cells through outward rectified cation channels that apparently open in response to Na^+-induced depolarization. The presence of Ca^{2+} and K^+ enhances Na^+ exclusion by controlling channel selectivity. High potassium concentration in the medium also ensures its adequate supply to the plant in the presence of excess Na^+.

Some plant tissue cultures and intact plants can be adapted to salinity. The same strategies for maintaining growth employed by salt tolerant plants can be induced in response to adaptation.

Plants in Saline Environments

ALEXANDRA POLJAKOFF-MAYBER AND H. R. LERNER
The Hebrew University of Jerusalem
Jerusalem, Israel

INTRODUCTION

Saline habitats are those whose soils contain a high percentage of soluble salts, and one or more of these salt components is usually present in excess. There are mainly two types of saline habitats, wet and dry. Wet saline habitats are usually maritime salt marshes. These are areas bordering the sea and subject to periodic inundations as a result of which the level of salinity fluctuates. Dry saline habitats are usually located inland and bordering deserts. Other types of saline habitats are seashore dunes, where salt spray is an important factor, and dry salt lakes. The common denominator for these types of saline habitats is the salinity of the soil and/or of the water resources, as well as the type of vegetation. The most abundant kinds of salinity are NaCl and Na_2SO_4, sometimes together with Mg^{2+} salts [1]. The vegetation of saline habitats is designated ''halophytic,'' distinguished from the vegetation of nonsaline habitats, sometimes referred to as ''glycophytic.'' Phenologically the halophytic plants may be succulent or xeromorphic, with small or grasslike leaves and often also having salt-secreting glands.

Halophytes in their saline environment are exposed not only to salt stress: the roots may also be exposed to osmotic water and low oxygen pressure stress. The latter occurs often in saline-alkaline soils in which aeration is very poor or only periodic during floods at high tide.

Glycophytes, like halophytes, vary in the degree of salt tolerance, so that it is difficult to draw a dividing line between the two groups [2]. Stocker [3] suggested a division by a critical salt concentration, stating that ''a halophyte is a plant that, at any stage of its life, will tolerate this critical salt concentration which will not be tolerated by a 'normal' nonhalophyte.'' Stocker [3] suggested the concentration of 0.5% (≈88 mM) NaCl as this critical value. Flowers et al. [4] mentioned 300 mM NaCl as the critical value. This definition implies that a halophyte will grow in a nonsaline medium as well as a glycophyte, but this is not always the case. Some halophytes do not grow in the absence of NaCl; for example, *Salicornia* spp. germinate but do not elongate in the absence of NaCl. However, with seawater irrigation, it has been possible to obtain a reasonable yield of *Salicornia* for use as fodder crop.

Individuals of the genus *Salicornia* show phenotypic variability in response to different exter-

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

nal conditions, but practically no genetic variability could be shown (assayed as electrophoretic mobility of enzymes). Among all plants, collected at different sites and examined, only two types could be distinguished: one typical of the upper marsh and the other typical of the lower marsh. In their distribution within an ecological gradient, each of the *Salicornia* types inhabits its specific ecological niche where salinity is presumably the dominant factor [5,6]. Usually, the external salt concentration for maximal relative growth rate is much lower than the maximal salt concentration endured by the halophytic plant [4,7]. For many halophytes, the optimal NaCl concentration for growth depends on other external conditions.

The interest in halophytes has two aspects: a purely scientific and theoretical interest, to understand their behavior and their adaptation to this specific, harsh habitat. A more applied interest [4] concerns the hope of understanding the response and metabolism of halophytes and how they differ from glycophytes. This will help in the selection or development of crops that are more salt tolerant than existing crops. These interests may be achieved by conventional methods or more recently by genetic engineering [8,9]. Although their growth was inhibited by salinity, Galapagos wild tomatoes (*Lycopersicon cheesmani L.*) could grow in full-strength seawater, but the cultivated, salt-tolerant cultivar of *L. esculentum* could hardly survive in 50% seawater. The two types of tomatoes differed markedly in nitrogen metabolism [10]. In studies of the differences between halophytes and nonhalophytes in their response to salinity, the following properties have been emphasized:

1. Ability to accumulate or to exclude ions selectively [11]
2. Control of ion uptake by the root and control of transport to the shoot and leaf [4]
3. Selectivity in xylem release [12]
4. Role of accumulated ions in osmotic adaptation [4,13]
5. Compartmentation of ions at the cellular and at the whole-plant level [4]
6. Accumulation of so-called compatible solutes and their role in salt tolerance [14]

Nevertheless, none of these characteristics could be used as markers for breeding salt-tolerant crops. In fact, none of these factors alone can be a basis even for a definition of a halophyte. It is difficult to define a halophyte by physiological traits, such as ion accumulation or synthesis and accumulation of compatible solutes. The difficulty arises from the fact that expression of such traits changes with the age of the plant, its physiological stage of development, and under changing environmental conditions. Such traits are multigenic in their origin; they are regulated by many genes located in a large number of loci and on different groups of chromosomes [5,6,15,16]. In addition to these genetic difficulties, the data resulting from the preceding research directions are very controversial and the conclusions drawn are in dispute [17].

Because of the high correlation between salt tolerance and vigor in wheat and barley addition lines, it has been suggested that breeding for agricultural traits may be more productive than breeding for physiological traits. However, the vigor genes and the tolerance genes were located on different groups of chromosomes having potentially opposing effects. These experiments were not successful, but the investigators believe that the idea can be developed further and that this approach has potential for success [15].

The large variability in the response of the different halophytes to the type and the level of salinity brought about attempts to classify them into groups based on either of the following: (a) their ability to accumulate or exclude Na^+ and/or K^+ [18,19] or (b) their ability to synthesize and accumulate sucrose and polyols as opposed to preferentially synthesizing methylated onium compounds [20]. It was suggested by Gorham et al. [18] that the monocotyledonous halophytes are mostly those that exclude Na^+ and accumulate organic solutes. Most of the data presented by Briens and Larher [20] conform to this concept, but some of the 16 plant species investigated by them did not conform, suggesting that the response to salinity is more complex. Greenway and Munns [16] considered high ion uptake the principal adaptation of the halophytes. These investigations [16] classified the halophytes further according to their ability to grow rapidly or slowly in salinities of 200–800 mM NaCl. These reporters [16] considered avoidance of high internal salinity as a

Table 1 Distribution (%) of Dry Matter Produced Between Plant Parts of Two Halophytes at Different Substrate Salinities[a]

	Atriplex triangularis 1985 data				Kosteletzkya virginica 1984 data			
	root	stem	leaf	fruit	root	stem	leaf	fruit
Nonsaline substrate (control)	15.7	42.6	16.2	25.5	39.0	31.5	25.4	4.2
NaCl, 15 g kg^{-1} H_2O (≈263 mM)	10.2	42.6	11.1	36.0	47.1	26.5	22.7	3.7
NaCl, 30 g kg^{-1} H_2O (≈526 mM)	14.3	30.3	14.9	40.5	68.9	14.4	16.8	0.0

more typical characteristic of nonhalophytes. One of the ways for avoidance is elimination of the ions from the xylem sap on the way from root to shoot. It has been suggested that the ions accumulate in the root or in the basal part of the shoot from where they are returned to the root system and excreted back into the medium [21]. Otherwise, salt may accumulate in the lower, older leaves, as in bean plants, leaving the upper younger leaves with low salt content [22]. A similar ion distribution along the plant shoot was also reported for such halophytes as *Kosteletzkya virginica* [23].

Philipp [24], in controlled lysimeter experiments, demonstrated the different life habits of different halophytes. This reporter [24] compared two halophytes, *Atriplex triangularis* (an annual) and *Kosteletzkya virginica* (a perennial) by percentage dry matter production and allocation to different plant parts (Table 1). In parallel, Philipp [24] measured the mineral distribution in the same plant parts. In both plants, grown in nonsaline substrate, most of the minerals were accumulated in root tissue. In *Atriplex*, under saline conditions, the mineral content of the roots markedly decreased (as a percentage of total) approximately by 50%, but in the leaves, it increased significantly. At a substrate salinity of 30 g kg^{-1} water (approximately 526 mM), the leaf mineral content increased by about 300%. In *Kosteletzkya* plants in nonsaline substrate, minerals also accumulated in the roots, but under saline conditions, the situation did not change much and most of the minerals remained in the roots. In general, these two plants show different strategies in response to salinity that are in accord with their mode of life. In *Atriplex*, the new dry matter production was allocated to the fruit; in *Kosteletzkya*, it was allocated to the root (Table 1), which remained in the soil and sprouted again during the next season.

The variability in the responses of plants to salinity, as well as their variability in maximal salinity level a plant can endure, makes it difficult to characterize the specific trait responsible for salt tolerance.

The most evident effect of salinity is disturbances in growth, and growth is affected by phytohormones. Indeed, evidence shows that many environmental factors (i.e., changes in the concentration of nutrients), including stresses, affect the level of endogenous plant hormones (Table 2), and thus the hormonal balance of the plant is disturbed. It therefore seems logical to assume a relationship between the effect of the stress on hormonal balance and the effect of the disturbed hormonal balance on the growth and development of the plant. Recently, a considerable amount of evidence has suggested that phytohormones are the signals sent between root and shoot, triggering responses to external stress [34] (see section on The Root as a Sensing Organ below). The information collected in our laboratory suggests that the endogenous hormonal balance has an important regulating role in the response of plants to salinity, and it may be possible to ameliorate the endogenous balance by application of exogenous hormones. In the following, we discuss plant-environment interactions with an emphasis on the role of phytohormones.

TABLE 2 Effects of Changes in Concentration of the Mineral Nutrients in the Medium on the Level of Endogenous Phytohormones[a]

Mineral nutrient	Concentration change (mol m^{-3})	Concentration change in phytohormone	Plant species	Reference
NO_3^- ↓	14–0	GA ↓, IAA ↓	Tomato	25
P_i ↓	1–0	CK ↓	Tomato	26
NH_4^+ ↑	0–3	GA ↑, IAA ↓	Pine	27
NO_3^- ↑	0–18	CK ↑	Apple	28
NH_4^+ ↑	0–16	CK ↑		
NO_3^- ↓	10–1	CK ↓	Sunflower	29
P_i ↓	1–0.1	CK ↓		
K^+ ↓	6–0.5	CK ↓		
N ↓	8–0.8	CK ↓	Birch,	30
P_i ↓	1–0.1	CK ↓	Sycamore	
K^+ ↑	0–1	GA ↑	Pine	31
Mineral nutrients ↑	30–260	ABA ↑ temp CK ↓ perm	Tomato	32
Mineral nutrients ↓	30–0.6	CK ↓	Plantago	33

GA, gibberlin; IAA, indole acetic acid; CK, cytokinin; ABA, abscisic acid.
[a] Decreased or increased concentration indicated by direction of arrow; temp = temporarily, perm = permanently. Indicated concentration changes are approximate values.

ROOTS IN THE SOIL ENVIRONMENT

A plant is an organism exposed simultaneously to two environments, the soil and the atmosphere. The aerial part of the plant, the shoot, depends on the root for its supply of water, minerals, nitrogenous components, and possibly other substances that are absorbed from the soil or synthesized or transformed by the root and transported to the shoot. On the other hand the root depends on the shoot for photosynthates and probably other substances synthesized in the shoot and transported to the root. Since root-shoot growth, development, and ratio are coordinated, there must be a regulatory system. About 60 years ago, the existence of rhizocaline and caulocaline was suggested [35]; now it is well known that plant growth substances play an important role in this system.

The soil is the environment of the root system, and the root is exposed directly to the changing conditions of the soil. It is through the root that the whole plant is affected by changing soil conditions. The root may be considered the plant's sensor in the soil. The most drastic and frequent changes occurring in the soil are in the availability of water (see section on The Root as a Sensing Organ below).

The Soil as the Root's Environment

The soil itself is a heterogeneous multiphasic system composed of minerals and organic particles that differ in chemical nature, size, and arrangement. The mode of packing of these particles determines the size and properties of the interparticular spaces. These spaces contain water and gases. Besides the mineral component, the solids of the soil contain colloidal components that imbibe water and bind ions. The soil water is therefore composed of free water and imbibed water. The free soil water is actually a solution of ions, gases, and other solutes; the ions are distributed between the imbibed water and the free water (soil solution).

The ratio between the volume of the interparticular spaces occupied by air and that occupied by soil solution varies in different soils and changes with time as a result of irrigation, rains, floods, and evaporation. In water-logged soils, practically all the interparticular volume is saturated with liquid solution; the air is driven out and the conditions in the soil become practically anaerobic. With cessation of flood or irrigation, a considerable part of the water is drained down gravimetrically, and aeration is reestablished. The soil particles are drawn together, and shrinkage of the soil may occur. The drainage becomes slower with time until it is so slow that it becomes insignificant (usually 2–3 days after flooding). At this stage, the water is retained in the soil mainly by surface tension effects.

Root Growth and Salinity

Root growth is a result of two processes, cell division and cell expansion. These two processes are independent, but sequential, and must be coordinated for growth to occur. Cell division in roots is localized in the apical meristem of the root tip and, to a certain extent, in the inner mature layers of the root tissue, the pericycle and the endodermis, for development of laterals. An accepted definition of growth is an irreversible increase in size through cell extension. Green et al. [36], for *Nitella*, and Green and Cummins [37], for coleoptiles, have proposed a mathematical expression describing rate of growth, also taking into account cell wall properties. The ''driving force'' for cell expansion is turgor, but for growth to occur, turgor pressure must be higher than a critical value defined as the yield pressure Y. The cell wall properties were defined as extensibility m, and P is the turgor pressure. The growth rate r is therefore

$$r = m(P - Y)$$

Growth modifiers, such as phytohormones, affect growth by changing m values, which eventually change Y. Salinity can affect P, m, and Y.

Turgor is a function of the water relation of the plant with its environment and is usually considered a purely osmotic phenomenon. However, by measurements of stress relaxation of turgor in vivo, it was shown that, at least in growth of young stems, water uptake was a consequence mainly of wall relaxation and turgor affected growth only slightly [38–40]. While discussing the relationship between osmotic adjustment and the role of turgor in growth, Munns [41] concluded that there are probably other factors that control growth. Later in this chapter (see section on The Shoot in the Aerial Environment—Sink Source, Photosynthesis, and Hormones), we present data collected from the literature suggesting that these factors could be phytohormones. The phytohormonal balance of the plant probably controls both photosynthesis (source activity) and growth (sink strength).

Cell division is apparently affected by other factors that regulate entry into mitosis, or cessation of the cell cycle, when the cell reaches a certain distance from the apex, where onset of cell differentiation occurs. These processes may be affected by yet another substance that accumulates in plant tissue in response to stress-the polyamines. Stresses (temperature, osmotic, drought, and others) stimulate the accumulation of polyamines. Polyamines affect the cell cycle at the transition from state G_1 to S [42]. Meristematic cells in the root apex, for example, age with distance from the tip; with aging, the level of polyamines also decreases and may cause cessation of mitosis by locking the cells in the G_1 state. This hypothesis may be supported by the finding of Bagni and Pistocchi [43], who showed that cell division requires polyamines. If the growing tissue is low in polyamines ($<10\mu M$), exogenous polyamines must be added to sustain cell division.

Extension growth and cell division must be coordinated and regulated. Plant growth regulators (plant hormones) must therefore play an important role in growth and development of the root and its response to external stimuli [44,45]. The plant hormone that was studied most extensively for its effect on root growth is indole acetic acid (IAA). Pilet [46] showed that the growth of maize roots was regulated by endogenous IAA and abscisic acid (ABA). Both hormones have been shown

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

to be present in elongating roots. The highest concentration of IAA was found in the root cap, in the first 0.5 mm of the root, 357 μg kg^{-1} fresh weight (FW). The highest concentration of ABA was found in the root apex located immediately above the root cap, 67 μg kg^{-1} FW. The IAA content in the region of the apex was half that in the cap itself. The ABA was lower both above and below the apical region. An interesting point is that 10^{-8} M ABA stimulated root growth, but higher concentrations inhibited it. Exogenous ABA induced a reduction in the endogenous IAA. In roots placed horizontally, the upper side grew more during the first 3h, but the growth of the lower side was inhibited. However, the distribution of phytohormones in the tissue showed that both IAA and ABA moved to the lower part of the horizontal root, making interpretation difficult. The IAA apparently did not originate in the root but moved acropetally (from the shoot) and accumulated in the root cap. ABA was synthesized, or released, in the cells of the root tips and moved basipetally (from root tip to shoot). Exposure to salinity has been shown to increase the ABA level and thus further complicates the interpretation.

The growth of the root system and increase in absorbing area occur to a large extent by development of laterals. Exogenous IAA inhibits the growth of laterals but not their initiation in the pericycle [47]. Wightman and Thimann [48] suggested that endogenous IAA stimulates development of laterals; endogenous ABA and cytokinins (CK) inhibit it. They are also of the opinion that IAA moves acropetally, but both ABA and CK are transported basipetally. They consider the gradients of these hormones, resulting from their movement in opposite directions, as the decisive factor affecting the development of laterals. However, there is no evidence yet that the plant is capable of sensing such gradients.

The growth induced by IAA is mainly due to cell extension, including extension of the cell wall. It has been suggested that cell wall extension is regulated by auxin-induced acidification caused by proton extrusion (acid growth theory). However, the suggestion of Key [49] that auxin induces the synthesis of specific mRNAs and their respective proteins seems more likely. Theologis [50], on the other hand, suggested that both mechanisms may be involved in cell elongation. This reporter [50] presented evidence showing that proton extrusion is not the initial driving force for growth. Although it eventually affects cell wall elongation, it is itself a result of a long process initiated by the induction by IAA of specific mRNAs. Theologis [50] did not mention the involvement of CK, gibberellins (GA), or ABA in the regulation of growth. The antagonistic effect of these hormones on growth was mentioned earlier.

Salinity induces growth inhibition, and in many cases the shoot is affected more than the root. Moreover, in many of the plants studied, glycophytes and halophytes, the effect of salinity on root growth is a function of salt concentration. Some concentrations can stimulate root growth while inhibiting shoot growth. This was the case, for example, in pea seedlings (a glycophyte); in *Kosteletzkya virginica* (a halophyte), the situation was more complicated. In pea plants 4–5 days after imbibition, the daily increment in root length, in the presence of 120 mM NaCl, was higher than in roots of the control plants (Fig. 1A), but decreased after that period. Higher NaCl concentration was inhibitory throughout. In shoots, no stimulation of growth by salinity was observed (Fig. 1B). The ABA content was measured in the cotyledons, as they were the first organs to be exposed to salinity stress at the beginning of germination. The ABA reached its peak on days 5–6 of germination (Fig. 1C); at that time, the relative growth of the root started to decline [51]. In *K. virginica* [52], the mean relative growth rate ($\overline{RGR}$) of the root was significantly stimulated by low salinity (85 mM) during the first 14 days of exposure, but after 30 days, it did not differ significantly from control values. In high salinities (175 and 255 mM NaCl), stimulation of the growth rate occurred only during the second week of exposure to salinity (Fig. 2A). During the first week, the plants were probably recovering from the osmotic shock or undergoing other steps of accommodation to salinity. The shoot responded to salinity in a similar way but more mildly (Fig. 2B).

Salinity may be considered to cause earlier aging of tissues, as can be seen by earlier differentiation of the xylem (lower down in the root) and more extensive lignification of the xylem elements [53].

Salinity inhibits growth, and this inhibition is usually measured in the laboratory as inhibition

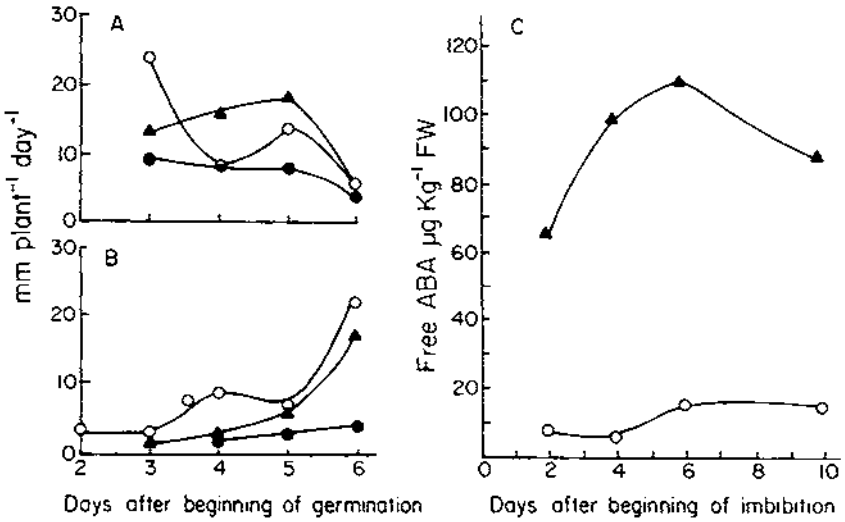

FIGURE 1 Effect of salinity of substrate on growth rate of pea seedlings. Growth as mm day^{-1} per plant: (A) roots, (B) shoots. Concentration of NaCl: open circles, 0 mM; closed triangles, 120 mM; closed circles, 195 mM. (C) Free ABA content of cotyledons of the seeds (µg kg^{-1} FW), grown in 192 mM NaCl. (Calculated from data in Ref. 53.)

of elongation, dry matter accumulation, or $\overline{R}\overline{G}\overline{R}$. However, as shown earlier, not all plant organs respond to salinity in the same way. Therefore, from an agricultural perspective, the ''damage'' of salinity differs in different crop plants depending on the part of the plant—seeds, fruits, roots, or leaves—being harvested.

Root-Soil Water Relations

The soil-root osmotic gradient is the main force responsible for water absorption by the plant. In normal soils (nonsaline), the osmotic contribution to water retention is rather small, but in saline soils, it may be considerably higher, causing reduced water availability for glycophytes. Halophytes apparently have the ability to maintain the necessary gradient even in saline soils. In agricultural practice, a soil water potential of −15 bars (−1.5 MPa) was considered the limit for water availability to the plants and the permanent wilting coefficient. This value is actually the average of the range −10–−20 bars collected from many experiments of permanent wilting [54]. The water present in the soil at field capacity is slowly depleted by the plants and by evaporation until the water potential of the soil reaches approximately −15 bars (−1.5 MPa). Tardieu et al. [55] considered the soil water between −11.0 and −1.5 MPa as transpirable soil water. This concept of a soil-plant water relation was later replaced by a new approach that regarded the soil-water-plant-atmosphere as one continuum.

Wilting occurs from loss of turgor in the leaves and thus depends on the osmotic equilibrium and a dynamic balance between tissue water potential and soil water potential. However, the roots of a transpiring plant can extract water from the soil at a lower soil water potential than those of a nontranspiring plant. Army and Kozlowski [56] showed that a transpiring tomato plant could absorb water from a sucrose solution with an osmotic potential of −17.8 bars (−1.78 MPa), but the detopped root system ceased to absorb water from a solution of only −2 bars (−0.2 MPa). The plant's water relations do not depend absolutely on the simultaneous activity of the whole root system, as shown by ''split-root'' experiments in sour orange seedlings [57]. In these experiments,

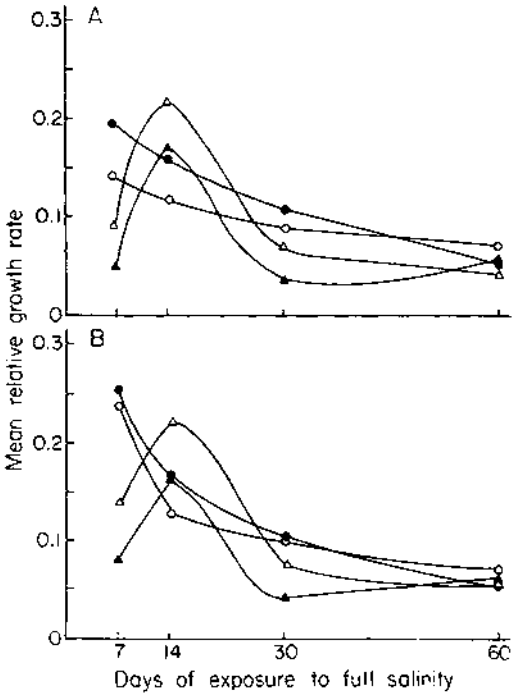

FIGURE 2 Relative growth rate of roots (A) and shoots (B) of seedlings of *Kostelezkya virginica* exposed to three levels of salinity. Concentration of NaCl: open circles, 0 mM; closed circles, 85 mM; open triangles, 175 mM; closed triangles, 225 mM. (Drawn from data in Refs. 23 and 52.)

the root system of a seedling was divided between two containers. One contained saline medium (−0.1 MPa NaCl) and the other contained normal medium. After 4 months of exposure, growth of the plants (with roots divided in NaCl and control containers) was only 9% lower than that of control plants with both halves of the root system in normal medium. If both halves of the root system were exposed to salinity, growth inhibition was 45%. Kirkham [58] reported a split-root experiment in which half the roots were in soil and the other half in a nutrient solution containing cadmium. In this setup, water and cadmium were transported from the liquid medium to the soil. Since cadmium was detected in the leaves, it was assumed that cadmium and water were taken up by the roots from the liquid medium, transported to the shoot, returned to the half-root system in the soil, and excreted to the soil. These data suggest that under drought conditions, when the soil is relatively dry, or in plants growing on saline patches, reasonable amounts of water can be supplied by only a small part of the root system, which is located in a place where water is available. Moreover, Caldwell [59] suggested that in arid soils, in deep-rooted plants with access to water, efflux of water may occur into the dry upper soil layer. This water may be available for the neighboring shallow-rooted vegetation. Such a rare situation is defined by the investigator as ''water parasitism.''

As already mentioned in the beginning of this section, in normal soil, salinity is not as high as to affect the osmotic gradient for water uptake. It is only in saline soils that it can be a problem. Within a reasonable range of salinity, however, there is an effective osmotic adjustment of the root and the shoot [13]. Slatyer [54] has shown that during such adjustment, turgor is restored to very

close to the initial value. It is now accepted that osmotic adjustment occurs at first as a result of ion absorption. Synthesis of organic solutes is another mechanism of osmotic accommodation.

THE ROOT AS A SENSING ORGAN

It is often observed that response to salinity in the shoot is observed earlier than in the root. This occurs despite that the root is the organ exposed to the soil salinity. The most sensitive processes are stomatal conductance and leaf growth. These effects do not show a high correlation with leaf salt content, but correlation is relatively high with the salinity of the root substrate. Therefore, the root seems to be a mediator capable of monitoring the changing conditions in the soil and transmitting the information to the shoot. As mentioned before, the existence of such an exchange of information between root and shoot must exist, but there was not enough evidence presented to support it. In this section, evidence from the literature is presented to demonstrate and support such an exchange of information in reference to various types of stresses exerted on the root with the response being observed in the shoot.

Water Stress

Davies et al. [34] suggested that the root is capable of monitoring the availability of soil water and of transferring this information to the shoot as a positive chemical signal. Recently, Gowing et al. [60] demonstrated this by a split-root experiment. The root of a whole plant was divided in two; each half was made to grow in a separate pot. The two pots were at first well watered, and after the roots were well established in their respective pots, irrigation was discontinued in one pot for 25–30 days. In the other pot, irrigation was continued. Measurements of the rate of leaf growth showed that in plants in which irrigation of one of the root halves was stopped, the growth rate was lower than in the control plants (both halves watered). This decrease in growth was not accompanied by any change in the leaf water status (water potential, solute potential, and turgor), which remained identical in the plants that only had half of their roots watered and those that had both halves watered. The investigators interpreted these results as a demonstration that the signal responsible for the decrease in growth was not a hydraulic effect. In the group in which half the root system was not watered for a few weeks, when the plants were watered again, or when this half of the root system was cut off completely, leaf growth rate increased with time and slowly became comparable to the growth of the well-watered control plants. This response indicates not only that half a root system is sufficient to sustain leaf growth [57] but also that the decrease in leaf growth of plants with half of their roots unwatered resulted from a positive root signal. An example of such a positive signal is an increase in ABA transported from the root to the shoot via the xylem, as suggested by several authors (see Ref. 61 and references therein). Negative signals probably also exist; for example, a decrease in cytokinins transported from root to shoot via the xylem [62].

These data and hypotheses suggest ways in which the root can function as a sensory organ. It senses the soil environment by the effect of environmental factors on the level of phytohormones reaching the xylem and thus affects shoot growth accordingly. Information in the literature shows that, besides soil water status, the root also senses several other soil parameters.

Salinity and Mineral Stress

The literature indicates that changes in mineral nutrient concentration of the medium result in a modification of endogenous phytohormone concentration (see Table 2). The data suggest that a deviation, either an increase or a decrease, from the optimum mineral concentration result in a decrease in the concentration of cytokinins and gibberellins.

Itai et al. [63] and Vaadia [64] reported that exposure of sunflower plants to NaCl resulted in a decrease in CK in the xylem exudate. Downton and Loveys [65] showed, in grapevine, a temporary increase in leaf ABA following salinization.

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

Low Oxygen Pressure Stress

Bradford and Yang [66], Jackson and Campbell [67], and Jackson [68] reported that decreased root aeration in tomato caused by flooding resulted in increased root ACC (1-aminocyclopropane-1-carboxylic acid) concentration and its increased export from the root to the shoot via the xylem. The ACC is thought to be converted to ethylene in petiole and leaves.

Exposure of pea root to anaerobiosis caused an increase in leaf ABA concentration, resulting in stomatal closure in the absence of dehydration of the leaf [68,69].

Temperature Stress

Atkin et al. [70] studied the effect of root temperature between 8 and 33°C on the growth of corn while shoot temperature was kept constant. Leaf growth increased with increasing root temperature. After 17 days of treatment, xylem exudate showed a maximum ABA concentration at 18°C and maximum CK and GA concentrations at a root temperature of 28°C. Sattin et al. [71] measured the rapid response of leaf growth in bean as a function of change in root temperature using a rotary variable displacement transducer (RVTD). The decrease in root temperature from 23 to 10°C caused a fall in leaf growth rate within 20 min to less than 10%. In parallel, leaf ABA concentration increased rapidly [72], but the hydraulic conductivity of water in the root decreased. When root temperature was returned from 10 to 23°C, growth rate increased within a few minutes, showing an overshoot of leaf growth for several minutes.

Soil Compactness Stress

With increasing soil compactness, a decrease in shoot and root growth was observed. Growth of the shoot was inhibited more than that of the root. Furthermore, increasing soil compactness resulted in increased leaf resistance to gas diffusion and decreased transpiration [73]. The signal from root to shoot has not been identified.

Table 3 summarizes the data in the literature on changes in phytohormone concentrations occurring in response to modifications of parameters of the soil environment. The information available is certainly not complete, but it is clear that there is a correlation between the soil environment, plant growth, and changes in the concentration of phytohormones. These data are in agreement with the idea that changes in the phytohormones transported via the xylem from root to shoot may serve as either positive or negative signals carrying the message of changing soil conditions.

TABLE 3 Response of Plants to Environmental Parameters in the Soil[a]

Parameter	Whole-plant response	Changes in phytohormone concentration
Water ↓	Growth ↓	ABA ↑
Oxygen ↓	Growth ↓	ABA ↑, ethylene (ACC) ↑
Mineral nutrients ↓	Growth ↓	CK ↓, GA ↓
Mineral nutrients ↑	Growth ↓	CK ↓, ABA ↑ temp
Salinity (NaCl) ↑	Growth ↓	CK ↓, ABA ↑ temp
Temperature ↓	Growth ↓	CK ↓, GA ↓, ABA ↑
Soil compactness ↑	Growth ↓	No data

ABA, abscisic acid; ACC, 1-aminocyclopropane-1-carbohylic acid; CK, cytokinins; GA, gibberellin.

[a] Decreased or increased concentration indicated by direction of arrows.

THE SHOOT IN THE AERIAL ENVIRONMENT

The plant's shoot in its aerial environment is exposed to the effect of external conditions. These include light, temperature, relative humidity, pollution, the mechanical effect of wind, and, in specific habitats, salt spray. The aerial environment is much less stable than the soil environment. Climatic factors are continuously changing in annual, seasonal, and diurnal cycles, and various unpredicted climatic changes are liable to occur. In addition, the shoot is affected by ''messages'' from the root, which fall in two categories: qualitative, such as the supply of water, minerals, and various substances, originating in the root; and quantitative, the change in the rate of supply of these substances, or some of them, as a result of changing conditions in the soil. The factors in the aerial environment are not directly affected by substrate salinity, but soil salinity may affect the signals sent from the root to the shoot. On the other hand, messages are also being sent from the shoot to the root; for instance, products of photosynthesis, various nitrogenous substances, plant hormones (such as IAA), and others.

The water balance of the plant is actually the equilibrium between supply from the soil through, and by, the root and loss by transpiration from the leaves through the stomata. Stomatal resistance and the evaporative demand of the atmosphere (which is an interaction between relative humidity [RH] and temperature) affect the rate of transpiration, which in turn also affects the CO_2 supply for photosynthesis. When transpiration exceeds supply, transitional water stress may develop in the plant even when the soil is wet, and wilting and/or heat shock may occur. Closure of stomata thus decreases transpiration and enables the plant to balance the water economy and restore turgor.

Shoot Growth in Salinity

Salinity affects the growth of different plants in different ways according to the mode of life of the plants (see Table 1). Although inhibition of growth by salinity is the most evident effect, it is not a simple phenomenon that affects all types of plants, or all organs of the plant, in the same way. As can be seen from Figures 1 and 2, shoot growth may be inhibited by salinity levels that stimulate root growth. In pea seedlings, inhibition of stem growth is mainly due to shortening the internodes, not to a decrease in their number. In *Kosteletzkya*, the relative growth rate of root and shoot are affected similarly. In rice, Yeo et al. [74] distinguished two stages of leaf growth inhibition by salinity: Exposure of rice plants to 50 mM NaCl caused immediate cessation of growth, but within 30 min the growth rate recovered. The investigators believed that it was difficult to assume that anything other than water supply could be perceived, transmitted, and translated in such a short time. On long exposure, growth was inhibited, longevity of leaves was reduced, and leaf mortality was high. Although the investigators ascribed these phenomena to excessive ion accumulation, they did not discard the possibility that hormonal signals from the roots may have been involved.

Now it is generally accepted that, in most plants, stress induces an accumulation of ABA and ABA plays an important role in the growth and development of the plants and also serves as a signal conveying information (see section on The Root as a Sensing Organ above).

Recently, Saab et al. [75] studied, in great detail, millimeter by millimeter, the extension growth of maize mesocotyl and the primary root under conditions of low water potential of the substrate. Earlier, Saab et al. [76] found that, under low water potential, in contrast to conditions of high water potential, the endogenous ABA enhanced root growth but inhibited shoot and mesocotyl growth. Treatment of the plant with fluridone actually reversed the effect of the endogenous ABA. After measuring endogenous ABA, water content, and elongation of millimeter segments, these investigators [76] concluded that a gradient of responsiveness to ABA developed in the cells of the elongation zone. The ability of ABA to protect cell expansion of the elongation zone, for instance in the root at low water potential, decreased with distance from the tip. In the mesocotyl at low water potential, ABA became more inhibiting to cell expansion with increasing distance from the meristem [75].

The different growth responses to salinity or stress can in general be interpreted as resulting

from changes in the allocation of resources (i.e., products of photosynthesis). Plants usually maintain a characteristic root-shoot ratio. When this ratio is disturbed, either through loss of part of the shoot by cutting or grazing or similarly by loss of a part of the root, the immediate response is a reduction in dry matter accumulation in both the root and the shoot. However, eventually the plant compensates by increased growth of the damaged part until the ratio is restored [77]. Klepper [77] presented ample evidence showing that removal of a part of the root system was followed by acceleration of root growth (relative to the shoot). If, on the other hand, the plant was partly defoliated, the remaining shoot parts showed enhanced photosynthesis and growth. However, this is by no means a universal behavior. The return to the initial root-shoot ratio is designated ''homeostasis'' by Klepper [77]. This can perhaps be interpreted as a change induced in the allocation of resources and partitioning of dry matter.

Carmi and Koller [78] showed that in bean plants detopped above the primary leaves compared with intact plants, neither the net assimilation rate (NAR) nor the net photosynthesis (NP) of the primary leaves was affected. The assimilates normally allocated to the top leaves in the intact plant were distributed in what remained from the top in the detopped plant. If the petioles or the stem below the primary leaves was girdled or steamed, thus not allowing the photosynthates to flow out of the leaf, the NAR and NP were still not affected, and the assimilates formed, remained, and accumulated in the primary leaf as starch grains (see the next section). From the following, it appears that, in nongirdled detopped plants, the distribution of resources may be directed by phytohormones. Treatment of the detopped stump with IAA diverted the allocation of dry matter to the root and increased root growth occurred. Treatment of the stump with GA directed the assimilate flow to the shoot. Even with this distribution of assimilates from the primary leaves, however, neither the NP nor the NAR was affected (see the next section). If instead of detopping, or in addition to it, $\approx$80% of the root system was excised, a considerable reduction in the photosynthesis rate of the primary leaves was observed [79]. This reduction was shown not to be due to inadequate supply of water or minerals but apparently to an inadequate supply of some essential substances activating the photosynthetic apparatus. The exogenous addition of benzyladenine could substitute for the missing part of the root system, indicating that cytokinin-like substances originating in the root participate in regulation of the rate of photosynthesis in the leaves, in this case, the primary leaves.

This information implies that loss of part of the plant's canopy, or loss of a part of the root system, changes the hormonal balance of the plant as a whole. Substrate salinity, as shown, to some extent mimics this ''mechanical'' effect, at least in the root system, and induces a change in the hormonal balance of the plant and a change in the allocation of resources.

Tshaplinsky and Blake [80], in their experiment with young poplar trees, showed a behavior different from that of the bean plant in the experiments of Carmi and Koller [79]. Decapitation was followed by reinvigoration of growth in the remaining stump leaf. Diurnal photosynthetic patterns of the retained stump leaves showed that 15 days after decapitation, the photosynthetic potential was increased by increasing NP in the early afternoon, thus eliminating the afternoon reduction in photosynthesis typical of the control leaves. The increase in NP was accompanied by increased transpiration rate and increased stomatal conductance. Thus, photosynthesis was increased without requiring activation of, or increase in, the photosynthetic apparatus, but water loss was not controlled.

In the experiments described by Carmi and Koller [79], the primary leaves of the detopped or partially defoliated plant are the source of the photosynthates. The roots and/or the leaves, and the shoots above these primary leaves, are the sink for these photosynthates. It was shown that phytohormones are capable of changing the direction of flow of the assimilates; that is, they may change ''the strength of the sink.''

Sink-Source, Photosynthesis, and Hormones

A considerable amount of information in the literature suggests that the accumulation of sucrose and/or sugar-phosphate intermediates in source leaves affects photosynthetic rates by feedback inhibition. This was proposed by several investigators in the past, for example Herold [81], and was

reaffirmed lately by Stitt [82]. Some investigators, however, for example Geiger [83], were not able to demonstrate this relationship in their experiments. Table 4 presents data of plants tested. In most of them (sunflower, tobacco, *Amaranthus*, peanut, soybean, cotton, and wheat), a decrease in the export of photoassimilates from source leaf rapidly resulted in an increase in soluble sugar concentration, as well as in a decrease in photosynthesis. This correlation can also exist in cucumber, although it requires 5, 6, or even up to 16 days to be observed (see Table 4). In bean, the phenomenon could not be demonstrated [83,96], possibly because the experiments were too short—4 and 2 days, respectively. The earlier study on bean [102] showed that decreased export of photosynthates resulted in a considerable increase in the dry weight of the source leaf, which the investigators suggested might be due to starch accumulation. The data in Table 4 show a negative correlation between photosynthesis and accumulation of soluble photosynthates in source leaves. Sometimes the two are tightly coupled and the response is rapid; in other cases, they are more loosely coupled, probably when relatively larger amounts of starch accumulate in the chloroplast, thereby decreasing sucrose and sugar-phosphate accumulation in the cytoplasm of source leaves. This phenomenon, although common, is not always observable, as exemplified by the following: (a) in certain cases, the phenomenon is only observed after a very prolonged lag and (b) the data of Carmi and Koller [78] show that starch accumulates when there is no outlet for the photosynthates from the primary leaves; no effect was observed on NP or NAR, and the decrease in photosynthesis occurred only when the supply of CK substance was decreased.

The data from the literature, summarized in Table 5, show that changes in auxin, ABA, GA, or CK concentration in many cases affect the sink-source relationship. Reports are sometimes contradictory, because phytohormonal effects depend on the developmental stage of the plant being studied; hormones can have an effect only if the plant tissue can perceive and respond to the stimulus. In general, the data in Table 5 suggest that auxin enhances export of photoassimilates from source to sink, apparently by enhancing phloem loading. The effect of ABA is the most unpredictable, because the sensitivity of the plant depends on its developmental stage. It often enhances phloem unloading. The GA seems to enhance phloem unloading, possibly by induction of invertase activity. The CK seems to enhance phloem unloading but through a mechanism other than that of GA. These generalizations are tentative, since the mechanisms of phytohormone action are not known. However, they strongly suggest that phytohormones may play a central role in the partitioning of photoassimilates.

Sucrose is the main product of photosynthesis exported from source leaves to sinks. The data in the literature indicate that its concentration is affected by salinity. The sucrose concentration in source leaves either increases or decreases depending on the particular plant being studied (Table 6). The data presented earlier permit the formulation of a working hypothesis that describes the response of plants to NaCl salinity. Salinization of the root environment causes a change in the hormonal balance of the plant, such as decreases in CK and GA and a temporary increase in ABA concentration. This change in the phytohormonal balance in the plant results in a decrease in photosynthetic activity as well as in the activity of the sinks. When the decrease in photosynthetic activity induced by the phytohormonal change is greater than the decrease in the activity of the sinks, the sucrose concentration in source leaves decreases. However, when the decrease in photosynthetic activity is relatively small compared with the decrease in sink activities, the sucrose concentration in source leaves increases. This increase in sucrose together with an accumulation of phosphorylated photosynthesis intermediates in source leaves eventually results in decreased photosynthesis by a feedback inhibition mechanism, and the sucrose concentration remains higher than in the absence of salinity.

To explain the effect of salinity on nonhalophytes, Munns and Termaat [127] suggested that phytohormones of root origin regulated metabolic processes in the leaf. However, since these investigators [127] were not able to counteract the effects of salinity by exogenous phytohormonal treatment, they did not pursue the idea further. Amzallag et al. [128], however, were able to show such an effect of phytohormones on salt-affected sorghum plants. Sorghum plants adapted to 150 mM NaCl salinity [129] did not grow when the salinity was increased to 300 mM NaCl, if the mineral

Table 4 Source-Sink Relationship and Photosynthesis[a]

Mechanism decreasing export from source leaf	Plant, species, organism	Effect on sugars in source leaf	Effect on photosynthesis in source leaf	Reference

nutrient medium was maintained at the concentration of half-strength Hoagland solution. When the concentration of the nutrient solution was increased to full-strength Hoagland, RGR was restored to the level of the controls. However, addition of an appropriate concentration of CK (10^{-7} M), GA (10^{-8} M), or, even better, a mixture of CK plus GA (both at 10^{-9} M) substituted for the increased mineral concentration, and RGR was restored to that of control plants. These results, as well as the data in Table 2, show an interrelationship between mineral nutrients and phytohormones in the regulation of growth.

Modification of the Effect of NaCl on Sink Activity by Increased Ambient CO_2 Partial Pressure

Zeroni and Gale [130] reported that rose plants (*Rosa hybrida*, Sonia, grafted on *Rosa indica*) showed a change in sensitivity toward salinity during prolonged exposure to a high CO_2 concentration. Exposure to 29 mM NaCl inhibited growth (dry weight) to 74% of control when CO_2 concentration in the air was 320 μmol mol^{-1}. At a CO_2 concentration of 600 μmol mol^{-1}, exposure to a similar salinity enhanced growth to 146% of control (plants exposed to 600 μmol mol^{-1} of CO_2, but no NaCl). If our hypothesis presented in the previous section is correct, these data suggest that at 320 μmol mol^{-1} of CO_2, addition of NaCl causes a decrease in sink activity; at 600 μmol mol^{-1} of CO_2, the salinity causes increased sink activity. At present, not enough data are available to explain this interesting effect. Similar data on the effect of CO_2 concentration in response to salinity were obtained by Bowman and Strain [131] in a study on *Andropogon glomeratus*. Increased CO_2 concentration in the air is known to effect numerous phenomena. It has been reported that increased CO_2 concentration affects the synthesis of ethylene [132], and at higher concentration, CO_2 also acts as a competitive inhibitor of ethylene activity [133]. The effect of increased CO_2 concentration on the response of the rose plants to salinity could result from this effect of CO_2 or perhaps from the effect of a change in sucrose concentration on genome expression [134].

ADAPTATION TO SALINITY

As outlined at the beginning of this chapter, most plants are capable of tolerating a certain range of salinity. This range varies in different species, varieties, and ecotypes. In some plants, this range is rather narrow; in others (i.e., in halophytes), it is wide. A large part of the research on salinity is carried out with the intention of accommodating crop plants to grow in salinities outside the natural range of tolerance and nevertheless obtain appropriate agricultural yields. Such expressions as accommodation, adaptation, and acclimation are used as synonyms in the literature. Since two types of plant responses to salinity have been distinguished, we prefer to use different terms: *preexisting resistance mechanisms* that enable the plant to cope with salinity within its natural range of tolerance, and *adaptation* [129]. Adaptation is achieved during a specific treatment and involves changes in the plant's behavior and expression of properties that were not evident before the treatment. A plant is considered ''adapted'' to salinity when at least one of the following cases occurs after the treatment that induces adaptation: (a) an increase in the mean relative growth rate of the salt-treated plant occurs, so that the growth is restored to a value more or less similar to that of the control plant; or (b) when the plant has acquired the capacity to complete its life cycle in a saline environment in which the nonadapted plant is not able to do so [129]. In the following, we present a few examples of adaptation.

Adaptation at the Whole-Plant Level

Phaseolus

The response of *Phaseolus vulgaris* to salinity was reported by Wignarajah et al. [135–137]. They exposed the bean plants to 48 mM NaCl 8 days following germination. At first, growth was inhibited

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

and leaf Na^+ and Cl^- concentrations increased rapidly. However, 25 days after the beginning of salinization, $\overline{RGR}$ was restored to a value similar to that of the control plants. The leaf Na^+ and Cl^- concentrations decreased to low and controlled values. The decreased ion concentration results both from dilution by growth as well as retranslocation from leaf to root followed by excretion to the medium. Both these properties, normal growth and controlled ion concentrations, suggest that the plants had adapted to salinity.

Sorghum

A period of 20 days of exposure of 8-day-old *Sorghum bicolor* plants to sublethal NaCl concentrations (above a threshold of about 30 mM) induced the ability to survive the presence of the otherwise lethal NaCl concentration of 300 mM NaCl [129]. Moreover, the plants grew, flowered, and set seeds if the Hoagland solution was brought to full-strength concentration, while the control plants died. Pretreatment of the plants with the low NaCl concentration resulted in adaptation to salinity. Adapted *Sorghum* plants exposed to 300 mM NaCl have $\overline{RGR}$ values similar to those of control plants. Furthermore, shoot Na^+ and Cl^- concentrations were stable and controlled. The process of adaptation to salinity is sensitive to exogenous plant growth regulators. The period required for adaptation was shortened by ABA treatment, but the process of adaptation was inhibited by exogenous CK and/or GA [128,138]. Adaptation to salinity occurred only if the pretreatment was initiated not later than 10 days following germination. After this period, adaptation was no longer possible. The short and defined period of time during which adaptation was possible was considered a ''developmental window.'' The growth of adapted *Sorghum* plants exposed to 300 mM NaCl showed a very high degree of variability, indicating that individual plants reached different levels of adaptation.

C_3 to CAM Shift

In facultative CAM (crassulacean acid metabolism) in plants, water stress or salinity induces a shift from C_3 to CAM photosynthesis. This shift has been extensively studied in *Mesembryanthemum crystallinum*. The plant has the capacity to shift from one physiological mode to the other. The shift, which takes about 10 days to occur, is composed of a series of events. The first event observed is the appearance of the early stress proteins and accumulation of proline. This is followed by an increase in PEPCase mRNA and its protein. Finally, the plant shifts into CAM [139]. Ostrem et al. [140] reported that this response is only inducible in plants that are at least 6 weeks old. Chu et al. [141] have shown that 10 μM exogenous ABA applied to the leaf induced the C_3 to CAM shift, and preliminary results reported by Piepenbrock and Schmitt [142] showed that 100 μM CK added to the medium inhibited NaCl induction of PEPCase in *M. crystallinum*.

There are many similarities between the increase in tolerance to salinity induced by NaCl in *Phaseolus, Sorghum*, and *Mesembryanthemum*. For *Phaseolus* and *Sorghum*, growth rates that are first inhibited by exposure to salinity are restored to values similar to those in the absence of salinity. Furthermore, the shoot Na^+ and Cl^- concentrations seem to be controlled as a result of adaptation. In *Sorghum* and *Mesembryanthemum*, phytohormones are seen to play a role in the adaptation process. The ABA accelerates the process, and CK and GA prevent its development.

Although three examples of adaptation have been presented here, the response of plants to salinity is often not by adaptation but rather through preexisting tolerance mechanisms. For example, the prolonged growth kinetic study by Greenway [143] on two varieties of *Hordeum vulgare* under saline conditions did not show any increase in salt tolerance of the plants.

Adaptation at the Cell Level

It is possible to adapt cells in suspension culture by a stepwise increase in the NaCl concentration. Using this technique, tobacco cells were made to grow in a medium containing 500 mM NaCl [144,145]. Adapted cells can be returned, progressively, to a medium containing no NaCl and grow for many generations. When these salt-adapted cells are transferred directly back to medium con-

taining 500 mM NaCl, they begin to grow within a few days. At first they grow slowly, but after several generations, the growth rate becomes similar to that of cells grown continuously at high salinity. These cells retain their adapted character even if grown for many generations in the absence of salinity. La Rosa et al. [146,147] showed that the process of adaptation is accelerated by the addition of 10 μM ABA to the medium.

The adaptation of cultured cells has often been performed in view of the possibility of regenerating plants with enhanced salinity tolerance. McCoy [148] compared the salt tolerance of the whole plant with that of its cells in culture for several species of *Medicago*. This investigator [148] did not find any correlation between the tolerance at the cultured cell level and that at the whole-plant level. In other experiments, McCoy [149] adapted cells of two *Medicago* species to salinity and compared the regenerated plants obtained from the adapted cells to plants regenerated from control cells. The plants regenerated from control cells all looked normal. In one species, all the plants showed normal chromosomes, in the other species, one type of chromosomal aberration occurred in 74% of the plants. In contrast, all the plants regenerated from the salt-adapted cells looked very abnormal; all of them showed multiple types of chromosomal aberrations. Exposure of cultured cells to salinity greatly enhances the frequency of occurrence of chromosomal aberrations, which suggests that NaCl causes gross changes in the organization of the genome in cultured cells.

CONCLUSIONS

In the past, the effects of salt on plants have been considered by some investigators as resulting from the physicochemical properties of the saline solution, and it was supposed that the tolerance of the plant resides in the tolerance of its cells. This has led to the development of several concepts concerning the growth inhibition observed following salinization of salt-sensitive species:

1. The decreased water potential of the medium results in a decrease in turgor, which is necessary for cell elongation. This was defined as physiological drought. To grow under saline conditions, the plants must accumulate solutes, either inorganic (such as NaCl itself) or organic.
2. The NaCl toxicity is a major reason for growth inhibition. Compartmentation of Na^+ and Cl^- in the vacuole and accumulation of compatible solutes in the cytoplasm prevent toxicity damage.
3. Plants regenerated from salt-adapted cells may yield more resistant species.

These concepts, however, are not adequate to interpret the data available at present on the response of plants to salinity. Salt tolerance may well be a property of the whole plant, not the sum of the tolerance of its cells [63]. This is supported by the unsuccessful attempts to produce salt-tolerant plants through regeneration from salt-adapted cell lines. In plants, different cell types cooperate to form an integrated organism. Moreover, interactions between different cell types result in characteristics that are proper to the whole organism.

Phytohormones play an important role in the integration of developmental processes in plants, including the responses of the whole plant to changing environmental factors. As described, deviations in the characteristics of the soil environment from optimal conditions result in changes in the phytohormonal balance of the plants that are correlated with inhibition of growth. The decrease in growth may be a necessary intermediary stage during which various changes occur, which may result in accommodation of the plant to the new environmental conditions. The plant may respond to salinity by using its preexisting resistance mechanisms. Under specific conditions, it may ''adapt'' to salinity; this adaptation is expressed, for example, by an expanded range of salt tolerance or a changed photosynthetic mechanism. In general, such a change may be described as a change in the plant's physiological ''mode.'' Whole plants, in the course of their development, may have only a short time period, a developmental window, during which they are susceptible to the treatment resulting in adaptation.

Many mechanisms play a role in the response of plants to salinity, but it seems that hormonal balance is a major factor affected by salinity. The disturbed hormonal balance seems to be one of the main factors responsible for growth inhibition.

ACKNOWLEDGMENTS

Our thanks are due to Professor A. M. Mayer of the Department of Botany, the Hebrew University of Jerusalem, for useful discussions, for his criticism, and for his patience and help in finding the compromises between our sometimes differing views. The writing of this review was stimulated by the research carried out under grant No. US-1869-9OR from the United States–Israel Binational Agricultural Research and Development Fund.

Germination of Seeds and Propagules Under Salt Stress

ABDUL WAHID, EJAZ RASUL, AND ALTAF-UR-REHMAN RAO
University of Agriculture
Faisalabad, Pakistan

INTRODUCTION

Germination is a complex phenomenon involving many physiological and biochemical changes and leading to the activation of embryo [1,2]. However, during initial phases of germination, propagules may behave differently as compared with seed, but fundamentally embryonic tissues in both of them show more or less the same pattern of growth. Any unfavorable change may jeopardize the process of germination to a large extent.

Salinity, as an abiotic hazard, induces numerous disorders in seeds and propagules during germination. It either completely inhibits germination at higher levels or induces a state of dormancy at lower levels [3,4]. It first reduces imbibition of water because of the lowered osmotic potential of the medium [5,6]. Second, it causes toxicity; that is, it changes enzymatic activity [7,8], hampers protein metabolism [9,10], upsets plant growth regulators balance [11], and reduces the utilization of seed reserves [12,13,14]. It may elicit changes at ultrastructural [5], cellular and tissue [15,16], or even at organ levels [17].

Salinity interacts with certain plant and environmental factors during germination. Among the plant factors, seed coat [18], dormancy [4], seed age [19], seed polymorphism [20,21], and seedling vigor [22,23] are prominent. Environmental factors include temperature [24], light [3], availability of water [25], and oxygen [26].

Efforts have been made to ameliorate the adverse effects of salinity on germination by employing certain chemical and biochemical agents. Gibberellic acid initiates germination by breaking salt-induced dormancy [27,28], whereas kinetin stimulates it [29,30,31]. Similarly, polyamines [32], thiourea [33], amino acids [34], betaines [6], and sugars [35] have been successfully used to accomplish a higher germination rate and seedling growth. The role of calcium has been well documented in the mitigation of ionic toxicity and regulation of membrane processes during germination [36,37]. Moreover ammonium, nitrate [38], potassium, and magnesium [23] have also proved their worth in germination and seedling development. This chapter encompasses the details of salt-induced

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

changes on the process of germination, interaction of some factors with germination of seeds (including caryopses) and propagules (e.g., buds, tubers, stem cuttings), and impact of some ameliorants to enhance germination under salinity.

PROCESS OF GERMINATION UNDER SALINITY

Germination of a viable seed or propagule starts with the imbibition of water and terminates with emergence of embryonic tissues. This involves the hydration of proteins, subcellular structural changes, respiration, synthesis of macromolecules, and cell elongation [1]. Whereas, Chong and Bible [39] have regarded growth of embryonic tissues as an important step in the completion of germination, some workers have given due emphasis to the establishment of seedlings under stressful conditions [40,41]. The latter seems crucial under salinity, as without a successful crop stand simple emergence of embryonic tissues will prove futile. The process of germination is greatly influenced by the nature and extent of salinity and, above all, on the behavior of seeds or propagules. For a better understanding of the adverse effects of salinity, we have categorized the process of germination into four events: (a) imbibition, (b) active metabolism, (c) emergence and elongation of embryonic tissues, and (d) establishment of seedlings (Table 1).

Imbibition of Water

Hydration of stored materials is the initial step for the onset of germination [60]. The osmotic component of salinity poses a strong inhibitory effect on the hydration of the embryo, cotyledon, and endosperm [16,61,62]. It is independent of types of salinity and growth media whatsoever [44,62], as use of any salt induces an osmotic effect.

Active Metabolism

The ions are inevitably taken up by seeds, during exposure to salinity, which cause toxicity to various physiological and biochemical processes. The activities of enzymes are hampered [9,63], leading to the altered and reduced synthesis of micro- and macromolecules [49] and their reduced mobilization to the developing tissues [16,49,59]. The synthesis of new proteins in response to saline stress was observed in wheat embryo which ceased on return to water [10]. This pattern of synthesis was attributed to the specific effect of ions on the activities of enzymes [9]. Salinity also causes the accumulation of soluble sugars, free proline, and soluble proteins [6,52]. These metabolites may prove to be beneficial to the germination; first by reducing osmotic inhibition and second by providing substrates for the growth of embryonic tissues [16,64].

Emergence and Elongation of Embryonic Tissues

Seed reserves are utilized in the growth of the embryo and the elongation of young tissues and involve the turnover and de novo synthesis of macromolecules. Germinating seeds in saline media exhibit a lowered and delayed production of radicle and plumule [54–56]. Sodium chloride affects the emergence of young tissues more adversely than other salinities [30,40,58].

Establishment of Seedlings

A successful crop stand depends on the establishment of young seedlings. Prolonged exposure to substrate salinity results in an extremely poor stand [14] caused by seedling mortality [42]. This may be more pronounced in the case of glycophytes owing to their high sensitivity to salinity [65]. A

TABLE 1 Effect of Different Types of Salinity on the Process of Germination of Seeds and Propagules

Germination event	Salinity applied	Response elicited	Reference
Imbibition	NaCl	Reduced hydration of embryo and cotyledon.	6,16,40,42,43
	$NaCl + Na_2SO_4 + CaCl_2\ MgCl_2$	Reduced water uptake.	44
Active metabolism	NaCl	Disaggregation of intermembrane particles: leakage of solutes; reduced mobilization of reserves; inhibited activities of carbohydrates and fatty acid metabolism enzymes; altered pattern of protein synthesis; production of osmotically active solutes.	9,10,16,19,45–50
Emergence and elongation of embryonic tissues	NaCl	Delayed and reduced emergence of radicle and plumule; reduced elongation of embryonic tissues.	5,16,22,36,40,48,51–55
	$CaCl_2$	Reduced emergence of seedlings.	41
	$Na_2SO_4 + CaCl_2 + MgCl_2 + NaCl$	Inhibited radicle emergence.	56
	$NaCl + Na_2SO_4 + MgCl_2 + CaSO_4$ (ψ from -2.5 to -15.0 bars)	Delayed emergence and final suppression of embryonic tissues growth.	57

good stand of crop was achieved in *Sorghum halepense* under mild salinity owing to the rapid rate of germination [57]. Plants having higher seedling vigor also show better stand under salinity [66].

GERMINATION OF SEEDS UNDER SALINITY

Germination and Salinity—Osmotic or Toxicity Effect?

Germination and salinity interaction is often studied on the premise that it has dual action; that is, osmotic and toxic actions [67]. Attempts to separate both the components of salinity by using isotonic solutions of salts and nonpermeating osmotica yielded conflicting data [43,68]. Some regard the osmotic effect as the crippling factor [22,27], whereas the majority consider ion toxicity as being a noxious component [7,9,42,64], or that both the components are equally detrimental to germination [57,69]. Wahid et al. [16] reported that incubation of seeds in salt solution followed by reduced germination in water gave credence to the major role of ion toxicity.

Metabolism of Stored Materials

Seeds, whether from monocots or dicots, comprise of storage tissue (endosperm and cotyledons respectively) and an embryo. The nature and extent of stored materials may be different in different species. Major stored materials include proteins, sugars, and oils, whereas nucleic acids, plant growth regulators, nitrogenous compounds other than proteins, and some nutrients may form a small component [1]. Salt stress hampers the metabolism of stored materials and the growth of the embryo. At the onset of germination, synthesis of enzymes and changes in the metabolic pattern are initiated [24], but salt stress either alters it or does not permit the synthesis of specific metabolites required for germination [7–9]. Application of salinity hampers the utilization and mobilization of materials required for the production of seedlings by affecting the enzymatic activities of seed essential for these reactions (Table 2).

Proteins

Salinity creates an impact on the activities of the enzymes for protein metabolism [9,47]. Protease, which catalyzes the turnover and solubilization of proteins to soluble nitrogen in seed is largely inhibited by salinity [38,62]. It interferes with the incorporation of [^{3}H]leucine and [^{35}S]methionine during protein synthesis in the wheat embryo [10,43] and modulates the production of a selected group of proteins not synthesized otherwise [10]. Ramagopal [50] found the synthesis of qualitatively and quantitatively different eight new proteins in germinating barley embryo under salt stress and seven during recovery.

Carbohydrates

Carbohydrates (as starch) constitute a major bulk of storage material in some seeds (e.g., caryopses). Amylases mainly regulate the metabolism of carbohydrates, and their activity is greatly attenuated by salinity. The activity of α-amylase is reduced under salinity in a concentration-dependent manner, depressing the growth of seedlings [34]. Greater salt tolerance of sorghum during germination was attributed to the enhanced activity of α-amylase [62]. Salt-treated lentil seeds indicated no variation in different solute contents; however, the activity of α-galactosidase increased and caused the accumulation of sucrose, galactose, and mannose in the embryonic tissues [68]. An accumulation of osmotically active sugars and proline was noted in different plants [16,52], which played an important role during and after relief from salinity.

Nucleic Acids

The most important factor in nucleic acid metabolism is the synthesis and activation of ribonuclease (RNase). Salinity delays the de novo synthesis and/or activation of RNase in *Vigna* cotyledons due

TABLE 2 Physiological and Biochemical Changes in Germinating Seeds Under Salinity

Metabolic activity	Effect of salinity	Reference
Proteins	Toxic to the protein phosphatase and protein kinase specific activities; strong inhibition of methionine and leucine uptake and incorporation into proteins chain; de novo synthesis of eight new heat-shock proteins during stress and seven during recovery; a major change in protein phosphorylation-dephosphorylation and a depression in seedling growth.	9,10,13,43,47,50
Carbohydrates	Reduction in endospermic α-amylase activity in a concentration-dependent manner; promotion of cotyledonary α-glycosidase activity; decrease in reducing and nonreducing sugars; accumulation of sugars as osmotica.	13,35,52,68
Nucleic acids	Slow rise in activity or inhibited de novo synthesis of RNase; inhibition of incorporation of precursor into nucleic acids reflecting their suppressed biosynthesis; decrease in DNA level throughout germination period; condensed chromatin material.	7,43,46
Lipid	Reduction in the activity of glyoxysomal enzymes; reduction in utilization of total lipids and triacylglycerol.	49
Polyamine	Induction of putrescine synthesis with the activation of arginine decarboxylase; no effect on spermine; significant increase in spermidine; accumulation of total polyamines.	32,70,71
Other compounds (nitrogenous and nonnitrogenous)	Increase in betaine aldehyde dehydrogenase; rise in betaine content; progressive accumulation of free proline and sugars and soluble proteins; decrease in the level of soluble amino nitrogen.	6,16,40,52,63

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

to its toxic effect [7]. A slight increase in the cotyledonary RNA level during the first day of germination was noted, but it decreased subsequently up to 7 days; however, DNA decreased continuously during this period [46]. Petruzzelli et al. [43] suggested that the suppression of nucleic acid biosynthesis in wheat embryo was due to salt-induced inhibition of the incorporation of precursors into nucleic acids.

Lipids

Glyoxysomal enzymes are responsible for the metabolism of stored lipids. Salinity exerts an inhibitory effect on glyoxysomal catalase, malate synthase, and iso-citrate lyase, decreasing the levels of triacylglycerol, diacylglycerol, and monoacylglycerol and increasing the levels of free fatty acids and polar lipids [49].

Polyamines

Polyamines have recently gained importance in the escape of seedlings from the adverse effect of salinity. They promote seedling growth by the production of ethylene-forming enzymes [32]. Lin and Kao [70] reported an increase in the level of spermidine under salinity but a low level of putrescine in the shoot and roots of rice seedlings. Accumulation of putrescine and spermidine, with the activity of arginine decarboxylase in rice seedlings, plays a specific role in salt tolerance owing to production of ethylene [71,72].

Other Organic Compounds

Various endogenous compounds are differentially metabolized during germination and seedling growth. The glycine betaine, a compatible solute, either disappears [6], exhibits no change [40], or accumulates as a result of salt-stimulated betaine aldehyde dehydrogenase activity and rescues the seed from the adverse effect of salt [63]. Similarly, the rise in the level of free proline and soluble sugars of seeds or seedlings also plays a beneficial role [6,16,52].

Seed Nutrients

The higher content of seed nutrients is of vital importance for germination, but salinity suppresses their role in the metabolism of seed and the production of seedlings [73]. During germination of sorghum caryopses, a higher content of potassium, calcium, phosphorus, and nitrogen was partitioned into the plumule and radicle as a strategy of tolerance to salinity [16]. Guerrier [74] attributed the reduced salt tolerance of tomato to its inability to accumulate and transport lower amounts of calcium and potassium.

GERMINATION OF PROPAGULES UNDER SALINITY

The initial events of propagule germination may be different from seeds. However, bud activation, elongation, and establishment of seedlings seem almost similar. Germination of sugar cane sets (stem cuttings) exhibited significant reduction in the rate and percentage of germination due to NaCl damage [55]. These plants had an enhanced content of Na^+ and Cl^-, a concomitantly reduced content of potassium, calcium, nitrogen, and phosphorus and reduced elongation and dry matter of seedlings. Citrus rootstocks used to raise plantlets had a negative correlation of Cl^- with certain nutrients [75]. Resting buds of salt-stressed poplar plant, grown in vitro, did not accumulate glycinebetaine and proline and thus had reduced growth of seedlings [76]. Similarly, tubers of hydrilla indicated the signs of salt damage and reduced germination [77]. There is a dearth of information particularly about the salt tolerance of propagules during germination.

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

REGULATION OF IONS IN SEEDS AND SEEDLINGS

Exposure of seeds or seedlings to salinity results in the influx of ions with the imbibition of water, which exerts an adverse effect on the growth of embryo [6,78]. This may lead to a marked decrease in the internal potassium concentration [43], a vital nutrient for protein synthesis and plant growth [79]. Seedlings exposed to salinity are highly prone to excessive ions, sometimes leading to their death shortly after emergence [42,80]. The ability of plants to cope with ion toxicity is principally related to the greater transport of ions to shoot. Grasses show a strategy of salt tolerance by storing toxic ions in the mesocotyl up to a certain limit [81,82]. This has significance in that the epicotyl and hypocotyl avoid ion toxicity, thus ensuring their better growth [16].

STRUCTURAL CHANGES IN SEEDS AND SEEDLINGS UNDER SALINITY

Salinity triggers structural changes at various levels of organization in seeds and seedlings (Table 3). At the subcellular level, major changes were found in (a) nuclear chromatin, which was condensed indicating suppressed nucleic acid biosynthesis; (b) formation of small provacuoles instead of single large vacuole; and (c) damaged mitochondrial apparatus and reduced oxygen uptake [5,43]. Salinity caused the contraction of plasmalemma away from the cell walls [43], which may be due to disaggregation of intramembranous particles [45]. The cell wall of salt-treated cotton roots and the sorghum mesocotyl became considerably thickened [16,17].

At cell and tissue levels, the salinity reduced the cortical cell area and as a result the mesocotyl of sorghum was considerably constricted and appeared to act as a repository of ions [16]. Furthermore, there was the induction of exodermis with a casparian band having suberin lamellae close to the root base and in the transition zone of the hypocotyl of cotton [17]. This protected the root from water loss and/or leakage of solutes important for osmotic adjustment. Salinity also stimulated the development and lignification of secondary tissues and enhanced the number of water-storage cells in the epidermis and cortical layer of the hypocotyl [15].

TABLE 3 Salt-Induced Changes in Anatomical Characteristics During Germination in Various Tissues

Level of organization	Salt-induced change	Reference
Subcellular	Formation of small provacuoles in coleorhiza cells.	5
	Diffusion and condensation of chromatin material in embryo.	5,43
	Reduced size of plasmalemma and mitochondria.	43
	Lignification and thickening of cell wall.	16,17
Cellular	Reduced size of cortical cells in mesocotyl of sorghum.	16
	Induction of endodermis with Casparian band and suberin lamellae close to root base.	17
Tissue	Earlier development and differentiation of secondary xylem in hypocotyl.	17
	Constriction of cortical tissue of mesocotyl.	16
	Increased lignification of secondary tissues.	15

FACTORS INTERACTING WITH SALINITY DURING GERMINATION

Plant Factors

Seed Coat

The seed coat is the first barrier to the entry of water and ions into the seed. The hard and thick seed coat offers resistance to the entry of water into the seed and minimizes the contact of ions with the embryo. It also acts as a buffering agent to ionic toxicity [6,18] and enhances germination.

Dormancy

One of the primary impacts of salinity is the induction of dormancy in the seed due either to inhibition of the synthesis of nucleic acids [83] or plant growth regulator imbalance [11]. Although dormancy carries no consistent relationship with salinity [84], it is important for the halophytes, since it permits the seed to remain viable for the period until the environment becomes conducive to germination [24,85].

Seed Age

Aging or prolonged storage of a seed affects its germinability [86]. This has been used to test and predict the salt-tolerance potential during germination. Smith and Dobrenz [19] found a strong negative relationship between salt tolerance and seed age in a sensitive but a significant decline in the solute leachate during imbibition of water in a tolerant alfalfa genotype.

Seed Polymorphism

The seed size of a species also shows a differential response to salinity [87]. The greater the seed size, the greater is the salt tolerance [20,88]. Smaller seeds containing a higher amount of toxic ions and a low amount of reserves per unit weight show higher dormancy-delayed germination and reduced weight of seedlings [21].

Seedling Growth and Vigor

Seedling growth and vigor is an important factor for the establishment of plants. Root growth, being the most important factor, determines the establishment of a stand under salinity [34,53]. This problem may be partially solved either by using a higher seed rate to obtain high seedling density or by selecting the crop for high seedling vigor, especially in arable farming [22].

Environmental Factors

Temperature

A slight variation in temperature may change the germination greatly. The adverse effect of high salinity is further aggravated by higher temperature regimens, which may prolong the time taken for emergence of seedling [24,89]. However, a synergistic effect of low temperature and high salinity has been noted in halophilic barley seeds [90].

Light

Light has a profound effect on the germination of many species [91]. The light may be effective in breaking the dormancy and promoting germination in some halophyte species. This may result in better establishment of a stand in marginally saline areas [3,24].

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

Water

Salt-induced lowering in the water potential of the germination medium enhances toxicity, whereas scarcity of water further aggravates it. Major interaction of water stress under salinity conditions includes a differential pattern of protein synthesis [43], delayed emergence of embryonic tissues [57], and a decrease in final rate and percentage of germination [92]. The supply of water to seeds or seedlings reverses these processes to a great extent [90,93], as it minimizes ionic toxicity.

Oxygen

Salt-induced dormancy reduces the availability of oxygen to the embryo for metabolic activities. High salinity coupled with hypoxia significantly reduces both emergence and elongation of the radicle and plumule [26]. Anoxia completely restricted the process of germination; however, no specific difference was discernible with respect to salinity and anoxia tolerance. *Spartina alterniflora* could better tolerate salinity and anoxia than *Phragmites australis*, as the former showed a rapid rate of coleoptile and mesocotyl growth [54].

ALLEVIATION OF SALT STRESS

Various chemical agents have been employed to ameliorate the adverse effects of salts. The plant-growth regulators are the most widely used. Some nitrogenous compounds, sugars, and certain nutrients have also been employed (Table 4).

Implication of Plant Growth Regulators

Both naturally derived and synthetic plant-growth regulators have been employed separately or in combination [2,31,97]. Kahn [27] suggested that primary action of osmotic inhibition is the reduction in water uptake, and plant-growth regulators may offset this inhibition and promote the process of germination. Presoaking in gibberellin after salt stress releases the seed from physiological dormancy [11,29], enhances water uptake, mobilizes starch [35], and improves the rate and percentage of germination. Auxins like indole butyric acid and indole acetic acid promote germination and seedling growth better than kinetin by eliminating osmotic effect of salinity [94].

Bozcuk [29] reported that kinetin releases the seed from salt-induced dormancy and enhances seed protein synthesis. Kinetin applied to salt-stressed seeds promotes germination by enhanced production of pregermination ethylene with the synthesis of 1-aminocyclopropane-1-carboxylic acid [31,95]. The use of kinetin in combination with gibberellin not only promotes germination but also stimulates the growth of seedlings under salinity [30]. It is likely that salinity suppresses the endogenous level of plant-growth regulators, and their exogenous supply fulfills this requirement for the initiation of germination.

Polyamines

The polyamines compete with the ethylene pathway, as S-adenosylmethionine is a common precursor [98]. The exogenous application of putrescine to seed not only counteracts the adverse effect of salinity, but also induces tolerance up to the seedling stage owing to their de novo synthesis in response to salinity [71]. Lin and Kao [70] found an increase in the level of putrescine by exogenously applying the precursors of putrescine biosynthesis (L-arginine and L-ornithine), but they did not induce a significant mitigation of salt toxicity.

Other Organic Compounds

Some organic chemicals have also been employed to lessen the adverse effect of salinity. Application of sucrose and glucose partially reverses the salt-inhibition of germination [35]. Noor and Khan

TABLE 4 Role of Organic and Inorganic Chemical Agents in the Alleviation of Adverse Effects of Salinity

Chemical agents	Class	Role in alleviation of salt stress	Reference
Growth hormones	Gibberellin	Counteracting inhibition of α-amylase activity in seed; breaking dormancy; stimulating rate and percentage of germination; promotion of seedling growth and development.	11,19,28,35,94
	Auxins	Breaking dormancy; eliminating osmotic inhibition; enhancing water uptake.	25,83,94
	Cytokinin	Breaking dormancy; enhancing protein synthesis; promoting radicle emergence; offsetting salt damage; increased water uptake.	11,30,25,29,31,83,94
	Ethylene	Promoting germination by its endogenous production.	31,95
Other organic agents	Fusicoccin	Counterinhibiting decreased water potential; enhancing protein synthesis; promoting seedling growth.	5,96
	Polyamines	Stimulating germination by their endogenous biosynthesis; enhancing salt tolerance; promoting seedling growth.	32,70,71
	Glutamine and glutamic acid	Increasing glutamine synthase and glutamine synthetase activity and counteracted growth inhibition due to salt.	34
	Thiourea	Reversal of salt-inhibited germination.	33
	Sugars	Promoting seedling growth.	6
	Proline	Enhancing hypocotyl growth; promoting seedling growth.	6,35
Inorganic agents	Calcium	Promotion of membrane activity; stimulating plumule emergence.	5,23,36,37,92
	Magnesium	Counterinhibition of root growth; ameliorating Na^+ toxicity.	23
	Ammonium	Promoting protease activity and enhanced solubilization of endospermic proteins.	38
	Nitrate	Higher counteractive effect of salinity than calcium; enhancing germination and seedling emergence.	37,38
	Potassium	Counterinhibition of root growth.	23

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

[33] reported the efficacy of a low amount of thiourea in breaking salt-induced dormancy. The application of glycinebetaine and proline increased the root growth but did not affect the hypocotyl growth [6]. Fusicoccin also counteracts the inhibitory effect of NaCl on the process of germination by cell wall loosening, promoting transport activity, incorporating amino acids in the protein chain [96], and enhancing potassium uptake owing to stimulation of proton efflux [25]. Addition of methionine sulfoximine was found to reduce the seedling growth of salt-stressed plants, which was reversed by stimulation of glutamine synthetase and glutamate synthase activity, and with the addition of glutamine and glutamic acid to the growth medium [34].

Inorganic Agents

Calcium has been extensively used to alleviate salt toxicity because of its crucial role in the maintenance of membrane processes, modulation of enzyme activities, and buffering of Na^+-toxicity [18,36,38]. Although presoaking of seed in $CaCl_2$ does not initiate germination, its application to a saline medium significantly improves the rate and percentage of germination [37]. In addition, supplying calcium stimulates plumule emergence [5] and root growth as well [23].

Application of ammonium promotes the protease activity in the endosperm, whereas nitrate enhances the seed germinability [37,38] owing to the solubilization and availability of catabolites for the synthesis of embryonic structures [38]. Furthermore, the use of potassium and magnesium also counteract the NaCl inhibition of the root growth of rice seedlings [23].

CONCLUSIONS

All the events of germination starting from imbibition of water to the establishment of seedling are adversely affected by increased levels of salinity. It cripples the rate and percentage of germination, partially through the osmotic effect on the imbibition of water and is mainly due to its toxicity to the metabolism of seed reserves. Salinity also induces structural changes at subcellular, cellular, tissue, and organ levels and affects the rate of respiration, transport of materials, and induction of new tissues in the seeds or seedlings.

Certain internal and external factors substantially interact with the germination and seedling growth under salinity. The seed coat minimizes the access of ions to the embryo. Dormancy allows the halophytes to escape the adverse effect of salinity. Aging has been used to test seed viability and to predict salt-tolerance ability. Seeds of large size exhibit greater germination and seedling vigor because of a higher content of seed reserves and absorb low content of toxic ions per unit weight. Water and temperature stresses further aggravate the impact of salinity on germination, whereas light may break dormancy in certain halophytes. Salinity-induced dormancy creates an anoxic condition and inhibits seed germination. The seedlings with vigorous growth may escape salinity successfully.

The osmotic and toxic effects of salinity can be successfully alleviated with the help of plant-growth regulators, polyamines, sugars, and certain nutrients. Among them the plant-growth regulators and some nutrients, including calcium, ammonium, nitrate, potassium, and magnesium, have been successfully used to promote the process of germination.

Crop Response and Management of Salt-Affected Soils

LELAND E. FRANCOIS[†] AND EUGENE V. MAAS
U.S. Department of Agriculture
Riverside, California

INTRODUCTION

Salinity is a major factor reducing plant growth and productivity throughout the world [1]. Approximately 10% of the world's 7×10^9 ha arable land surface consists of saline or sodic soils. The percentage of cultivated lands affected by salts is even greater. Of the 1.5×10^9 ha cultivated lands, 23% are considered saline and another 37% are sodic. Although the data are tenuous, it has been estimated that one-half of all irrigated lands (about 2.5×10^8 ha) are seriously affected by salinity or waterlogging [2]. Historically, soil salinity contributed to the decline of several ancient civilizations [3]. Despite the advanced management technologies available today, salinization of millions of hectares of land continues to reduce crop production severely in the United States and worldwide [4]. The National Academy of Sciences [5] includes salinization of soils and waters as one of the leading processes contributing to a worldwide biological catastrophe.

Sustained and profitable production of crops on salt-affected soils is possible if appropriate on-farm management decisions are made. To be successful, growers require an understanding of how plants respond to salinity, the relative tolerances of different crops and their sensitivity at different stages of growth, and how different soil and environmental conditions affect salt-stressed plants. This chapter discusses the effects of soil and water salinity on agronomic and horticultural crop plants, presents data on the tolerance of crops to salinity, and considers consequences of various cultural and management practices on crop yield responses.

PLANT RESPONSE TO THE SOIL ENVIRONMENT

Saline Soils

All soils contain a mixture of soluble salts, some of which are essential for plant growth. When the total concentration of salts becomes excessive, plant growth is suppressed. The suppression increases

[†] Deceased.

as the salt concentration increases until the plant dies. Although all plants are subject to stunting, their tolerance threshold and the rate of growth reduction at concentrations above the threshold vary widely among different crop species. Growth suppression seems to be a nonspecific salt effect that is directly related to the total concentration of soluble salts or osmotic potential of the soil water. Within limits, isosmotic concentrations of different combinations of salts cause nearly equal reductions in growth. On the other hand, single salts or extreme ion ratios are likely to cause specific ion effects; namely, ion toxicities or nutritional imbalances. Since saline soils in the field generally consist of a mixture of different salts, specific ion effects are minimal and osmotic effects predominate. Some exceptions to this generalization exist. Woody fruit and nut crops tend to accumulate toxic levels of Cl^- or Na^+ that cause leaf burn, necrosis, and defoliation. Some herbaceous crops, such as soybean, are also susceptible to ion toxicities, but most do not exhibit leaf-injury symptoms even though some accumulate levels of Cl^- or Na^+ that cause injury in woody species.

The relative contribution of osmotic effects and specific ion toxicities on yield are difficult to quantify, however. With most crops, including tree species, yield losses from osmotic stress can be significant before foliar injury is apparent. Reports that citrus yield reductions occur without excessive accumulations of Cl^- or Na^+ and without apparent toxicity symptoms indicate that the dominant effect is osmotic [6–11]. However, salts tend to accumulate in woody tissues over several years before toxic symptoms appear; consequently, the effects of leaf injury and loss can occur dramatically when the salts reach the leaves. When specific ion toxicities occur, the effects on yield are generally additive with the growth-suppressive effects of osmotic stress. Besides causing specific toxic effects, salinity can induce nutritional disorders in plants [12,13]. Some specific nutrient deficiencies or imbalances, which vary among species and even among varieties of a given crop, are described later in this chapter and by Grattan and Grieve [14].

Sodic Soils

Sodic soils, previously called alkali soils, contain excess exchangeable Na^+, with 15% or more of the cation-exchange sites in the soil being occupied by Na^+ [15]. These soils may be either saline or nonsaline depending on the concentration of salts present in the soil solution. In nonsaline-sodic soils, the total salt concentrations are low, and this, coupled with high ratios of exchangeable Na^+ to Ca^{2+} and Mg^{2+}, can lead to Ca^{2+} and/or Mg^{2+} deficiencies. These deficiencies, rather than Na^+ toxicity, are frequently the cause of poor growth among nonwoody species. In contrast, saline-sodic soils contain higher concentrations of Ca^{2+} and Mg^{2+} and may therefore remain nutritionally adequate. With saline-sodic soils, salinity effects predominate and the nutritional effects of sodicity are usually absent.

In addition to the nutritional imbalances encountered in sodic soils, the hydraulic conductivity and permeability of both water and air are significantly affected by the deterioration of the soil physical condition caused by the high exchangeable Na^+ content. To alleviate the poor permeability of these soils, the electrolyte concentration in the soil water must be increased. This is accomplished by the addition of gypsum ($CaSO_4$), sulfuric acid, or acid-forming compounds to the soil or irrigation water [16]. The acid and acid-forming compounds react with the soil lime ($CaCO_3$) to release Ca^{2+} into the soil solution. The use of gypsum and the importance of Ca^{2+} in relation to sodic soils and their reclamation have been extensively reviewed by Oster [17] and Rengasamy [18].

Soil Fertility

Plants grown on infertile soils may appear to be more salt tolerant than those grown with adequate fertility. This is because inadequate nutrition depresses yields more under nonsaline than under saline conditions [19,20]. When fertility is low, proper fertilizer applications increase yields regardless of the soil salinity, but proportionally more if the soil is nonsaline [21]. When both salinity and fertility limit yields, decreasing salinity or increasing fertility is beneficial.

Despite some claims to the contrary, fertilizer applications exceeding those required on nonsa-

line soils do not increase the salt tolerance of plants. Unless salinity causes certain nutritional deficiencies or imbalances, excess applications of N, P, or K rarely alleviate the inhibition of growth by salinity [14]. In fact, additional fertilizer adds to the salinity already present in the soil profile and may aggravate salt injury.

Irrigation Water Quality and Management

The principal criteria to determine irrigation water quality are salinity, sodicity, and specific ion concentrations. However, the effects on crops of a given water are not determined solely by its solute composition. These water quality factors should be considered in relation to the specific conditions under which the water is to be used [22,23]; that is, soil properties, irrigation methods, cultural practices, climatic conditions, and the crop to be grown.

Salinity control is frequently a major concern of irrigation management even though the primary objective of irrigation is to maintain soil water in a range suitable for optimum crop yield. To avoid plant water stress, saline soils should be irrigated when the soil water content is appreciably above the permanent-wilting percentage of the soil, as determined under nonsaline conditions. Plant water stress is a function of total soil water potential, which includes both matric and osmotic potential components. As the soil dries, the matric potential decreases, and because the salts are concentrated, the osmotic potential also decreases, further decreasing the total soil water potential.

The extent of permissible water depletion for a given crop is determined by the maximum acceptable salt concentration for that crop [24]. When additional water depletion occurs and no irrigation water is applied to recharge the root zone and dilute this concentrated soil water, yield is reduced. Therefore, increased irrigation frequency is generally required under saline conditions [2]. With shorter irrigation intervals, the concentrating effect for evapotranspiration on soil salinity is minimized [25,26].

Evidence indicates that plants respond primarily to the soil salinity in that part of the root zone with the highest total water potential [25,27]. With more frequent irrigations, this zone corresponds primarily to the upper part of the root zone, where soil salinity is influenced primarily by the salinity of the irrigation water. With infrequent irrigations, the zone of maximum water uptake becomes larger as the plant extracts water from increasingly saline solutions at greater depths.

In soils that are not well drained, the frequency and amount of irrigation water must be closely monitored. Application of excess water over that required for the crop and for leaching should be avoided. Not only are valuable nutrients lost with overirrigation, but flooded or poorly drained soils suffer from poor aeration, which may affect the crop's response to salt stress. Studies have shown that low levels of oxygen interact with salinity to affect shoot growth of tomato [28]. If drainage is inadequate, a shallow water table may develop, which can directly affect the crop response. Plants can extract water directly from this source and, depending on the quality of the water, respond much differently than expected from the level of salinity in the soil.

Most irrigation waters contain more salts than are removed by the crop, so that continued irrigation without leaching progressively salinizes the land. Water in excess of consumptive use (evapotranspiration) must therefore be applied to carry the residual salts out of the root zone. In addition, soils must be sufficiently permeable to allow the extra water needed for leaching to infiltrate in a reasonable time. In practice, it is usually necessary to grow crops for which evapotranspiration is sufficiently less than attainable infiltration to achieve the necessary drainage and salinity control.

Previous studies have shown that salt can be stored in the lower portion of the root zone with only moderate yield reduction, provided the upper portion of the root zone is maintained relatively free of salinity [27,29]. With most irrigation waters and crops, regularity of leaching is not critical. Even when salinities in the lower root zone approximate the tolerable limit for a crop, leaching intermittently can be as effective as leaching every irrigation [25].

Sensitive crops require the drainage of larger percentages of applied water from the root zone to maintain soil water concentrations within tolerable limits. Generally stated, the leaching requirement is inversely proportional to the salt tolerance of the crop [24].

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

The goal of irrigation management should be increased irrigation efficiency to reduce the amount of infiltrated water that is not used by the plant but passes beyond the root zone as deep percolation. The irrigation reuse of this water and the disadvantages of blending this water with low-salinity water for reuse has been thoroughly reviewed by Rhoades and colleagues [30–32].

PLANT RESPONSE TO CULTURAL PRACTICES

Planting Patterns and Population Density

Failure to obtain a satisfactory stand of furrow-irrigated row crops planted on raised beds is a serious problem in many places. The practice of planting a single row in the center of the bed has frequently resulted in poor seed germination even when the soil is only slightly saline at the time of planting. This is because the wetting fronts from both furrows transport salt in the soil to the center of the bed, where it accumulates. Therefore, whether a single row or double row bed is used, the seed row should be planted near the bed shoulder, where the salt accumulation is the lowest. Another method used to minimize salt accumulation when using single-row beds is to irrigate alternate furrows, so the wetting front carries the salt beyond the seed row to the nonirrigated side of the bed.

With either single- or double-row plants, increasing the depth of water in the furrow can also improve germination in salt-affected soils. Salinity can be controlled even better by using sloping beds, with the seed row planted on the slope just above the irrigation water line. Irrigations move the salt past the seed row to the peak of the bed with this method. Planting in furrows is satisfactory from the standpoint of salinity control but may cause emergence problems from soil crusting or poor aeration.

Increasing plant populations in cotton has been shown effectively to lessen the yield reduction associated with salinity [33,34]. Since nearly all crops are stunted to some degree by salinity, a large portion of the field is without canopy cover. When canopy closure is incomplete and solar radiation is lost to the soil, potential yield is lost. Increasing the number of plants per unit area by decreasing row width compensates for the smaller plant size [33,34]. In contrast, reducing intrarow spacing of cotton showed no effect in maintaining yield [34].

Irrigation Methods

The response of crops to soil and water salinity depends on the method of irrigation and the frequency of water application [35–38]. Numerous irrigation systems are used to apply water to crops, but except for minor variations, they all fall within one of the following categories: gravity, sprinkler, or drip. The differences in water distribution by these systems directly affect the distribution of soil salinity in the root zone. In flooded or fully sprinkled soils, water and salt movement is essentially downward, or one dimensional. In furrow-irrigated soils, water flow is two dimensional; that is, both downward and lateral. When water is applied in small flooded basins or by minisprinklers or drip emitters, flow is three dimensional. This method is used primarily with tree or vine crops. Because water and salt move radially away from the source, salts tend to accumulate at the periphery of the wetted zone. This concentration of salts at the outer edges of the root zone can be a problem for plants when winter rains wash the salts back into the root zone.

Crops irrigated with sprinkler irrigation are subject to injury not only from salts in the soil but also from salts absorbed directly through wetted leaf surfaces [39]. In tree crops, the extent that leaves are wetted can be minimized by sprinkling under the canopy. However, even with undercanopy sprinklers, severe damage of the lower leaves can occur [40]. The extent of foliar injury depends on the concentration of salt in the leaves, but weather conditions and water stress can influence the onset of injury. For instance, salt concentrations that cause severe leaf injury and necrosis after a day or two of hot, dry weather may not cause any symptoms while the weather remains cool and humid. Numerous factors affect the amount of salt accumulated by leaves, including the leaf age, shape, angle, and position on the plant, the type and concentration of salt, the ambient temperature

and humidity, and the length of time the leaf remains wet. In addition, the leaf surface properties, such as a waxy cuticular layer or pubescence, may restrict ion absorption.

Susceptibility to foliar injury varies considerably among crop species (Table 1). A comparative study by Maas et al. [44] with 11 herbaceous species revealed wide differences in the rates of Na^+ and Cl^- absorption when the plants were sprinkled with saline water. Leaves of deciduous fruit trees (almond, apricot, and plum) appear to absorb Na^+ and Cl^- even more readily than herbaceous crops [41]. Citrus leaves absorbed these ions more slowly but in amounts adequate to cause severe leaf burn [40].

Francois and Clark [42] reported a linear increase in Na^+ and Cl^- concentration in grape leaves when sprinkled with saline water. When Cl^- is readily absorbed directly by the leaves, chloride-resistant grape rootstocks that reduce Cl^- uptake by the roots would be of little benefit with sprinkler irrigation.

If sprinkler irrigation must be used, then good water management is essential. Since foliar injury is related more to frequency of sprinkling then duration [42,43], infrequent, heavy irrigations should be applied rather than frequent, light irrigations. Slowly rotating sprinklers that allow drying between cycles should be avoided, since this increases the wetting-drying frequency. Sprinkling should be done at night or in the early morning when evaporation is less. Hot, dry, windy days should be avoided. In general, poorer quality water can be used for surface-applied irrigation than can be used for sprinkler irrigation.

PLANT RESPONSE TO THE AERIAL ENVIRONMENT

The influence of environmental factors significantly affects the response of plants to salinity. Most crops can tolerate greater salt stress when the weather is cool and humid than when it is hot and dry. Magistad et al. [45], working with identical soil salinities, showed that crops grown in a coastal climate (cool and humid) consistently produced higher yields than those grown in a desert climate (hot and dry). Hoffman and Rawlins [46] reported that the salt tolerance of kidney beans grown with cool temperatures and high relative humidity was more than double that obtained with high-temperature, low-humidity conditions.

These factors also affect the expression of specific salt-injury symptoms. Fruit crops and woody plants, susceptible to leaf injury by excess Cl^- or Na^+ accumulation, often develop leaf necrosis with the onset of hot, dry weather in late spring or early summer [47]. Ehlig [48] reported

similar results with grapes, which showed no leaf-injury symptoms during cool, cloudy spring weather even though the leaves contained levels of Cl^- considered toxic.

Although high humidity has been shown consistently to improve growth under salt stress [49], temperature is believed to be the dominant factor in plant response to saline conditions [50]. Other studies have confirmed that temperature influences plant salt tolerance to a greater degree than relative humidity [46,51].

Light intensity has also been implicated in growth reduction caused by salinity. Studies have shown that growth depression from salinity is generally greater under higher than under low-light intensities [52–54]. With citrus, leaf toxicity symptoms are frequently observed on the south side of trees in response to higher light intensities, whereas leaves on the north side may remain symptom free [55].

It is likely that at least part of the reduction in plant growth on saline media is a result of increased transpiration, since high temperature, low relative humidity, and exposure to light are conditions that favor a high rate of transpiration. This may explain why some crops grown outside, where these environmental conditions exist, are more salt sensitive than when the same crop is grown in the greenhouse.

Ozone, a major air pollutant, decreases the yield of some oxidant-sensitive crops more under nonsaline than saline conditions [56–59]. This aberration has the tendency to make many crops grown in air-polluted regions appear to be more salt tolerant than they really are. This salinity-ozone interaction may be agronomically important in air-polluted areas. However, the increased ozone tolerance induced by salinity may be more than offset by the detrimental effects of salinity on the harvestable product [57,58,60].

In contrast to ozone, higher CO_2 concentrations in the atmosphere have been shown to increase the salt tolerance of bean, corn, and tomato [61,62]. This increased tolerance is believed to be the result of an increased rate of photosynthesis [63].

PLANT RESPONSE IN RELATION TO BIOLOGICAL FACTORS

Stage of Growth

Information about the salt tolerance of crops at different stages of growth is extremely limited. Most salt-tolerance data have been obtained from studies in which salinity was relatively constant from seeding to harvest or from the late seedling stage to harvest. These studies provided no information about the salt sensitivity or tolerance at individual stages of growth.

What data are available generally agree that the early seedling stage of growth is the most salt sensitive for most crops [64–68]. It is during this stage of growth with cereal crops that leaf and spikelet primordia are initiated and tiller buds are formed [69]. Consequently, high soil salinity during this stage can severely affect final seed yield.

Although salt stress delays germination and emergence, most crops are capable of germinating at higher salinity levels than they would normally tolerate at the vegetative or reproductive stages of growth [69]. However, this high tolerance is of little benefit when the plants are so much less tolerant during the following seedling stage.

It is generally agreed that after the seedling stage, most plants become increasingly tolerant as growth proceeds through the vegetative, reproductive, and grain-filling stages. Rice may be an exception. Pearson and Bernstein [70] reported that rice yields are significantly reduced if salt stress is imposed at either the seedling stage or during pollination and fertilization. However, a subsequent study by Kaddah [65] did not confirm the salt sensitivity at this latter stage of growth. Increased tolerance with age has also been observed in asparagus, a perennial crop that is much more tolerant after the first year's growth [71].

Influence of Rootstocks

The tolerance of many fruit trees and vine crops can be significantly improved by selecting rootstocks that restrict Cl^- and/or Na^+ accumulation. The Cl^- tolerance levels presented in Table 2 indicate the maximum Cl^- concentrations permissible in soil water that do not cause leaf injury. However, yield of some crops may be decreased without obvious injury symptoms when the osmotic thresholds of the rootstocks are less than these limits.

Although citrus is not considered very salt tolerant, there are differences in salt tolerance among the various rootstocks [55,73,74]. These differences are attributed to salt exclusion, particularly to chloride exclusion [75,76]. Citrus apparently excludes Cl^- from shoots, not by sequestering it in the root but by restricting its entry into and/or movement within the roots. The Cl^- concentration differences found in leaves and to a lesser extent in stems emphasize pronounced rootstock differences in transport of chloride from the root to the shoot [76]. The scion appears to have no major influence on Cl^- transport from the roots to the shoot [77].

Differences among rootstocks is much greater for Cl^- accumulation than for Na^+, and there appears to be no correlation between Cl^- tolerance and Na^+ tolerance [78]. These differences are due to the existence of apparent separate mechanisms that operate to limit or regulate the transport of Na^+ or Cl^- to the leaves [72].

The Cl^- tolerance range for avocado rootstocks is much narrower than for citrus. In addition,

TABLE 2 Chloride Tolerance Limits of Some Fruit Crop Rootstocks

Crop	Rootstock	Maximum permissible Cl^- in soil water without leaf injury[a] (mol m^{-3})
Citrus		
(*Citrus* spp.)	Mandarin (Sunki, Cleopatra), grapefruit, Rangpur lime	50
	Rough lemon,[a] tangelo (Sampson, Minneola), sour orange, Ponkan mandarin	30
	Citrumelo 4475, Calamondin, sweet orange, trifoliate orange, Cuban shaddock, Citrange (Savage, Rusk, Troyer)	20
Grape		
(*Vitis* spp.)	Salt Creek, 1613-3	80
	Dog Ridge	60
	Thompson seedless, Perlette	40
	Cardinal, black rose	20
Stone fruit		
(*Prunus* sp.)	Marianna	50
	Lovell, Shalil	20
	Yunnan	15
Avocado		
(*Persea americana*)	West Indian	15
	Guatemalan	12
	Mexican	10

[a] For some crops, these concentrations may exceed the osmotic threshold and cause some yield reduction. Data from Australia indicate that rough lemon is more sensitive to Cl^- than sweet orange [72].
Source: Adapted from Ref. 21.

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

because of the wide variation among varieties of the same rootstock, the rootstock tolerances tend to overlap [79]. However, it is generally agreed that the average Cl^- tolerance is West Indian > Guatemalan > Mexican [78–80]. The general pattern for Na^+ accumulation with avocado rootstocks tends to follow that for Cl^- accumulation and, like Cl^-, shows differences among varieties on the same rootstock [80,81].

Cold hardiness has been implicated in the salt tolerance of citrus and avocado rootstocks. Wutscher [82] reported that citrus rootstocks, which have good Cl^--excluding characteristics, tend to be relatively cold hardy. For some citrus species, a short-term, moderate salt stress has been shown to enhance cold hardiness in seedlings by modifying growth, water relations, and mineral nutrition [83].

In contrast to citrus, the more salt tolerant avocado rootstocks, such as West Indian and West Indian–Guatemalan hybrids, are the least cold tolerant. Likewise, the salt-sensitive Mexican rootstock is the most cold-tolerant [84].

Chloride toxicity has been the principal limiting factor for grapevines grown on their own roots. However, a significant reduction in Cl^- accumulation has been shown to occur in Cl^--sensitive scions grown on Dog Ridge or 1613-3 rootstocks [85]. The salt tolerance of these two rootstocks is probably limited by soil osmotic effects long before Cl^- reaches toxic levels.

Differences Among Cultivars

Most commercially grown cultivars are developed under nonsaline conditions and are not bred to endure salt stress. Therefore, their relative tolerances to salinity are often similar and difficult to measure. In addition, many cultivars developed in the past were derived from a narrow genetic base and thus possessed similar traits. Currently developed cultivars are from a much more diverse genetic base and may therefore possess a wider range of salt tolerance.

Among the crop species that already show some diversity in salt tolerance are Bermuda grass, brome grass, creeping bent grass, rice, wheat, barley, soybean, berseem clover, squash, muskmelon, and strawberry. Cotton and sugar cane also show significant cultivar differences, but these differences occur only at high salinity where yields are below commercially acceptable levels [86,87].

Salt Effects on Nitrogen Fixation and Nodulation

Most *Rhizobium* species are relatively unaffected at soil salinity levels that are less than the tolerance threshold values reported for most leguminous crops (Table 3). At soil salinities greater than their threshold, their ability to survive and fix N may be severely reduced [142–144]. This is particularly important, since legumes that are already weakened by salinity stress will be deprived of essential N fertilization as well.

There appears to be a wide range of tolerance to salinity among the various species of rhizobia. Some strains of *R. meliloti* can survive soil water salinities greater than that of seawater (≈46 dS m^{-1}), but most strains of *R. japonicum* grow poorly at salinities of 12 dS m^{-1} [145]. Studies comparing various *Rhizobium* species report the salt tolerance of *R. meliloti* > *R. trifolii* > *R. leguminosarum* > *R. japonicum* [145,146].

The salt effect on rhizobia appeared to be ion specific, with Cl^- salts of Na^+, K^+, and Mg^{2+} being more toxic than corresponding SO_4^{2-} salts [147,148]. In addition, Mg^{2+} ions inhibited growth at a much lower concentration than Na^+ or K^+ [149,150].

Since rhizobia can withstand large increases in salinity, they must be able to regulate and adjust their internal solute concentration. Osmoregulation in *Rhizobium* species grown at high external salt concentrations involves the accumulation of organic and/or inorganic solutes. Although some strains respond to salt stress by increasing their intracellular K^+ level [151], others accumulate organic compounds, such as amino acids, betaine, and carbohydrates, in the cytoplasm [152,153].

EC_e, electrical conductivity of the saturated-soil extract; FW, fresh weight; DW, dry weight; S, sensitive; MS, moderately sensitive; MT, moderately Tolerant; T, tolerant.

[a] These data serve only as a guideline to relative tolerances among crops. Absolute tolerances vary depending on climate, soil conditions, and cultural practices.

[b] Botanical and common names follow the convention of *Hortus Third* [140] when possible.

[c] In gypsiferous soils, plants tolerate EC_e about 2 dS m^{-1} higher than indicated.

[d] Ratings are defined by the boundaries in Figure 1. Ratings marked by an asterisk are estimates

[e] Less tolerant during seedling stage, EC_e at this stage should not exceed 4 or 5 dS m^{-1}.

[f] Unpublished U.S. Salinity Laboratory data.

[g] Grain and forage yields of DeKalb XL-75 grown on an organic muck soil decreased about 26% per dS m^{-1} above a threshold of 1.9 dS m^{-1} [141].

[h] Because paddy rice is grown under flooded conditions, values refer to the electrical conductivity of the soil water while the plants are submerged. Less tolerant during seedling stage.

[i] Sesame cultivars Sesaco 7 and 8 may be more tolerant than indicated by the sensitivity rating.

[j] Sensitive during germination and emergence, EC_e should not exceed 3 dS m^{-1}.

[k] Data from one cultivar, Probred.

[l] Average of several varieties. Suwannee and Coastal are about 20% more tolerant and common and Greenfield are about 20% less tolerant than the average.

[m] Average for Boer, Wilman, Sand, and Weeping cultivars. Lehmann seems about 50% more tolerant.

SALT–TOLERANCE DATA

Yield-Response Functions

Yield-response curves indicate that most crops tolerate salinity up to a threshold level above which yields decrease approximately linearly as salinity increases. Maas and Hoffman [89] proposed a two-piece linear response model to characterize the curves. The two parameters obtained from this model are the threshold, the maximum allowable salinity without yield reduction, and the slope, the percentage yield decrease per unit increase in salinity beyond the threshold. Table 3 presents these yield-response parameters for many field, forage, vegetable, and fruit crops. The data are presented in terms of the electrical conductivity of the saturated-soil extract, EC_e [15] at 25°C with units of decisiemens per meter (1 dS m^{-1} = 1 mmho cm^{-1}). These data serve only as a guideline to relative tolerances among crops. Absolute tolerances vary, depending on climate, soil conditions, and cultural practices.

The threshold and slope obtained from the model can be used to calculate relative yield Y_r for any given soil salinity exceeding the threshold by using the equation

$$Y_r = 100 - B(EC_e - A)$$

where A = the salinity threshold expressed in dS m^{-1}; B = the slope expressed in % per dS m^{-1}; and EC_e is the mean electrical conductivity of the saturated-soil extract of the root zone [89].

The data in Table 3 apply to soils in which Cl^- is the predominant anion. The EC_e of saturated soil paste from gypsiferous soils (nonsodic, low Mg^{2+}) generally ranges from 1 to 3 dS m^{-1} higher than that from nongypsiferous soils with the same conductivity in the soil water at field capacity [154]. The higher salinities are the result of gypsum dissolution during preparation of the soil paste. The extent of this dissolution depends on the exchangeable ion composition, cation-exchange capacity, and solution composition. Therefore, plants grown on gypsiferous soils tolerate salinity levels approximately 2 dS m^{-1} higher than those indicated in Table 3.

The salt-tolerance classifications in Figure 1 are presented for quick comparisons among crops. Division boundaries for the classes were chosen to correspond with previously published salt-tolerance terminology ranging from sensitive to tolerant. Generally, the threshold and linear slope for

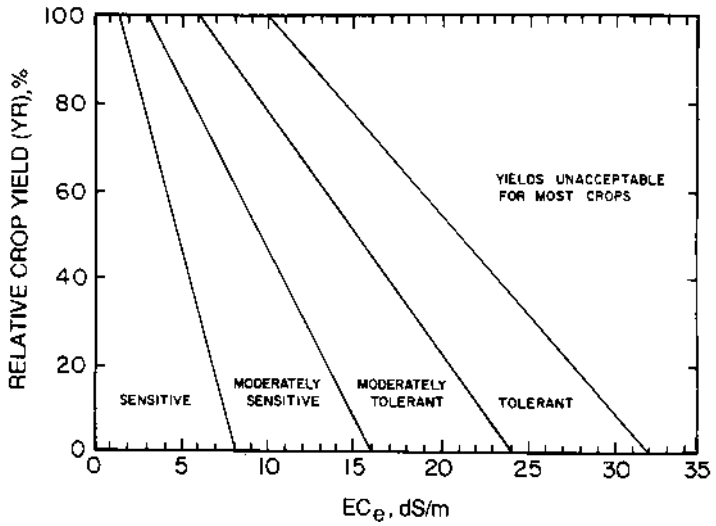

FIGURE 1 Divisions for classifying crop tolerance to salinity.

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

a crop remain within one class. Where the linear curve for a crop crossed division boundaries, the crop was classified based on the tolerance at lower salinity levels at which yields are commercially acceptable. Classification for some crops in Table 3 are listed with only a qualitative rating, because the data are insufficient to calculate the threshold and slope.

Salt Tolerance of Vegetable Crops

Vegetable crops tend to fall into the more sensitive salt-tolerant categories. The only notable exceptions are asparagus, red beet, and zucchini squash. Since most vegetables are salt sensitive, the choice of land and/or irrigation water where they can be successfully grown is severely restricted. Under marginal conditions of salinity, the growth of many vegetables is stunted without showing other visible injury symptoms [155]. At high salinity levels, some vegetables exhibit pronounced injury symptoms in the later stages of growth. Bean leaves develop a marginal chlorosis-necrosis with an upward cupping of the leaves [156]. Onions have also been shown to develop a leaf necrosis [157]. In addition to growth suppression, some vegetable crops exhibit symptoms of nutritional imbalance or deficiency. Some lettuce cultivars develop calcium-deficiency symptoms when sulfate levels in the soil are too high. Excessive calcium may restrict the uptake of potassium, which may be a factor in reduced yields of bean and carrot [158]. With most vegetable crops, however, the osmotic effect predominates and nutritional effects are either absent or of decidedly secondary importance.

High levels of exchangeable Na^+ frequently restrict vegetative growth because of the unfavorable physical conditions associated with sodic soils. Most vegetable crops appear to be at least moderately tolerant to exchangeable Na^+. Bean plants, however, are sensitive to nutritional factors in sodic soils and may be severely affected even before the physical condition of the soil is impaired.

Most vegetable crops produced on saline soils are not of prime market quality. This is seen in such diverse ways as smaller fruit size of tomatoes and peppers [158], reduced petiole length of celery [123], and misshapen potatoes [159]. It has been generally observed, however, that tomato yields are reduced more by decreases in fruit number than in fruit size or weight [160,161]. Not all salinity effects on quality are detrimental. The flavor of carrots [162] and asparagus [71] is enhanced by a measurable increase in sugar content when grown under saline conditions. Likewise, a number of studies [160,163–165] have shown that total soluble solids in tomatoes is significantly increased as salt stress is increased. Unfortunately, this gain in quality is more than offset by lower yields.

Salt Tolerance of Cereal Crops

Most of the major cereal crops exhibit high tolerance to soil salinity. In this group are sorghum, wheat, triticale, rye, oats, and barley. The only exceptions are corn and rice [21].

Regardless of the overall salt tolerance, all cereals tend to follow the same sensitivity or tolerance pattern in relation to their stage of growth. The seedling or early vegetative stage appears to be the most sensitive, with subsequent stages showing increased tolerance. This phenomenon has been reported for sorghum [67], wheat [66], barley [64], corn [166], and rice [70]. The other cereal crops, although not tested but with similar growth patterns, are also expected to show sensitivity at the early vegetative stage of growth.

Since the life cycle of cereals is an orderly sequence of developmental events, salinity stress can have a significant effect on the developmental process occurring at a particular time. The sequence of events has been separated into three distinct but continuous developmental phases [69]. In the first phase, which encompasses the early vegetative growth stage, leaf and spikelet primordia are initiated, leaf growth occurs, and tiller buds are produced in the axils of the leaves. High soil salinity at this time reduces the number of leaves per culm, the number of spikelets per spike, and

the number of tillers per plant [69,167]. Differentiation of the terminal spikelet signals completion of this phase.

During phase II, the tillers grow, mainstem and tiller culms elongate, and the final number of florets is set [168]. Salinity stress during this phase may affect tiller survival and reduce the number of functional florets per spikelet. This phase ends with anthesis. Carpel fertilization and grain filling occur during the final phase [168]. At this time, salinity affects seed number and seed size.

The effect of salinity on spikelet and tiller number established during phase I has a greater influence on final seed yield than the effects exerted on yield components in the latter two phases [66,67,166].

Salt Tolerance of Forage Crops

Forage crops fall into two broad salt-tolerance categories. Most grasses belong to the tolerant group, with the majority of legumes being in the sensitive group. Exceptions to this generalization are meadow foxtail (*Alopecurus pratensis*), love grass (*Eragrostis* spp.), and orchard grass (*Dactylis glomerata*), which are moderately sensitive to salt stress, and birdsfoot trefoil (*Lotus corniculatus* var. *tenuifolium*) and the sweet clovers (*Melilotus* spp.), which are moderately tolerant [89].

Many of the forage grasses possess the same growth habit as the cereal grasses and, like the cereals, are more sensitive to salinity during the early seedling stage of growth [169]. Unlike the cereals, however, many of the grasses are maintained in a perpetual vegetative stage of growth from continued grazing or mowing. Therefore, it appears that these grasses, once they are beyond the early seedling stage and well established, are less sensitive to soil salinity.

Because of their fibrous roots, grasses alone or in combination with forage legumes are frequently used in the reclamation of saline and sodic soils to restore good soil structure [170]. Under nonirrigated conditions, grasses that accumulate significantly high concentrations of Na^+ and Cl^- in the shoots may be used to restore soil structure and also to remove these ions from the soil profile [171]. Grasses used for this purpose may be unfit for animal feed because of the high salt content [170].

Clovers are the predominant legume of pastures and are frequently grown in combination with various grass species. However, salt-sensitive clovers tend to die out on saline soils as the more tolerant grass becomes the predominant vegetation. Loss of the clover from the pasture mixture significantly reduces the nutritional value of the pasture [172].

The salt tolerance of clovers [173] and alfalfa [174] is highly dependent on the stage of growth at which salinity is first imposed. The salt tolerance of alfalfa has been reported to be closely associated with Cl^- accumulation in the leaves [174,175]. Salt-affected plants are characterized initially by a dark green leaf coloration and reduced leaf size [175] followed by a general reduction in plant size [12].

Although the salt tolerance of alfalfa appears to depend on a salt-exclusion mechanism [175], no consistent correlation seems to exist between salt tolerance and salt exclusion for legumes in general [176]. There appears to be sufficient evidence that the genetic variability that exists among the grass and legume species and cultivars offers the possibility of developing strains with higher salt tolerance [169,173,176–178].

Salt Tolerance of Fruit Tree and Vine Crops

With the exception of date palm and a few others believed to be moderately tolerant, most fruit trees are relatively sensitive to salinity (Table 4). Stone fruits, citrus, and avocado have all shown specific sensitivity to foliar accumulations of Cl^- and Na^+. The accumulation of these ions to harmful levels, as well as the general osmotic growth inhibition, contribute to the reduction in tree growth and fruit yield.

Different cultivars and rootstocks absorb Cl^- and Na^+ at different rates, so tolerance can vary

Abbreviations as in Table 3.

[a] These data serve only as a guideline to relative tolerances among crops. Absolute tolerances vary depending on climate, soil conditions, and cultural practices. The data are applicable when rootstocks are used that do not accumulate Na^+ or Cl^- rapidly or when these ions do not predominate in the soil.

[b] Botanical and common names follow the convention of *Hortus Third* [140] when possible.

[c] In gypsiferous soils, plants tolerate EC_e about 2 dS m^{-1} higher than indicated.

[d] Ratings are defined by the boundaries in Figure 1. Ratings marked by an asterisk are estimates.

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

considerably within a species. In the absence of specific ion effects, however, the tolerance of these crops can be expressed as a function of the concentration of total soluble salts or the osmotic potential of the soil solution.

Some of the more sensitive fruit crops may accumulate toxic levels of Na^+ and/or Cl^- over a period of years from soils that would be classified as nonsaline and nonsodic [209,210]. Chloride toxicity in woody species is generally more severe and is observed on a wider range of species than Na^+ toxicity. The differences among species, cultivars, or rootstocks in susceptibility to Cl^- usually reflect the capability of the plant to prevent or retard Cl^- accumulation in the plant tops.

The initial symptoms of excess Cl^- accumulation in fruit crops is leaf tip necrosis developing into marginal necrosis. With citrus, a chlorosis and bronzing of the leaves occur without a well-defined necrosis. As Cl^- continues to accumulate, the effects become more severe with premature leaf drop, complete defoliation, twig dieback, and in extreme cases death of the tree or vine [210,211].

Injury by Na^+ can occur at concentrations as low as 5 mol m^{-3} in the soil solution [21]. However, injury symptoms, which are characterized as tip, marginal, and/or interveinal necrosis, may not appear for a considerable time after exposure to salinity. Initially, the Na^+ is thought to be retained in the sapwood of the tree. With the conversion of sapwood to heartwood, the Na^+ is released and then translocated to the leaves, causing leaf burn [212]. This may partly explain why stone fruits and grapes appear to be more sensitive to salinity as the plants grow older. With succeeding years, the Cl^- and Na^+ accumulate more rapidly in the leaves, causing leaf burn to develop earlier and with increasing severity [201].

Recent studies have shown that Na^+ accumulation in plum leaves did not significantly increase until the leaves were already severely damaged by Cl^- accumulation [201].

These studies indicate that when Cl^- and Na^+ are present in the soil solution, Cl^- is the primary damaging ion on stone fruits. Sodium accumulation only occurs after the leaf membranes have already been damaged.

Growth and yield reduction may occur with woody fruit species in the absence of specific ion toxicity. Francois and Clark [213], working with Valencia orange, reported a 50% reduction in fruit yield from salinity with no visible leaf-injury symptoms. Once salts have accumulated to toxic levels, however, growth and yield are suppressed by the additive effects of osmotic stress and specific ion toxicities [210].

Salt Tolerance of Ornamentals, Trees, and Flowers

In contrast to crop species that produce a marketable product, the salt tolerance of ornamental shrubs, trees, and flowers is determined by the esthetic value of the plant species. Injury or loss of leaves or flowers caused by salt stress is unacceptable even though growth may be unaffected. A significant growth reduction might be acceptable and possibly desirable for some species, as long as they appear to be healthy and attractive. The salt tolerance limits presented in Table 5 for some ornamental shrubs, trees, and ground covers indicate the maximum permissible EC_e for an acceptable appearance.

The type of injury seen on woody ornamentals and trees is similar to damage recorded for fruit trees and vines. A number of reports have shown that although some species accumulate Na^+, salt tolerance is closely associated with their ability to limit Cl^- uptake and accumulation [214,216,217].

In northern climates, where NaCl and/or $CaCl_2$ are used as deicing salts, typical salt-injury symptoms occur on roadside trees. These trees are subjected to both soil salinity from runoff and saline spray from passing automobiles. Although salt spray is thought to be the more detrimental of the two modes of deposition [218,219], soil-salinity effects may be accumulative and over a period of years may result in a slow but progressive decline of the trees.

A limited number of floricultural plants have been tested for salt tolerance. Chrysanthemum, carnation, and stock are considered moderately tolerant to salt stress; aster, poinsettia, gladiolus,

EC_e, electrical conductivity of the saturated-soil extract.
[a] Species are listed in order of increasing tolerance based on appearance as well as growth reduction.
[b] Salinities exceeding the maximum permissible EC_e may cause leaf burn, loss of leaves, and/or excessive stunting.
[c] Maximum permissible EC_e is unknown. No injury symptoms or growth reduction was apparent at 7 dS m^{-1}. The growth of all iceplant species was increased by soil salinity of 7 dS m^{-1}.
Source: Data compiled from Refs. 47, 214, and 215.

azalea, gardenia, gerbera, amaryllis, and African violet are considered somewhat sensitive [220,221]. Like other ornamental species, the esthetic value of floral plants is the determining factor for salt tolerance.

INTRODUCTION

Plants acquire mineral nutrients from their native soil environments. Most crop plants are glycophytes and have evolved under conditions of low soil salinity. Consequently, they have developed mechanisms for absorbing, transporting, and utilizing mineral nutrients in nonsaline soils. Under saline conditions, which are characterized by low nutrient-ion activities and extreme ratios of Na^+/Ca^{2+}, Na^+/K^+, Mg^{2+}/Ca^{2+}, and Cl^-/NO_3^-, nutritional disorders can develop and crop growth and quality may be reduced. This is not surprising, since under saline conditions, Na^+ and/or Cl^- often exceed macronutrient concentrations by one or two orders of magnitude and even more in the case of micronutrients. Halophytes, native to saline environments, may also develop nutrient disorders despite their remarkable ability to absorb nutrients selectively from soil solutions dominated by Na^+ and Cl^-.

Nutrient imbalance can develop in salt-stressed plants in different ways. It may result from the effect of salinity on nutrient availability, uptake, transport, or partitioning within the plant or may be caused by physiological inactivation of a given nutrient resulting in an increase in the plant's internal requirement for that essential element. It is likely that salinity may affect one or more of these processes at the same time, but whether or not this imbalance results in loss of crop yield or quality depends on its severity, which is influenced by a number of environmental factors.

Nutrient availability and uptake by plants grown in saline environments is related to (a) the activity of the nutrient ion in the soil solution which depends on pH, pE[1] (the negative log of

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

the activity of the electron), concentration, and composition; (b) the concentration and ratios of accompanying elements that influence the uptake and transport of this nutrient by roots; and (c) numerous environmental factors. Unless the salinizing ions are nutrients (e.g., Ca^{2+}, Mg^{2+}, SO_4^{2-}), increasing salinity generally decreases nutrient availability.

Plants vary not only in the rate by which they absorb an available nutrient element but also in the manner by which they spatially distribute the element within the plant. Moreover salinity can affect this internal distribution. For example, sodium can have a profound influence on calcium mobility and distribution within organs, particularly when it is the sole salinizing cation.

Even in the absence of salinity, nutrient availability, uptake, transport, and distribution in plants are affected by a number of biotic and abiotic factors resulting in complex interactions [1]. The presence of salinity, however, adds a new level of complexity to the mineral nutrition of plants.

NUTRIENT CONCENTRATION AND PLANT RESPONSE

In the absence of salinity, plant growth in relation to the concentration of an essential nutrient element in the root media is often described by the function illustrated in Figure 1. This relationship is a modification of the ''generalized dose response curve'' illustrated by Berry and Wallace [2]. Plant growth, usually expressed as absolute or relative biomass, is suboptimal when the concentration or activity of the essential nutrient element is less than A and optimal when the concentration is between A and B. Nutrient concentrations that exceed B may inhibit growth owing to either a toxicity or to a salt-induced nutrient deficiency.

A substantial body of information in the literature indicates that the plant may not exhibit the same response function under saline conditions as it does under nonsaline conditions. In some cases, the optimal range may be widened, narrowed, or it may shift in one direction or the other depending on the plant species (or cultivar), the particular nutrient, the salinity level, or environmental conditions. In most studies, salinity (either concentration or composition) is a major variable, and the experiment may only have a few treatments that vary in nutrient concentration. Therefore, most reported studies present insufficient data under saline and nonsaline conditions to develop response functions similar to Figure 1. Nevertheless, many studies demonstrated that an optimal concentration or activity of a particular nutrient element in nonsaline conditions may be deficient or, in a few cases, excessive under saline conditions.

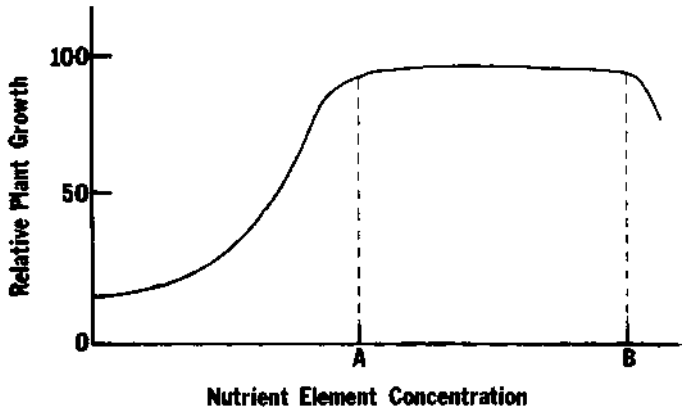

FIGURE 1 Relative growth of plants in relation to a wide range of concentrations of an essential nutrient element.

INTERPRETATION OF SALINITY–NUTRIENT INTERACTIONS

Salinity and mineral nutrient interaction studies are conducted in the laboratory, greenhouse, and the field and correspondingly test a broad range of agronomic, horticultural, or physiological hypotheses.

In many salinity-fertility studies conducted in the field, a major objective is to test if fertilizing salt-stressed plants either alleviates the growth-limiting effect of salinity or actually increases crop salt tolerance. In most of these field studies, two major factors operate simultaneously to limit growth and development: the presence of salinity and the imbalance of a particular nutrient element. The ''salt-tolerance'' of a crop, as defined by Maas and Hoffman [3], may vary depending on whether salinity or nutrition is the factor more limiting to growth. Bernstein et al. [4] defined three different types of idealized salinity and nutrition interactions that could occur: (a) no effect on salt tolerance, (b) increased salt tolerance, and (c) decreased salt tolerance. In contrast to the definition of Bernstein et al. [4], we prefer to define the interactions based on plant performance at optimal fertility relative to the performance at suboptimal fertility, and this interpretation is shown in Figure 2(a–c). Generally, plant growth will be promoted more if the limiting factor is relieved rather than the next limiting factor. For example, if nutrient deficiency limits growth more than salinity, a crop may appear to be more salt tolerant than it would if the plant was adequately supplied with that nutrient. That is, improving soil fertility to an adequate level would improve plant performance proportionally more in nonsaline conditions than under saline conditions.

Bernstein et al. [4] concluded that the effects of salinity and nutrition on grains and several vegetables are independent and additive when stresses imposed on them by nutrient deficiency and salinity are moderate. When either of these factors severely limit growth, the other has little influence on yield. Ten years later, the work of Okusanya and Ungar [5] with two halophytes and a glycophyte gave results that support Bernstein's salinity and fertility interaction model [4]. In the study by Okusanya and Ungar [5], nutrient applications increased the growth of the halophytes in saline conditions, presumably because salinity was moderately growth limiting. On the other hand, nutrient applications did not improve plant growth of the glycophyte under saline conditions, presumably because salinity was severely growth limiting.

It should be made clear, however, that the salinity and fertility interactions described by Bernstein et al. [4] are idealized and, therefore, can be misleading if interpreted improperly. These investigators emphasized that growth (or yield) is controlled by the factor (salinity or nutrient deficiency) that is most growth limiting. Yet the interactions are based on the plant response to salinity as it increases from nonlimiting to severely limiting levels. In many experiments, the nutrient concentration is the most limiting factor in low-salinity conditions, yet when the identical concentration is present in a highly saline environment, salinity will be the limiting factor. This point was emphasized by Champagnol [6] in his literature review on the relationship between salinity and phosphorus nutrition of plants.

Much of the data in the literature that describes salinity $\times$ N or salinity $\times$ P response functions can be reanalyzed by examining the interactions under low-, moderate-, and high-salinity levels. In many cases, a response function similar to that illustrated in Figure 3 will be obtained. Under low-salinity stress, nutrient deficiency limits plant growth more than salinity and a positive (+) interaction or an increased salt-tolerance response occurs. Under moderate salinity, nutrient deficiency and salinity stress may be equally limiting plant growth and no interaction (0) occurs. Under high-salinity conditions, salinity limits growth more than nutrient deficiency. In fact, plant performance would always exhibit a negative (−) interaction or a ''decreased salt tolerance'' (see Fig. 2c) response if a nutrient element was limiting growth under nonsaline conditions and the upper salinity treatment was lethal or severely growth limiting. In this case, only plants grown in nonsaline environments would respond to a nutrient addition.

In light of the above discussion and the multitude of interactions that could occur, results reported by various scientists on this subject may not be as contradictory as reviewers (e.g., see Refs. 7–10) have suggested.

SOIL AND SOLUTION CULTURE STUDIES

Many of the studies in the area of plant nutrition and salinity interactions have been conducted in sand or solution cultures. A major difficulty in understanding plant nutrition as it is affected by soil salinity is reconciling results obtained in experiments conducted in the field and in solution cultures [7]. In the field, the concentrations of some nutrients in the soil solution, particularly, P, K^+, and the micronutrients, are controlled by the solid phase and concentrations are much lower than those in nutrient solutions. To complicate matters further, field studies must contend with extreme variability in salinity, nutrient concentration, soil moisture, and soil texture, all of which vary with depth, location, and time. In solution cultures, nutrient ratios are much different than those found in soil solutions and concentrations of nutrients and salts are controlled over the course of the experiment. Furthermore, it is well known that root development is entirely different in both systems, so it is likely that plant responses and interactions observed in artificial media may not necessarily occur, at least with the same magnitude, as they would under natural conditions. Nevertheless, solution culture studies are extremely beneficial, since they have advanced our understanding of plant salt tolerance and of the physiological mechanisms responsible for nutrient uptake and discrimination.

STUDIES WITH SINGLE VERSUS MIXED SALTS

Salinity and salt type vary among soils and water supplies across the globe. In most cases, the major cations in the water supply or soil solution are Na^+, Ca^{2+}, and Mg^{2+}, whereas the major anions are Cl^- SO_4^{2-}, and HCO_3^-. Despite the variation in composition, there is a general relationship between salinity and the ratio of $Na^+/(Na^+ + Ca^{2+})$ in waters around the world [11]. Those waters very high in salinity such as those in oceans and seas have a ratio near 1, indicating that Na^+ is the major

salinizing cation. However, the bulk of the inland waters with low (60 mg/L total dissolved salts) to moderate (1300 mg/L) salinity have ratios between 0.1 and 0.7, indicating that Ca^{2+}, although not the major cation, is a substantial contributor to the salinizing media.

Based on this information, one would expect that using single salts, for example, NaCl, would be more appropriate when conducting salinity-nutrient studies with halophytes, whereas a mixed salt solution of some type would be more suitable for nonhalophytes (i.e., most crop plants). Surprisingly, a large percentage of salinity studies on agronomic and horticultural crops use NaCl as the sole salinizing agent, which limits the extent by which one can interpret the results or relate them to field conditions.

The same argument for the cations can also be taken for the anions. The majority of salinity studies use Cl^- as the sole salinizing anion, yet most agricultural fields affected by salinity have a substantial amount of SO_4^{2-} and HCO_3^-. We argue that much more can be learned if a larger fraction of future salinity-nutrient studies, regardless of experimental scale or objectives, are conducted with more realistic ion ratios.

The remaining portion of this chapter is directed toward plant performance and acquisition of the major nutrient elements (N, P, K^+, Ca^{2+}, Mg^{2+}, and S) and micronutrient elements in saline environments. This chapter includes references to both soil and solution culture studies as well as those that use single-salt (i.e., NaCl) and mixed-salt compositions. It is beyond the scope of this chapter to address salinity-nutrient interactions at the biochemical or molecular level, nor are salinity-microbe interactions addressed despite their importance in mineral nutrition. The emphasis is placed on glycophytes at the organ and whole-plant level. Discussion of halophytes is included where appropriate and where information is available.

NITROGEN

In most soils, saline or nonsaline, N is usually the most growth-limiting plant nutrient. Consequently, addition of N usually improves plant growth and yield. In many field studies, researchers set out to test the hypothesis that N fertilizer additions alleviate, at least to some extent, the deleterious effect of salinity on plants.

Most salinity and N interaction studies were conducted on soils deficient in N. Therefore, additions of N improved growth and/or yield of apple [12], barley [13], bean [14–16], carrots, cowpea, tomato, corn, clover, beans, millet and vetch [17], coastal bermudagrass [18], corn and cotton [19], corn and millet [20], tomato [21], spinach [22], wheat [23,24], and rice [23] when the degree of salinity was not severe. In most of these studies, the fact that applied N did not improve the growth under extreme saline conditions suggests that applied N decreased plant salt tolerance (see response in Fig. 2c). On the other hand, only one study showed an increase in crop yield under saline conditions where N was applied above a level considered optimal under nonsaline conditions [25,26]. In this case, additional N did in fact increase the salt tolerance of millet and clover. Selassie and Wagenet [27] also reported that the salt tolerance of well-watered corn may have been increased with urea additions up to 375 kg/ha to a soil initially supplied with sufficient N. This practice, however, is not necessarily practical and would most likely be undesirable from both economical and environmental perspectives.

Despite the majority of evidence indicating that N applied to saline soils above a level considered optimal under nonsaline conditions does not improve plant growth or yield, a number of laboratory and greenhouse studies have shown that salinity reduces N accumulation in plants [28–33]. This is not surprising, since with few exceptions [8,34], an increase in Cl^- uptake and accumulation is accompanied by a decrease in shoot nitrogen concentration. Examples of this effect are also found in barley [35–38], cotton [39], cucumber [40], eggplant [41], tomato [42], tomato and melon [43], and wheat [44,45]. Many attribute this reduction to Cl^- antagonism on NO_3^- uptake [42,43,46], whereas others attributed the response to salinity's effect on reduced water uptake [47].

Gorham et al. [48] observed that despite drastic reductions in leaf NO_3^- concentrations in

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

response to salinity, other nitrogen-containing fractions either increased (e.g., proline, glycinebetaine, total soluble protein) or were not greatly reduced (e.g., total amino acid content). These results argue against N deficiency per se as a mechanism of salt injury. This conclusion is also supported by Munns and Termaat [49]. In their review, these investigators suggested that although NaCl-treated plants may contain less N than nonstressed plants, there is no strong evidence to support that this effect is growth limiting.

In contrast to the effect of Cl^- on NO_3^- uptake, reported data indicate that increased NO_3^- in the substrate decreased Cl^- uptake and accumulation [4,42,43,50]. This type of interaction may be particularly important to tree and vine crops that are susceptible to Cl^- toxicity. In one study with citrus and avocado, additions of NO_3^- above concentrations considered sufficient for optimal growth decreased the Cl^- concentrations in leaves to the extent that foliar injury was reduced, thereby lessening growth inhibition by salinity [46]. The authors did, however, caution the reader that such practices could promote NO_3^- contamination of the ground water.

The form in which N is supplied to salt-stressed plants may influence salinity-N relations as well as affect salinity's relationship with other nutrients [50–52], although the form of N did not influence the yield of moderately salt-stressed wheat [53]. NH_4^+-fed maize and wheat plants were more sensitive to salinity than NO_3^--fed plants when grown in solution cultures [51,52]. Similar responses were found in melon [54]. Addition of Ca^{2+} to the media improved the growth rate of the plants in the NO_3^- treatment but not those treated with NH_4^+ [51]. In addition, Martinez and Cerdá [50] found that Cl^- uptake was enhanced in cucumber when half the NO_3^- in the solution was replaced by NH_4^+. These investigators further noted that when NO_3^- was the only N source, accumulation of K^+ in the plant was increased in saline conditions. When the media contained both NO_3^- and NH_4^+, K^+ was reduced. Similar effects were found in salt-stressed melon [54]. As the NH_4^+/NO_3^- ratio was increased, plants accumulated more Na^+ and Cl^- and less Ca^{2+} and K^+ in their leaves. Based on the results of their nutrient solution experiments, Leidi et al. [55] suggested that NO_3^- is a better N source than NH_4^+ for wheat. This conclusion was supported by Silberbush and Lips [56,57], who reported that mean grain weight of wheat grown in sand cultures was negatively correlated with the NH_4^+/NO_3^- ratio. In a more recent study [58], however, it was recommended that the best source of N for wheat was a mixture of NH_4^+ and NO_3^-.

The results of salinity and N-source studies conducted in hydroponic or sand cultures, cited above, contrast to those where plants were grown in soil. Shaviv et al. [59] found that wheat grown in soil salinized with NaCl was more tolerant in terms of grain yield under a combination of NH_4^+ and NO_3^- than NO_3^- alone. This was also found for peanut in a salinity study testing the plant response to different forms of N in soil and solution cultures [60]. This is a classic example of how plant-nutritional experiments conducted in solution cultures alone may lead to inappropriate fertilizer recommendations for the field.

Halophytes grown in highly saline, N-deficient environments and glycophytes grown in mildly saline, N-deficient environments respond similarly to added N [5,61–64]. Skeffington and Jeffrey [63] found that N additions increased the growth of *Plantago maritima* L. even when grown in seawater. Furthermore, N additions increased plant survival. Okusanya and Ungar [5] found that the poor growth of two *Spergularia* species grown in 50% seawater was improved by $Ca(NO_3)_2$ additions. Naidoo [62] studied the interactive effects of N and NaCl salinity on young mangroves (*Avicennia marina* [Forsk.] Vierh.). The N was supplied as NH_4^+ rather than NO_3^- to simulate the saturated, and thus anaerobic, environments that are typical of the natural habitat of mangroves. Therefore, nitrate reduction is prominent and most plant-available N is in the NH_4^+ form. Naidoo [62] found that increased salinity decreased N and K^+ in tissues. The decrease in tissue N is probably caused by NH_4^+/Na^+ competition, since Bradley and Morris [65] found that sea-salt salinity reduced the kinetics of NH_4^+ uptake in *Spartina alterniflora* Lois. Furthermore, as NH_4^+-N increased from 1.4 to 14 mg/L, shoot growth increased in the 100- and 300-mM NaCl treatment, but not in the 500-mM NaCl treatment. Therefore, in agreement with most of the work with glycophytes, it would be interpreted that added N decreased salt tolerance of these halophytic species if the response was characterized over the entire range of salinity.

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

In some halophytes, the minimum internal shoot N concentration required for biomass accumulation may be affected by salinity. Bradley and Morris [66] found that the minimum tissue concentration of N required to sustain biomass accumulation in *Spartina alterniflora* increased with increasing salinity.

Some halophytes have salt glands, a unique anatomical feature that allows the plant selectively to excrete salt (particularly NaCl) from its shoot. Not only does this feature allow the plant to reduce its internal salt load, at least to some extent, it improves the nutrient relations within the plant. Waisel et al. [67] suggested that salt glands, by selective removal of Na^+ and Cl^- from the leaves of *Avicennia marina* (Forsk.) Vierh., may help this mangrove species metabolize normally by decreasing the ratios of Cl^-/NO_3^-, $Cl^-/H_2PO_4^-$, and Na^+/K^+ within its leaves.

PHOSPHORUS

The interaction between salinity and phosphorus (P) nutrition of plants is perhaps as complex as that between salinity and N. The interaction is highly dependent on the plant species (or cultivar), plant developmental age [68], the composition and level of salinity, and the concentration of P in the substrate. Therefore, depending on plants selected and conditions of the experiment, different results can occur.

Nearly two decades have elapsed since Champagnol [6] reviewed 17 publications and found that P, added to saline soils, increased crop growth and yield in 34 of the 37 crops studied. However, added P did not necessarily increase crop salt tolerance as defined by the nutrient × salinity response model originally developed by Bernstein et al. [4]. After analyzing studies with barley, carrot, clover, maize, millet, sorghum, sugar beet, tomato, vetch, and wheat, Champagnol [6] concluded that added P increased, had no effect, or decreased salt tolerance as salinity increased from low, to moderate, to high levels, respectively. This demonstrates the complexity of interpreting salinity-fertility studies regarding whether or not the addition of P to deficient soils or media increases crop salt tolerance. The most useful conclusion from studies reviewed by Champagnol [6] is that P additions to P-deficient soils are beneficial providing that the crop is not experiencing severe salt stress.

The influence of salinity on P accumulation in crop plants is variable and depends on the plant and experimental conditions [6]. In most cases, salinity decreased the concentration of P in plant tissue [69], whereas in others, it increased P or had no effect. It is not surprising that these differences among studies occur, since plant type and environmental conditions play a large role in P accumulation and P concentrations vary widely in different experiments. Champagnol [6] concluded that it is unlikely that Cl^- and $H_2PO_4^-$ ions are competitive in terms of plant uptake. However, Papadopoulos and Rendig [21] concluded that Cl^- may have suppressed P uptake and accumulation in tomato shoots. Martinez and Läuchli [70,71] found that not only did NaCl salinity reduce phosphate uptake by cotton roots but also showed a reduction in P transport within the roots and from the roots to the shoots. Zhukovskaya [68] found that Cl^- as well as SO_4^{2-} salts reduce P uptake in barley and sunflower. In other cases, a reduction in plant P concentration by salinity may result from the reduced activity of P in the soil solution owing to the high ionic strength of the media [72].

Many of the studies that show salinity-reduced P concentrations in plant tissues were conducted in soils. Phosphate availability is reduced in saline soils not only because of ionic strength effects that reduce the activity of P but also because P concentrations in soil solution are tightly controlled by sorption processes and by the low solubility of Ca-P minerals. Therefore, it is understandable that P concentrations in field-grown agronomic crops decreased as salinity ($NaCl + CaCl_2$) increased [69]. In many cases, tissue P concentration was reduced between 20 and 50%, yet there was no evidence of P deficiency in the crops. In cases where plants are P deficient, they may be more sensitive to salinity. Gibson [73] found that P-deficient wheat plants were more sensitive to salinity than those with adequate P and that deficient plants had a lower cellular tolerance for the accumulated ion.

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

Since the solubility of P in the solutions of saline soils containing high levels of Ca^{2+} is controlled by sorption processes on Al hydroxides and by the solid phase of Ca-P minerals, it is reasonable to question why some plants respond positively to added P. Evidently the kinetics of sorption and/or precipitation are relatively slow and initial forms of calcium phosphate are thermodynamically unstable (D.L. Suarez, U.S. Salinity Laboratory, personal communication, 1990). Later, more stable phases are formed, plant availability decreases, and repeated P applications to saline/calcareous soils are required.

Some research indicates that salinity may increase the P requirement of certain plants. Awad et al. [72] found that when NaCl increased in the substrate from 10 to 50 and 100 mM, the P concentrations in the youngest mature tomato leaf necessary to obtain 50% yield increased from 58 to 77 and 97 mM/kg dry weight (DW), respectively. Their conclusion was also supported by foliar symptoms of P deficiency that were evident on plants grown at high NaCl but were not evident on others at lower salinity with equal leaf P concentrations.

Unlike studies conducted in the field, most studies which demonstrated that salinity increased tissue P were conducted in sand or solution cultures. Phosphate concentration in solution cultures is often orders of magnitude higher than that in soil solutions (e.g., 2 mM vs 2 μM). Several studies conducted in solution cultures have shown that P concentrations that are optimal in nonsaline solutions may adversely affect growth or be toxic to corn [4,74], lupin [75], sesame [76], and certain soybean cultivars [77] when grown in saline solutions. This is evidence that the optimal P range (A to B in Fig. 1), in these instances, narrows under saline conditions. In all these studies, salinity increased P accumulation in plants at the highest substrate P level. The increased P accumulation in the shoot is independent of the composition of salts in the growth media and is presumably controlled at the root level [78]. However, the actual mechanism of this salinity-enhanced uptake rate of P by roots is still unknown [79]. It should be emphasized, however, these adverse interactions in the studies described above would rarely occur under field conditions, because P concentrations in soil solutions are usually orders of magnitude less than those used in these studies. Nevertheless, these interactions are important from an academic viewpoint and pose interesting questions regarding the mechanisms of P uptake and transport within the plant.

Although the majority of studies that report salinity-induced P toxicities to crops have been conducted in solution cultures, this phenomena has also been observed in field conditions [80]. Additions of P greater than 18 kg/ha to paddy rice under salt stress were found to be toxic and resulted is a substantial reduction in yield.

Phosphate additions to halophytes grown in highly saline environments have also resulted in increased plant growth. Okusanya and Fawole [81] showed that phosphate stimulated the growth of *Lavatera arborea* L. much more at 40 and 50% strength seawater than under nonsaline conditions. The magnitude of this effect may be partly due to the increase in the shoot/root ratio by salinity. When no phosphate was added, salinity reduced plant growth. However, when 0.05 and 0.25 mM phosphate was added to the nutrient sand culture, salinity, at the concentration of 40% seawater, actually increased plant growth. Therefore, addition of phosphate increased the salt tolerance of *L. arborea*.

POTASSIUM

Potassium is the most prominent inorganic plant solute, and as such it makes a major contribution to reducing the osmotic potential in root cells to facilitate turgor pressure–driven solute transport processes and to sustain the overall water balance of the plant [1]. Therefore, maintenance of adequate levels of K^+ is essential for plant survival in saline habitats.

Potassium, like P, is present in relatively low concentrations in the soil solution. Potassium is readily adsorbed onto the surface of soil particles and is fixed, and thus unavailable, within layers of expandable 2:1 clay minerals. In some vermiculitic soils, applications of K as high as 700 kg/ha were ineffective at correcting visual symptoms in K-deficient cotton [82]. Because of the plant's

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

requirement for an adequate amount of K^+, it is fortunate that the plasma membranes of root cortical cells have a high affinity for K^+ over Na^+ even though the degree of selectivity can vary quite drastically among species [83]. This is particularly important in saline/sodic and sodic environments, where concentrations of Na^+ in the soil solution are orders of magnitude higher than that of K^+. The high K^+/Na^+ selectivity within plants is maintained provided that the calcium status in the root is adequate [84–87] and that the roots have a sufficient supply of O_2 [88].

Although plants selectively absorb and translocate K^+ in preference to Na^+, the degree of selectivity varies among species as well as cultivars within a species. Kafkafi [10] reported the data of Bower and Wadleigh [89] as the fraction of monovalent cations (Na[Na+K] or K[Na+K]) in the exchange complex versus that within the roots of bean and beet. Kafkafi [10] concluded that the roots of the salt-tolerant species (beet) had a higher affinity for K^+, in exchange for Na^+, than the salt-sensitive species (bean). Rathert [90] found that salinity ($Na^+/K^+ = 9$) reduced the concentration of K^+ in the leaves of the salt-sensitive cotton cultivar (Dandara) more than that in the salt-tolerant cultivar (Giza 45).

There is evidence that Na^+ can partially substitute for K^+ in many glycophytic species without affecting growth. Marschner [1] classified many crop species into four groups depending on the extent by which Na^+ can replace K^+. Crop species in group A can replace a high proportion of K^+ by Na^+ (e.g., beets, turnip, and swiss chard), whereas in crop species in group D (e.g., maize, bean, and lettuce) no substitution of K^+ is possible.

Rice has been classified as a group C crop where only a minor substitution of K^+ by Na^+ is possible and Na^+ has no specific effect on growth, which is unlike those crops in groups A and B [1]. However, the addition of 17 mM NaCl to solution cultures low in available K^+ improved vegetative growth and increased panicle yield [91]. Sodium chloride decreased the K^+ content only when the K^+ supply was low. Thus, a relatively high Na^+ content may benefit K nutrition in rice under saline conditions when the supply of K^+ is low [91]. Supplemental K^+ improved all yield components in salt-stressed rice and decreased Na^+, Ca^{2+}, and Mg^{2+} in the straw [92]. Despite the plant's high affinity for K^+ over Na^+, the K^+ status in plants is related to the ratio of Na^+/K^+ in the saturated-soil extract [93]. If it is assumed that the composition of the soil solution is at least close to equilibrium with that on the exchange phase, then it would follow that K^+ accumulation by the root would be reduced if the exchangeable sodium percentage (ESP) on the exchange phase were increased. This effect was observed in bean and beet [89].

Numerous studies have shown that the K^+ concentration in plant tissue is reduced as Na^+ salinity or the Na^+/Ca^{2+} ratio in the root media is increased (e.g., see Refs. 5,86,87,94–96). Reduction in K^+ uptake in plants by Na^+ is a competitive process and occurs regardless of whether the solution is dominated by Na^+ salts of Cl^- or SO_4^{2-}. Janzen and Chang [95] found that barley plants exposed to Na_2SO_4 salinity contained only one-third the concentration of K^+ in their shoots than those grown in nonsalinized solutions. Sodium-induced K^+ deficiency has been implicated in growth and yield reductions of various crops, including tomato [97,98], spinach [99], fennel [100], and maize [101].

Halophytes, like glycophytes, have also shown a high degree of K^+ selectivity and increasing Na^+ concentrations in the substrate have caused reduced K^+ concentrations in their shoots. Excised leaf tissue of the mangrove, *Avicennia marina* (Forsk.) Vierh., was highly selective for K^+ over Na^+ [102] and *Hordeum jubatum* L. was found selectively to transport K^+ to the shoot against a strong external concentration gradient of Na^+ [103]. Nevertheless, increased NaCl salinity decreased shoot K^+ in the same mangrove species even though there was no effect on root K^+ [62]. Ball et al. [104] concluded that NaCl salinity produced a salinity-induced K^+ deficiency in *A. marina*. In contrast, Clough [105] found no differences in leaf or stem K^+ in *A. marina* when plants were grown in different dilutions of seawater. The author did note, however, that the K^+ concentration in the media increased ninefold as the percentage of seawater increased from 0 to 100.

Although plants show high selectivity of K^+ over Na^+, excessive amounts of K^+ may be detrimental to some plants. Rush and Epstein [106] found that the wild tomato species (*Lycopersicon cheesmanii* ssp. minor [Hook.] C.H. Mull.) could tolerate 200 mM Na^+ but 200 mM K^+ was toxic.

On the other hand, the domestic and more salt-sensitive tomato species (*Lycopersicon esculentum* Mill.) showed the opposite behavior; it could tolerate K^+, but not Na^+, at the same concentration. The adverse effects of high K^+/Na^+ at high total salt concentration have been observed in both halophytes (e.g., *Atriplex amnicola, A. inflata, A. nummularia* Lindl., *Suaeda maritima* [L.] Dum., and *Vigna radiata*) [107,108] and glycophytes [90,93,108].

Despite the overwhelming amount of data that show reduced uptake and translocation of K^+ by plants grown in high Na^+ substrates, there are little data that show that the addition of K^+ to sodium-dominated soils improved plant growth or yield. Bernstein et al. [4] found that increasing solution K^+ from 0.4 to 2.0 mM did not affect leaf K^+ or yield of corn. Bar-Tal et al. [109] did find an increase in the yield of corn grown in sandy soil, but the response was proportional at all salinity levels. These investigators concluded that despite its beneficial effects on increasing K^+/Na^+ within the plant, K^+ fertilization did not reduce the deleterious effects of salinity. Using solution cultures, Muhammed et al. [110] found that shoot and root growth of rice plants grown in 100-mM NaCl solutions were increased when substrate K^+ increased from 1 to 7 mM. In other nutrient culture studies, Chow et al. [99] showed that differences in the shoot growth of spinach, between plants grown at low (50 mM NaCl) and high (250 mM NaCl) salinity at a given level of K^+, can be reduced when K^+ is added to the highest salinity treatment. However, plant growth at the low-salinity level only doubled when K^+ in the solution was increased from 0.01 to 10.0 mM. In field conditions, soil solution K^+ remains relatively low even after fertilizer additions of K^+. Therefore, it is difficult to imagine many situations where reasonable amounts of K^+ added to the soil would completely correct Na^+-induced K^+ deficiencies in plants suffering from this disorder.

CALCIUM

Calcium (Ca) plays a vital nutritional and physiological role in plant metabolism. It is essential in processes that preserve the structural and functional integrity of plant membranes [111], stabilize cell wall structures, regulate ion transport, and control ion-exchange behavior as well as cell wall enzyme activities [112]. Because Ca^{2+} is readily displaced from its extracellular binding sites by other cations, these functions may become seriously impaired by reduced Ca^{2+} availability. Root growth and function may be restricted by high Na^+/Ca^{2+} [85,113–116]. From the results of a quantitative study of plasma membrane–bound Ca^{2+}, Yermiyahu et al. [117] concluded that salt-resistant genotypes may have a lower requirement for the fraction of surface charges bound to Ca^{2+}. Solomon et al. [118] observed abnormal root morphology and anatomy of pea (*Pisum sativum* L.) grown in nutrient cultures containing 120 mM NaCl as the sole salinizing salt. These ''salinity-induced'' changes, characterized by curvature of the root tip as well as constriction and thickening above the apex, were completely reversed by the addition of 10 mM Ca^{2+} [119]. Sodium-induced Ca^{2+} deficiencies have notorious growth-distorting effects on developing leaves as illustrated on several grass species grown in solution cultures [120–122].

The presence of Ca^{2+} as the dominant cation in agricultural soils generally ensures that the absolute Ca^{2+} level is not a primary growth-limiting factor. As salinity increases, the requirements of plants for Ca^{2+} increases [123]. In saline soils, as contrasted with sodic soils, Ca^{2+} concentrations usually increase as the total salt concentration increases. At the same time, however, the uptake of Ca^{2+} from the soil solution may decrease because of ion interactions, precipitation, and increases in ionic strength that reduce the activity of Ca^{2+}. These combined effects are at least partially responsible for reduced yields under saline or sodic conditions [95,124–126]. Therefore, in reference to Figure 1, the optimum range is shifted to the right for most crops grown under saline conditions, particularly, if the solution is dominated by Na^+ salts.

The critical Ca^{2+} requirement for plants has been estimated as the ratio of soluble Ca^{2+} to the total cations (Ca^{2+}/TC) rather than to the absolute concentration of Ca^{2+} in the soil solution. Physiological disorders that are related to Ca^{2+} deficiency occur when the Ca^{2+}/TC falls below a critical level [127,128]. In the Solonetzic soils of the Canadian prairie, ion imbalances result from

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

high Na^+ and low Ca^{2+} together with predominately sulfate salinity. Severe Ca^{2+} deficiency in barley occurs in these regions when the Ca^{2+}/Mg^{2+} molar ratio or the Ca^{2+}/TC ratio is less than 0.15 [129]. The critical Ca^{2+} requirement for the optimum rate of extension of cotton root has been related to the molar Ca^{2+}/TC ratio [130]. Subsequently, the Ca^{2+}/TC ratio, expressed in terms of ion activity, was considered to be a more accurate measure of Ca^{2+} availability [131–133]. However, it would seem preferable to distinguish specific ion competition; for example, Ca^{2+}/Na^+ and Ca^{2+}/Mg^{2+} rather than Ca^{2+}/TC.

The Ca^{2+}/TC in the soil solution has been related to the Ca^{2+}/TC in saturated-paste extracts [95]. Carter and Webster [134] used this relationship to predict plant-available Ca^{2+} as well as Ca^{2+} accumulation in plant tissues. Critical levels of Ca^{2+} in barley and wheat (63 mM/kg DW) and alfalfa (250 mM/kg DW.) corresponded to a Ca^{2+}/TC ratio of 0.10 in the soil extract.

Although NaCl salinity reduced shoot Ca concentration in barley, this decrease was not due to reduced influx of Ca^{2+} into the roots by the salinizing salts [135]. Lynch and Läuchli [135] proposed that sodium may inhibit the radial movement of Ca^{2+} from the external solution to the root xylem by screening of cation exchange sites in the apoplast. Cramer et al. [94,136] suggested that the primary response to NaCl stress in cotton roots is the displacement of membrane-associated Ca^{2+} by Na^+ leading to increased membrane permeability and to loss of K^+/Na^+ selectivity. The addition of 10 mM Ca^{2+} to the saline cultures preserved membrane integrity and prevented leakage of K^+. Exchange constants, calculated from the relationship between the activities of Ca^{2+} and Na^+ in nutrient cultures and the equivalent fraction of Ca^{2+} and Na^+ in corn shoots indicated that the cation uptake process is strongly selective for Ca^{2+} against Na^+. As the activity of Na^+ in the substrate increases, however, the system becomes less discriminating and the selectivity for Ca^{2+} is impaired [137]. Likewise, Davenport et al. [138] concluded that the maintenance of a critical Ca^{2+} activity in the substrate rather than a specific Ca^{2+}/Na^+ ratio was essential for normal growth of salt-stressed wheat.

Nutritional imbalances in salt-stressed cereals have been studied in isosmotic nutrient solutions salinized with various molar ratios of Na^+ and Ca^{2+}. This investigation included corn [122], rice [139], and sorghum [121] as well as wheat, barley, rye, and oats (E.V. Maas and C.M. Grieve, unpublished data, 1984). The cereals show striking intergeneric differences in their response to different Na^+/Ca^{2+} molar ratios in cultures of equal osmotic potential (OP). A salt stress of -0.6 MPa with $Na^+/Ca^{2+} = 52$ reduced the relative dry matter yield of wheat less than that of rye or oats. At -0.4 MPa, rice was more sensitive at $Na^+/Ca^{2+} = 5$ than was corn.

In a comparative study of a cultivated barley and a wild barley variety that exhibits higher salt tolerance, the wild species was able to maintain higher tissue concentrations of calcium and was more effective at compartmentalizing Na^+ in the root rather than the shoot [140]. This difference between barley species may partly explain why increasing the $Ca^{2+}/(Ca^{2+} + Mg^{2+} + Na^+)$ ratio from 0.02 to 0.09 in the solution culture only benefited the cultivated species. Wild barley (*Hordeum jubatum* L.) populations also differ in their response to salinity. Wang et al. [141] identified three ecotypes, two of which were more tolerant of $MgSO_4$-salinity and high Na^+ than was the third. The investigators attributed the enhanced growth of the tolerant ecotypes to their superior Ca^{2+}-use efficiency and their ability to restrict Na^+ and Mg^{2+} translocation to the leaves.

Genotypes may also vary in their susceptibility to Ca^{2+} disorders at high substrate Na^+/Ca^{2+}. Grieve and Maas [121] compared the response of three sorghum cultivars and suggested that the Na^+ tolerance of Hegari cultivar was related to the efficiency of Ca^{2+} transport to the developing leaves. At $Na^+/Ca^{2+} = 34.6$ and OP $= -0.40$ MPa, many of the expanding blades of the sensitive cultivars NK 265 and NB 9040 were deeply serrated and tightly rolled with withered, often necrotic, tips. These symptoms have been associated with severe Ca^{2+} deficiency [142], and this diagnosis was confirmed by mineral analysis. Yeo and Flowers [143] reported that the elite breeding line (IR 2153) of rice was very unresponsive to external Ca^{2+}. Shoot growth of this line was not affected over a wide range (5–500) of Na^+/Ca^{2+} ratios and Ca^{2+} concentration had a limited effect on NaCl uptake. In contrast, high Na^+/Ca^{2+} inhibited shoot growth in two rice cultivars (M9 and M201) developed for specific regions of California [139]. Ca^{2+}-deficiency symptoms were observed at an

OP of −0.4 MPa and Na^+/Ca^{2+} molar ratios of 198 and 78. Shoot growth improved and the Ca^{2+} disorder was eliminated when the Na^+/Ca^{2+} ratio was reduced to 17.8 [139]. The shoot and root growth of the rice cultivar KS282 was significantly influenced by external Na^+/Ca^{2+} [110]. Rolling and bleaching of the young leaves occurred when the Na^+/Ca^{2+} ratio exceeded 100. Muhammed et al. [110] also attributed differences in root growth to an interaction between Na^+/Ca^{2+} and Na^+/K^+ ratios in the root media. Norlyn and Epstein [144] observed that triticale lines differed in tolerance to high Na^+/Ca^{2+} (i.e., 500) during emergence and germination. Emergence of only one line improved when the Na^+/Ca^{2+} was reduced to 37, whereas other lines showed no effect of added Ca^{2+}. Kingsbury and Epstein [145] contrasted the response of two wheat genotypes to isosmotic solutions that varied in ionic composition. One line was highly resistant to Na^+ toxicity and, in response to high external Mg^{2+}/Ca^{2+}, showed superior Ca^{2+} -use efficiency. Ashraf and O'Leary [146] reported that in response to varying external Na^+/Ca^{2+}, transpiration and stomatal conductance in a salt-tolerant sunflower were unchanged, whereas these parameters in a salt-sensitive line decreased significantly. In closely related *Brassica* species, Ashraf and Naqvi [147] found that although supplemental Ca^{2+} improved dry matter production of *B. napus* and *B. juncea*, growth of *B. campestris* and *B. carinata* was unaffected by increases in Ca^{2+} concentration in growth media salinized with 150 mM NaCl (13 dS/m). In contrast, growth of these four species, along with *B. oleraceae* and *B. nigra*, was not influenced by the addition of Ca^{2+} to saline solution cultures (Instant Ocean*, 8 dS/m) containing a mixture of salts [148].

Several studies [110,121] have shown that as the injured cereal leaves mature and become less dependent on root pressure for their supply of water and nutrients, their Ca^{2+} demands are then met via increased transpiration rates. Eventually, the Ca^{2+} concentration in the older blades of salinized plants was as high as in those in the nonsaline controls.

The limited capacity of plants to regulate internal Ca^{2+} distribution in relation to the demands of low-transpiring organs has been implicated in numerous Ca^{2+} -related physiological disorders [149–151]. Even under nonsaline conditions, failure to meet the Ca^{2+} requirements of developing leaves may result in necrosis of these tissues as in blackheart of celery [152], tipburn of lettuce and Chinese cabbage [153], and internal browning of cauliflower and Brussels sprouts [151]. Root crops may be similarly affected; for example, cracking and cavity spot of carrots and parsnips [150]. Calcium disorders in reproductive tissues are associated with heavy economic losses in the fruit industry due to such diseases as blossom-end rot (BER) of tomato, pepper, and melon, bitter pit of apples and pears; and end spot of avocado. Under saline or sodic conditions, the calcium status of these organs may become even more impaired, which will affect their marketability.

The use of low to moderately saline irrigation waters or nutrient cultures for tomato production has been advocated to improve fruit quality by increasing firmness as well as the levels of total soluble solids; for example, reducing sugars and organic acids [154–156]. Depending on the cultivar, this practice may, however, reduce Ca^{2+} content of the fruit and increase the incidence of BER [157,158].

Ca^{2+}-related disorders are profoundly influenced by the interaction of salinity with environmental factors [159]. Although conditions that increase transpiration rates may stimulate the uptake of Ca^{2+}, it may be disproportionately delivered to older leaves and cause localized deficiency in young tissues. Reduction of Ca^{2+} accumulation in fruit was associated with increased incidence of BER of salt-stressed tomatoes grown under low daytime humidity [160], high root temperature, and high irradiance [161]. Differences in environmental conditions most probably account for the disparate results obtained by two separate teams of researchers investigating the response of artichoke to salinity. In the first instance, plants were grown under controlled greenhouse conditions in pot cultures irrigated with saline (NaCl) waters with an electrical conductivity (EC) ranging from 0.74

* Mention of brand names is for the benefit of the reader and does not imply endorsement or preferential treatment by the University of California or the U.S. Department of Agriculture.

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

to 15 dS/m. Plant injury due to salinity was restricted to moderate necrosis on the older leaves [162,163]. The second study was a field trial conducted during two consecutive years in a desert area whose high daytime temperatures and desiccating winds resulted in very high transpiration rates. Although irrigation waters were salinized with NaCl and $CaCl_2$, the Ca^{2+} requirements of the developing buds were not met and internal browning occurred. More than half the plants irrigated with saline water at 10 dS/m produced buds that were unmarketable. These investigators [164,165] attributed this disorder to poor Ca^{2+} partitioning rather than restricted uptake inasmuch as the transpiration-mediated Ca^{2+} transport to the leaf blades increased, whereas root pressure–driven Ca^{2+} transport to the shoot apex decreased.

Salinity's effect on root pressure has also been associated with Ca^{2+}-related injury in young tissues that depend on diffusion to meet their demands for plant resources, for example, Chinese cabbage [166], lettuce [167], and celery [168]. In wheat and barley, the reduction of spikelet primordium numbers may also occur through a similar process or through Ca^{2+-}-mediated signaling of salinity stress [169].

Increased root permeability, caused by reduction in the availability of external Ca^{2+}, may lead to increased Cl^- uptake. Elevated internal Cl^- concentrations have been associated with decreased shoot growth in several species such as cowpea [170], tobacco [171], pigeon pea [87], and *Leucaena leucocephala* [115,116].

Maintaining an adequate supply of Ca^{2+} in the soil solution is an important factor in controlling the severity of specific ion toxicities [172]. This is particularly important for tree and vine crops, which are more prone to Na^+ and Cl^- injury than most annual crops. In citrus, calcium was found to be effective at reducing the transport of both Na^+ and Cl^- from the roots to leaves, thereby reducing foliar injury [173–176].

The importance of maintaining a balanced nutrient solution to optimize plant performance of glycophytes under saline conditions has been known for over 80 years [177], yet an alarming percentage of salinity studies conducted to date use NaCl as the only salinizing salt. We must, therefore, emphasize that the use of extreme ratios of Na^+ and Ca^{2+} may introduce unique nutritional problems and result in misleading and erroneous interpretations about the plant response to salinity.

MAGNESIUM

Many studies have analyzed the plant tissue for Mg^{2+}, yet most salinity-nutrient studies have directed little attention to magnesium nutrition as affected by salinity.

Calcium is strongly competitive with Mg^{2+}, and the binding sites on the root plasma membrane appear to have less affinity for the highly hydrated Mg^{2+} than for Ca^{2+} [1]. Thus, high concentrations of substrate Ca^{2+} usually result in increased leaf Ca along with a marked reduction in leaf Mg [178]. Increased concentration of $CaSO_4$ in the nutrient solution decreased Mg^{2+} in roots, stems, and leaves of *Leucaena leucocephala* [116]. Calcium-induced Mg^{2+} deficiency has been observed in sesame [179] as well as corn [180]. Both the photosynthetic rate and water-use efficiency declined in salt-stressed corn (OP = −0.4 MPa) as the external Ca^{2+}/Mg^{2+} ratio increased [180]. Carter et al. [129] found that barley growth was reduced as the Mg^{2+}/Ca^{2+} ratio increased above 1. Similarly, grain yield of wheat decreased significantly in soil cultures irrigated with saline waters (EC = 6 dS/m) containing an Mg^{2+}/Ca^{2+} ratio of 4. With increasing external Mg^{2+}/Ca^{2+}, Na^+ and P in the straw increased, whereas K^+ decreased [181].

Increases in salinity, however, are not always associated with reductions in leaf Mg^{2+} concentration. Bernstein et al. [4] found that increases in salinity (NaCl + $CaCl_2$) reduced leaf Mg^{2+} concentration in beet but had little or no effect in leaves from the five other vegetable crops that they tested.

In the case of plants grown in seawater or dilutions of seawater, it is possible that nutrient disorders could develop because of the high Mg^{2+}/Ca^{2+} ratio. In most seawater compositions, Mg^{2+}: Ca^{2+} is 5:1 on a molar basis. It has been known for over 30 years that solutions with an Mg^{2+}/

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

Ca^{2+} ratio greater than 1 reduces the growth of corn and soybean [182]. In a more recent study, Mg-salts reduced root growth of eucalyptus more than Na-salts [183]. Reduced root growth was associated with low Ca^{2+} concentrations in the root.

SULFUR

Most salinity studies that include sulfur as an external variable have not examined the influence of salinity on sulfur nutrition in the plant. Rather these studies were directed more toward how the plant responds to sulfate salinity as compared to chloride salinity. Differences in crop response to chloride and sulfate salinity have been measured in terms of identical electrical conductivities [184–186], molar or equivalent basis [187–193], or isosmotic potentials [194–199]. Whether or not differences in plant response are found between chloride and sulfate salinity may depend on the salinity indices chosen [10].

Very little attention is given to salinity's influence on sulfur uptake and accumulation in crops. In one study that compared the effects of both Cl^- and SO_4^{2-}-salinity on pea, Mor and Manchanda [186] found that chloride salinity reduced the sulfur content in the straw. Sulfur accumulation in the roots, however, was enhanced by Cl-salinity.

Many crops are very sensitive to high internal chloride levels, and species are generally more tolerant of sulfate salinity; possibly owing to enhanced P or N nutrition [199,200]. Consequently, Bernstein [201] suggested that for most vegetable crops, the salt tolerance would be 2 dS/m greater in a sulfate system as opposed to chloride system. At low salt levels, the response of salinized sorghum followed this general rule [195,202]; however, as salinity increased (-0.6 MPa), growth was inhibited more by sulfate than chloride salinity, probably through disruption of the Na^+-exclusion mechanism which resulted in an increase in shoot Na^+ and concurrent nutrient ion imbalances [195]. Likewise, sulfate salinity was more damaging to the halophyte *Chenopodium rubrum* than NaCl salinity, particularly at high concentrations [203].

MICRONUTRIENTS

The concentrations of micronutrients in soil solutions, with the exception of Cl^-, are low (μM range) and depend on the physical and chemical characteristics of the soil. The availability of most micronutrients depends on the pH and pE of the soil solution as well as the nature of binding sites on organic and inorganic particle surfaces. Consequently, the relationship between salinity and trace element nutrition is complex [204]. In saline and/or sodic soils, the solubility of micronutrients (e.g., Cu, Fe, Mn, and Zn) is particularly low, and plants grown in these soils often experience deficiencies in these elements [205,206]. Nevertheless, the micronutrient concentration in plant shoots may increase, decrease, or have no effect depending on the type of plant, tissue, salinity, micronutrient concentration, and environmental conditions.

Zinc (Zn) concentration has been found to increase in shoots of salt-stressed barley [204,207], bean [208], squash, tomato [209], pepper [210], and rice grain [211] but decrease in corn [212], bean [213], and mesquite [214]. Salinity increased the manganese (Mn) concentration in the shoots of barley [204,207], rice [211], sugar beet [215], and tomato [209] but decreased its concentration in the shoots of barley (cultivar CM72) [216], squash [209], pea [217], corn [212], peanut, and cucumber [218]. In the study with sugar beets [215], salt ($NaCl + CaCl_2$) additions increased Mn in the saturated soil extract. Others did not find an effect of salinity on shoot Mn, but increasing sodicity in soil-grown maize had a significant reduction in shoot concentration [219].

Although differences were found in the literature regarding salinity's effect on shoot Mn concentration in barley, the differences may be explained, in part, by the composition of the salinizing salts [204]. Saline solutions rich in divalent cations increase shoot-Mn concentration, whereas a saline environment dominated by monovalent cations reduces shoot Mn concentration. Likewise,

270 Madison Avenue, New York, New York 10016

the accompanying anion in the salinizing media was important in Zn nutrition of soybean. Shoot Zn was higher in chloride-dominated salinity than in the sulfate system [190].

Reports on the influence of salinity on the iron (Fe) concentration in plants are as inconsistent as those that concern Zn and Mn concentration. Salinity increased the Fe concentration in the shoots of pea [217], tomato, soybean, squash [209], bean [213], and rice [211] and decreased its concentration in the shoots of barley, corn [207,212], peanut, and cucumber [218]. In other investigations with barley, salinity had no effect on shoot Fe concentration, but at low Ca^{2+}, salinity increased root Fe in certain *Hordeum vulgare* L. species [204]. This was not observed with foxtail barley (*H. jubatum* L.).

Although the influence of salinity stress on the micronutrient concentration in plants is highly variable, there is evidence that NaCl salinity may induce an Fe deficiency. In the presence of 100–400 mM NaCl, root epidermal cells of *Atriplex hastata* L. and *A. hortensis* L. developed features that are characteristic of transfer cells; for example, bladder-shaped root hairs and thickened convolutions on the outer peripheral cell wall. Further evaluation of these results showed that alterations were not a specific response to salinity but were a symptom of Na^+-induced iron deficiency [220].

BORON

For most crops, the optimal concentration range of plant-available B is very narrow, and various criteria have been proposed to define those levels that are required for adequate B nutrition but at the same time are not so high as to induce B toxicity [221–223]. Although B deficiency is more widespread than B toxicity, particularly in humid climates, B toxicity is more of a concern in arid environments where salinity problems also exist [224].

Toxicity occurs in horticultural crops when boron concentrations increase in either stem and leaf tissues to lethal levels, but soil and plant-tissue analyses can only be used as general guidelines for assessing the risk of B toxicity [223]. Although experimental evidence indicates that plants absorb B passively as H_3BO_3, contradictions between experimental results and observations in the field suggest that other factors, yet unknown, may affect B uptake [225]. Once B has accumulated in a particular organ within the shoot, it has restricted mobility in most plant species but not all [226]. In some plant species, particularly those that produce substantial amounts of polyols, B is readily translocated as B-polyol complexes.

Despite the common occurrence of high boron and high salinity in many parts of the world, very little research has been done to study the interaction of the two. From sand culture experiments conducted in a greenhouse, researchers found that wheat responded to boron in the soil solution independently of salinity ($NaCl + CaCl_2$) [227]. The salinity-B interaction was insignificant with respect to leaf B concentrations. Other investigators found that mixed salt solutions (i.e., Na^+, Ca^{2+}, Cl^-, and SO_4^{2-}) reduced leaf B concentrations in chickpea [228] and wheat [229,230] grown in pot cultures. Grain yield of salt-stressed wheat declined markedly with increasing concentrations of external B, whereas the yield under nonsaline conditions was unaffected by added B [230]. From these results, Manchanda and Sharma [230] concluded that increasing soil salinity decreased the B tolerance of wheat even though B levels in the plant decreased significantly. In other studies using a mixture of chloride and sulfate salts, El-Motaium et al. [231] found that salinity reduced B uptake and accumulation in the stem of several *Prunus* rootstocks, thereby decreasing B-toxicity symptoms. They also found a negative relationship between B and SO_4^{2-} concentrations in tissue suggesting that SO_4^{2-} could be responsible for the salinity-induced reduction in tissue B. Others have also found that a mixture of chloride and sulfate salinity reduces leaf B accumulation in *Eucalyptus camaldulensis* Dehnh. [232]. In neither study were the investigators able to suggest the actual mechanism that supports this phenomenon such as direct ion interactions, reduced transpiration in salt-stressed conditions, or both.

In addition to the potential sulfate-boron interaction, the interaction between B and Ca^{2+} in the nutrition of both mono- and dicotyledonous plants has long been recognized [233,234]. High

concentrations of substrate Ca^{2+}, particularly under calcareous conditions, decreased B absorption and can induce a B deficiency [223]. Therefore, in reference to experiments with mixtures of salts where salinity reduced B uptake and transport to the shoot [228,231,232], it is difficult to distinguish influences of either sulfate or calcium on B uptake since in each case, these ions increased in the substrate with increasing salinity.

CONCLUSIONS

The relations between salinity and the mineral nutrition of plants are extremely complex, and a full understanding of these interactions would require a multidisciplinary team of scientists. It is no easy task to reconcile results from salinity-nutrition experiments conducted in the field versus the greenhouse; in soils versus solution cultures; using single salts versus mixed salts; under one set of environmental conditions versus another set; or studies conducted over the short term versus the long term. Nevertheless, by accounting for these differences in experimental parameters, one can begin to see more consistencies in salinity-nutrient interactions and obtain a better understanding of the salinity-nutrient relations in plants overall.

Plant performance, usually expressed as a crop yield or plant biomass, may be adversely affected by salinity-induced nutritional disorders. In the field, additions of nutrients have increased the growth of both glycophytes and halophytes provided that the plants were not experiencing severe salt stress. Relief of the growth-limiting stress, salinity or nutrient deficiency, promotes growth more than relief of the next limiting factor. Therefore, addition of a limiting nutrient may increase, decrease, or have no effect on plant salt tolerance depending on the severity of salinity stress. Consequently, interpretation of plant salt tolerance expressed on a relative basis under variable soil fertility can be misleading.

Salinity-induced nutritional disorders may develop on plants from the effect of salinity on nutrient availability, competitive uptake, transport, or partitioning within the plant. For example, salinity reduces phosphate uptake and accumulation in crops grown in soils primarily by reducing phosphate availability, whereas in solution cultures, reductions may be due to a competitive process. Salinity dominated by Na^+ salts not only reduces Ca^{2+} availability but also reduces its transport and mobility to growing regions of the plant, thereby affecting the quality of both vegetative and reproductive organs. These disorders are aggravated when transpirational demands are high. Salinity can directly affect nutrient uptake, as has been observed in the reduction in K^+ uptake by Na^+ or NO_3^- uptake by Cl^-. The occurrence of these disorders and their ultimate effect on crop yield or quality depends on the plant species and the experimental conditions where the study was conducted.

Salinity can cause a combination of complex interactions affecting plant metabolism or susceptibility to injury. In several studies, it has been shown that salinity increases the internal requirement for a particular nutrient. Examples were given for N in the halophyte *Spartina alterniflora*, P in tomato, and K^+ in spinach. In other studies, it was shown that salinity can cause plants that are deficient in an element to have a lower cellular tolerance for a specific ion. Moreover, there are undoubtedly a multitude of other interactions yet to be found.

Despite a large number of studies that demonstrate that salinity reduces nutrient uptake and accumulation or affects nutrient partitioning within the plant, little evidence exists that adding nutrients at levels above what is considered optimal in nonsaline environments improves plant growth or crop yield in saline environments. Nutrient additions, on the other hand, have been more successful in improving crop quality. For example, Ca^{2+} additions to soils or as foliar sprays can sometimes correct disorders caused by Na-induced Ca^{2+} deficiencies.

Nutrient additions may also reduce the incidence of injury. An adequate supply of Ca^{2+} maintains membrane integrity and selectivity, thereby reducing Na^+ and Cl^- toxicity in tree and vine crops. Benefits from added Ca^{2+} are usually observed in solution culture studies when NaCl is the sole salinizing agent. There are also studies that have shown that increased concentrations of NO_3^-

can reduce Cl^- toxicity in certain tree crops. Although these studies may have practical implications, there is a danger that this practice may increase NO_3^- concentrations in the groundwater.

It is reasonable to believe that numerous salinity-nutrient interactions are occurring at the same time, but whether they ultimately affect crop yield or quality depends on the salinity level and composition of salts, the crop species, the nutrient in question, and a number of environmental factors.

In the area of salinity-mineral nutrition relations, halophytes have received less attention than have glycophytes. Nevertheless, some halophytes, despite their remarkable ability to absorb nutrients selectively from solutions dominated by Na^+ and Cl^-, may also exhibit symptoms of mineral imbalances and disorders.

Padova, Italy

INTRODUCTION

Organisms which live in aerobic environments must constantly cope with the threat of oxidation, and almost any cell process that involves oxygen can create activated oxygen [1]. Reactions involving free radicals are a common feature of plant stress and appear to contribute to a process of oxidative deterioration which leads to cell death when the water potential (Ψ_w) is very low.

Water stress conditions may trigger an increased production of reactive oxygen forms, which can explain the remarkable damage to the enzymes with active sulfydrylic groups, the chloroplast pigments, the membrane lipids and proteins, and the alteration of their structural integrity [2,3]. This formation is a consequence of the Mehler reaction, which provides a pathway for the removal of excess electrochemical energy caused by drought stress [4].

During water depletion, $O_2^{\bullet -}$ can also react nonenzymatically with H_2O_2 giving rise to products, such as hydroxyl radicals and singlet oxygen, which are even more reactive than $O_2^{\bullet -}$ itself [3,5]. Photosynthetic cells can tolerate elevated oxygen levels because of the endogenous mechanisms that effectively scavenge and remove the toxic products before cellular damage occurs [6]. In photosynthetically active cells, it is clear, however, that in the light, reductants generated as a consequence of electron transport can participate in the process of free radical scavenging, whereas in the dark or in heterotrophic tissue, various respiratory pathways must serve as a comparable source of the reductants themselves [7].

ACTIVE OXYGEN SPECIES AND WATER STRESS

Mechanisms of Active Oxygen Production in Plant Cells

The production of active oxygen species (AOS) is an unavoidable consequence of life with oxygen. Atmospheric oxygen ($^3O_2$), being a diradical with a parallel spin state, is particularly unreactive, so

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

that its divalent reduction is kinetically limited by the relatively slow spin inversion process. The spin conservation rule states that spin must be conserved during the time necessary for a chemical reaction to occur, so that O_2 in the ground state cannot accept a pair of electrons of opposite spin. For this reason, ground-state O_2 tends to accept additional electrons one at a time. When $^3O_2$ is involved in metabolic oxidation, in order to have productive collision, it must be transformed into more reduced or electronically excited status via a univalent pathway (Equations. [1–4]).

$$O_2 + 1\ e^- \rightarrow O_2^{\bullet -} \quad (1)$$

$$\downarrow +\ e^- + 2\ H^+$$

$$H_2O_2 \quad (2)$$

$$\downarrow +\ e^- + H^+$$

$$^{\bullet}OH \quad (3)$$

$$\downarrow +\ e^- + H^+$$

$$H_2O \quad (4)$$

The first reduced product (Equation [1]) of this univalent pathway is superoxide ($O_2^{\bullet -}$). Superoxide in a nonpolar environment is a powerful nucleophile and base (proton acceptor), which can act as both an oxidant ($E_0 = O_2^{\bullet -}/H_2O_2 = 0.87$ V) with compounds that can donate H^+ such as ascorbate, tocopherol, and catechol as well as a mild reductant ($E_0\ O_2/O_2^{\bullet -} = -0.33$ V).

The successive univalent reductions produce (Equation [2]) hydrogen peroxide (H_2O_2) and (Equation [3]) hydroxyl radical ($^{\bullet}OH$). The redox potential of $^{\bullet}OH$ at approximately 2 V clearly marks this radical as a highly oxidizing agent. This species in biological systems has a very short lifetime (in the range of a few microseconds), because it randomly reacts with almost all organic molecules. Likely candidates are small molecules, enzymes, nucleic acid, proteins, and lipids of membranes.

Hydrogen peroxide is the first stable product of the intermediate reduction of oxygen without radical properties. The formation of H_2O_2 at physiological pH is rather slow, with its rate constant being $1 \times 10^5\ M^{-1}\ s^{-1}$, but superoxide dismutase (SOD, EC 1.15.1.1), an enzyme present in all cell compartments, increases the reaction rate constant to $2 \times 10^9\ M^{-1}\ s^{-1}$ [8]. Hydrogen peroxide, like $O_2^{\bullet -}$, can be a mild reductant as well as an oxidant but, with a standard reduction potential of 1.77 V, it is also a nucleophilic oxidizing agent. Hydrogen peroxide in the chloroplasts is a highly toxic molecule, because, even at low concentrations, it inhibits several Calvin cycle enzymes, so that it is a powerful inhibitor of the photosynthetic CO_2 assimilation. The most sensitive enzymes are fructose-1,6-bisphosphatase and sedoeptulose bisphosphatase, although $NADP^+$-dependent glyceraldehyde-3-phosphate dehydrogenase and phosphoribulokinase can also be attacked [9]. Superoxide radicals and H_2O_2 can either directly attack lipid membranes and inactivate SH-containing enzymes or, in the course of the chain reaction, interact to generate the more toxic $^{\bullet}OH$ (Equation [5]), which can also damage membrane lipids and proteins [10,11].

$$O_2^{\bullet -} + H_2O_2 \rightarrow OH^- + {}^{\bullet}OH + O_2 \quad (5)$$

The Haber-Weiss reaction (Equation [5]) is very slow, but the presence of transition metals such as iron and copper [12,13] catalyzes the reaction (Equations [6 and 7]) [14].

$$O_2^{\bullet -} + M^{n+1} \rightarrow O_2 + M^n \quad (6)$$

$$M^n + H_2O_2 \rightarrow {}^{\bullet}OH + OH^- + M^{n+1} \quad (7)$$

The Fenton reaction (Equation [6]) may also occur when the antioxidant ascorbate is present in the cells at high concentrations [14].

Singlet oxygen ($^1O_2$) is an excited species of oxygen not produced by redox reactions but by absorption of electromagnetic energy. It possesses two electrons with antiparallel spins formed from

the ground state of atmospheric oxygen ($^3O_2$) by transfer of energy from photoexcited compounds (photosensitizers) naturally present in plants, such as chlorophyll, protoporphyrin IX, and many other secondary compounds, including quinones [15]. The change in the spin state from parallel ($^3O_2$) to antiparallel ($^1O_2$) increases its reactivity and eliminates the spin restriction. Singlet oxygen is highly destructive, reacting with most biological molecules almost at diffusion rates [15,16].

Oxygen activation may potentially occur in all compartments of plant cells [17]. The sources of superoxide in plant cells are electron transport activities in which electrons are diverted from their normal course and leak to oxygen. Normally, this leakage is very limited and proportional to the local oxygen concentration, but under certain conditions, such as in water-deficit stress, the possibility of electron leakage to O_2 is enhanced. In mitochondria, the flavoprotein region of the NADPH dehydrogenase segment of the respiratory chain has been identified as a site of production of $O_2^{\bullet -}$ insensitive to cyanide and antimycin A. A second site has been identified close to complexes I and III at the ubiquinone level [18]. When the electron transport is blocked beyond ubiquinone by cyanide or antimycin A, the rate of $O_2^{\bullet -}$ formation increases [19]. In peroxisomal and glyoxisomal membranes, a NADPH-dependent superoxide formation by cytochrome b_5 reductase has been shown to occur [20,21]. A microsomal redox system can form superoxide at the expense of NADPH via cytochrome P-450 or cytochrome P-450 reductase [19]. Moreover, microsomal $O_2^{\bullet -}$ generation in soybean seedlings has been monitored in the presence of either NADPH or NADH as cofactors [22]. It has been suggested that the superoxide found in microsomes of senescent carnation flowers is generated enzymatically, presumably by a membrane-associated oxidase [23].

The concurrence in chloroplasts of a high energy level, high oxygen tension, and abundant catalyst such as chlorophyll, iron-sulfur proteins, and quinones increases the probability of energy transfer to ground-state oxygen [5,17,24,25]. In the chloroplasts, from a thermodynamic viewpoint, O_2 can accept electrons from both photosystems forming superoxide [26]. In addition, chloroplasts, besides being the major site of superoxide production (see section Generation of AOS in Chloroplasts in Water-Deficit Conditions below), are likely sites of singlet oxygen production and action.

Little is known about the enzymes responsible for the reduction of O_2 to form $O_2^{\bullet -}$. An apoplastic NADH, NAD radical, and NAD^+ pathway has been suggested for the production of superoxide by means of cell wall peroxidases [17,27]. A plasma membrane peroxidase is responsible for the formation of $O_2^{\bullet -}$ at the plasmalemma surface [28,29]. More recently, it has been demonstrated that the enzyme responsible for the synthesis of $O_2^{\bullet -}$ by elicitor-treated plant cells is similar to mammalian neutrophil NADPH oxidase [30], and that one function of the flavins and *b*-type cytochromes may be to produce $O_2^{\bullet -}$ in plant plasma membranes [31].

Effects of Oxidative Stress in Cells

It is clear that the toxicity of O_2 comes from its reduction products or from its excitation to the single state and perturbation in cell metabolism would markedly affect AOS levels. The destructive potential of AOS on pigments, lipids, proteins and DNA is well documented [15,17,24,32,33]. AOS can destroy membranes since their target includes phospolipids and glycolipids, whose deesterification produces free fatty acids which, remaining in membranes, lead to more rigid and disassembled structures [34]. Furthermore, oxidation of polyunsaturated fatty acids leads to many different products, such as short-chain alcohols, aldehydes, and alkanes. Under most oxidative conditions, malondialdehyde (MDA) is a product too often considered as a marker of peroxidative damage. It is important to interpret such measurements with caution, since there are a lot of drawbacks linked to the thiobarbituric acid (TBA) test for MDA determination [35–39]. In particular, in regard to its use to monitor peroxidative damage due to water-deficit conditions, we must consider that TBA may react with several oxidized products of amino acids, among which proline, and carbohydrates, which are known to accumulate for osmotic adjustment [40].

The formation of toxic oxy radicals is a facet of normal cell metabolism. Indeed the rate of O_2 photoreduction has been estimated to range from 15 to 25 μmol (mg Chl)$^{-1}$ h^{-1} even under normal

conditions [41]. Superoxide, produced by the transport of electrons to oxygen, is not compatible with metabolism; hence all organisms that have evolved in aerobic environments must possess an efficient mechanism capable of preventing or removing oxidation of cellular components. Thus the equilibrium between the oxidative and antioxidative capacities determines the fate of the plant.

Essentially, antioxidant defenses fall into three general classes comprising: (a) the water-soluble reductants, for example, compounds that contain thiol groups (e.g., cysteine, glutathione), ascorbate, urate, cathecols (epinephrine); (b) liposoluble vitamins, for example, α-tocopherol and carotene; and (c) enzymatic antioxidants, for example, SOD, catalase, and peroxidases.

A low steady-state concentration of superoxide may be maintained by the several isozymes of SOD localized in the subcellular compartments where superoxide is produced [42], since superoxide, being a charged molecule, cannot cross biological membranes. Detoxification of H_2O_2, arising from dismutation of superoxides by SOD (Equation [9]) is mediated by catalase (EC 1.11.1.6). However, catalase has a very low affinity for H_2O_2 and it is mostly localized in peroxisomes and glyoxisomes [43], being that its activity is either extremely low or not detectable in the cytosol, mitochondria, and chloroplasts [44]. In plant cells, the ascorbate-glutathione cycle (Asada-Halliwell cycle) represents an alternative and more effective detoxification mechanism against H_2O_2. It may remove H_2O_2 in a series of reactions involving glutathione and ascorbate [45,46] and related enzymes such as ascorbate peroxidase (APX, EC 1.11.1.11), monodehydroascorbate reductase (MDHAR, EC 1.6.5.4), dehydroascorbate reductase (DHAR, EC 1.8.5.1), and glutathione reductase (GR, EC 1.6.4.2). Rapid operation of the cycle and regeneration of the intermediates through photosynthetically generated reductant are necessary, since at least one of its constituent enzymes, APX, is inhibited by H_2O_2 itself [47]. The high affinity of APX for H_2O_2 indicates that this enzyme, rather than catalase, is responsible for most H_2O_2 removal outside the peroxisomes. This pathway may exist in the cytosol, in the chloroplast, and in other compartments as well as in nonphotosynthetic tissues such as roots, although the level of enzyme activity at these locations appears to be lower than in chloroplasts [48–52].

It is clear that an efficient removal of the first two intermediates of oxygen reduction (Equations [1 and 2]) will prevent the formation of the third (Equation [3]). This is fortunate, since the hydroxyl radical is a highly powerful reagent and its specific enzymatic scavenging would be impossible [53].

Furthermore, glutathione peroxidase (GP, EC 1.11.1.9) and glutathione transferase (GT_s) reduce organic peroxides, thus protecting cell proteins and cell membranes against oxidation [50,54,55]. In addition, reduced glutathione (GSH) can break the chain propagation of lipid peroxidation by regenerating the liposoluble α-tocopherol [50].

Active Oxygen Species in Water-Deficit Conditions

During water deficit, when stomata close in order to limit water loss, there is either a restricted CO_2 supply or a CO_2-limited carbon fixation and a decreased availability of oxidized nicotinamide adenine dinucleotide ($NADP^+$) as an electron acceptor for photosystem I. Photosynthetic electron transport is, however, maintained at a relatively higher rate in the stressed leaves as compared with the large decrease in the rate of CO_2 fixation [56,57]. This unbalance between electron transport and CO_2 fixation rates may result in the overreduction of the electron transport chain components and facilitate the transfer of electrons to O_2. This is probably a mechanism that plants adopt to protect the photosynthetic electron transport chain components from photodamage during water stress. Under these conditions, O_2 in the thylakoids can compete with $NADP^+$ as a Hill reductant and can produce superoxide [2]. In addition, when plants are exposed to excess energy or when there is a limitation in CO_2 availability, the possibility of an increase in singlet oxygen production may exist. A consequence of the drought-induced limitation of photosynthesis is indeed the exposure of plants to an excess of energy. If this is not dissipated in a harmless way, it may damage the photosynthetic apparatus because of the overreduction of the photosynthetic reaction centers [58] and the increased production of AOS species in leaf tissue [40].

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

The O_2-dependent flow, as well as photorespiration, may be regarded as being regulatory mechanisms for the protection of the photosynthetic apparatus against damage by $^1O_2$, especially when its production is not sufficiently prevented by carotenoids. Carotenoids, and particularly β-carotene, may react with excited triplet chlorophyll and $^1O_2$ [58]. On the other hand, it is now a widely held view that the excess excitation energy is normally dissipated via nonradiative energy dissipation in the pigment bed [58]. Development of excessive energy is also accompanied by deepoxidation of violaxanthin to zeaxanthin (Fig. 1), and there is increasing evidence that zeaxanthin is involved in mediating nonradiative energy dissipation, although the mechanism is not well known [59,60].

Furthermore, the increase in the production of $O_2^{\bullet -}$ gives rise to an increased formation of H_2O_2 and $^{\bullet}OH$, highly reactive oxygen forms, which together with $^1O_2$ can damage cell structure and function. An extensive literature [19,33,61,62] suggests that the origin of the peroxidative damage occurring under water-stress conditions is likely due to the formation of transient but highly reactive, partially reduced or activated forms of oxygen. Evidence for increased generation of activated oxygen producing superoxide as the first product of radical-mediated reactions is scanty. Such evidence comes mainly from the fact that the activities of enzymes, such as SOD, peroxidases, and Asada-Halliwell pathway recycling enzymes, as well as the concentrations of antioxidant molecules, are generally increased in plants exposed to stressful conditions [63–66]. This increase correlates with increased stress tolerance [67].

A stable, C-centered, free radical, determined by electron paramagnetic resonance (EPR), which is formed in vivo has been also used as marker of previous oxidative stress [68–70]. The increase in the amplitude of the EPR signal of water-stressed sunflower seedlings [69] indicates that water-deficit conditions have determined the further production of the stable radicals as found during the loss of desiccation tolerance in seed tissues [68,71–73] and during the desiccation of two species of mosses [74].

Measurements of $O_2^{\bullet -}$ in biological systems are technically difficult. Generally, the methods used lack specificity and/or sensitivity, making it difficult to determine the rate of $O_2^{\bullet -}$ production accurately, as the radicals are very unstable and terminate quickly by disproportionation or other mechanisms [75]. However, 1,2-dihydroxybenzene-3,5-disulfonic acid (Tiron), a disulfonate catechol that is readily oxidized to the corresponding semiquinone (a more stable radical) by $O_2^{\bullet -}$, can be used to detect the superoxide as soon as its production has been induced by illumination of

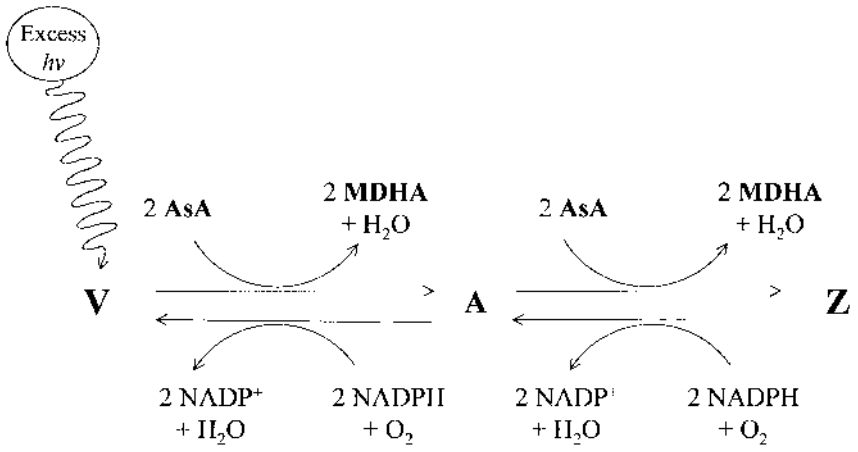

FIGURE 1 Nonradiative energy dissipation via the xanthophyll cycle. The energy dissipation process involves deepoxidation of violaxanthin (V) to antheraxanthin (A) and to zeaxanthin (Z). Epoxidation of zeaxanthin (Z) regenerates violaxanthin (V).

isolated thylakoids or other biological systems [3,49,75–77]. The generation of the signal of the Tiron radical depends on oxygen and is obscured by scavenger of $O_2^{\bullet-}$, such as ascorbate, L-adrenaline or reduced glutathione, showing that the Tiron radical is derived from $O_2^{\bullet-}$ [49]. Exogenous SOD is less effective in obscuring the signal, because the larger size of the enzyme, in comparison with Tiron, makes it less able to permeate the site of $O_2^{\bullet-}$ production. This reflects a steric problem in which the SOD is unable to access the $O_2^{\bullet-}$ which is available for the much smaller Tiron molecule [75,76,78].

Several factors seem to be involved in $O_2^{\bullet-}$ production under drought conditions: electron transport rate, composition of membranes, higher exposure of chlorophyll molecules to oxygen, plant species, intensity of stress, repeated stress periods, and plant age [3,5,49,63,77,79].

Attempts have also been made to compare directly the formation of reactive oxygen species from stressed and unstressed plants. These investigations provide some evidence for an increased rate of formation of $O_2^{\bullet-}$ in stressed plants. Isolated thylakoids from drought-stressed wheat show increased superoxide formation [78]. Superoxide formation in thylakoids from wheat and sunflower seedlings subjected to increasing stress by water deficit is higher than in the control [49,79]. An increase in superoxide in wheat mitochondria after desiccation has been also found [18].

Generation of AOS in Chloroplasts in Water-Deficit Conditions

Chloroplasts are likely to be particularly subjected to oxidative injury, because they are the most aerobic compartment in plant cells. This is due to the fact that they both consume and produce oxygen and their functionality depends on the redox capacity of their photosynthetic apparatus. Furthermore, they contain a large amount of polar lipids and polyunsaturated fatty acid residues. The photosensitizing pigments absorb light and as the electron transport chain operates in a high O_2 environment, its tendency to leak electrons to oxygen is correspondently greater. Molecular oxygen possesses the physicochemical properties that permit this molecule to serve as an alternative Hill oxidant within the chloroplasts in vivo [41]. The solubility of O_2 in the aprotic interior of membranes is higher than in water [80] and $O_2^{\bullet-}$ production is not limited by O_2 availability [81]. In the interior of the chloroplasts, the O_2 concentration has been estimated to range from 275 to 300 μM, and even at moderate light intensities (350 $\mu E\ m^{-2}s^{-1}$), the rate of superoxide formation may be as high as 15 $\mu mol\ (mg\ Chl)^{-1}\ h^{-1}$ [41].

The production of $O_2^{\bullet-}$ in chloroplasts has been extensively reviewed [80]. Briefly, thermodynamically feasible sites for superoxide production in the chloroplasts can be either photosystem I (PSI) and/or photosystem II (PSII). Two mechanisms are associated with $O_2^{\bullet-}$ generation on the reducing site of PSI. Most superoxide production proceeds via the univalent reduction of oxygen by reduced ferredoxin. Ferredoxin undergoes an oxidation in a one-electron step when the availability of $NADP^+$ is low (i.e., under water-deficit conditions). An alternative source is from the nonhaem Fe-S center [80]. At the PSII acceptor side, superoxide may be formed as the result of passing electrons from pheophytin to plastoquinone (Q_A) to O_2 [40,41,82–84]. In this way, when the CO_2 supply is limited, O_2 can act as an alternative acceptor, thereby maintaining Q_A in a partially oxidized state and maintaining electron transport. The possibility that superoxide may also arise by autooxidation of Q_B cannot be excluded. A direct oxidation of plastoquinone to produce $O_2^{\bullet-}$ has not yet been demonstrated under physiological conditions, although several nonendogenous quinones have been shown to produce H_2O_2 on illumination of chloroplasts. Cytochrome *f* and plastocyanin can instead accept electrons from $O_2^{\bullet-}$, and in physiological conditions, a superoxide-mediated cyclic transport around PSI cannot be excluded [80].

When plants are exposed to light levels exceeding those they have experienced during growth, photoinhibition may occur, because there is an exposure to more light that can be used for CO_2 fixation. Water deficit could also lead to exposure of the leaves to excess energy when plants are grown in natural sunlight. In these conditions, the light becomes excessive, because the utilization of energy through photosynthetic carbon assimilation decreases. This occurs whether the limita-

tion of photosynthesis is caused by stomatal limitation to the carbon dioxide supply or by direct inhibition of carbon fixation without significantly decreasing the rate of electron transport.

Moreover, type I photodynamic reactions (Equation [8]), undergoing charge separation within the excited pigment, have been postulated in the production of superoxide radicals [5], and the direct involvement of chlorophyll in the production of the Tiron radical signal, via superoxide, has been demonstrated [75].

$$P + h\nu \rightarrow P^* \rightarrow {}_+P^- \text{ (charge separation)}; \; {}_+P^- + {}^3O_2 \rightarrow {}_+P + O_2^{\bullet -} \tag{8}$$

When normal pathways and acceptors of photosynthetic electron transport are restricted under water-stress conditions, photodynamic reaction type I (Equation [8]) may be intensified.

The reaction initiated by light is mediated by the photosynthetic electron chain [7,77,85,86]. The impairment by drought of photosynthesis, without significantly decreasing the flow of electrons through the photosystems, and the transient disruption of the photosystems during water stress, making them ''leaky,'' both result in the transfer of electrons to molecular oxygen, thus increasing the production of superoxide (Fig. 2).

Chloroplasts lack glycolate oxidase which in leaf peroxisomes, through a two-electron pathway, produces hydrogen peroxide. Therefore, in the absence of such oxidase, hydrogen peroxide in chloroplasts derives from the dismutation of superoxide catalyzed by SOD (Equation [9]).

$$O_2^{\bullet -} + O_2^{\bullet -} + H^+ \xrightarrow{\text{SOD}} H_2O_2 + O_2 \tag{9}$$

In addition, other reductants (ascorbate, Mn^{2+}, GSH, reduced ferredoxin) may reduce superoxide, but the low stromal concentrations of these reductants and their low reaction rate constants with superoxide make their contribution to the formation of hydrogen peroxide very unlikely [80].

Trace amounts of transition metals, such as Fe^{2+} and Cu^+ [87–89], or reduced ferredoxin

[90] may catalyze the formation of hydroxyl radicals from hydrogen peroxide (Equations [5–7]). Superoxide, ascorbate, and/or GSH reduce back the oxidized metals.

ANTIOXIDANT PROTECTION IN CHLOROPLASTS

Ascorbate-Glutathione System in Chloroplasts and Its Role in Water-Deficit Conditions

The steady state of AOS in the chloroplasts depends on the critical balance between those factors that would tend to generate them and the mechanisms that protect cells from their production [26,91,92]. Under normal conditions, this balance is tightly controlled, but environmental constraints can lead to an increase in the steady-state concentration of AOS. Thus AOS production overcomes the protection afforded by antioxidant defense mechanisms; thereby leading to oxidative damage to tissues. An increase in low molecular mass antioxidants, as well as in the activities of antioxidant enzymes [62,93–95], plays an irreplaceable role in stressful conditions and those augmentations are correlated with enhanced tolerance [96].

An important strategy in the ability of antioxidants to protect cells is an early intervention in order to break the sequence of chain reactions determined by the production of AOS. Thus the mobility, as well as a radical-trapping ability, of antioxidants are important in determining their effectiveness in biological systems. The liposoluble antioxidants and membrane-bound antioxidative enzymes of higher plants serve as the first line of defense against AOS produced within membranes, whereas the water-soluble antioxidants serve to eliminate AOS in the aqueous phase. Active oxygen species, except for hydrogen peroxide, cannot diffuse very far from their locus of formation, since in biological systems, they have a very small average radius of diffusion and a half-life of only a few microseconds [97]. For this reason, in order to prevent damage, protective measures have to be available in the immediate surroundings of those cellular compartments where the production of AOS takes place. It is reasonable to assume that chloroplasts are a primary site for AOS injury (see Section Generation of AOS in Chloroplasts in Water-Deficit Conditions below) and their efficient removal is critical, since H_2O_2 can inhibit photosynthesis even at concentrations as low as 10 μM [98]. For this reason, specific mechanisms of detoxification have evolved that act at both stromal and thylakoid level. The lipophilic antioxidants tocopherol and carotenoids fulfill essential antioxidant action in thylakoid membranes. Furthermore, in the chloroplasts, two separate oxygen radical–scavenging systems are present, a soluble system comprising GSH and reduced ascorbate (AsA) and a membrane-bound system that comprises SOD and APX [80]. The proposed pathway is as in Figure 3.

As soon as $O_2^{\bullet -}$ has been generated from the activity of PSI and PSII (see section Generation of AOS Chloroplasts in Water-Deficit Conditions below), it is rapidly dismutated by SOD (Equation [9]) attached to thylakoids [99,100]. The H_2O_2 produced from this dismutation is reduced to H_2O by the thylakoid-bound APX; the monodehydroascorbate radical (MDHA) so generated is reduced back to AsA by photoreduced ferredoxin or by reducing equivalents of NAD(P)H through the FAD enzyme MDHAR. As compared with the half-time of linear electron transport of the thylakoids (10 ms), the half-times of $O_2^{\bullet -}$, H_2O_2 and MDHA (0.1–10.0 μs) are shorter by several orders of magnitude [101]. Superoxide and H_2O_2, which escape this first line of defense, spread into the stroma where they are scavenged by a stromal SOD and via a reaction cycle initiated by stromal APX. Any MDHA radical formed by APX, which is not reduced to ascorbate by MDHAR, alternatively can disproportionate into ascorbic acid and dehydroascorbic acid, which is unstable at physiological pH [102]. Dehydroascorbate is converted into ascorbic acid by DHAR, which uses GSH as an electron donor. The regeneration of GSH requires GR and NADPH. Ascorbate and glutathione have little influence on the spread of oxygen radicals along or within the membranes, so it seems reasonable to consider that they may intercept only the oxygen radicals spreading outward. The more likely function of GSH is its involvement in the ascorbate-glutathione cycle, but a function in the

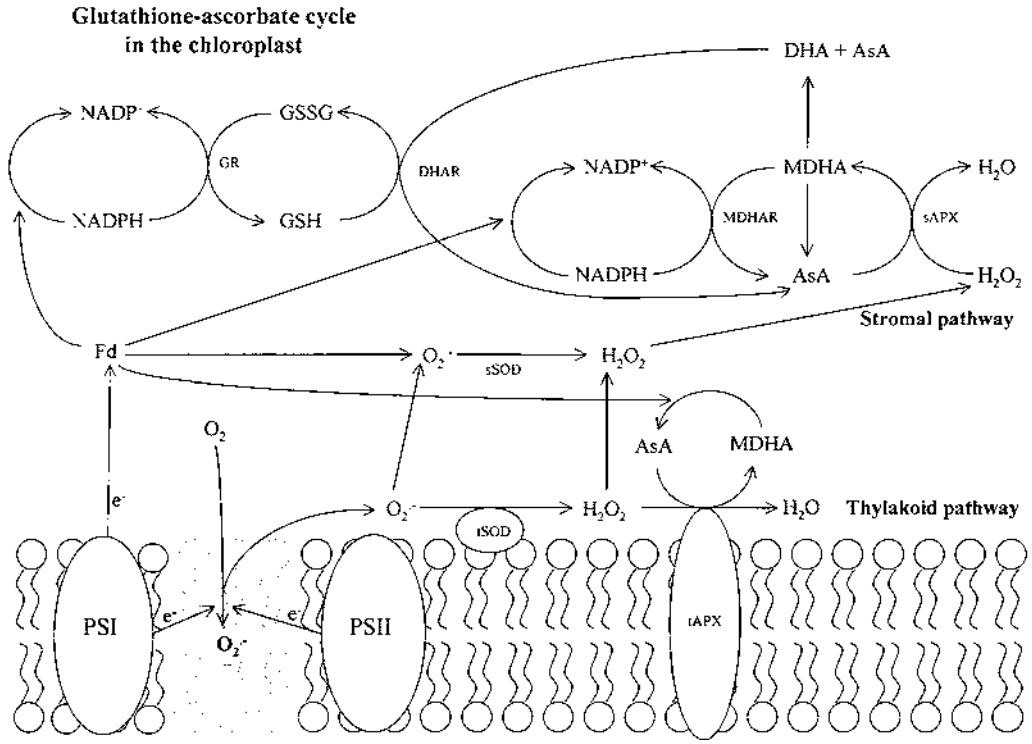

FIGURE 3 Thylakoid and stromal scavenging systems in chloroplasts. Superoxide radicals ($O_2^{\bullet -}$) generated by PSI and PSII are dismutated by thylakoid-bound superoxide dismutase (t-SOD). Hydrogen peroxide formed is reduced to water by the thylakoid-bound ascorbate peroxidase (t-APX). Monodehydroascorbate radical (MDHA) is reduced back to ascorbate (AsA) by the photoreduced ferredoxin (Fd). The escaped MDHA would be reduced back to AsA with FAD enzyme monodehydroascorbate reductase (MDHAR). The $O_2^{\bullet -}$ and H_2O_2 escaped to thylakoid system are scavenged by a stromal superoxide dismutase (sSOD) and by a glutathione-ascorbate cycle initiated by stromal APX (sAPX). Dehydroascorbate (DHAR) formed by MDHA is converted into AsA by dehydroascorbate reductase (DHAR). (Adapted from Ref. 80).

direct removal of oxygen radicals cannot be excluded [103], so that the reaction between GSH and $O_2^{\bullet -}$ may potentially be of importance in oxidative stress and/or in conditions of lowered SOD activity [104]. However, both ascorbate and glutathione may serve as mediators between hydrophylic and lipophilic phases to maintain the antioxidant properties of membrane-localized protective systems (see Section Lipid Oxidation Chain Reaction Breaking in Chloroplasts below). The above depicted cycle in chloroplasts is a mean of photoprotection both when the carbon dioxide supply is reduced and/or when there is an excess of excitation energy.

Effect of Water-Deficit on the Antioxidant Systems

Physiological and genetic evidence suggest that the increase in the AOS-scavenging systems in plants exposed to oxidative stress is an important component of stress-protective mechanisms [62,94,96]. During stress by water deficit, the water status of the plants plays a key role in the activation of defense mechanisms. Contrasting results under the same experimental conditions can

be related to the fact that, besides the difference in species, growth conditions, and stage of the plants, different levels of water deficit experienced by the plants should modulate the enzyme activities. The SOD activity responds to water deficit differently in different experiments and species: increasing, decreasing, or remaining unchanged [40,69,70,105–112]. Wheat and barley experiencing a gradual imposition of water deficit, obtained by withholding water from the soil, increased the activity of SOD [40,70], whereas sunflower showed a decrease [40,69]. Catalase activity seemed to be little affected in the early phase of water-deficit imposition, but with an increased degree of water depletion, a decrease in activity generally occurred [4,70,106–108,111,112]. Inhibition of protein synthesis induced by water depletion [113,114] could explain, at least in part, the decrease in catalase activity when a severe water deficit is imposed. Catalase turns over very rapidly in the light if protein synthesis is inhibited [40]. Catalase is not a robust enzyme. It is susceptible to photoinactivation and degradation, and it is also limited in its effectiveness by the relatively poor affinity for H_2O_2 as well as for the subcellular localization in the peroxisomes [1,94,95]. The GR activity catalyzes the rate-limiting step of the ascorbate-glutathione cycle. Comparison of two maize strains with different sensitivity to water stress showed in the more tolerant cultivar a higher GR activity, which further increased when the two cultivars were submitted to oxidative stress by paraquat or H_2O_2 [115]. Drought tolerance in maize strains was correlated with a high level of both SOD and GR [116], but the criteria used in the classification of tolerant and sensitive strains were not clearly stated. In the leaves of nonirrigated field-grown winter wheat and cotton, the observed increase in GR arises primarily from a smaller inhibition in activity as the leaves mature in comparison with control leaves rather than from an increase from the control level [4,117]. When a leaf water deficit was induced by withholding water, an increase was also monitored in the GR of wheat, sunflower, and sorghum [107,112] and in the GR and MDHAR of *Eragrostis tef* [118]. In sunflower seedlings submitted to a water deficit of increasing intensity, the specific activities of GR, APX, and DHAR have been seen to be dependent on water stress intensity [113], as it has also been observed for SOD and peroxidase activities [69,70,106]. Thus, after 5 days of water depletion, decreases of 0.2 MPa in water potential and osmotic potential were sufficient to induce oxidative stress, to increase H_2O_2, DHA, and GSSG, and to reduce the specific activities of APX, DHAR, and GR to 30–50% of the control seedlings [113]. At a moderate level of stress, when an osmotic adjustment occurred in the seedlings, H_2O_2 did not increase further, and the specific activity of the enzymes of the ascorbate-glutathione cycle were activated [113]. Transcriptional and translational events have been seen to be implicated in metabolic responses to oxidative stress [91], although the possibility of the mobilization of ordinarily inactive enzyme pools and adaptative changes in their catalytic properties must be remembered. At severe water stress, the decrease in enzyme activities was accompanied by the highest H_2O_2 level. The conservation or induction of enzyme activities might be linked to the rate of decline in water potential, which is in agreement with the fact that plants are more tolerant when water deficit stress is slowly imposed [119]. Consistent with the previous findings, in wheat subjected to two water-deficit periods, obtained by withholding water and rewatering at the end of the first period of stress, the decreased defense activities of GR, DHAR, and APX following the second period of stress might be a consequence of a reduced rate of activated oxygen production (Table 1) [49]. In maize, when drought imposition was gradual and acclimation may have occurred, GR activity and H_2O_2 levels were unaffected by dehydration [120]. It has been suggested that when plants are allowed to acclimate to drought, the $O_2^{\bullet -}$ may not accumulate [77]. The previous findings are in agreement with other reports on the decreased activity of GR, DHAR, and APX in plants in which H_2O_2 did not accumulate [109]. It remains to be clarified whether under drought the changes in activity shown in the previous reports are related to particular isoforms. Studies on the individual responses of the different isozymes to drought might in fact provide more useful information. In tomato, for example, it was found that the cytoplasmatic, but not the chloroplastic, CuZn-SOD was induced under drought [62]. GR isoforms have been associated with different cell compartments [121], MDHAR in tomato leaves has at least two isoforms [40], and soluble APX has six isoforms of which at least three are chloroplastic [99].

In pea nodules subjected to a water stress of −2.03 MPa, a general decrease in all the above

Source: From Ref. 49.

reported enzymes but MDHAR and in the content of ascorbate and reduced and oxidized glutathione has been reported as being due to a restricted supply of NAD(P)H in vivo for the ascorbate-glutathione pathway [122]. The MDHAR appears to be more important than DHAR in AsA regeneration [26]. The high concentrations of soluble antioxidants ascorbate and glutathione found in the cells suggest that their roles are not restricted to being substrates for APX and DHAR (see section Ascorbate-Glutathione System in Chloroplasts and Its Role in Water-Deficit Conditions above). Both metabolites may contribute to maintain the highly reducing conditions required by the cells and to protect them by direct scavenging of activated oxygen, especially organic radicals [37]. The GSH during drying may protect, via thiol-disulfide exchange, the thiol status of proteins, therefore maintaining their metabolically active form and the activity of the enzymes which possess exposed thiol groups. In addition to the previous reported functions, GSH is involved as a substrate for the glutathione peroxidase (GP, EC 1.11.1.9), which reduces H_2O_2 and organic peroxides, thus protecting cell proteins and cell membranes against oxidation, as found in wheat and in *Boea hygroscopica* [123,124]. The importance of glutathione in the establishment of water-deficit stress tolerance has been pointed out [51,52]. The water content required to cause GSH oxidation has been reported to be very near the limit of survival for desiccation-sensitive species [40]. In wheat plants subjected to a moderate level of water stress by withholding water, the maintenance of a low GSSG/GSH ratio, despite a decrease in total glutathione content as a consequence of its decreased synthesis and/or its increased degradation, has been established [49,123]. Therefore, the greatest portion of the glutathione in the cell is maintained in the reduced form, which plays an important role in the stabilization of many enzymes and a more general role as an oxidant scavenger. In pea plants, drought caused a 25% decrease in GSH [109], which also has been observed in sunflower seedlings where, as seen in resurrection plants (see section Production of AOS and Protection Mechanisms in Resurrection Plants below), GSH oxidation at the beginning of water depletion may have been the trigger for increased glutathione synthesis at a moderate level of water-deficit stress. In droughted seedlings, GSSG/GSH ratios, always higher than in the control, increased further when under severe water-deficit stress owing to the degradation in GSH [112,113]. This indicates that the induction of defense mechanisms was established late in response to higher oxidative stress. An increase in the GSSG/GSH ratio with increasing drought conditions has also been reported in pea nodules, with most glutathione pools remaining in the GSSG form [122]. At a late stage of drought, however, the GSH level increased in sorghum and the GSSG level decreased at the middle and late stages

[112]. Other investigators do not distinguish between reduced and oxidized glutathione and ascorbate. In addition, the imposition of water deficit by removing roots from the nutrient medium for some hours each day, may have rapidly induced very large changes in water status. Contrasting patterns in the GSH pool emerge from these studies. Although total GSH increased in some grasses [110], no change occurred in *Armeria maritima* and a decrease was observed in *Cochlearia atlantica* [108]. On the contrary, the total ascorbate pool has been seen to decrease largely in all species investigated by the same workers. A decrease in reduced ascorbate was observed in sunflower seedlings subjected to increasing water-deficit stress. During drying, a maintained total ascorbate pool was observed in the seedlings up until the point of severe stress [113]. Similarly, a reduction in AsA was observed in other species [112,125]. When plants are slowly dehydrated, a different picture emerges in that total ascorbate is maintained at high levels, owing to a good functionality of ascorbate-glutathione cycle, and resulting in being less susceptible to changes than GSH [49,109]. During drying in wheat, the higher AsA/DHA ratio in comparison with the control, despite the decrease in DHAR, may be an indication of the key role of MDHAR in the regenerating AsA [40,49] and of the decrease due to drought in APX, so that ascorbate may accumulate without being consumed. A high level of AsA is necessary for a plant's defense in water-deficit conditions, since in addition to its role in the H_2O_2 detoxification cycle, in the regeneration of tocopherol, and in the zeaxanthine synthesis, AsA can also directly act as a scavenger of hydroxyl radicals.

WATER DEFICIT INDUCES MEMBRANE LIPID CHANGES

Oxidative Stress and Damage to Membranes

Oxidative damage can be described as a consequence of insufficient antioxidant potential or an excessive oxidative stress. Several models, among which is AOS-induced peroxidative damage to membrane lipids, have been regarded as critical initiating events leading to injury of cell membranes during dehydration [126–129]. There is an increasing body of evidence that under water-deficit conditions, plants undergo increased exposure to AOS and accumulation of free radicals, which are associated with damage to membranes and degradation of lipid components. Reduced damage has been linked to increased synthesis of antioxidants and induction of enzymatic defenses against AOS [3,4,11,50,68,69,74,77–79,108,110,114,130–134]. Among AOS, the superoxide radical can promote degradative reactions by a nucleophilic attack on the carbonyl groups of the ester bonds linking fatty acids to the glycerol backbone [135,136], thus releasing free fatty acids (FFA) and thereby changing membrane polar lipid composition. Furthermore, the hydroperoxyl radical ($HOO^{\bullet}$), derived from the reaction of superoxide with protons (Equation [5]), and the hydroxyl radical ($^{\bullet}OH$), derived from the reaction of superoxide with hydrogen peroxide (Equations [6 and 7]), are able to initiate the peroxidation of lipids [137]. Peroxidation of membranes interferes with the normal membrane functioning, and lipid peroxides can decompose to form a wide range of highly cytotoxic products. The AOS are able to produce chemical modifications and/or damage to proteins, lipids, carbohydrates, and nucleotides [62,138]. The AOS may injure cells (a) by covalent binding to membrane components, enzymes, and/or receptors; (b) by impairing transport processes through sulfydryl group oxidation, change in lipid/protein ratio, or covalent binding; (c) by deesterification of polar lipids; and (d) by initiation of lipid peroxidation.

Evidence supporting the above statements derives from the fact that (a) stress conditions increase the production of free radicals [69,78,114,139]; (b) chemical and physical changes observed in membranes isolated from stressed plant tissues can be simulated in vitro by exposure to oxygen free radicals [140,141]; (c) membranes from tolerant plants tissues are more tolerant of free radical treatment than those from susceptible tissues [140,141]; (d) membranes from dehydrated plants producing more superoxide suffer higher decreases in fluidity and changes in composition than those producing less superoxide [11]; and (e) the production of $O_2^{\bullet -}$ increases by about two orders of magnitude when the integrity of thylakoids is damaged by detergents [142]. All the above-mentioned

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

observations indicate that the integrity of membranes depends on the acquisition of dehydration tolerance, which makes the membranes more resistant to AOS.

Oxidative Stress and Membrane Lipids

The generally accepted mechanism of free radical attack involves acyl chain oxidation which should lead to a decrease in the unsaturation level of membrane lipids. Such a phenomenon has not been observed in water-stressed tissues [11,69,129,140,143,144], in seeds exposed to the action of free radicals [141], and in resurrection plants during desiccation [3,139,145]. This suggests that changes in the unsaturation level of plants, which are often considered to be the only result of oxidative stress, are in fact a comparatively minor response to the action of free radicals [34,69,127]. There are alternative mechanisms of free radical attack on plant membrane lipids [34,97,135], so that the target for oxidative damage need not necessarily be unsaturated lipids. As reported in a previous section on the effects of oxidative stress in cells, the fatty acid ester linkage may be broken as a result of the nucleophilic addition of a superoxide radical to the ester bond; thus the fatty acids so liberated remain in membranes and destabilize them by changing the fluidity.

The free radical reactions in model membrane systems and plant membranes are quite distinctly different. Liposomes exposed to oxygen free radicals resulted in peroxidative reactions leading to degradation of the unsaturated fatty acids. In contrast, in winter wheat treated with free radicals, in spite of the lack of change in fatty acid unsaturation, there was a substantial loss of esterified fatty acids without a subsequent increase in peroxidation, suggesting the presence of terminating antioxidants that prevent the chain reaction from continuing [127]. Under conditions of oxidative stress, changes in membrane polar lipids and accumulation of free fatty acids with no changes in unsaturation level were also observed in sunflower and barley seedlings [69,135].

In the absence of changes in fatty acid unsaturation, the inherent danger of AOS lies in their ability to mediate the degradation of polar lipids, with accumulation of free fatty acids (FFA) or other uncharged lipids such as triacylglycerols (TG) [11,69,132,135]. The accumulation of these neutral lipids destabilizes the bilayer, leading to the formation of gel phase domains [127]. Both nucleophilic attack and peroxidation may result in membrane disorganization owing to changes in membrane composition that determine the formation of nonbilayer configuration and possible displacement of membrane proteins, with the consequence being a loss of functional integrity of membranes.

In thylakoids, lipid damage is an ever-present problem because of the high quantity of polar lipids and polyunsaturated fatty acid residues, which are particularly susceptible to free radical attack [146], Furthermore, alterations in bulk membrane lipids and in lipids of the boundary layer surrounding proteins [147], such as those caused by dehydration, hinder cell function by inducing changes in the structure and function of several intrinsic protein complexes [148,149]. Therefore, removal of activated oxygen species and hydroperoxyl fatty acid radicals is a priority if the functional integrity of thylakoid membranes is to be preserved.

Lipid Oxidative Chain Reaction Breaking in Chloroplasts

The process of lipid peroxidation has been shown to be associated with loss of membrane polyunsaturated fatty acids and the formation of hydroperoxides, free radical intermediates, and other secondary products. Lipid peroxidation products generated, such as hydroperoxides, aldehydes, and epoxides, may react with and inactivate essential proteins, enzymes, and nucleic acids. Thus, the process of lipid peroxidation, if not interrupted, may lead to the alteration of cell membranes and to the release of destructive enzymes.

The ascorbate-glutathione system in chloroplasts play an irreplaceable role in protection against oxidative damage (see section Ascorbate-Glutathione System in Chloroplasts and its Role in Water-Deficit Conditions above), but other antioxidative protective mechanisms must be present in chloroplasts which serve to break the peroxidative chain reaction. Ascorbate and glutathione may

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

serve as mediators between the hydrophilic and lipophilic phase to maintain the antioxidant properties of membrane-protective systems. In combination with tocopherol, they can result in synergistic inhibition of oxidative damage to cell membranes [150] by trapping the lipid radicals and suppressing lipid peroxidation rather than by scavenging $O_2^{\bullet -}$ or singlet oxygen [151,152]. The chain-breaking activity of tocopherol is predominantly maintained by ascorbate, whereas GSH predominantly acts as a preventive antioxidant [153]. Ascorbate has been seen to protect against lipid peroxidation as long as tocopherol is present, but in tocopherol-deficient microsomes, ascorbate initiates lipid peroxidation immediately, demonstrating its pro-oxidant effect. On the contrary, GSH is effective at low tocopherol concentrations, thereby also providing a protective role in tocopherol deficiency. GSH may prevent lipid peroxidation from entering the propagation stage by scavenging lipid alkyl or lipoxyl radicals formed during the initiation stage of peroxidation [154].

Tocopherol is able to quench and scavenge singlet oxygen even if carotenoids are probably more important in this role, since they react with singlet oxygen at a diffusion-controlled rate and they can also quench those excited triplet states of chlorophyll that lead to singlet oxygen formation [61]. Chloroplasts are the site of synthesis of tocopherol and the thylakoid membrane is very rich in tocopherol. Tocopherol is an amphipatic molecule with its hydrophobic phytil tail located in the membrane, associated with the acyl chains of fatty acids, whereas its polar ''head'' group (chromanol) is oriented toward the membrane surface, with the phenolic hydroxyl group being located near the polar group of the lipid matrix [155]. Tocopherol is an unspecific trap for the activated oxygen species, but it reacts rapidly ($2.4 \times 10^6\ M^{-1}\ s^{-1}$) with alkyl peroxyl radicals formed in the lipid phase [156] and becomes irreversibly oxidized [157]. The tocopheroxyl radical must be reduced back to act again as a chain-breaking antioxidant, but no enzyme systems for such a function have been described until now. Fast regeneration of the tocopheroxyl radical by ascorbate and GSH has been detected by EPR [97,158]. Direct interaction at the membrane surface with either ascorbate [154] or reduced glutathione [153] allows tocopherol many chain-breaking events before its degradation, producing the monodehydroascorbate and glutathiyl radicals. However, ascorbate and GSH will act as radical scavengers only when there is an efficient removal of their radical forms. The radicals formed to regenerate tocopherol are in turn recycled by available reducing equivalents, such as NAD(P)H [26], in association with their specific reductase enzymes. This mechanism creates a link between the free radical reactions initiated in the lipid phase and the scavenging activity in the aqueous phase (see section Ascorbate-Glutathione System in Chloroplasts and its Role in Water-Deficit Conditions above).

Changes in Lipid Composition

Water-deficit conditions are frequent in crops even in a normal season during some steps of their cultural cycle, with the result being a limitation in their growth and production. Limited growth and production are the result of structural modification of membrane components, particularly lipids [159–161]. Many vital activities of the cell originate in the membrane, the structure and function of which are profoundly altered following water stress that leads to destructive events, such as transition from a liquid-crystalline to a gel phase, fusion, and increased permeability [128,162–164]. Therefore lipids, being one of the major components of membrane, are obviously affected by water stress. The composition and physical state of the lipid bilayer influence the lipid-protein and the protein-protein associations, enzyme activities, and transport capacity of membranes [148,165,166].

Studies concerning the effects of water deficit on lipids have demonstrated that lipids are affected by drought [143,167], but the data have often been contradictory owing to the lack of information on the water status of the plants. Very often only the number of days without watering is given, and this is unable to provide a clear description of stress effects on plants. Further uncertainties arise from the numerous factors that are implicated in the plant response. The nature and the extent of changes in lipids are a function of intensity and duration of stress and of the tissue examined and growth stage, as well as of the genetically determined ability of the plant to cope with the

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

environment [144,168–170]. The main lipids in leaves are polar acyl lipids [171,172], which are associated with membraneous structures in plant cells. More than 60% of chloroplast membranes are composed of glycolipids (GL), whereas the phospholipids (PL) are generally considered to be the most important mitochondrial and plasma membrane lipids [173]. Evidence from cotton, barley, and wheat indicates that GL amounts decrease in response to water deficit [162,174], but the authors cited failed to specify the stress intensity imposed or else exposed the plants to excessive levels of stress. When the water status of the plants is monitored, it has been shown that the levels of GL depended on stress severity, so that GL may decrease, remain constant, or even increase [144,170,175,176]. This disparity in behavior may be a further indication of the great impact that stress severity has on plant metabolic responses. The adaptation of plants to water depletion may maintain or even stimulate the production of GL, which are an important structural feature of photosynthesis and play an essential role in the maintenance of the electron transport system and in thylakoid stabilization [177]. With regard to the main glycolipid, it is known that monogalactosyldiacylglycerol (MGDG), on isolation, forms a cylindrical inverted hexagonal configuration instead of the bilayer configuration adopted by the other thylakoid lipids [178]. Stabilization of thylakoids can be achieved by reducing the tendency of MGDG to form nonbilayer arrangements. Furthermore, increasing the saturation reduces the tendency of MGDG to form a nonbilayer structure [179]. The more MGDG is present in the lipid mixture, the larger is the tendency to form a nonbilayer configuration [180]. Dry land conditions caused different rearrangements in two cultivars of wheat with different sensitivities to water-deficit conditions (Table 2) [11]. Whereas oligalactosyldiacylglycerol (DGDG) was unaffected by water deficit in both cultivars, an increase in the MGDG/DGDG molar ratio occurred in the more sensitive cultivar and a decreased ratio in the less sensitive, which also showed less unsaturation in MGDG. The lower MGDG and the lower unsaturation found in thylakoid membranes of the tolerant cultivar in comparison with the sensitive one may have maintained membrane fluidity, although the potential of acyl lipids to form lamellar or nonlamellar configurations is dependent on several other factors, such as temperature, water content, pH, and cation type and concentration [181]. Water-deficit conditions increased the proportion of FFA in the sensitive wheat, whereas the level was unchanged in the tolerant plant. The FFA accumulated in the stressed sensitive wheat may have induced an increase in membrane microviscosity and may have changed

TABLE 2 Chemical and Physical Changes and $O_2^{\cdot-}$ Formation Rate in Thylakoids of Two Wheat Cultivars Differently Sensitive to Water Deficit Conditions

lipid-protein interactions and protein conformation. In the stressed drought-sensitive cultivar, a higher superoxide radical production has also been found in comparison with the tolerant cultivar, in which no increase was observed following water depletion [182].

Investigations on various crop species [69,144,170,176,183–187] report a general decrease in the PL of leaf tissue exposed to long periods of water deficit even though only a few of the previous works specify the intensity of the stress applied. In some cases, a degradation of PL with a decrease in water potential has been found, but a PL decrease is not always accompanied by an accumulation of FFA. Other lipid components, such as TG, resulting from the esterification of stress-induced increase in FFA and diacylglycerols (DAG), may play a role in destabilizing the membrane, as demonstrated in senescent tissue. In this tissue, discrete gel and liquid crystalline domains are formed because of the presence of several components, with the exception of FFA, in the neutral lipid fraction [188]. These components, identified as TG, 1,2-diglicerides, free sterols, and sterol esters, could interact with PL and induce a lateral phase separation resulting in a mixture of gel phase lipid in the liquid-crystalline domains [140,141]. As the polar lipid level of the cell has been correlated with the content of its membraneous system [189], the decrease following water depletion may indicate a disorganization of the cellular membranes with accompanying loss of permeability, electron transport capacity, and enzyme-bound activity [190,191].

It is important to point out that in the previously reported investigations the changes in PL and in Gl in stressed plants take place without significant changes in the fatty acid unsaturation. The loss of PL following stress seems to be related to enhanced hydrolysis rather than to an inhibition of PL synthesis, since it is accounted for by an increase in the neutral TG [144,170,176,192]. The breakdown of PL, in fact, may support TG accumulation through the formation of the precursors DAG, which in some cases have been seen to increase following water depletion [144,160,175]. The accumulation of TG may be considered to be a way of storing fixed carbon and a greater energy reserve than starch. It provides an adaptative advantage, because TG accumulated during water deficit can be readily utilized when drought stress is relieved, and it makes no demands on the available water for accumulation. In further support of this hypothesis, starch, sucrose, and the export of photosynthates are severely decreased by water deficit [193]. Such conditions would be conducive to the storage of fixed carbon such as TG during drought and may indicate an alteration of normal translocation processes. However, oleosome lipids, consisting mainly of TG, are not involved in the storage of products of photosynthesis [194], and the increased levels of TG and DAG have been attributed to de novo synthesis rather than to breakdown or utilization of existing glycerolipids and fatty acids [175]. In addition, it must be borne in mind that every membrane has a characteristic lipid composition and lipid/protein ratio, which represent two important factors in the biochemical functioning of membranes [172]. Therefore, it may be postulated that the presence in stressed seedlings of increased amounts of TG, which are uncharged lipids, disturbs the normally orderly arrangement of the membrane by aggregating to form lipid bodies between its amphiphilic phospholipid-protein layers. The increase in TG levels would induce a certain instability in the bilayer and may play a role in the transport of protein across membranes, changing the overall physical status of the latter [144].

It has been suggested that the molecular basis of water-deficit stress sensitivity in plants is related to the nature of the fatty acyl residue associated with membrane lipids. Compared with sensitive strains, drought-resistant strains of *Vigna unguiculata*, which contain a high proportion of linolenic acid, increased the unsaturation level when droughted, whereas in the drought-sensitive plants, it decreased [195]. On the contrary, in two genotypes of *Lupinus albus* [196], one resistant and the other sensitive to water-deficit conditions, a high percentage of linolenic acid was found in both watered and unwatered plants. The total unsaturation in both sets of lines was remarkably stable, as also seen in other plants [70,132,144,170,187]. From studies with [1-^{14}C]-acetate, it emerges that under water stress, a marked decrease of precursor incorporation into cotton leaf lipids occurs, particularly in phosphatidylcholine (PC) and in galactolipids. On the contrary, the relative incorporation into neutral lipids increases [186]. An inhibition of the fatty acid desaturation, further evidenced in experiments with [1-^{14}C]-oleate and [1-^{14}C] linoleate, has also been demonstrated [197].

The overall physical state of membranes is also regulated by free sterols, which are membrane stabilizers. When their relative proportion increases, they reduce the mobility of the acyl chains and thus the fluidity of the bilayer by inserting themselves into the PL cavities [198,199]. Therefore, in order to have a complete picture, one must take into account whether or not free sterol changes occur in water-deficit conditions. Mild water stress did not lead to alterations or reduced slightly the free sterol level [70,169,192,200], whereas severe water stress or repeated stress periods increased their amounts significantly [144,201]. It is likely that mild water-deficit stress involves some metabolic adjustments in membrane lipids which stabilize cell membranes when severe stress occurs. Furthermore, several inducive cycles or a critical intensity of water-deficit stress may be required in order to obtain modifications in sterol metabolism. Besides the amount, the composition of FS also alters membrane status because of the specific effect of the individual sterols. In *Zea mays* hybrids exposed to mild osmotic stress, an increased molar ratio of stigmasterol to sitosterol in stressed tissues has been observed [200]. The same thing occurred in sunflower and maize grown in the field under water-deficit conditions [144,170]. Changes in this ratio may be an example of an early event that may control membrane function. The increase in the stigmasterol/sitosterol ratio could be an index of metabolic disorder, because the increase in stigmasterol is indicative of cell disorganization and of a reduced adaptative capacity to stress conditions [202]. The ''more planar'' sterols (cholesterol + campesterol) are far more effective in stabilizing membranes and reducing membrane permeability than the ''less planar'' sterols (stigmasterol + sitosterol), and their ratio may be used as an index of membrane permeability [202,203]. This ratio has been seen to be maintained on stress in maize and sunflower which experienced a water deficit of −1.05 MPa [144,170]. The stability of this ratio and the constant level of lipid unsaturation, together with the increase in the amount of free sterols, may reflect the relative abilities of plants to regulate membrane stability and permeability under conditions of water deficit in an attempt to maintain normal cell function.

The reported changes, however, are relative to lipids from all intracellular membranes and show only more general changes. In water-stressed plants, the first cellular perturbation was found to be an increase in solute leakage, which is positively correlated to the decrease in water potential. This provides evidence that plasma membranes (PM), which limit solute efflux, had been damaged. There is little information available on changes in lipids from purified PM in response to water stress. The main lipid components of PM are PL and FS [168,204], and there is some evidence that water stress can induce changes in these lipids. In plasma membrane isolated from sunflower seedlings exposed to a water deficit of − 1.3 MPa, a loss of PL and glucocerebrosides together with an increase in TG, a non–bilayer-forming lipid, have been observed [132]. The decrease in the membrane PL and the increase in FS, resulting in an increase in the FS/PL molar ratio [132,185], could initiate changes in the fluidity of the membrane [168]. Greater disorganization of the PM may be also due to a change in the more planar/less planar sterol ratio and to the increase in the stigmasterol/sitosterol ratio already observed in the whole plants [144,194,170,200,202]. The unsaturation of PM lipids has been seen to remain constant under water-deficit stress [132,185] as often observed at the whole plant level [170,176] and higher than 60%, which is an adequate value to ensure correct membrane functioning without the need for any specific qualitative or quantitative fatty acid composition [205].

In the plasma membrane of sunflower, in accordance with other findings on oat roots and wheat shoots, the PC/PE ratio increased during desiccation [132,184,206]. It is known that PC tends to form a bilayer configuration under physiological conditions, whereas PE, a non–bilayer-forming lipid, orients into a hexagonal H_{II} configuration. The balance between non–bilayer-forming and bilayer-forming lipids is an important factor in determining membrane function. Therefore, accumulation of PC during drought may result in increased membrane fluidity and prevents the formation of a nonbilayer lipid configuration under stress conditions. Methylated species, such as PC, hydrate to nearly twice the extent of other lipids and may also influence the structure of the water layer adjacent to the membrane, since the interfacial water layer is more ordered in the crystalline than in the gel phase owing to increased interactions between the polar head groups and water [207]. Therefore, higher levels of PC can limit the increase in the transition temperature and the formation

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

of the increased proportion of gel phase in the liquid crystalline domain in contrast to the effect of PE [164]. On the other hand, a tighter lipid packing, such as that obtained with PE, reduces the accessibility of the polar head groups to water.

Plants are more tolerant of drought when water stress is slowly imposed, since such a condition favors osmotic adjustment, which, in sorghum for instance, becomes negligible only when the dehydration rate is increased to 1.2 MPa/day [208]. The dehydration rate in sunflower seedlings was about 0.1 MPa/day, which is a decrease that is quite consistent with the above considerations. On the other hand, acclimation to dehydration reveals a different picture, since in the PM of oat roots, a decrease in the PC/PE ratio occurred, which was regarded as a system capable of increasing the curvature of the membrane and facilitating its repeated invaginations [185]. A different water status experienced by the plants may explain these contrasting results even if the different response may also be due to the system used by Norberg and Liljinberg [185] to impose water-deficit conditions. Indeed, the oat plants were periodically removed from the nutrient medium and placed on a coarse stainless steel net to allow the roots to air dry.

AN EXTREME CASE OF DESICCATION TOLERANCE: RESURRECTION PLANTS

Production of AOS and Protective Mechanisms in Resurrection Plants

Under conditions of low relative humidity, the viability of higher plant tissues may become seriously affected because of the evaporation of cellular water. Adaptation to cellular dehydration is one of the most important characteristics that determines the distribution and the yield of crops. Most desiccation-tolerant species show definite limits of tolerance beyond which tissue damage or death occurs. In only a few cases is an organism able to withstand severe dehydration. In higher plants, the ability to survive water loss is normally limited to embryos in developed seeds and to a small group of plants called ''resurrection'' plants. These are a group of plants whose fully differentiated tissues have the ability to withstand dehydration down to air dryness and to resume full biological activity on rehydration [209–212]. In these poikyloidric plants, the water content closely follows the changes in the dryness of the environment. The remarkable tolerance to prolonged anhydrobiosis in these plants suggests that they are able to maintain essential structure and physiological integrity in the dry state or are able to repair dehydration rehydration-induced damage. Several structural, chemical, and molecular aspects have been suggested to explain the ability of resurrection plants to survive a severe reduction in water content [3,51,124,139,213–218]. The distinction between desiccation tolerance and intolerance has been suggested over the years to be a function of the plant's ability to (a) process AOS by maintaining their defensive mechanisms or amplify them during the desiccation and rehydration phase, (b) retain integrity in the dry state, and (c) develop repair mechanisms on rehydration. The free radical damage hypothesis of desiccation injury states that the molecular defenses are unable to detoxify AOS during dehydration and rehydration.

The use of EPR and electron nuclear double magnetic resonance (ENDOR) showed the formation of a stable carbonium-centered free radical both in desiccation-tolerant and desiccation-intolerant mosses, but damage only occurs in sensitive species [74] that have a smaller amount of the antioxidants tocopherol and glutathione and antioxidant-recycling enzymes [133]. *B. hygroscopica* is a resurrection plant that experiences either viable (slowly dried leaves) or nonviable (rapidly dried leaves) dehydration. Illuminated thylakoids of dried leaves showed a lower superoxide production in comparison with the control and rehydrated leaves. In addition, viable dehydrated leaves had a lower production of superoxide in comparison with nonviable dehydrated leaves [3]. Both viable and nonviable dehydrated leaves decreased their electron transport rate notably (F. Navari-Izzo, personal communication), and this may account for the decrease in superoxide production in comparison with control and rehydrated samples. Furthermore, the destabilization of membranes due to lipid changes during nonviable drying (see section Membrane Lipid Composition During Dehydration and

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

Rehydration below) might take into account the increase in superoxide production in comparison with slowly dried leaves.

Only a few studies deal with the antioxidative defenses during the dehydration and rehydration cycle in resurrection plants. In droughted plants, conservation or resumption of enzyme activities depend on species, rate of water loss, and enzyme considered. Generally, a rapid water loss is more harmful than a slow water loss for the redevelopment of enzyme activities during rehydration [219]. In *Selaginella lepidophylla*, the mean of photosynthetic enzyme conservation is significantly lower than the mean of glycolitic enzymes [220], thus explaining the rapid resumption of respiratory activity and the delayed development of photosynthetic activity seen in this, as in other resurrection species, on rehydration. In detached leaves of *Sporobolus stapfianus*, the enzymes related to the glutathione-ascorbate cycle respond individually to a rapid water loss; the specific activities of GR and DHAR were more than twice as high as in control leaves, whereas the APX activity decreased to 40% of the well-hydrated sample [52]. Two major mechanisms seem to be involved in the survival of resurrection plants: the synthesis of glutathione during dehydration and the activation of the ascorbate-glutathione cycle during rehydration. Glutathione seems to play a very important role in the survival of detached leaves of *B. hygroscopica*, which during dehydration increase the amount of constitutive GSH by up to 50 times and utilize it when rehydrated [51]. The enhanced formation of reduced glutathione plays an irreplaceable role in limiting lipid peroxidation [3,51,221] and in protecting enzymes which possess exposed thiol groups [123]. In the moss *Tortula ruralis* and in the resurrection plant *S. lephidophylla*, the $NADP^+$–glyceraldehyde-3-phosphate dehydrogenase activity was severely reduced following GSH oxidation and was restored only after the addition of GSH [222–225]. Notably, during dehydration of *B. hygroscopica* plants, the activity of the enzyme remained constant [124]. Dehydration of *B. hygroscopica* plants to 80% relative water content (RWC) determined a dramatic decrease in GSH, which on further dehydration began to accumulate by up to 20 times at 23% RWC [124]. The release of feedback inhibition of the synthesis of GSH through an initial decrease in GSH might have been involved [226]. In flowering plants, as an oxidative stress is imposed, there is also a rapid decline in the GSH level, which is immediately restored over time [113,227]. It is quite interesting that an induction in ABA has been observed in *B. hygroscopica* dehydrated to 80% RWC (A. Bochicchio, personal communication), with ABA presumably being involved in the induction of gene expression during water loss [228]. A more reduced status of the cells during desiccation may also be maintained through the induction in the synthesis of ascorbate, and the decrease of DHAR and GR activities on drying is probably due to the accumulation of AsA and GSH [51]. The activation of MDAR, DHAR, and APX has been observed during dehydration of *S. stapfianus* plants [84]. Antioxidants such as AsA and GSH, which accumulate during drying, might constitute a reserve which allows the plant to tolerate oxidative damage during desiccation and rehydration, when the injury caused by desiccation must be repaired, and when plants recover their catabolic and/or anabolic activities. Indeed detached leaves of *S. stapfianus* which during drying do not accumulate reduced ascorbate and glutathione [52] are not able to revive on rehydration [215]. Both GSH [51,124] and AsA [84] may have helped to break the chain of peroxidative reactions by maintaining tocopherol in a reduced form, thus preventing lipid peroxidation and/or oxidation of protein sulfydryl groups in desiccated resurrection plants [84]. During rehydration oxidative processes intensify and resurrection plants might be more exposed to AOS, since the levels of $O_2^{\bullet -}$ [3] and H_2O_2 as well as the oxidation of GSH and AsA have been seen to increase [51]. During this phase the oxidation of these two antioxidants stimulates the activity of the enzymes of the ascorbate-glutathione cycle [51], which may thus play an important role in the resurrection of these plants and in the regeneration of AsA and GSH at the end of rehydration.

Membrane Lipid Composition During Dehydration and Rehydration

Drastic changes in the volume of the cells and in cellular components due to dehydration and rehydration subject endomembranes to multiple stress leading to structural changes and possible breakdown and perturbation of membrane stability [11,77,132]. Mechanisms of desiccation tolerance are

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

thought to be based on membrane behavior [40], and an efficient recovery and full reconstitution of membrane structure and composition during rehydration may be a requisite to cell survival [229]. Removal of water is likely to induce demixing and/or liquid crystalline to gel phase transitions, but when water enters the cells, an efficient repair mechanism is necessary to restore membrane integrity much more than during dehydration. Rehydration of membranes causes a part of them to pass again to the crystalline phase and leads to solute leakage [230]. During dehydration-rehydration, cycle changes in lipid composition and in activities of enzymes involved in lipid metabolism have been found in desiccation-tolerant mosses [131,231] and in the resurrection flowering species *Ramonda, Haberlea* [229,232], *B. hygroscopica* [139], and *S. stapfianus* [233]. Thylakoids of *B. hygroscopica* have a lipid composition characteristic of bryophites and of plants grown in arid or semiarid climates [234,235], showing a low MGDG content, a low MGDG/DGDG molar ratio, a low degree of unsaturation, and a low proportion of linolenic acid [18:3]. Dehydration causes a large decrease in MGDG levels and in MGDG/DGDG molar ratios. Similar results have been reported in the resurrection plants *Haberlea rhodopensis* [232], *Ramonda serbica* [229], and *S. stapfianus* [233]. A decrease in this ratio has been also monitored on water-deficit stress in a drought-tolerant wheat [11,182] and in a tolerant variety of *V. unguiculata* [195], whereas sensitive varieties showed an increase in this ratio [11,182,195].

A higher proportion of DGDG, a bilayer-forming lipid, may play a role in the control of ionic permeability in the chloroplasts [232]. Even though biological membranes are a complex mixture of several lipids, variations induced by water deficit in the relative proportions of MGDG and DGDG influence the physical state of membranes and their functionality [11,178] because of their different arrangements within thylakoid membranes (see section Changes in Lipid Composition above). During dehydration, the metabolic activities of resurrection plants, including photosynthesis, decline but they undergo functional recovery at rehydration. A decrease in MGDG could be a mechanism for maintaining a low efficiency of photosystems, in agreement with the role of $MGDG_s$ in electron transfer between the antennae and the cores of the photosystems [236]. The only lipid organization found to be compatible with functional membranes is the bilayer or lamellar phase [237]; for this reason, the decrease in MGDG/DGDG molar ratio following dehydration may help the survival of the plant by retaining the bilayer arrangement, since DGDG adopts only the lamellar phase [178].

In photosynthetic membranes, the most abundant fatty acid is the polyunsaturated acid 18:3, and its high level suggests that it is important in maintaining photosynthetic activity. On the other hand, linoleic acid 18:2 is generally only a minor component of chloroplast membranes (1–3% of chloroplast lipids), whereas it is the main constituent of PL in nonphotosynthetic tissues.

It is also present at a fairly high level (30% of polar lipids) in algae and bryophites [238]. In *Ramonda* species and *H. rhodopensis*, 18:3 was found to be the main fatty acid component in MGDG, but it was present in lower percentage compared with the levels present in the typical flowering plants [239]. Dehydration decreased its content, whereas it sharply increased the 18:2 content [229,232]. Thylakoid membranes of *B. hygroscopica* [139] as well as the whole leaves of other resurrection plants [145,229] have a peculiarly low 18:3 content, and in addition, in *B. hygroscopica*, a high level of 18:2 has also been detected. An 18:3 deficiency in chloroplast membranes has been seen to decrease the photosynthetic capacity [240]. Therefore, it seems likely that the low 18:3 and the high 18:2 levels found in *B. hygroscopica* may play a role in maintaining a low photosynthetic activity in these plants. Thylakoids of *B. hygroscopica* [139] as well as leaves of other resurrection plants [229,232,233] are rich in neutral lipids in comparison with other higher plants [132,135,144]. Among neutral lipids, TGs accumulate on dehydration [139,229,233] and decrease during rehydration [139,233]. The storage of neutral lipids in dehydrated leaves and their reduction during rehydration indicate that the reserves are used for restoration of respiration, which is more rapidly reactivated than the photosynthetic membrane reaction [241–243], as soon as the water is available again. On rewatering, the synthesis of lipids is strikingly fast [229,231,233] owing to the stability of mRNA under desiccation, which leads to a rapid synthesis of polyribosomes on rehydration [244].

During dehydration and rehydration of *B. hygroscopica* and *S. stapfianus*, peroxidative dam-

Marcel Dekker, Inc.

age to polyunsaturated fatty acids does not occur. The absence of peroxidative processes in the dehydrated and rewatered plants can be due, at least in part, to the increase in carotenoids on dehydration [233] and to the maintained levels of the lipophilic antioxidant tocopherol (F. Navari-Izzo, personal communication). The storage of higher amounts of FFA and TG, although usually leading to concomitant changes in the packing, fluidity, and/or physical arrangement of the membranes [3,11,139,233], may be considered to be a readily available source of precursors for the reconstitution of the lipids during rehydration and for energy supply as soon as water is available again [139], since the properties of membranes have been maintained. In addition, an increased or maintained unsaturation level was observed on desiccation in these as well as in other resurrection plants. This may indicate that FFA accumulation is caused not only by polar lipid degradation and unsaturated MGDG in particular, but that it is likely to be due to active synthesis during the early dehydration period to produce precursors to be used when rewatering is resumed. Following rehydration, the unsaturation level returns again to that of undesiccated leaves [3,145]. The changes in unsaturation on desiccation may be the result of the decrease in both enzymic oxidation [245] and oxidation due to AOS and of the increase of superoxide radicals on rehydration [3]. Furthermore, in dried *Craterogstigma plantagineum* and in *S. stapfianus* colneleic and colnelenic acids, inhibitors of lipoxigenase, have been found [245,246]. According to these results, the target for oxidative damage needs not necessarily to be unsaturated lipids and the free radical–induced polar lipid deesterification hypothesis has to be considered [34,135]. On rewatering, a general trend toward recovery has been observed in the individual lipids [3,139,229,233], showing that an efficient repair occurs in these plants.

The rate of water loss during the desiccation phase of the dehydration-rehydration cycle is particularly significant. Dehydrated leaves of most resurrection plants do not survive desiccation unless they are slowly dried as was observed in *B. hygroscopica* [3,51,139] and in *Borya nitida* [215]. Apparently, only slow desiccation stimulates some processes which allow the plant to survive dehydration. This may suggest that only slow drying could increase the chances for survival by giving the plants additional time to carry out the structural and compositional changes necessary to achieve a viable dehydrated status. The revival of the plants might also be due to a higher water content of the slowly dried leaves to 1.8% RWC in comparison with the rapidly dried leaves to 0.3% RWC, as shown in *B. hygroscopica* [3,51], which has been seen to lose the ability to survive when slowly dehydrated plants were dehydrated to the same water content of rapidly dried leaves [247]. Rapid dehydration results in a higher accumulation of FFA, which is known to destabilize the membrane bilayer and to alter the conformation of proteins [248]. Other differences that may be correlated to the different capacity of slowly and rapidly dried leaves to withstand dehydration are a higher total polar lipid/free sterol molar ratio, a lower proportion of free sterols, and a lower MGDG/DGDG molar ratio. These are all changes that all together may lead to the destabilization of membranes [3,139].

Cell Structure Preservation

Cell preservation in a desiccated state is not related only to functional conditions but also depends on a structural basis. The safeguard of both a physiological integrity and a certain structural organization can be seen as intrinsically linked [249]. For this reason, the ultrastructural changes which occur during dehydration and rehydration of desiccation-tolerant cells assume a major significance, being able to provide useful information on cell structure stability and on their contribution in surviving an extreme water loss.

The preservation of structural integrity of cellular membranes is a determinant factor in surviving desiccation and subsequent rewatering. Electron microscopy on freeze-fractured cells of different resurrection plants shows that in the dry state, membranes exhibit the bilayer configuration with normally dispersed intramembranal particles [250]. This is noticed in the fern *S. lipidophylla* and also in the moss *T. ruralis*, a species with a desiccation tolerance essentially based on a repair system [251]. Moreover, the ability to preserve cell membrane integrity results from the far lower differences

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

in the rate of electrolyte leakage among fully hydrated, dry, and rehydrated cells of desiccation-tolerant plants compared with that of desiccation-sensitive ones [252]. The structural and functional features of the membranes in completely dried cells of desiccation-tolerant species mean that, besides those already described, additional protective mechanisms have to operate during dehydration in order to defend the membrane against the rigor of extreme water loss and to preserve the bilayer organization far below 20% hydration, which is regarded as the critical value to maintain this configuration [253]. However, most of these mechanisms, which are essentially based on the accumulation of soluble sugars and proteins, are not exclusive to the vegetative cells of resurrection plants but are shared with seeds, embryos, and organisms which can acquire tolerance to different environmental conditions causing a water deficit [214,216,254–256].

The production of soluble sugars, particularly disaccharides, as protectants against the dry damage of cell membranes is a method common to all living beings able to cope with complete dehydration [257] and seems to be a very ancient mechanism, since even archaebacteria can activate it to tolerate extreme drought stress [258]. In animal anhydrobiotic organisms, the disaccharide employed is trehalose, whereas in plants, it is usually substituted by saccharose [145,245,259–261]. However, in desiccation-tolerant embryos and in leaves of some resurrection plants other sugars, with the same trehalose among them, have been found [215,246,261,262–264]. The synthesis of soluble sugars is an early and massive event in desiccation-tolerance induction. This is shown in drying cells of *C. plantagineum* by the immediate increase in transcripts of saccharose phosphate synthase and saccharose synthase [216], which leads to a saccharose content up to 40% of dry weight in fully dehydrated leaves [265]. At the ultrastructural level, this can account for the observed disappearance of starch from chloroplasts of resurrection plants during cell desiccation [252,266–270]. In desiccation-tolerant leaves of *S. stapfianus*, the loss of starch occurs during dehydration (Figs. 4 and 5), whereas in detached drought-sensitive leaves of the same species, starch persists in chloroplasts of dried cells (Fig. 6) [233]. The soluble sugars seem to play different roles in protecting the cell against desiccation damage. First of all, they can preserve membranes by stabilizing the dry double layer through direct interaction between their —OH groups and the phosphate ones of membrane phospholipids [216,257]. In this way, the packing of phospholipid head groups, due to water removal, is prevented, the phase transition temperature is depressed, and dry phospho-

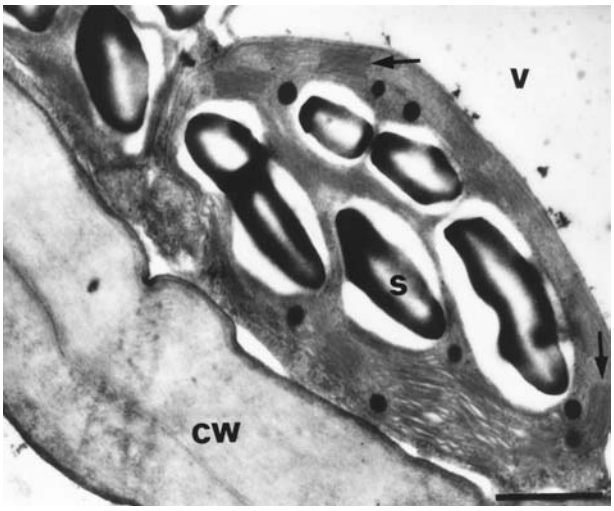

FIGURE 4 Bundle sheath chloroplast in a fully hydrated cell of a leaf of *Sporobolus stapfianus.* The organelle contains a granal (arrow) thylakoid system and large stach grains (s). (cw = cell wall; v = vacuole) (bar = 1 μm). (From Ref. 233.)

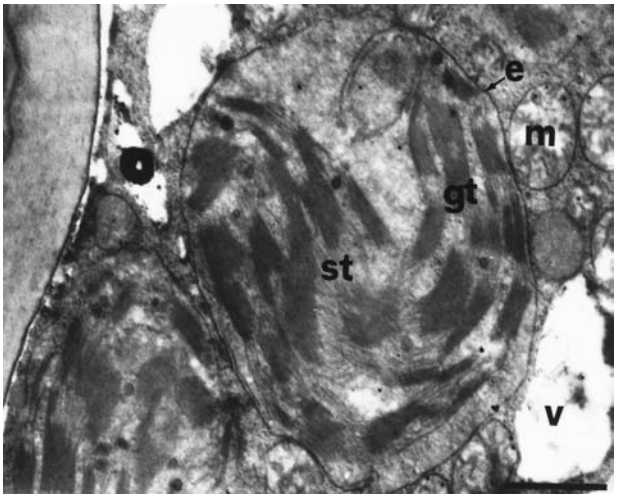

FIGURE 5 In the dry bundle sheath cell of a desiccation-tolerant leaf of *Sporobolus stapfianus*, a chloroplast with well-defined envelope (e), several grana (gt), and stroma (st) thylakoids but devoid of starch can be seen. Note also the well-preserved mitochondrion (m) and small vacuoles (v) (bar = 1 μm). (From Ref. 233.)

lipids remain in the liquid crystalline phase in the absence of water. As a consequence, the leakage which should occur during rehydration with the phospholipid bilayer passage from gel to liquid crystalline phase can be avoided. Apart from the stabilizing action on membranes, disaccharides are able to protect the protoplast against severe desiccation by forming glass. Thus, during dehydration, a supersaturated liquid, with the mechanical properties of a solid, is produced, which hinders cellular collapse and maintains a stable quiescent state [271]. Moreover, disaccharides can preserve the

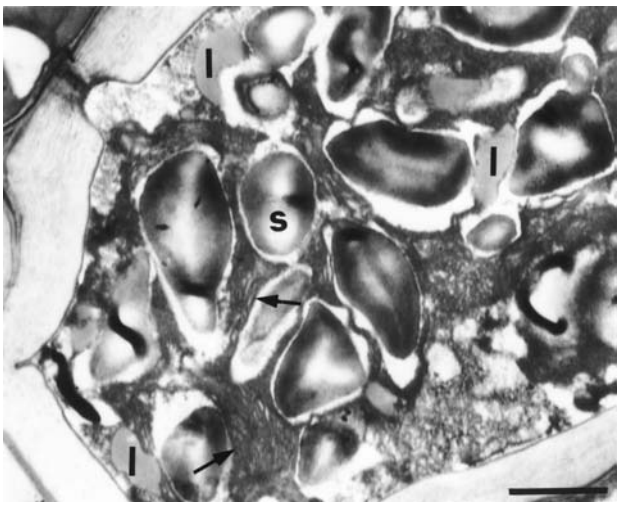

FIGURE 6 Rather indistinct chloroplasts containing swollen thylakoids (arrows), lipid-like inclusions (l), and several starch grains (s) are present in the dry bundle sheath cell of a desiccation-sensitive leaf of *Sporobolus stapfianus* (bar = 1 μm). (From Ref. 233.)

activity of enzymatic molecules in drying cells, probably through formation of hydrogen bonds between their —OH groups and the protein polar residues [257]. It has been demonstrated, for instance, that the tetrameric enzyme phosphofructokinase, which irreversibly dissociates into inactive dimers when dehydrated, is stabilized in vitro in the active form by disaccharides [272].

The production of specific proteins involved in preservation of the structural integrity and functionality of drying cells is another defense strategy adopted by resurrection plants. In the cytosol of dehydrating cells of *C. plantagineum*, three desiccation-related proteins are synthesized [273], which exhibit homology with a family of late embryogenesis–abundant (LEA) proteins accumulated during the final stage of seed development [274]. LEA-like proteins, also termed ''dehydrins'' [275], have been found not only in angiosperms but also in desiccation-tolerant species taxonomically different, such as ferns [276], liverwort [277], mosses [278], and even cyanobacteria [279], so that their presence as components of dehydration-tolerance pattern seems to be ubiquitous among photosynthetic organisms [275]. Dehydrins are cytosolic and nuclear soluble proteins characterized by an extreme hydrophilic nature, being rich in charged and polar amino acids. This feature makes dehydrins able to operate in desiccation tolerance by replacing the water of the hydration shell of macromolecules with their superficial hydroxilated groups and with a protective action superior to that of saccharose because of the fact that they are less likely to crystallize [216]. Synergically with compatible solutes, such as proline and glycine-betaine, dehydrins seem also to act as ''chaperones'' maintaining the drying proteins in their correct folded state. Moreover, the dehydrin bonds with both anions and cations can counteract the damaging effects caused by the increasing ionic strength in dehydrating cells [216]. Thus, this kind of proteins seems to occupy a key place in cell desiccation tolerance.

The desiccation-tolerant *T. ruralis* lacks any water-conservation mechanism, so the rate of drying is directly controlled by the water status of the environment and can be too fast [280] to permit the activation of protecting systems such as the production of soluble sugars and dehydrins. This may account for the fact that in this species two major dehydrins are constitutively expressed and are already present in fully hydrated tissues [278] together with saccharose quantities (10% dry weight) sufficient to offer membrane protection during cell drying [281]. Thus, *T. ruralis*, and probably other truly ''desiccation-tolerant'' or ''truly poikilohydric'' species [218] appear to adopt a tolerance strategy which, during the dehydration phase, is based on constitutive protection systems. On the contrary, in pteridophytes and angiosperms, which have more complex ways of water use and regulation, the mechanisms of drying tolerance are inductive and require a certain amount of time to be put in place. These modified ''desiccation-tolerant'' plants [218] do not survive rapid dehydration [218,282] and employ morphological and physiological systems to control and retard the rate of water loss [210,218,283]. In resurrection plants belonging to pteridophytes and angiosperms, a major role in desiccation-tolerance induction seems to be played by abscisic acid (ABA) [218,284–287]. However, this hormone may be also involved in acquisition of desiccation tolerance in lower plants that do not possess constitutive systems of cell protection, such as the moss *Funaria hygrometrica* [288] and the liverwort *Exormotheca holstii* [277].

Through all the protecting mechanisms so far described, their interactions [257], and the possible complementary action of further more species-specific factors [289], resurrection plants succeed in preserving the basic cell structures and in maintaining a certain degree of cellular order. This fact is confirmed by the numerous ultrastructural observations of dry cells, which show defined plasmalemma and tonoplast outlines, cytoplasm rich in ribosomes, an intact nucleus surrounded by the envelope, and well-preserved mitochondria, although with few cristae [230,249,250,252,266–269,290].

Differently from the other cell components, chloroplasts can undergo great changes during dehydration of leaf cells. Resurrection plants can adopt different strategies in order to defend the photosynthetic apparatus, which is very sensible and liable to injury, against desiccation stress. The so-called ''poikilochlorophyllous'' species lose the photosynthetic pigments and the entire thylakoid system during dehydration, with formation in dried tissues of organelles devoid of any inner membranal structure termed ''desiccoplasts'' [291]. On the contrary, the ''homoiochlorophyllous'' ones

maintain most of the pigments and thylakoids in the dry state [233]. In the homoiochlorophyllous resurrection plants, the preservation of a membrane system with quite a good level of ultrastructural organization (see Fig. 5) [233,250,252] also requires the activation in chloroplasts of protecting mechanisms like those operating in the cytoplasm. In *C. plantagineum*, which is a homoiochlorophyllous resurrection plant, three ABA-inducible desiccation-stress proteins (dsp), termed dps21, dps22 and dps34, are synthesized in the drying chloroplasts [273,292,293]. One of them (dps21) is a stromal protein which shows homology with dehydrins, and the other two are inserted in the thylakoid membranes. The dps34 does not exhibit homology with any other so far known stress-related protein, but studies are now being carried out to characterize a protein with the same molecular weight found in thylakoids of drought-stressed *Solanum tuberosum* [294]. On the contrary, dps22 shows homology with early light-inducible proteins (ELIPs), a class of stress-related proteins expressed in greening etiolated leaves and in green leaves exposed to excess light [295]. It is interesting to note that, as in the case of ELIPs [295], the expression of dsp22 transcripts in drought-stressed leaves, besides being stimulated by light, also seems to depend on a circadian oscillator [295]. The functions of the two thylakoidal dsps have been suggested to be structural and protective [273,292]. They could play major roles in maintaining membrane order and in cooperating with other photoprotective systems [296] to cope with the light-damaging effects due to the photoinhibitory condition which always occurs in thylakoid membranes during severe water stress [295,297]. The stroma dehydrin, besides stabilizing the membranes, might operate in preserving the structural and functional integrity of soluble proteins. In the homoiochlorophyllous plants, the stromal enzymes are not degraded. Active ribulose-1,5-bisphosphate carboxylase-oxygenase (Rubisco) can be found in the dry state [298], and CO_2 fixation can occur at an extremely low osmotic potential [299]. Thus, in this kind of resurrection plant, the photosynthetic apparatus is maintained in a recoverable form during dehydration. In the poikilochlorophyllous species, on the contrary, the drying chloroplasts lose chlorophylls, most carotenoids, and the entire thylakoid system, so the photosynthetic apparatus has to be completely reconstructed during rewatering. However, pigment loss and demolition of the other thylakoid components are highly organized responses to desiccation [267] realized according to regulated metabolic pathways. In dehydrating poikilochlorophyllous plants, mitochondria remain functional for a longer time with respect to the homoiochlorophyllous ones, thus maintaining the respiration (desiccation respiration) necessary for the energy supply which allows the controlled transformation of chloroplasts into desiccoplasts.

On rewatering, the desiccation-tolerant species are able to recover the complete organization and functionality of their cells in a time which can depend on the kind of plant, the dehydration rate, the pattern of events occurring on drying and the ability to put in place repair mechanisms. In *T. ruralis*, the mitochondrion and chloroplast reactivation occurs in a few minutes. Photosynthesis can be fully restored in less than 1 h and, despite the high rate of dark respiration, a positive carbon balance can be achieved within 20 min [300]. In this species, cell recovery is as fast as the previous water loss was slow. This is because a quickly dried moss suffers a greater amount of damage on rehydration than a slowly dried one. However, *T. ruralis* can rely on very efficient repair mechanisms which enable it to cope with the added damage associated with a too rapid dehydration [250]. During the rewatering phase, new proteins termed ''rehydrins'' are synthesized, owing to a gene expression regulated in large measure at the translational level by recruitment of specific mRNA into polysomes [218,301]. The precise functions of rehydrins are so far unknown, although it appears likely that they might be enzymes somehow involved in the rapid cellular repair of eventual desiccation-induced damage. Interestingly, some of these proteins show homology with proteins related to seed imbibition and dormancy [218]. In modified desiccation-tolerant plants, cell recovery on rewatering is far slower and can require several hours or even days. Normally it takes a shorter time in homoiochlorophyllous than in poikilochlorophyllous species. This is because in these latter plants, the entire photosynthetic apparatus had to be reconstructed during rehydration. In poichilochlorophyllous resurrection plants, an intensive respiration (rehydration respiration) starts early on rewatering and characteristically lasts up to 30 h [242]. During this period, the whole recovery of mitochondria occurs, whereas 3–8 days are required to rebuild well-structured and fully functional chloro-

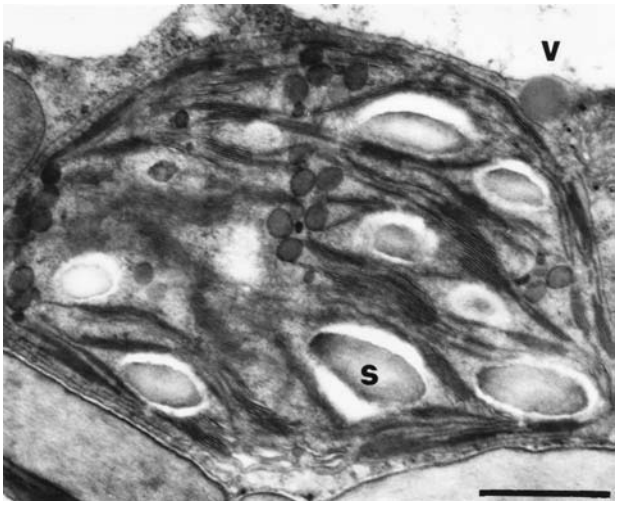

Figure 7 Well-organized bundle sheath chloroplast in a fully rehydrated cell of a desiccation-tolerant leaf of *Sporobolus stapfianus* (s = starch, v = vacuole) (bar = 1 μm). (From Ref. 233.)

plasts [242,252,270,291,302]. In homoiochlorophyllous species, the dark respiration is restored within few hours of rewatering [241], and chloroplasts reach the height of their functionality in 1–2 days [252,290].

At the beginning of rehydration, all the desiccation-related proteins synthesized during cell drying disappear in *C. plantagineum*, whereas the transcription of new rehydration-specific genes is activated [302]. Since these rehydration genes essentially codify for components of the photosyn-

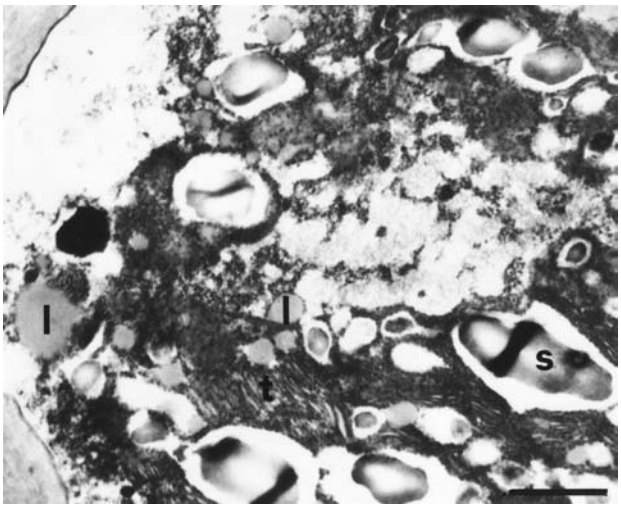

Figure 8 The rehydrated bundle sheath cell of desiccation-sensitive leaf of *Sporobolus stapfianus* shows widespread chloroplast remnants in a dismantled cytoplasm (l = lipid-like inclusions, s = starch, t = thylakoids) (bar 0 1 μm). (From Ref. 233.)

thetic apparatus, such as the Rubisco small subunits (SSU) and a chl *a/b* binding protein, and for enzymes such as a transketolase, the molecular events which occur on rehydration are not related to repair mechanisms but only contribute to a rapid restoration of the metabolism. Thus, in this species as well as in other higher resurrection plants, the desiccation tolerance seems essentially to depend on the events occurring during the dehydration phase. In *S. stapfianus* [233] cells dried in conditions which induce desiccation tolerance totally recover their original organization on rewatering (Fig. 7), whereas cells which cannot activate tolerance mechanisms during dehydration undergo dramatic damage when remoistened (Fig. 8).

Constraints by Water Stress on Plant Growth

Francisco I. Pugnaire

Almeria, Spain

Luis Serrano and José Pardos
Universidad Politécnica
Madrid, Spain

INTRODUCTION

In regions where temperature allows plant growth, water is among the most limiting factors for plant productivity and growth rates are proportional to water availability. Because of its essential role in plant metabolism, at both the cellular and whole-plant levels, any decrease in water availability has an immediate effect on plant growth, and processes ranging from photosynthesis to solute transport and accumulation are seriously affected (Fig. 1) [1]. Plants are generally subjected to shortages in water availability varying in length from hours to days. Water lost by transpiration causes transient water deficits even in plants growing in wet places, so that most plants suffer at least regular and daily water shortages [2]. When drying soil causes water absorption to lag behind loss by transpiration, permanent water deficits develop that may result in permanent wilting and death by dehydration. Therefore, most plants must deal with some water stress. Plants have evolved physiological responses as well as ecological strategies to cope with water shortages by either stress avoidance or stress tolerance. These responses allow them to survive and even to maintain some growth under very harsh circumstances [3].

Water stress has been defined as the induction of turgor pressure below the maximal potential pressure [4,5]. The magnitude of such stress is determined by the extent and duration of the deprivation. Therefore, plant responses depend on the nature of the water shortage and may be classified as (a) physiological responses to short-term changes, (b) acclimation to a certain level of water availability, and (c) adaptations to drought. Short-term responses to water stress, acting within seconds after the onset of stress, are primarily linked to stomatal regulation, thereby reducing water loss by transpiration and maximizing CO_2 intake. An optimum efficiency in this process would lead

Marcel Dekker, Inc.

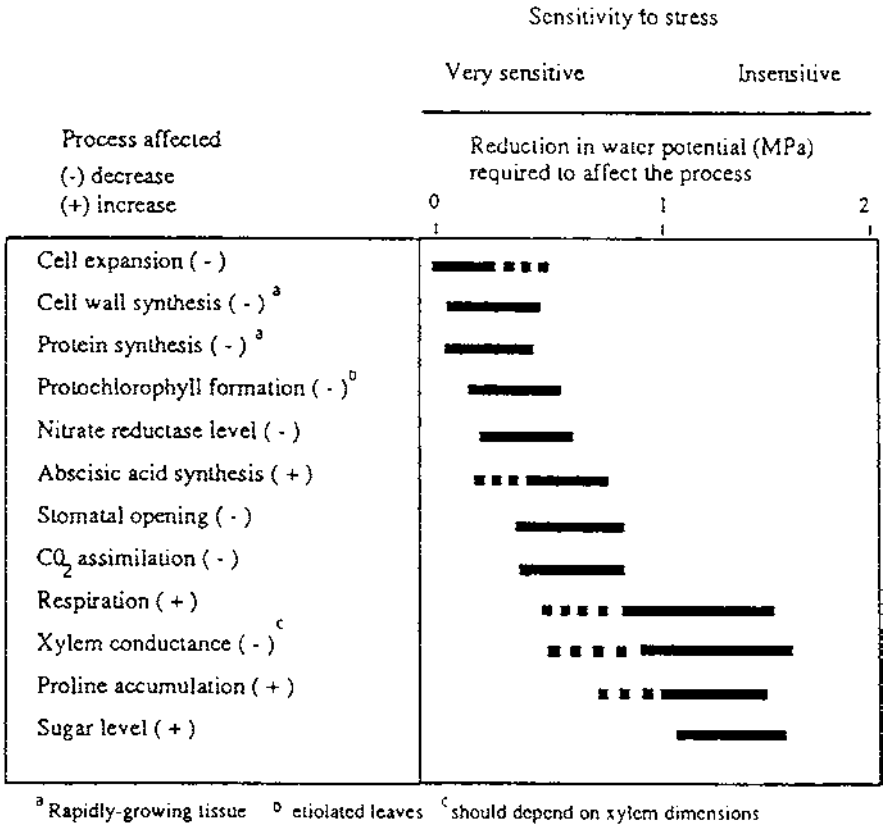

FIGURE 1 Relative sensitivity to water stress of various plant processes. The solid horizontal bars indicate the range of stress levels within which a process is first affected; the broken bars refer to the portion of the water potential range in which the response is not well established. (From Ref. 1.)

to a constant ratio of transpiration to photosynthesis [6]. Midterm responses (acclimation) include the adjustment of the osmotic potential by solute accumulation, changes in cell wall elasticity, and morphological changes. Long-term adaptation to drought includes genetically fixed patterns of biomass allocation, specific anatomical modifications, and sophisticated physiological mechanisms, with an overall growth reduction to balance resource acquisition [7,8].

EFFECT OF WATER STRESS ON NUTRIENT UPTAKE

Nutrients are less mobile in a drying soil, because the pores between soil particles are replaced by air and the pathway from the soil to the root surface is less direct [9]. Since the rate of ion diffusion to the root is very often the step limiting nutrient uptake, a decrease in soil water availability can affect plant growth. Whenever water stress limits growth more strongly than it limits nutrient uptake, tissue nutrient concentrations are higher than if water stress limits nutrient uptake more than growth [10]. Normally, the concentrations of growth-limiting nutrients decline during water stress, showing

that the indirect effects of soil water content on nutrient uptake may be as important as the direct effects of water stress on plant growth [8].

CONTROL OF STOMATAL CLOSURE

Gas-Exchange Dynamics

A certain degree of water stress is generally experienced by plants irrespective of life cycle and habitat [2]. Particularly in trees, the decrease in water potential may be greater, since hydraulic resistance increases through embolism in the xylem. The plant water content recovers at night, equalizing the soil water potential and allowing the plant to reach its highest water potential just before dawn.

In light, stomata open and begin to lose water; the leaf reaches its lowest water content when transpiration is maximum near midday. Stomata have a high capacity of response to changes in the plant water status, and they close as the leaf water potencial decreases. They are even more sensitive to changes in atmospheric humidity [11,12], however, and they close as the vapor pressure deficit between the leaf and the air increases (Fig. 2). Stomatal response to ambient humidity is a species-specific trait of the guard cells [4]. Since stomata are the way by which CO_2 enters the leaf, the changes that water stress induces on stomatal apertures affect CO_2 intake and assimilation and therefore plant growth. Apparently the evolution of leaf structures favorable for high rates of photosynthesis had more survival value than that of structures favorable to low rates of transpiration except in

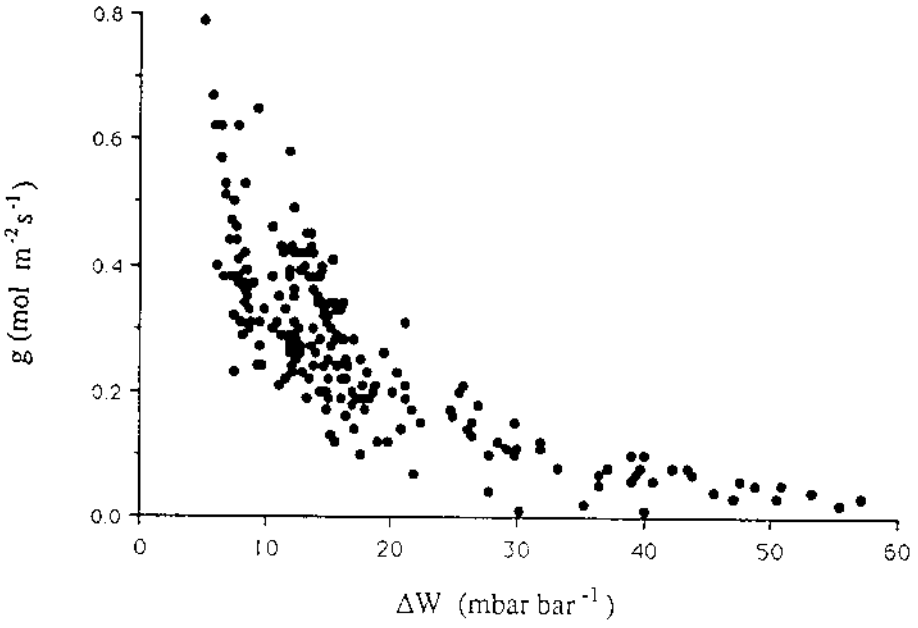

FIGURE 2 Decrease in stomatal conductance (g) as leaf-to-air water vapor mole fraction difference (ΔW) increased in field-grown Eucalyptus globulus trees. Conductance and ΔW were measured at midday between February and December 1991. Temperature ranged from 21 to 40°C and dawn water potential from −0.21 to −2.6 MPa during this period. (From L. Serrano and J. Pardos, unpublished observations.)

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

very dry habitats [13]. Stomatal opening is affected by the CO_2 concentration, and responses of isolated pairs of guard cells suggest a sensing mechanism that responds to low levels of internal CO_2 [14]. Under water stress, internal CO_2 drops in the stomatic chamber, thereby decreasing CO_2 assimilation. Since water stress directly affects photosynthetic capacity at the chloroplast level, the stomatal limitation to growth is presumed to be modest [15]. However, the stomatal or nonstomatal inhibition of photosynthesis is still a controversial topic [6].

Many trees often reach xylem pressures close to that provoking cavitation [16]. This small safety margin between minimum pressures experienced by trees and that at which cavitation is initiated induces a reduction in the transpiration rate and consequently in the stomatal conductance [17].

The process of cavitation involves a restriction on xylem pressure and a decrease on hydraulic conductance that affects the stomatal response to water stress in order to regulate leaf water potential [18]. Changes in stomatal conductance related to cavitation tend to match the progressive reduction in leaf-specific hydraulic conductance. Under these conditions, plants avoid an uncontrolled reduction in leaf water potential that otherwise would cause cavitation to continue until all xylem is embolized [18,19].

When water content in the soil diminishes, cavitation could be interpreted to be an adaptive mechanism having important implications in the control of water use [18].

Role of Growth Regulators

There is substantial evidence for the physiological role played by abscisic acid (ABA) in the regulation of the stomatal aperture [20]. Endogenous ABA increases after a period of wilting, and when applied to plants, ABA strongly inhibits transpiration. It has been hypothesized that ABAs accumulation in leaves during water stress is responsible for stomatal closure, but its overall role at the whole-plant level is still not clear. Some aspects concerning the form (free or conjugated) and location of ABA within the mesophyll cells (mainly determined by pH) must be taken into consideration.

The stomatal aperture is regulated by ABA, which is synthesized in the cytosol and accumulates in chloroplasts of the mesophyll cells [21]. Water stress results in the release of the accumulated ABA to the apoplast, from which it is carried by the transpiration stream through the leaf to the guard cells [15]. Epidermal water relations have been suggested [22] as modulators of the responses of stomata to ABA. Environmental factors and plant development also influence the process, so N-deficient media increase the release of ABA, with older leaves being more responsive than younger ones [23]. Plants with dried root systems may exhibit increased stomatal resistance despite unchanged leaf water potential, indicating that this reaction is the result of a hormonal sign sent by the roots to the shoots [24–27].

Other growth regulators influence stomatal opening. Cytokinins open stomata, but usually in environmentally stressed plants (e.g., with some nutrient deficiency) [28], and both cytokinins and auxin antagonize the action of ABA [27].

Overall, water stress triggers a change in hormonal balance, including an increase in leaf ABA and/or a decline in cytokinins. The increase in leaf ABA reduces cell wall extensibility and therefore causes a decline in leaf elongation. In other plants, the altered hormonal balance reduces root hydraulic conductance and tissue turgor, thereby reducing leaf growth. Regardless of the mechanism by which it is achieved, the decline in growth reduces the plant demand for carbon, so carbohydrates accumulate and photosynthesis declines to match the reduced requirement for carbohydrates. These rapid changes in response to environmental stress serve as an early warning system that reduces plant growth and alters allocation before there is a severe imbalance in C- and N-containing metabolites [8,29].

TURGOR AND GROWTH

Because plant growth is the result of cell division and enlargement, water stress directly reduces growth by decreasing CO_2 assimilation and reducing cell division and elongation. The effect of

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

water stress is more evident on cell wall expansion [13], because cell enlargement involves the extensibility of the cell wall under turgor pressure. Therefore, any loss in turgor pressure as a consequence of the imbalance in the plant water content could result in reduced growth and even in the total absence of growth under dry environmental conditions. Nevertheless, the relationship between turgor loss and cell enlargement is unclear [30].

Cell growth rate, Gr, can be expressed as a function of turgor pressure, P, and the extensibility coefficient, Φ, by the equation

$$\mathrm{Gr} = \Phi\,(P - Y)$$

where Y is the yield threshold pressure [31]. The equation shows that growth rate decreases as P decreases, but it could also be maintained if either Φ increases or Y decreases. Therefore, reduced growth rate may not rely only on reduced turgor caused by desiccation [32]. There is some evidence of reduced growth without loss of turgor in plants subjected to desiccation stress [33], but this reduction may be part of the osmotic adjustment process [34]. Some mechanism may control cell wall extensibility through the perception of soil dryness [32], giving rise to smaller plants and, hence, lower water requirements and higher survival.

RESPONSES TO DROUGHT STRESS

Conversion of light energy into carbon-based energy implies loss of water. Indeed, water loss is considerably greater than C gain on a molar basis, because the diffusion gradient from water vapor in the leaf to the atmosphere is steeper than the gradient in CO_2 from the atmosphere to the leaf. Therefore, plant adaptations dealing with water conservation have a special meaning in dry environments when water stress is either permanent or temporary and severely limits plant growth. Since a large proportion of the Earth's surface is arid or semiarid, and since even in temperate regions, those environments with a Mediterranean-type climate suffer seasonal water stress, the distribution of natural vegetation and yield of cultivated plants are largely restricted by water availability. Plants living in such environments have adapted by increased drought tolerance and water use efficiency.

There are a number of modifications in plant structures and processes as a consequence of drought stress. These include sensitivity of stomatal response, osmotic adjustment, smaller cell volume, reduced leaf area, increased leaf thickness, hairy leaves, and increased root-shoot ratio, as well as several changes in enzyme and hormone production and activity.

Depending on their response to drought, plants may be classified as drought avoiders or drought tolerators [3,13,35]. Drought-avoidance strategies include short seasonal cycles, as in desert annuals, or earlier maturity, as in C_3 grasses in Mediterranean climates [36]. The drought-tolerance strategy includes either dehydration postponement or dehydration tolerance.

Drought Avoidance

Plants avoiding drought show adaptations leading to the acquisition of the maximum amount of available water or restrict their activities to the periods of water availability. A greater allocation to roots is a main feature of drought-avoidance plants in dry environments where roots consist of 60–90% of plant biomass. In contrast, in coniferous forests, the root biomass is 21–25%, and this figure reaches 30–40% in drier, tropical savanna woodlands [4]. With decreasing water availability, root growth is enhanced at the cost of aboveground biomass production [7,37].

Under well-watered conditions, plants extract water very intensively from the upper soil layers; deep rooting and subsoil water extraction become increasingly important under limited water supply. Perennial shrubs in dry habitats usually have unbranched root systems tapping water to 30 m below the surface [38,39]. In tropical savanna grasslands and North American prairies, the pattern of rooting is a profuse branching in the top layer of soil and deep roots, so that water and nutrients are efficiently absorbed from the top soil layers during wet periods and deep stored moisture is

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

tapped during the dry season [4]. Root growth and distribution follow the water reserves of the soil, but severe drought may promote initiation and elongation of lateral roots [40]. As a consequence of greater root allocation, aboveground biomass is smaller and the growth rate is decreased to reduce overall resource requirements [8,41]. Most plants adapted to dry environments also have mycorrhizal symbiosis, which improves water and nutrient supply but is also a sink for carbohydrates and may consume 5–10% of total photosynthate [42,43].

Among the plant adaptations to water stress, leaf modifications are especially important [44]. Since the diffusive resistance offered by a leaf to CO_2 uptake is greater than that offered to water loss, any change in the resistance of the common part of the pathway has a greater influence on the transpirational loss of water than on CO_2 intake. Therefore, many species have features that favor photosynthesis over transpiration by increasing the diffusive resistance of stomata using depressions in the epidermis, pores, or cutin or waxes. [4]. By reducing their evaporative surface, plants may reduce water loss, and for this reason, leaves tend to be smaller (Fig. 3) and thicker in dry habitats [45] but maintain a high photosynthetic rate [46]. Also, by reducing leaf size, the convective heat flux to the atmosphere is increased, and by adjustment of leaf angle, the interception of solar radiation can be reduced [47]. Leaf pubescence is a feature of dry habitats that increases light reflectance, decreases leaf temperature, and allows the leaf to gain a higher rate of carbon under arid conditions than the leaf could acquire without hairs. Pubescence also allows the plant to avoid potentially lethal high leaf temperatures and to lower daily water loss, allowing the plant to extend its growth for a longer period into the drought [48]. All these mechanisms help to maintain the leaf energy balance and tend to optimize plant growth and functioning.

High water use efficiency (expressed as a ratio between A and E) could be considered as an adaptive feature of plants submitted to extended periods of drought or growing under competition [49]. Variations observed in A and E after environmental changes occurring as a consequence of stomatal regulation can be optimized when a constant ratio is maintained through time [50]. This optimal stomatal behavior might be seen as one of many possible functional adaptations against drought [17]. However, this only has been confirmed in some species [12,51].

Sclerophylly is regarded as being a typical feature of Mediterranean-type plants and is interpreted as an adaptation to drought [52,53]. However, similar sclerophyllous plants differ broadly

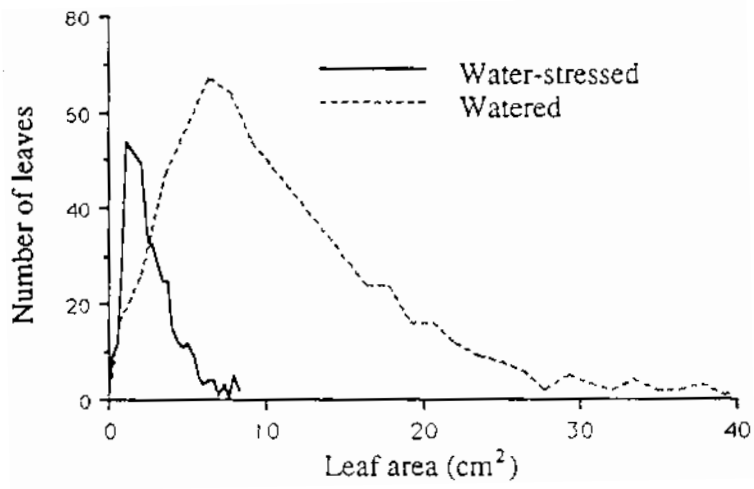

FIGURE 3 Frequency of leaves by size in clonal plants of Eucalyptus globulus after being watered and after several cycles of drought reaching the wilting point. (From L. Serrano and J. Pardos, unpublished observations.)

in water relations [54], leading to the hypothesis [55] that sclerophylly cannot be considered significantly related to a drought-avoiding strategy but rather to nutrient limitation [56]. Wax of sclerophyllous leaves keeps cuticular transpiration at a minimum once stomatal transpiration and CO_2 exchange have ceased, thereby conserving water. Since the production and maintenance costs of schlerophyllous leaves are higher than the costs of more mesic leaves [57], the slow growth of Mediterranean evergreen shrubs may be partially due to a greater investment in leaves along with resource limitation.

Drought deciduous shrubs (the most characteristic desert group) rely on morphological changes in the quality and the quantity of their foliar biomass to remain metabolically active through most of the year. Typically, these species develop a relatively large canopy of mesomorphic leaves when water is available and therefore maintain a relatively high rate of productivity. These leaves are replaced by smaller and more xeromorphic summer leaves as seasonal water stress increases [58]. These changes in total canopy leaf area reduce sharply the productivity of xeromorphic plants. However, the increase in water use efficiency (WUE), combined with adaptations in tissue water relations, allows photosynthetic activity through all but the most extreme water stress. Early shedding of leaves during drought often prevents death by desiccation in tropical and temperate zone woody plants [6]. A gradual leaf fall seems to be an adaptation in water stress–prone environments to maximize photosynthetic gain and nutrient cycling [59]. The capacity for leaf shedding during drought varies appreciably among species, but because water deficits frequently limit the growth and survival of trees, selective pressure for adaptation to drought is often high [6]. Because nutrient cycling and nutrient use efficiency are related to leaf fall [60,61], water stress at the time of leaf shedding may severely affect the plant's nutrient budget by decreasing nutrient resorption from leaves [62]. Leaflessness is another feature of dry habitats that allows for a reduced water loss, relying on photosynthetic stem tissues. Cortical stem tissue is structurally very similar to leaf tissue but maintains a net positive rate of photosynthesis even in drought-stressed shrubs and allows a quick recovery from herbivory [63].

Dehydration Postponement

Increased stomatal sensitivity is a functional mechanism that allows plants to maintain high water status during drought periods. This response occurs as a consequence of various events: soil water depletion, increase in the vapor pressure deficit (VPD) in the atmosphere, or both together [17].

The effect of water stress acclimation has been shown in different species to be a further reduction in stomatal conductance [64]. Other species exhibit a variation in stomatal conductance concomitant with changes in VPD and no great variations in leaf water potential [12].

Stomatal closure, although an effective means of postponing dehydration, can reduce photosynthesis to below the compensation point and, especially in dry environments, may cause heat imbalance because of the reduced transpiration rate and photoinhibition [65,66]. Furthermore, no general statement can be made concerning the adaptive value of sensitivity of guard cells to ambient humidity [67], since the response to humidity in a large number of species surveyed was not related to their natural habitat [68]. Thus, changes in the stomatal sensitivity are quite variable; nevertheless, they can be considered as an adaptive response to drought which is species-specific [4].

Metabolic adaptations to water stress cause plants with different photosynthetic pathways to differ in their sensitivity to atmospheric humidity and the resultant gradient in water vapor pressure from leaf to air. Clearly associated with dehydration postponement are CAM and C_4 photosynthetic pathways.

In CAM plants, the daytime closure of stomata combined with dark fixation of CO_2 reduces water loss without limiting photosynthesis. CAM plants, mostly desert succulents, show the highest water use efficiency but the lowest growth rate. Nevertheless, the productivity of some CAM plants may be high, for example, *Opuntia ficusindica* in Mexico and Chile (47 ton ha^{-1} $year^{-1}$) or some *Agave* species (38–42 ton ha^{-1} $year^{-1}$), which surpass the average 30–40 ton ha^{-1} $year^{-1}$ of such crops as wheat, sugar beet, and alfalfa or many tree species over a range of productive soils [69].

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

The C_4 species evolved as a response to a reduction in atmospheric CO_2 levels that began during the Cretaceous era and continued until the Miocene [70]. Stomata of C_4 species are less sensitive to a desiccating atmosphere than those of C_3 plants, which would provide a greater C gain in low-humidity atmospheres [71]. The ecological advantage of a C_4 photosynthetic pathway is still unclear even though it allows a greater WUE than in the C_3 species [72]. Plant traits other than those related to the photosynthetic pathway should be responsible for the adaptation of some C_4 species to dry habitats [67,73]. When water and N are available, C_4 plants show a high growth rate, and photosynthetic N use efficiency is highest [46]. When limited in either of them, however, C_4 productivity is lower than in ecologically similar C_3 species [72].

Water storage is generally of little importance in drought avoidance because of the high leaf water turnover. Only in a few plants, such as baobab (*Adansonia digitata* L.) and saguaro (*Carnegia gigantea* L.), is water stored in a significant amount [13]. In general, the cost of water storage is high, and most plants have little or nothing in terms of water-storing structures [74].

Dehydration Tolerance

During dry periods, plants may delay dehydration, but as drought continues, dehydration may become severe, causing injury and death. Dehydration tolerance is a species-specific trait, ranging from -1.2 MPa in aquatic plants to -10 MPa or higher in some xerophytes, but differences in species tolerance are not well understood [13]. Many species of algae, lichens, and mosses, as well as some 70 higher plant species, can be air dried and later recover [75].

Dehydration usually causes severe damage and disorganization of membranes and organelles, mechanical rupture of protoplasm, degradation of cell membranes, protein denaturation, and gene mutations. Chlorophyll content remains relatively unaffected by water stress, but the content of proteins, glycolipids, and phospholipids in chloroplasts generally decreases [76]. Damage caused by desiccation particularly affects photosystem II [77]. Reduction in C assimilation by water stress is also caused by the decreased activity of many enzymes of the Calvin cycle. This effect is completely reversible as long as the water stress is not too severe [78]. The activity of nitrate reductase is also depressed [79] and dark respiration enzymes are enhanced, so that dissimilation processes are more than doubled.

Different experiments have indicated that desiccation tolerance involves changes in the viscosity of the cytoplasm during drought hardening, the protection of membrane properties by the release of organic solutes, and a reduction in the number and reactivity of thiol groups carried by macromolecules [4].

A means of increasing drought tolerance is by decreasing osmotic potential by accumulation of solutes, so that turgor and turgor-dependent processes may be maintained at a significantly lower water availability. This osmotic adjustment allows cell enlargement and plant growth at high water stress and keeps open stomata and CO_2 assimilation at otherwise inhibitory levels [13]. However, evidence indicates that osmotic adjustment may maintain growth only for short periods of time and may not contribute greatly to continued leaf growth in water-stressed plants [80] or play a major role in the distribution of the species [81]. Nevertheless, osmotic adjustment can accomplish two functions: (a) extend the lifetime of active tissues between ephemeral showers and (b) extend the period of tissue preparation for drought (drought hardening) [71]. Furthermore, although stomatal control or reduction in leaf area gives an almost certain reduction in productivity, osmotic adjustment provides the potential for maintaining photosynthesis and growth of at least some parts of the plant as the water deficit increases. Thus, in terms of growth, the cost of osmotic adjustment must be lower even though the solute accumulated cannot be used elsewhere [35]. Osmotic adjustment is reversed when water stress is removed and may reach up to -0.7 MPa in daily changes, although values of -0.1 MPa are more usual [35,80]. It seems that there is a metabolic ceiling for each species [80].

Many solutes may be used in osmotic adjustment. Inorganic ions, such as Na^+, K^+, and Cl^-, accounted for most of the osmotic potential in several species [82,83], but sugars and amino acids,

especially proline [84,85], are major osmoregulators in vascular plants [86]. The reason is probably the convenience of osmolyte storage in large, osmotically inactive molecules, such as starch or protein, which may serve several functions and from which they can be retrieved under conditions of stress. It appears that neither the synthesis of new compounds nor biochemical pathways are involved during osmotic adjustment [35]. Rather, it appears that the disturbance of normal metabolic pathways by water stress is responsible for producing the solutes involved in osmotic adjustment.

Some studies have indicated that the degree of drought tolerance is associated with the ability to undergo changes in the cell elastic properties. A drought-induced increase in the bulk modulus of elasticity, ϵ, would permit the maintenance of a large water potential gradient through the soil-plant-atmosphere continuum, with little change in the relative water content [87], therefore increasing the ability to extract soil moisture from progressively drier soil. Although increases in ϵ have been observed in response to drought stress [88], seasonal patterns differed among wild plants under the same environmental stress [54] and were inconclusive in cultivated plants [81].

CONCLUSIONS

Generally, the daily or seasonal water stress to which a plant is subjected induces a range of plant responses that depends on the extent of the water shortage. Water stress causes primarily stomatal closure, decreasing assimilation and therefore growth. Water stress also reduces plant growth by reducing cell division and enlargement and causes a decline in ion transport to the root surface, which leads to a further decrease in plant growth.

Multiple responses allow the plant to tolerate water stress. These range from stomatal sensibility to soil and atmosphere dehydration to changes in cell wall elasticity and osmotic adjustment. In plants adapted to dry environments, anatomical and morphological changes at the leaf and whole-plant levels (such as reduced leaf size, hairy leaves, sclerophyll, or higher allocation to roots) prevent metabolic imbalance and help to improve water relations. These adaptations impose a cost on plant growth, with the overall effect of reducing growth to match all levels of resource acquisition. The C_4 photosynthetic pathway may have some remarkable advantages in water-limited environments, but CAM plants represent a higher degree of plant adaptation to dry environments.

Nutrient Uptake by Plants Under Stress Conditions

SYED MANZOOR ALAM
Nuclear Institute of Agriculture
Tando Jam, Sindh, Pakistan

INTRODUCTION

The term *stress* is defined as an environmental change that tends to inhibit the normal cycle systems from functioning. Plant species or varieties differ in terms of their optimal environments and their susceptibility to particular stress. Some workers prefer to consider as stressful only those environments that actually damage the plants and cause a qualitative change, such as membrane damage or cell death, whereas others consider that in stressed systems, energy expenditure is increased or potential energy of the system is decreased. Commonly, plants are considered to be under stress when they experience a relatively severe shortage of an essential constituent or an excess of a potentially toxic or damaging substance.

The external constraints or form of stresses may be biotic (e.g., pests or diseases) or they may be physical and related to shortage or excesses in the supply of solar energy, water, mineral nutrients, and/or atmospheric pollutants. Sometimes the stresses are chronic and sometimes they are imposed for short periods.

Stress factors do not usually operate alone, so that interactions between the covariation of stresses are the norm in the natural environment. Stress may also have a greater damaging effect during certain phases of the plants life cycle than others. Seedlings establishment and floral development are often particularly sensitive. To predict the impact of stress on plants, we need to know something about (a) the temporal variation in stresses, (b) the plant's potential to acclimatize to stress, and (c) interactions between different stresses and the plant responses. In both natural and agricultural communities, the environment is seldom optimal for plant growth. Environmental stress limits the overall productivity of agricultural crops. It is a well-documented fact that maximum growth potential of horticultural and agronomic crops seldom is attained under natural conditions because of limitations imposed by large seasonal fluctuations in light, moisture, high soil temperature, high soil strength, flooding, cold, heat, low soil oxygen, acid soil complex, salt toxicities, imbalance of nutrients, combination of Al-Mn-H toxicities and/or deficiencies of Mg-Ca-K-P, soil pH, climatic changes, and other environmental stresses [1]. Moreover, most natural environments

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

are continuously suboptimal with respect to one or more environmental parameters, such as water or nutrient availability.

At present, most research on the physiological responses of plants to environmental stress has focused on the responses of plants to specific stress. For example, plants adjust osmotically in response to salt and water stresses, increase their potential to absorb nutrients in response to nutrient stress, and alter the quantity and balance of photosynthetic enzymes in response to shade or light stress.

Soil is a basic anchor to support plant growth, and it is one of our most valuable natural resources. When properly fertilized, a handful of soil gives a meaningful crop yield. Many soils are fragile, especially in tropical areas, and overuse generally leads to a continuing problem of millions of hectares of land every year becoming unproductive and affecting the growth of plants. The amount of a nutrient that a plant may need for growth and reproduction varies among plant species and/or varieties. A common perception is that plant response to insufficient nutrient supply involves physiological changes that are unique to nutrient stress. Nutrient uptake by crop plants grown in soil is greatly influenced by root morphology, soil properties, climate, cultural and management practices, and plant species [2,3]. Similarly, soil water potential at the soil-root interface appears to be the main soil characteristic controlling the availability of soil water for plant growth, and nutrient concentrations at the root surface directly control nutrient uptake. It has also been reported that the uptake of water and ions by a plant root creates a concentration gradient in response to which water and ions flow from the surrounding soil to the root [4].

The quantity of a nutrient taken up by a plant generally depends on the configuration and growth rate of the root extension, mean root radius, mean root-hair density, and length of the root. Among the various physiological factors contributing to plant growth, nutrient element availability plays a vital role. However, these factors may simultaneously interact, antagonistically or synergistically, in the nutrient solution, in the soil, in the plant, and or at the root absorption sites of the plants [5,6].

Numerous essential plant nutrient elements are known to regulate the plant metabolism even under stress conditions by acting as cofactors or activators of enzymes. Examples of these are Mg as a component of chlorophyll, Fe as a component of ferridoxin and cytochromes; Zn as a component of glutamic, alcohol and lactic dehydrogenase, and carbonic anhydrase; Cu as a component of laccase, cytochrome oxidase, ascorbic acid oxidase, and polyphenol oxidase; Mn as a component of arginase and phosphotransferase; and Mo as a component of nitrogenase, nitrate reductase, and aldehyde oxidase [7]. The mobilization and utilization of certain mineral elements by plants may be influenced by the adverse or favorable environmental growth conditions.

Mineral stresses include both deficiencies of essential nutrient elements and/or excesses of toxic elements. Mineral nutrients generally play fundamental cellular roles. Likewise, the toxic ions affect injury via the disruption of fundamental cellular mechanism; for example, competition with essential elements for uptake, inactivation of enzymes, and displacement of essential elements from the functional sites [8].

In agricultural productivity, soil fertility is considered to be the status of a soil with respect to its capacity to provide plants with a sufficient amount of nutrients, rate, and balance, needed for optimum growth. Fertility depends on (a) the presence of water, oxygen, and adequate nutrients in the forms the plants can absorb; (b) soil capacity to deliver oxygen and nutrients by mass flow and diffusion to the root surface; (c) the presence of a favorable ionic composition; and (d) the absence of substances that interfere with the movement of nutrients in balanced amounts into roots. The poor soil aeration, which normally indicates an insufficient supply of oxygen to plant roots, generally influences the uptake and utilization of important plant nutrients, such as, for example, N, P, K, Ca, Mg, Fe, Mn, Zn, Cu, B, Mo, Na, and Cl, and all of which are essential to plant growth.

Many nutrient elements are actively taken up by plants. Potential energy is required for active uptake of nutrients, and aerobic respiration in the soil system is the chief supplier of this energy. During the period of respiration, oxygen is taken up and carbon dioxide is given off. For adequate

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

aeration, plant roots generally need air in the soil to survive. Warm aerobic soil conditions provide a better environment for the uptake of elements than cool and anaerobic conditions.

The major stresses of the world which are considered to be of massive nature and create gigantic problems on a global basis in the normal growth and nutrient uptake by crop plants are mainly flooding, water stress (drought), and salinity, which are discussed below.

STRESS AND ITS EFFECT ON NUTRIENT UPTAKE BY PLANTS

Flooding—Induced Stress

Flooding stress results in extensive destruction or impairment of goods, services, health, and crops. The growth, distribution, and cultivation of crop plants are controlled chiefly by too little or too much available water. Temporary or continuous flooding with either fresh or brakish water is very common for cultivation of crops throughout the world, with about 72% of the Earth's surface being covered by submerged soils [9]. It is a well-established fact that for most agricultural crops and native species not adapted to wetland conditions, flooding the soil reduces the shoot and root growth, dry matter accumulation, and final crops yield [10–16]. When a soil is temporarily flooded, a number of physical and chemical changes can take place, any of which may profoundly influence the soil properties, which ultimately reduces the growth of plants. In addition, the physiological damage arises within the plant roots, because incompletely oxidized metabolic products may generally accumulate to toxic levels. Plant growth may be severely affected, because root systems deprived of oxygen can no longer perform, energy-requiring processes, such as the active uptake and retention of essential plant nutrients. Flooding damage to plants follows the depletion of dissolved oxygen from the soil by the respiration of root and soil microorganisms [17]. Shortly after they are flooded, plants exhibit sequential changes in metabolism and physiological processes. Reduced absorption and closure of stomata leading to a lowered rate of photosynthesis are among the earliest plant responses to flooding [18]. Subsequent changes include decreased permeability of roots [19], reduced or increased mineral uptake [20–24], alterations in growth hormone balances [25–29], lowered the permeability of roots to water [30–35], leaf epinasty, chlorosis, and abscission [36].

A further complication is that, in a flooded soil, the soil population of microorganisms, reacts vigorously to a deficiency of lifesaving oxygen. But on the other hand, the potentially inhibitory concentrations of carbon dioxide, hydrogen sulfide, methane, ethylene, manganese, iron, sulfate, and many organic substances may accumulate abnormally in large concentrations and lead to plant damage as a result of a reduction in the oxygen level [37,38].

Flooding stress causes an increase in abscisic acid (ABA) that could be responsible for changes in growth [39]. After reduction in the growth rate, there are decreases in the potential to absorb nutrients, concentrations of photosynthetic enzymes, rate of photosynthesis, root hydraulic conductance, tissue water potential, and turgor [39].

The ways in which flooding influences plant mineral nutrition are very complex, being determined by several concomitant flooding effects on the soil, initial soil conditions, and nutrient absorption mechanisms, as well as other physiological processes and responses of the particular plant species under study. It has been reported that soil flooding stress may severely reduce water and ion uptake directly by increasing the permeability of roots to water and indirectly by reducing the size and volume of the plant roots, as well as by decreasing the ion uptake per unit weight of roots. Such uptake implies a disruption in root metabolism [40] and reducing the effective root surface area available for ion uptake. Much evidence indicates that dysfunction in nutrient absorption by roots under flooding conditions is largely caused by a lack of O_2 and attendant deleterious metabolic effects. The accumulation of dioxygen in the Earth's atmosphere allowed for evolution of aerobic organisms that use O_2 as the terminal electron acceptor, thus providing a higher yield of energy compared with fermentation and anaerobic respiration. For example, in aerobic metabolism, the

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

complete breakdown of one molecule of glucose yields a total of 38 molecules of adenosine triphosphate (ATP), whereas the anaerobic breakdown of this same glucose molecule to ethanol and CO_2 yields only 8 molecules of ATP [41]. Oxygen stress may inhibit guttation either by increasing the root resistance to water movement or by inhibition of ion transport to the xylem and arrest of vegetation and reproductive growth.

In addition, ammonia volatilization, denitrification, and leaching can lead to a major loss of nitrate from the soil solution [11,42–46], so that plants may suffer from nitrogen-deficiency symptoms. It is considered to be true that the N decline in plant parts reflects a lack of carbohydrate, which is a situation that delays conversion of NH_4^+ to the amines. Nitrogen leaching losses reported from pot studies range from 11 to 60% for ammonium sulfate, and about 4–30% in field studies under wet soil condition [14]. The larger losses might be expected with urea, but measured only 17% loss from a basal urea application in the flooded field.

The reduced uptake of nitrate as a result of the effects of low O_2 tension on root metabolism also appears to play an important role in reducing nitrogen levels in flooded plants. In waterlogged soils, slowing down of shoot and root growth was more closely related to the declining O_2 concentration in the soil solution than to the concentration of dissolved inorganic nitrogen [47]. In waterlogged soils, there is a rapid depletion of NO_3^- N, as free O_2 is quickly consumed by soil biota, anaerobic conditions develop, and loss of active soil N is freely promoted through denitrification. The normal aerobic N cycle is arrested in the mineralization stage in anaerobic soils, since oxygen is not available for oxidation of NH_4^+ to NO_3^- except in the oxidized layer [48]. This situation encourages in the presence of an excess of NH_4^+ in the anoxic layer. Flooding enhanced ammonification of soil N but retarded the nitrification process. On the other hand, under aerobic conditions, the NH_4^+ form of soil mineral N is oxidized to NO_3^-, which may accumulate in the soil or be utilized by crops from there [49].

Flooding of soybean plants grown on Crowley silt loam at R_2 growth stage adversely affected N nutrition in terms of concentration and total amount accumulated. The soybean plants recovered from this effect 2 weeks after the floodwater was removed [50]. The decrease in the accumulation of N by shoots of legumes in waterlogging soil is partly the consequence of the reduced nodulation of the roots by nitrogen-fixing bacteriods (*Rhizobium* spp.) [51]. For maize plants, diminished N uptake, proved to be a major limiting factor, its concentration generally decreased to the maximum extent, and deficiency symptoms appeared on the tops within 2–3 days of initiation of flooding stress. Brown et al. [52] found that soil moisture contents from 20 to 50% by weight resulted in a significant decrease in N uptake by soybean. Constable and Hearn [53] noted the coincidence of visual symptoms of flooding and reduced rates of N uptake. Cotton plant susceptibility to flooding may be due to a lowered soil oxygen supply or to reduced availability and uptake of N [54]. Flooding and the occurrence of prolonged soil moisture content above the field capacity suppressed the accumulation of N by cowpea (*Vigna unguiculata* L.) [55] as a result of decreases in O_2. Singh and Ghildyal [56] attributed part of the reduction in N concentration in corn shoots to reduced NO_3^- availability in the soil. In an experiment, Sallam and Scott [50] found N concentration of the whole soybean plant to be decreased immediately after flooding and remained lower in the flooded than in the nonflooded soybean plants for the first 3 weeks following the flood. Because nitrates may be quickly lost during flooding and mineralization is slow down at high soil water pressures following flooding, N deficiency was probably at least partially responsible for the slow recovery of the growth.

In a series of experiments, Drew and Lynch [57] studied growth and nitrogen-uptake patterns of wheat subjected to several anaerobic regimens. Waterlogged wheat plants exhibited reduced nitrogen concentration, chlorosis, and generally accelerated senescence of older leaves, with the latter two occurring with the onset of remobilization of N from old to young leaves [58]. Generally a lack of O_2 in the root environment causes an immediate decrease in nutrient uptake and redistribution of N from older to younger leaves [8].

Under conditions of low N availability, there was a decline in leaf allocation and water uptake as a result of decreased demand by the plants [40]. The concentration of N in the leaves, stems,

and branches were lower in the flooded soybean than in the nonflooded soybean plants [50]. On the other hand, the pods of the flooded soybean plants had higher N concentrations (4.3–5.1%) than those of the nonflooded soybean plants (3.5–4.60%). Both the N uptake and grain yield of wheat were found to increase linearly with an increase in water use [14]. The flooding of rice generally increased the tissue concentrations of N [20,22]. Primary tillage depth exerted a significant influence on mineral N availability in submerged soil [59]. The addition of NO_3^- to soil apparently prevented flooding stress in barley [23], corn [60], and other crops [61].

The crop plants, tolerant of flooding stress, often grow well and take up more available nutrients in response to flooding compared with the well-watered control plants. Such beneficial responses have been reported for rice (*Oryza sativa* L.) plants and for several species of flood-tolerant woody angiosperms and conifers [62]. Several morphological adaptations of flood-tolerant species allow continued nutrient absorption under waterlogging conditions. Many flood-tolerant species initiate vigorous adventitious roots that proliferate most abundantly in the upper, well-aerated portion of submerged soil [62].

It is an accepted fact that, under flooding stress, the N concentrations in plant parts of wheat (*Triticum aestivum* L.) [63], barley (*Hordeum vulgare* L.) [23,34,64], field corn (*Zea mays* L.) [34,56,65–67], pea (*Pisum sativum* L.) [68], cotton (*Gossypium hirsutum* L.) [33], sunflower (*Helianthus annuus* L.) [33], soybean (*Glycine max*. L. Merrill) [13,50], subterranean clover (*Trifolium subterraneum* L.) [67], bent grass (*Agrostis stolonifera* L.) [31], orchard grass (*Dactylis glomerata*), perennial ryegrass (*Lolium perenne* L.), timothy (*Phleum pratense* L.), fescue (*Festuca arundinacea* L.) [69], avocado (*Persea americana* L.) [70], sweet gum (*Liquidambar styraciflua* L.) [71], hackberry (*Celtis laevigata*) [71], and orange (*Citrus sinensis* L.) [72] are reported to be significantly decreased. One contributor to the reduction of N in tissues of flooded plants is that, in waterlogged soils, NO_3^- N is rapidly depleted as oxygen is quickly consumed by soil biota and anaerobic conditions develop. As a result, volatilization and loss of N are promoted through denitrification in which nitrates serve as a terminal electron acceptor for anaerobic microbes [9].

Phosphorus is one of the most important nutrient element in the growth and development of plants. It plays a key role in cellular energy transfer, respiration, and photosynthesis. Phosphorus is present in nucleic acids, phospholipids, and sugar phosphate. A phosphorus deficiency causes immediate and severe disruptions of metabolism and development [8]. Phosphorus is generally present at a very low concentration in the soil solution in comparison with the other essential plant nutrients, and it diffuses only slowly in the soil media. Soil solution P is an immediate P source for the plant, and standard solution P concentration (0.2 mg P/L) provides P adequately for many crops if it is continuously maintained in the growing medium [73]. Soils vary greatly in the amount of fertilizer P required to provide an adequate supply of available P to plants, and plants also vary in their P requirements for optimum growth.

The P composition of flooded plants, like the N composition, is greatly influenced by both soil conditions and plant uptake responses to soil inundation. Where the amounts of soluble P available in the soil are adequate, flooding stress of intolerant plants generally lowers both the tissue concentration and total content of P [74]. Flood-intolerant plants that have shown the lower uptake of P are barley [23], cowpea [55], *Citrus sinensis* [72], corn [65,66], wheat [17], *Helianthus annuus* [33], *Liquidambar styraciflua* [71], maize [66], *Persea americana* [70], ryegrass [69], and jojoba (*Simmondsia chinensis*) [35]. These declines in P concentration have been attributed to the inhibited uptake under anaerobiosis [57]. However, the situation is more complex for soils that are moderately or severely deficient in P. In such well-aerated soils, much P may be held in unavailable forms. When soil is flooded, soil pH moves toward neutrality and soil reduction levels increase; as a result, P can be released from insoluble adsorbed and bound forms [9], thereby becoming more available for uptake by roots. The increase in the concentration of water-soluble phosphate and desorption of sulfate caused by flooding the soils may be the result of a decrease in anion exchange capacity and an increase in the bicarbonate concentration. Hence, if P uptake is not severely limited by the imposed level of anaerobiosis and the levels of soil P before flooding are not inordinately high, flooding can result in temporarily increased plant P content [67].

In addition, some flood-intolerant plants, such as subterranean clover [67], hackberry (*Celtis laevigata*) [71], and pea [68], have been shown to increase the uptake of P from flooded soils. Similarly, plants tolerant to flooding often grow better and take up more P in response to flooding compared with well-watered controls. Such responses have been reported for cereal species and several species of flood-tolerant woody angiosperms (*Fraxinus pennsylvanica, Frs. profunds, Nyssa aquatica, Salix nigra, Acer negundo, A. rubrum, A. saccharinum, Populus deltoides*, and *Platanus occidentialis; conifers* (*Taxodium distichum*); and rice (*Oryza* spp.) [71,75,76]. Reducing conditions that develop when soils are flooded for rice production appear to increase the availability of soil P. Some reports also stated that lowland rice generally responds to P fertilization under flooded condition [77].

The mechanism of P release in flooded soil generally includes the reduction of insoluble ferric phosphate to more soluble ferrous phosphate, release of occluded P by reduction of hydrated ferric oxide coatings, displacement of P from ferric and aluminium phosphates by organic anions, hydrolysis of ferric and aluminium phosphates as a result of the increase in alkalinity, and anionic phosphate exchange between clay and organic anions. It was reported [43] that more soil P was released by reduced soils than by oxidized soils. Plants subjected to prolonged flooding generally have reduced tissue P concentration and total content, because increased P availability cannot compensate for the severe degeneration of the plant root system.

In general, the inhibitory effects of flooding stress on potassium uptake are similar to those for N. Severe inhibition of K uptake characteristically follows soil submergence, and this response may limit plant growth in certain flooded crops. It has generally been reported that on giving flooding stress to soils, the K content in crop plants, such as barley [23,64] wheat [58], corn [65], subterranean clover [67], avocado (*Persea americana*) [70], *Liquidambar stayraciflua* [71], *Celtis laevigata* [71], *Pinus elliotti* [79], *Citrus sinensis* [72], *Gossypium hirsutum* [33], *Simmondsia chinensis* [35], *Dactylis glomerata* [69], *Phleum pratense* [69], *Lolium perenne* [34], sweet gum and hackberry [71], and orchard grass and bent grass [31] generally decreased.

Reduction in K absorption is most likely attributable to the effects of anaerobiosis on uptake mechanisms of roots [30,56,58,80]. If organic matter is available and cation exchange capacity of the soil is low, submergence may increase soluble K somewhat in the soil solution through displacement of exchangeable K from the exchange complex by competing ions [81]. However, the flood-associated increases in K available to the plants are generally too small to overcome the large inhibitory effects of anaerobic conditions on K uptake by crop plants. Some other investigators [82–84] have found greater efficiency of K fertilizer with increasing soil moisture of the growth medium. The K content also decreased even in flooded tolerant rice plants [85]. Lack of K was found drastically to reduce the oxidizing power of rice roots [86].

In a 4-month-old loblolly pine (*Pinus taeda* L.), seedling flooding stress reduced total concentration of N, P, K, Ca, Mg, Zn, and Mn as compared with those grown in well-drained conditions [87]. Flooding stress appears to have much less pronounced inhibitory effects on the accumulation of Ca and Mg than on N, P, or K. Hence, Ca and Mg concentrations are not altered as much by flooding as are those of N, P, and K. However, concentrations may decrease slightly and their total contents decline appreciably because of severely reduced growth. It has been suggested that the absorption of Ca and Mg may be metabolically mediated, and therefore may be dependent on an adequate supply of O_2, but some data suggested that Ca and Mg ions are actively extruded from the plasmalemma [88]. Moreover, based on comparisons of mineral element, analyses of xylem exudate, and culture solutions, Trought and Drew [47] suggested that Ca and Mg were excluded relative to water movement in anaerobically cultured wheat root systems and that the Ca and Mg contents of the exudate could be accounted for by simple mass flow. Accordingly, the lack of close coupling between active uptake mechanisms and Ca and Mg concentrations by crop plants may explain the reduced effect of flooding on tissue concentrations of these two secondary elements. Flooding of rice increased the tissue concentrations of Ca, N, P, and Fe, whereas those of Mg were not significantly altered. On the other hand, the concentrations of Ca and Mg were generally decreased in crop plants, such as wheat [58] corn [66], subterranean clover [67], *Persea ameri-*

cana [70], *Celtis laevigata* [71], *Citrus sinensis* [72], *Helianthus annuus* [33], and *Agrostis stolonifera* [31].

Sulfur occurs in most soil largely in organic forms and is subject to numerous biological transformations. All forms of organic S in soil contribute to S mineralization and greater availability to crops [89]. Elemental S, which is biologically oxidized to H_2SO_4 under aerobic conditions, is often applied to reduce soil pH and dissolve insoluble nutrients [90]. In calcareous soils with low organic matter, addition of organic matter with S stimulates S oxidation [91].

Sulfur deficiency has been recognized as an important growth-limiting factor for both dryland crops and wetland rice [92]. Sulfur deficiency of wetland rice has been also reported in many Asian countries [92]. Sulfate concentrations in most of the soil solutions decreased to 1.8 mg/L within 8 weeks of submergence [93].

Sulfate-containing fertilizers applied to flooded or submerged rice soils may undergo reduction to sulfide in the paddy fields, with the subsequent problem of plant availability and/or H_2S production. Reduced or flooded conditions in the paddy soil may also inhibit the oxidation of elemental S and render this form of fertilizer useless to rice. Incubation studies of S transformations in flooded soils are of limited value in predicting fertilizer reactions in the presence of rice plants because of the modifying effect of oxidized zone adjacent to the rice root. The change in pH range that occurs when a soil is flooded means a drastic change in sulfate adsorption. It is pH dependent, with adsorption being negligible above the pH value of 6.5. The flooding of an acid soil raises the pH to an equilibrium value ranging from 6.7 to 7.2 [94], and at this pH, sulfate adsorption is negligible. Since crop plants can take S only in the sulfate form (SO_4^{2-}), the oxidation state of the S present in the paddy soil is important. Because of the reduction of sulfate to S, the availability of S to rice has been found to be lower under flooded than upland conditions.

It has been found that sulfur uptake from $K_2{}^{35}SO_4$ and $Na_2{}^{35}S$ sources was found to be equal in experiments conducted at the International Rice Research Institute (IRRI) Manila, the Philippines [95]. Blair et al. [92] reported that all the sources of fertilizer S were equally effective for rice growth when applied at transplanting. This contradicts the suggestion of Wang [96] that, ''chemicals containing S, other than sulfate are not particularly useful for rice,'' and shows that the assumption that a rice paddy is anaerobic below the surface-oxidized layer may be incorrect. Gypsum ($CaSO_4$, $2H_2O$) is often considered as an insoluble or slightly soluble sulfate source because of its solubility in chemical terms (241 mg/100 mL cold water). However, a rice paddy covered with 5 cm of water has the capacity to dissolve 1205 kg gypsum ha^{-1}, which is well above the rate used for agricultural and horticultural purposes. Gypsum is a good source of Ca, and an increase in its application increased the leaching of Mg, K, Na, and Mn [97]. Gypsum provided a better soil environment, and it is known to increase the depth of root penetration [98].

Under submerged soil conditions, the iron and manganese solubilities generally increase as first the ferric and manganic forms are converted to the more reduced and soluble ferrous and manganous forms [9]. The change in availabilities of these two elements in waterlogged soils is reflected in increased tissue concentrations by several plants, including wheat [17], cotton [33], and some other flood-intolerant plants [71]. Some workers have not found any change [64] or a decrease [70] in the plant uptake of Fe and Mn. However, the total content of Fe and Mn most often declines because of severely inhibited growth.

Flooding of tolerant plants such as rice also increased the content of Fe and Mn [20,22,99,100]. Uptake of both Fe and Mn increased in French bean (*Phaseolus vulgaris* L.) and maize as a result of flooding, although the reoxidation of the soil affected Fe more than Mn [101]. It appears that a high moisture content, by reducing aeration, causes an increased in the ferrous Fe in the soil solution, which reduces from ferric iron and thus promotes Fe uptake and an increase in the total Fe content of the plant leaf tissue. The reduction of Fe is a consequence of anaerobic metabolism, and it appears to involve chemical reduction by bacterial metabolites. It has been observed that 5–50% of the active ferric iron present in a soil may be reduced within a few weeks of submergence depending on temperature, organic matter content, nitrate concentration, and crystallinity of the oxides. The reduced Fe acts as a sink for oxygen diffusing into the soil and is a source of ferrous ions. The

concentrations of several nutrients (Fe, Mn, Zn, Cu, and P) were higher in mycorrhizal wetland rice than in nonmycorrhizal rice under flooded conditions [102]. Reduced aeration also restricts carbon dioxide escape from the soil causing, in alkaline soils, an increased bicarbonate concentration in the soil solution, which is known to reduce the availability of Fe in the plants. The bicarbonate ion is reported to inhibit the activity of cytochrome oxidase in the roots of soybean (*Glycine max* L.) and spinach (*Spinacea oleracea* L.) [103].

A high soil moisture content caused poor utilization of Fe by peanut (*Arachis hypogaea* L.) from alkaline soil. However, Alam and Azmi [104] have reported an increase in available Fe, Mn, and P in alkaline calcareous soil due to flooding. Factors including poor soil aeration, a high concentration of phosphate, the presence of heavy metals (Ni, Zn, Co, and Cr), extreme light, plant root damage, and viral incidence have also been reported to cause plants to fail either to absorb Fe from the soil or to utilize it efficiently. Couto et al. [105] conducted a glasshouse experiment to determine how soil-reducing conditions would affect plant nutrient availability and uptake by two tropical forage species in a red-yellow latosol. They found that the grass andropogon (*Andropogon gayanus* kunth) and the legume stylo (*Stylosanthes capitata* Vog.) responded differently to reducing conditions. Andropogon showed a low Fe and Mn, P, Ca, and Mg content in the shoots, but an intense coating of oxidized Fe was observed on the surface of roots. The stylo plant, on the other hand, showed no Fe deposition on the root surface but a high Fe content in the shoots. No decreased in P, Ca, or Mg content was observed in this case. They concluded that, in water-saturated soil, reduction took place and plant performance was affected not only by restricted root development but by preventing P, Ca, and Mg uptake in andropogon and increasing Fe uptake in stylo plants.

The amounts of Fe and Mn of the root coating extracted from trees under reduced soil conditions were much higher for the green ash (*Fraxinus pennsylvanica* Marsh) and water oak (*Quercus nigra* L.) root [106]. It is argued that this reflects differences in the ability of these two species to maintain rhizosphere oxidation under a continuous prolonged periods of flooding and to prevent the accumulation of reduced potentially phytotoxic growth-inhibiting compounds. Flooding causes the microbial reduction of Fe and Mn in the soil systems. Varying the water conditions is expected to modify the flooding effects on Fe and Mn and, consequently, the uptake of these elements by crop plants.

Under flooding condition, soil organic matter contributes to Fe and Mn availability through the formation of metallo-organic complexes with organic substances. This phenomenon may be attributed to the production of chelating agents from compost that generally keep the micronutrient elements soluble and, consequently, more available to crop plants. Increased Fe and Mn solubility in flooded soils benefits rice, which has a higher requirement for these elements than the other plants. There was an increase in pH, CO_3^{2-}, and DTPA extractable Fe and Mn on the submergence of a lowland rice plants [107].

The abundance of ferrous and manganous ions in flooded soils may result in acute phytotoxic effects in certain plant species. Differential responses of plant species to the build-up of soluble ferrous and manganous ions have been suggested as the potential factors in species ecology and habitat distribution. The cut shoots of a dune-slack species (*Erica cinerea*) characteristically found on waterlogged soils were much less injured by Fe sulfate introduced into the water supply than were those of a drier-site dune species (*E. tetralix*). These results suggest that high soluble-iron concentrations in wet habitats might exclude or reduce the abundance of the latter species [81].

It has been observed that generally high levels of Fe are found in the soil solution of submerged soil. In dry soil that has low pH and abundant sulfate, extremely high amounts of soluble ferrous-Fe are found soon after submergence, causing bronzing of rice leaves [108]. As the pH rises toward neutrality with prolonged flooding, Fe availability decreases, as does Fe toxicity. Excessive Fe can also interfere with the uptake of other nutrients. High concentrations of Fe in flooded soil can induce P-deficiency symptoms in rice plants. Manganese concentrations of flooded rice plants grown on certain soils may reach 3000 mg/L, but visual toxicity symptoms on plants are unusual.

Under flooding conditions, the solubility of Zn, Cu, B, and Mo generally change with time and growth environmental conditions. It has been found that, under flooded conditions, the production of organic complexing compounds and reductions of Fe and Mn tend to enhance the solubility of Zn and Cu in the growth media. Increase in soil pH in acidic to near neutral soils on submergence plays the most dominant role in depressing Zn and Cu availability in flooded rice soils, whereas the role of increased concentrations of CO_2 and S, although considerable, is less than that of pH. On calcareous soils, the rice plants frequently exhibit Zn deficiency possibly as a result of Zn fixation. Deficiency occurs primarily during early growth of the crop and during this period may be exacerbated by immobilization of Zn in roots by bicarbonate ions that are produced in alkaline soils soon after submergence [108]. Alkaline soils subjected to prolonged flooding exhibit increased Zn availability as pH declines with increasing soil reduction [9].

Submergence increases the accumulation of CO_2 in soil solution resulting in an increase in the formation of H_2CO_3, HCO_3^-, and CO_3^-, which has been shown to depress the Zn availability in flooded soils. In an experiment, the percentage decrease in Zn and Cu to 57 and 59%, respectively, in soil on submergence are partially due to their insoluble precipitation as sulfides, hydroxide, carbonate, phosphate, oxide, and chelate and their adsorption-precipitation by iron compounds [107].

Long-term flooding of noncalcareous soils generally tends to increase the availability of Cu and Mo and depress that of Zn [108]. It has been observed that tissue concentrations and the total content of Zn generally decline in flood-intolerant plants, such as wheat, corn, bent grass, and subterranean clover [65,70]. In an experiment, it was found that urea and ammonium sulfate had more effects than ammonium nitrate on the availability of Zn under flooded conditions. The total contents of Cu and B decreases in plants and the growth is markedly inhibited. It has been reported that, under flooding conditions, the tissue concentration of Mo increased in the ear leaf of corn. The behavior of Cu and Zn under flooded conditions seems to be complex; both decreases and increases in readily available forms have been reported. When a soil has undergone reduction by flooding, the breakdown of Fe and Mn oxides can provide an increased surface area with a high adsorptive capacity onto which Cu and Zn may be firmly adsorbed [101].

It has been reported by a number of workers that, under flooding stress or anaerobiosis conditions, the uptake and transport of Na ions generally increased in a number of crop plants, such as *Persea americana* [70], *Citrus sinensis* [72], cotton [33], sunflower [33], and jojoba [35]. Contrary to this, some workers have reported substantial decreased in the Na content by crop plants like subterranean clover [67] and *Persea americana* [70] under flooding stress.

Waterlogging of the rootzone of tomato resulted in significantly higher concentration of Na ions in plant parts when tested at temperatures of 20 and 28°C [109]. This response is consistent with the current understanding of nutrient element metabolism in that plant roots are thought to extrude Na^+ ions at the plasmalemma [88]. It is also possible that under flooding stress, with the O_2 depletion, exclusion of Na from the growth media becomes less efficient and the tissue Na concentrations rise away to a considerable extent. Some evidence, however, shows that Na uptake by root systems occurs under both aerobic and anaerobic conditions; hence that anaerobic condition itself cannot account for observed changes of Na in flooded plants. In any case, the tendency for Na to accumulate in flooded plants suggests the possibility of Na toxicity, particularly in Na-sensitive species.

There is some evidence that flooding stress effects on nutrient contents vary among the plant organs. Although not apparent in all studies, high concentration of elements in the roots of flooded plants may be coupled with decreased shoot concentration of some minerals like N, P, and K [35]. To account for these responses, it has been suggested that reduced O_2 availability to roots inhibited translocation of ions from roots to shoots, which decreased ion uptake [66]. In control, the Na concentration in flooded plants was sometimes increased in shoots and decreased in roots [35]. As root system of unflooded plants in these studies had a higher Na concentration compared with shoots, metabolically related reduction in the efficiency with which Na is excluded from the shoot may occur in flooded plants.

Salinity-Induced Stress

Salinity stress is a major environmental factor that drastically affects the crop productivity throughout the world [110–123]. It is a menace to both agriculture and the soil body. Historically, soil salinity contributed greatly to the decline of several ancient civilizations. Despite the advanced management technologies available today, salinization of millions of hectares of land continues severely to reduce crop production on a worldwide basis. Soil salinity is thus threatening human civilization by persistently reducing the areas of agricultural crop production all over the world.

All soils contain a mixture of soluble salts, some of which are essential for plant growth. When the total concentration of salts become excessive, plant growth is suppressed. The suppression increases as the salt concentration increases until the plant dies. The most common cations associated with soil salinity are Ca^{2+}, Mg^{2+}, and Na^{+}, and the anions are Cl^{-}, SO_4^{2-}, and HCO_3^{-}. In some instances, K^{+} and NO_3^{-} may contribute to salinity, and when the pH of the medium is greater than 9, CO_3^{2-} becomes an important anion. Excessive Na^{+} causes deterioration of the physical structure of the soil and can be toxic to plants. Chloride and B are also toxic. Boron has received considerable attention, because it has been identified in a number of saline waters.

Plant growth is severely affected by excessive concentrations of soluble salts in the growth media. Soluble salts decrease the solubility and availability of water to the plants by decreasing the free energy of water. Generally plant biomass is inhibited by an excess of solute taken up by plants from saline growth media. Salts may exert detrimental effects on plant growth through the toxicity of one or more specific ions present in higher relative concentrations.

The salinity stress problem arises when semiarid or arid lands are subjected to cultivation either because the soils are already saline and/or irrigated with saline water, which adds to the salinity of the soil. In addition, the excessive use of chemical fertilizers and irrigation have turned hundreds of hectares of cultivated fertile lands into saline lands. Plant responses to salinity depend on the kinds of salts (sulfates and chlorides) contributing to salinity as well as the total electrolyte concentrations [124].

Generally plants react to salinity by a reduction in growth, but there are quantitative differences in the degree of response. The growth response of a plant to salinity, expressed as yield, decreased under saline conditions compared with nonsaline is called plant salt tolerance [125]. Studies have shown considerable variations in salt tolerance between species of the same genus, between cultivars, or within varieties [126]. These differences are very often correlated with differences in translocation of Na^{+} and Cl^{-} in aboveground parts of plants.

The mechanism of salt tolerance of cultivated crop species that differ considerably in tolerance to salinity generally range from restricted ion uptake and translocation into the shoot to structural metabolic changes that decrease salt injury. The reduced water potential at high salt concentrations may further aggravate the effects. Salt tolerance under such conditions is generally related to the ability to regulate Na^{+} and Cl^{-} uptake by plant roots and subsequent translocation to the shoots [127–129]. The toxicity caused by salinity is considered to be due to water stress, which is a result of osmotic imbalance between plant and soil or ionic imbalance due to excessive salt uptake.

Salinity stress is known to retard growth [112,130] through its influence on several vital facets of plant metabolism, like osmotic adjustment [131], ion uptake [110,112,130,132–138], protein and nucleic acid synthesis, photosynthesis, organic solute accumulation, enzyme activities, hormonal balance, injury to tissue, alteration in respiration rates, interaction of salt with microbial activity, and reduced water availability to crop plants [139].

Salinity stress under certain experimental conditions may curtail or promote nutrient uptake by plant species by affecting the mobility of a nutrient within the plant or by increasing the nutrient requirement by plants in the cells. The simultaneous presence of salts and nutrient elements in the rootzones can influence nutrient uptake by plants and thereby affect their chemical composition. Synergistic and antagonistic effects may increase or decrease the intensity of these processes. At high salt stress, leaf scorching was predominant in older leaves and also was observed in the younger ones. The relationship between this toxic symptom and internal Cl^{-} level has been earlier demon-

strated. Specific injury through Na^+ and Cl^- accumulation rather than osmotic stress was suggested to be the main reason for NaCl susceptibility. Symptom of Na^+ toxicity can be easily seen when the leaves of sensitive plants contain approximately 0.25% Na on a dry weight basis. The Na^+ toxicity is characterized by leaf burn, necrotic spots, and limited leaf expansion, which in turn directly reduces plant photosynthesis and yield [140]. Salinity stress is generally recognized as being injurious to the growth of many crops owing to a disturbance in the electrolyte balance resulting in the deficiency of some essential nutrient elements and in an excess of certain unwanted salts in the plant tissue.

Preferential accumulation of either Na [141,142], Cl [143,144], and/or both Na and Cl [127,136,145,146] is also reported to account for salt tolerance in crop plants. The harmful effects of a high Na concentration in the medium on plant growth can be divided into three groups: (a) inhibition of water uptake due to osmotic potential of the culture solution [147], (b) disturbance of normal metabolism caused by high Na concentration in plant tissues [148], and (c) inhibition of the absorption of other essential cations by plants [149].

Increased Na content generally disturbs the nutrient balance and osmotic regulation and causes specific ion toxicity. It is the ionic balance of a growth medium rather than absolute Na content which determines the salt tolerance of a plant. The Na accumulations were significantly higher in salinity treatments compared with control for barley cultivars, and they were of the order about 10-fold at the 20 dSm^{-1} salinity level [150].

In a saline environment, plants take up excessive amounts of Na at the cost of K and Ca. High Na/Ca and Na/K ratios in a saline nutrient solution may cause an increase in membrane permeability [151], and this may have result in the passive accumulation of Na^+ and Cl^- in the root and shoot of salt-stressed plants. The higher K/Na ratio in shoots of barley cultivars compared with that in root medium solution indicated selective uptake of K, which seems to be among the processes involved in tolerance of cultivars to salinity stress [150]. Addition of K suppressed the uptake of other cations by rice and tomato plants in the order of Na>Mg>Ca. The depression of Na uptake by K could be due to the antagonism between the two cations [152]. It is widely recognized that a high Na concentration inhibits K uptake by plants [153]. On the other hand, Na appeared to stimulate the K uptake by plants [154]. The greater accumulation of Na in plant roots may be due to a regulatory mechanism located within the roots which prevents the translocation of excessive cations such as Na from roots to aerial parts resulting in Na retention [142].

Salt tolerance in many crop plants depends on the efficiency of root system, which can regulate the excess of Na^+ and Cl^- and/or SO_4^{2-} ions to reach the shoot. Roots have a definite capacity to act as storage for Na and other ions taken up from the external medium [143]. The acquisition of mineral nutrients and water and tolerance of the plant to the presence of potentially toxic levels of elements such as Na in the soil solution may, therefore, depend on the continued growth of the adventitious roots. The adventitious roots in salt-stressed plants represent a potential reservoir for the storage of Na^+ and Cl^- [143]. The presence of Na and Cl in the rooting environment have been shown to affect plant metabolism by affecting ion uptake.

The generally higher root Na^+ and Cl^- concentrations of various plants and lower leaf Na^+ and Cl^- concentrations suggested that some plants have a relatively high tolerance of Na^+ and Cl^- in roots coupled with the mechanisms for reduced translocation of Na^+ and Cl^- to the shoots. Such finding was observed for love grass (*Eragrostis tenella* L.) [155]. In a field experiment, Bhatti and Wienke [156] studied the uptake and distribution of Na^+ and Cl^- in ''salt-tolerant'' Kallar grass (*Diplachne fusca* L.) and found that increasing NaCl concentrations significantly raised Na^+ and Cl^- concentrations in the roots, as well as in the shoots, without showing any visual toxic symptoms in the leaves. Furthermore, these investigators reported that the old leaves were able to extrude a larger percentage (30–40%) of their total Na and Cl. Flowers and Yeo [126] obtained an inverse relationship between the Na uptake to the leaves and plant survival. Jones [157] reported that, when Na was present in high concentration in the growth medium, the transpiration rate of peas was reduced to proportion to salinity. High Na in soil solution also has an antagonistic effect on Ca^{2+} and Mg^{2+} uptake. Sodium salinity caused Ca-deficiency symptoms in tomato, pepper, and celery

(*Apium graveoleus*) plants. This is most likely caused by Na^+ displacing Ca^{2+} from membranes of root cells rendering the membranes nonfunctional.

Chloride is a more sensitive indicator of salt damage than Na, since it is stored by the plant, whereas Na is absorbed in smaller quantities despite high Na concentrations in the soil. The chloride content of pigeon pea (*Cajanus cajan* L.) was greater than Na, which is in agreement with the increased Cl contents in plants irrigated with salt water [158]. Leaf burning caused by the effects of salinity on peach trees was attributed to the accumulation of Cl^- in the leaves. These conclusions may have been based on the study of plants that take more Cl^- than Na^+ into the leaves. In fact, many of the more salt-susceptible species, such as maize, cress, sunflower, pepper, and bean, have higher Cl^- than Na^+ concentrations in their leaves [159]. This is also true for crops like *Acer Saccharum, Glycine max, Panicum repens, Spinacea oleracea*, and *Fagus sylvatica*. On the other hand, some of the most salt-tolerant species have higher concentrations of Na^+ than of Cl^- in the leaves; for example, *Plantago maritima, Suaeda monoica, Atriplex spongiosa, Suaeda maritima*, and *Puccinellia maritima* [160].

Salinity stress has significant inhibitory effects on the concentrations of K, Ca, and Mg [127,131,132,134,135,145,146,148,161–163] as well as stimulatory effects of these nutrient elements [131,132,145,148] on different crop plants.

Potassium, which is an essential cytoplasmic element [164], because of its involvement in osmotic regulation and its competitive effect against Na, is frequently considered to be important under saline conditions. Potassium participates not only in osmotic adjustment under saline conditions but also plays an important role in turgor-mediated responses such as stomatal and leaf movement. Numerous studies have shown that the K^+ concentration in plant tissue is reduced as the Na^+ salinity or the Na^+/Ca^{2+} ratio in the root media is increased [130,144]. Reduction in K^+ uptake by Na^+ is a competitive process and occurs regardless of whether the solution is dominated by Na^+ salts of Cl^- and SO_4^{2-}. In sheaths of sorghum, K was found to be the predominant cation, suggesting that the K ion may be operating as counter ion to Na, thereby contributing to osmotic adjustment in salt-stressed sorghum (*Sorghum bicolor* L.) [143]. With the increasing concentration of NaCl salts, K concentration decreased in the leaves, stems, and roots and was accompanied by a substantial increase of Na^+ in the organs. In Na_2SO_4–treated sorghum plants, an increase in Na^+ and SO_4^{2-} and a decrease in K^+ uptake was observed with increasing concentrations of the salt [130]. The dry weight of rice decreased markedly with the increase of NaCl concentration (50–200 mM NaCl) in the nutrient medium compared with that of barley. The salt tolerance of barley was higher than that of rice. The high salt tolerance of barley was ascribed to the fact that Na translocation from root to shoot was prevented at high NaCl concentration in the growth medium [165]. Excessive Na decreased the dry weight contents of essential cations, especially K in rice and tomato plants, and that the addition of K was able to improve their growth [152]. Using nutrient culture solution, Muhammad et al. [166] found that the shoot and root growth of rice plants grown in 100 mM NaCl solutions were increased when substrate K increased from 1 to 7 mM. In another nutrient solution experiment, Chow et al. [167] showed that differences in the shoot growth of spinach between plants grown at low (50 mM NaCl) and high (250 mM NaCl) salinity at a given level of K^+ can be reduced when K^+ is added to the highest salinity treatment. Application of 150 mg K kg^{-1} soil to the high Na–treated plants reduced seed Na concentration by greater than 50% [168].

Calcium plays a vital nutritional and physiological role in plant metabolism. Calcium, which like K also is an essentail mineral nutrient, helps in maintaining membrane integrity, is important in senescence processes, and is known to counteract the harmful effects of Na on crops [169]. Plant growth is dependent on Ca^{2+}, and both cell division and cell elongation processes are affected by the Ca^{2+} ion concentration. Calcium also plays a crucial role in controlling cell membranes' permeability and selectivity. It is thus important in regulating the salt economy of plants, and it may protect them against some of the deleterious effects of salinity. Several studies have highlighted the role of Ca in mediating salt responses in plants [170].

Calcium, which is a component of the cell membrane, contributes to the maintenance of the structure and function of the membrane. Calcium is needed preferentially in actively growing tissues.

A high Na concentration inhibits Ca absorption by plants. Alternatively, the addition of Ca improved plant growth under saline conditions by depressing Na absorption and accelerating K absorption. Also, Ca reduced the efflux of K^+, NO_3^-, and $H_2PO_4^-$ caused by the high Na concentration [149]. The addition of 10 mmol Ca/L improved rice growth by decreasing the Na uptake and increasing the K and Ca uptake [152].

The presence of Ca^{2+} as the dominant cation in agricultural soils generally ensures that the absolute Ca^{2+} level is not a primary growth-limiting factor. As salinity increases, the requirement of plants for Ca^{2+} increases. The uptake of Ca^{2+} from the soil solution may decrease because of ion interactions, precipitation, and increases in ionic strength that reduce the activity of Ca^{2+}. These combined effects are at least partially responsible for reduced yield under saline conditions. Calcium protects cell membranes from the adverse effect of Na and minimizes the leakage of cytosolic K. The vital roles of Ca^{2+} are the regulation of ionic relations in plants and improving the soil physical conditions.

It is wellknown that Ca^{2+} is readily displaced from its extracellular binding sites by other cations, and these functions may become seriously impaired by reduced Ca^{2+} availability. Root growth and function may be restricted by high Na^+/Ca^{2+}. Soloman et al. [170] observed abnormal root growth and anatomy of pea plants grown in nutrient culture containing 120 mM NaCl as the sole salinizing salt. These salinity-induced changes, characterized by curvature of the root tip as well as constriction and thickening above the apex, were completely reversed by the addition of 10 mM Ca^{2+}. Sodium-induced Ca^{2+} deficiencies have notorious growth-distorting effects on developing leaves, as illustrated in several grass species grown in solution cultures. A case of Na-induced Ca deficiency in corn salinized with NaCl has been documented. The symptoms of Ca deficiency disappeared when part of the NaCl was replaced with $CaCl_2$. From a study comparing the salt tolerance of a commercial barley cultivar with that of wild barley (*Hordium jubatum* L.), Suhayda et al. [171] concluded that the greater salt tolerance of the wild species was partly attributable to its ability to maintain high tissue levels of Ca under salt stress. Further, the commercial barley cultivar was more tolerant to salinity when the Ca concentration in the salt medium was increased.

Cramer et al. [172] concluded that the primary response to NaCl stress in cotton roots is the displacement of membrane-associated Ca^{2+} by Na^+ leading to increased membrane permeability and loss of K^+/Na^+ selectivity. The addition of 10 mM Ca^{2+} to the saline culture preserved membrane integrity and prevented leakage of K^+. Under saline conditions, a high Ca^{2+} supply alleviated the inhibition of NO_3^- uptake and increased Na^+/K^+ selectivity [173]. Elevated Ca^{2+} levels may protect the plant from NaCl toxicity by reducing displacement of membrane-associated Ca^{2+} and by reducing Na^+ uptake and transport to the shoots. In citrus, Ca was found to be effective at reducing the transport of both Na^+ and Cl^- from the roots to leaves, thereby reducing the foliar injury. Maintaining an adequate supply of Ca^{2+} in the soil solution is an important factor in controlling the severity of specific ion toxicities. This is particularly important for tree and vine crops, which are more prone to Na^+ and Cl^- injury than most annual crops [174].

The magnesium content of the leaves of saline-treated bean plants increased, whereas it decreased in the root. Hodson et al. [175] found potentially toxic concentrations of Mg^+ in salt-marsh soil solution samples and demonstrated that a salt-marsh clone, *Agrostis stolonifera*, was considerably more tolerant to Mg^{2+} than was an inland clone. Magnesium concentration of avocado leaves was decreased with an increase in the exchangeable Na^+ in the soil. In rice, Mg transport to the tops was suppressed by Na compared with Mg uptake [152]. The Mg content in the roots revealed the competition between Mg and Na uptake and transport to the tops [163].

Under salt-stress conditions, the uptake of N by crop plants is generally affected. Reports show inhibitory [134,145,176] and stimulatory [177,178] effects on the plant N uptake under salinity stress. A substantial number of laboratory and greenhouse studies have shown that salinity reduces N accumulation in plants. It has been reported that an increase in Cl^- uptake and accumulation is accompanied by a decrease in shoot nitrate concentration. Examples of these effects are also found in barley, cotton, watermelon (*Citrullus lanatus*), and wheat. In his experiment, Aslam et al. [173] have reported that Cl^- inhibited NO_3^- uptake more than SO_4^{2-} when these anions were present on

an equal osmolarity basis. In contrast to the effect of Cl^- on NO_3^- uptake, reported data indicated that increased NO_3^- in the substrate decreased Cl^- uptake and accumulation. The possible decrease in N uptake by increasing salinity has been partly attributed to a probable substitution of Cl^- for NO_3^- [179]. For example, the N-deficiency symptom increased the Cl level in corn, barley, and some other crops. Sodium chloride salinity significantly decreased the amount of total N in all parts of the wheat plants possibly as a result of the antagonism of nitrate by chloride in the growth medium [180]. Both the chloride salts of Na and K inhibited the nitrate uptake similarly, suggesting that the process was more sensitive to anionic salinity than to cationic salinity [173].

Although, Cl^- salts were primarily responsible for reduced NO_3^- uptake by plants, NO_3^- reduction in plants was not affected by salinity in studies with barley [173]. Salinity also stimulated nitrate reductase activity in peanut plants as well as decreased the nitrate reductase activity in tomato and cucumber (*Cucumis sativus* L.) plants, and reduction in NRA may be due to inhibition of NO_3^- uptake by Cl^- in plant species [180].

The source in which N is applied to salt-treated plants also is important. In an experiment, the NH_4-fed maize and wheat plants were more sensitive to salinity than NO_3-fed plants grown in nutrient solution culture. Supplementation of Ca^{2+} to the growth media improved the growth rate of the plants in the NO_3 treatment but not those treated with NH_4^+. Based on the results of their nutrient solution experiments, Leidi et al. [181] suggested that NO_3^- is a better N source than NH_4^+ for wheat grown in salt-affected soils.

Phosphorus, which has a crucial role in the energy metabolism of cells, is involved in a number of anabolic and catabolic pathways. A recent study indicates that salinity may increase the P requirement of certain plants. Awad et al. [182] found that when NaCl increased in the substrate from 10 to 50 or 100 mM, the P content in the tomato leaf increased from 58 to 70 and 97 mmol kg^{-1} dry weight.

The influence of salinity on P accumulation in crop plants is variable and depends on the plant and experimental conditions. In many cases, salinity decreased the P concentration in plant tissue [183]. It is unlikely that Cl^- and $H_2PO_4^-$ ions are competitive in terms of plant uptake. However, it has also been observed that Cl^- may have a suppressing effect on P uptake in tomato shoots [179].

The presence of Cl^- as well as SO_4^{2-} reduced P uptake in barley and sunflower plants. In other cases, a reduction in plant P concentration by salinity may result from the reduced activity of P in the soil solution due to the high ionic strength of the growth media [182]. Phosphate solubility-availability is reduced in saline soils not only because of ionic-strength effects that reduce the activity of phosphate but also because the P concentration in soil solution is tightly controlled by sorption processes and by the low solubility of Ca-P minerals. It is, therefore, understandable that P concentrations in field-grown agronomic crops decreased as salinity increased in the media. When plants are P deficient, they may be more sensitive to salinity [183].

The concentrations of micronutrients in the soil solutions, with the exception of Cl^-, seem to be low and depend on the physical and chemical characteristics of the soil bodies. The availability of most micronutrients depends on the pH of the soil solution as well as the nature of binding sites on organic and inorganic particle surfaces. In saline soils, the solubility of micronutrients such as Fe, Mn, Zn, and Cl is particularly low and plants grown in these soils often experience deficiencies in these elements [184]. Nevertheless, the micronutrient concentration in plant shoots may increase, decrease, or have no effect depending on the type of plant tissue, salt tolerance of plant species, salinity, micronutrient concentration, environmental conditions, and/or abrupt changes in the permeability of the crop cell membranes.

Both Fe and Mn contents were reported to increase in all parts of the salt-treated peanut plants [158]. The increase in Fe contents was more prominent than that of Mn. Salinity increased the Fe concentration in the shoots of pea and rice and decreased its concentration in the shoots of barley and corn [185]. In other investigations with barley, salinity had no effect on shoot Fe concentrations, but at low Ca, salinity increased root Fe in certain barley (*Hordeum vulgare* L.) species [171].

Salinity increased the manganese concentration in the shoots of barley, rice sugar beet (*Beta*

vulgaris L.), soybean, and tomato plants, but decreased in concentrations in the shoots of barley, squash, pea, and corn [171,185,186] plants. In the study with the sugar beet, the addition of NaCl–$CaCl_2$ increased Mn in the saturated soil extract. Other investigators did not find the effect of salinity on shoot Mn, but did find that increasing the sodicity in soil grown maize had a significant reduction in shoot concentration. Saline solutions rich in divalent cations increase shoot Mn concentration, whereas a saline environment dominated by monovalent cations reduces shoot Mn concentration. Zinc concentration has been found to increase in salt-stressed bean, barley, soybean, squash, and tomato plants but to decrease in corn and mesquite (*Prosopis juliflora* L.) plants [185].

Drought-Induced Stress

Water availability plays a major role in the regulation of plant growth and seed development [187]. Water is generally considered as one of the limiting factors which affect the numerous metabolic physiological and biochemical process affecting crop productivity [188–192]. On the global basis, water stress limits plant growth and yield more than any other single environmental factor [1].

Water stress develops when the water efflux from the plant is greater than the water influx into the plant. Although plant growth rates are generally reduced when the soil water supply is limited, the shoot growth is often more inhibited than the root growth.

Water, which is a combination of oxygen and hydrogen gases, is the Earth's most distinctive constituent and is an essential ingredient of all creatures living on the Earth's surface. Its availability is one of the most limiting environmental factors affecting crop productivity and numerous human applications. It is a well known fact that crop growth is frequently subjected to water stress during the course of its lifetime. However, certain growth stages, such as germination, seedling, and flowering, are the most critical for water-stress damage. Stress imposed during these periods drastically affects crop growth, ultimately leading to a massive loss in yield and quality [193–197]. Water stressing or droughting can be intensified by gradually lengthening the drought period each day or by applying drought over a period of days or weeks.

As a natural hazard, drought is a unique syndrome. It differs from other natural hazards in that it is a creeping phenomenon that is pervasive in nature. The effects of drought accumulate gradually and may persist over a long period of time, making it difficult to determine when a drought has begun or when it has ended. Water deficits are very common in the production of most crops, and numerous studies have indicated that they can have substantial negative impacts on plant growth and development [198–203].

Water-stress conditions of soils have wide-ranging effects on several morphological and biochemical alterations in plants. It causes a decrease in the cytokinin transport from roots to shoots and/or an increase in the amount of leaf abscisic acid. These changes in hormone balance cause changes in the cell wall extensibility, a decline in the concentrations of photosynthetic enzymes, and growth of the biomass. Water stress leads to a reduction in the efficiency of key plant processes, including protein synthesis, photosynthesis, respiration, and nucleic acid synthesis, causes activation or inhibition of the activities of many enzymes, and leads to changes in the ultrastructures of plant tissues.

The potential capacity of plant roots to absorb water and nutrients generally declines in water-stressed plants, presumably because of a decline in the nutrient element demand. There is some evidence that roots are the primary sensors of water deficit in the soil, causing the observed physiological and biochemical perturbations in the stems and the decline in growth to be generally interconnected with changes in plant nutrition, carbon dioxide balance, and water relations.

The internal transport of plant nutrients largely depends on the synthesis, utilization, and translocation of photosynthesis, because the switching over of these processes is regulated by nutrient metabolism. Any perturbation in the system may severely affect both the supply and demand of nutrients for crop plants. Plant nutrient elements and available water are absorbed by plant roots in independent processes, but they are closely related to one another. In soil systems, water relationships affect all of the physiological processes, which are closely associated with the nutrient element

solubility or availability. These processes involve element concentrations in the soil solutions, because of nutrient diffusion and mass flow to the root surface, and then absorption of the elements by the roots, translocation from roots to shoots, and utilization of minerals by the other plant parts.

Nutrient uptake by crop plants is generally decreased under water-stress conditions owing to a substantial decrease in transpiration rates and imparied active transport and membrane permeability [190], and resulting in a reduced root-absorbing power of crop plants. Nutrient uptake from the soil solution is also closely linked to the plant root and soil water status. A decline in the soil moisture content is associated with a decrease in the diffusion rate of nutrients from the soil matrix to the absorbing root surface. The plant water status and an internal water deficit are related to root system development, and during water stress, root activity and mainly root permeability may change substantially to lower levels. The reductions in uptake and transpiration are usually associated with a reduction in the water content of the shoots and stomatal aperture, suggesting that water stress has developed in the leaves. Maximum water uptake occurs in young roots, but continued aging of the roots after cessation of growth would result in a reduction in the root permeability to water and nutrients. Inadequate water availability and nutrient element uptake owing to reduced root permeability causes a disturbance in the root metabolism [204]. The changes in the soil moisture regimen can alter the root morphology and anatomy, the pore size distribution, and the angle of roots penetration, which affect root proliferation.

It is a bit difficult clearly to deliniate the potential effects of water stress on the mineral uptake and accumulation in crop plants. Many workers have reported varied effects of plant species and genotypes on nutrient concentrations, and most studies have reported that mineral uptakes are decreased when the intensity of water stress is decreased.

Under water-stress conditions, the uptake of N decreased in soybean plants [205]. This decline in shoot N uptake can be attributed to the decreased transpiration rate to transport N from roots to shoots. The high N level under water stress has largely been attributed to the proline accumulation in grasses, as evidenced by others [206]. Nitrogen deficiency sensitized cotton plants to water stress, causing the effects of stress to occur at a higher water potential. The common opinion extended by Barnett and Naylor [207] holds that the high N level of crop plants subjected to water stress is primarily due to the fast accumulation of free amino acids that are not converted into proteins. It is also plausible that the slower growth rate of plant crops under moisture stress prevents the dilution effect of nutrient elements. As such, the availability or solubility of N can be reduced significantly by leaching under normal irrigation. Although water and nutrient uptake by plants are the independent phenomena, the transpirational equilibrium under irrigation favors the leaching down of the soluble forms of N from the soil strata. Therefore, it has been clearly emphasized that water acts as a vector for nutrient transport within the system. The main effects of moisture stress on anion transport to the live green component of *Dichanthium annulatum*, a dominant perennial, and a weed, *Polypogon monspeliensis*, are due to retardation of the mass flow of actively absorbed ions arresting their regular delivery to the active sites of uptake.

Tanguilig et al. [205] reported that total shoot N uptake of water-stressed plants decreased in rice plants despite its high root dry matter weight. It has been reported that under water-stress conditions, absorption of both NH_4^+ and NO_3^- decreased, and the decrease was greater for NO_3^- than for NH_4^+. In water-stressed plants, dry matter production and total N/plant decreased, but N concentrations increased and proline synthesis was inhibited. Plant concentrations of N decreased rapidly when osmotic water stresses were initially imposed. This decrease in N was apparent for wheat within 24 h at -1 bar potential and was more pronounced in plants stressed for longer times. The effects of water stress on N concentration was as severe or more severe at -1 bar as at higher water stress. Viets [208] generalized the opinion that moisture stress induces a definite increase in the N level in plants, whereas it induces a decrease in the P level and variable effects on the K level. However, besides the increase in N and the decrease in the P level, a definite reduction in the K level was observed in all grasses.

During the wilting of tomato (*Lycopersicon esculentum* L.) leaves, the uptake of N and P was reduced and both N and P were translocated from the laminae to the petioles and stems. When

plants were rewatered, the active uptake of N and P resumed and both passed preferentially to the laminae rather than remaining in the stems. Nitrogen accumulation in stems under water stress was also noted [209]. Nitrogen was less liable than P, and wilting depressed the uptake of P more than that of N. The uptake of N and P was decreased relatively early in the drying cycle and preceded water-stress effects on dry-matter yield. Dry-matter yield usually decreased faster than total nutrient uptake [204]. In mature maize plants grown with inadequate water, component accumulations of P, N, Mg, K, and Ca were 40, 50, 65, 71, and 91%, respectively, of those found in mature plants grown with adequate water [210].

In contrast to the reduction of mineral element uptake by plants with water stress, nutrient elements in many range and forage plant species increased with water stress [204]. Water stress generally favored the increases of N, K, Ca, Mg, Na, and Cl and the decreases of P and Fe [211]. The relative deficit of N accumulation as a function of increased water stress was less than the deficits for dry-matter yields and the decrease in the accumulation of other nutrients. For several grassland plants, total nutrients generally decreased with increasing water stress [204].

Phosphorus is essential for plant growth, as it is involved in most metabolic processes. Phosphorus is a constituent of nucleic acids, phospholipids, phosphoproteins, dinucleotides, and adenosine triphosphate. Hence, P is required for the storage and transfer of energy, photosynthesis, the regulation of some enzymes, and the transport of carbohydrates. Phosphorus is phloem mobile, and the purple symptoms of P deficiency appear first in old leaves as P is redirected to young leaves.

Water-stress conditions of the growth media has far-reaching effects on the uptake and concentration of phosphorus by crop plants. Gerakis et al. [204] pointed out that of the many studies conducted before about the mid 1950s, 12 of the 21 papers reported that water stress decreased P concentrations in plants, and 9 papers reported that water stress did not affect the P status of plants. Since then studies have reported both decreases [212–214] and increases [204,211] in P and other mineral element concentrations with increased water stress. It is generally accepted that the uptake of phosphorus by crop plants is reduced in dry soil conditions [215–217], although it has been reported [213] that only severe water stress reduced plant phosphorus absorption.

In an experiment [218], phosphate and water were added differently to surface and subsurface layers of reconstituted soil profiles. The layers were subjected to brief periods of drying and to partial or complete remoistening at frequencies ranging from daily to every 2 week. Their findings have revealed that P uptake from surface applications and shoot yield were proportional to the frequency of remoistening of the soil surface to field capacity, and the response to additional subsurface phosphate presence diminshed as the amount of surface water increased. In the treatments where moistening did not achieve field capacity, yield was linearly proportional to the amount of water applied to the surface. These investigators have further described that watering the surface to field capacity twice a week led to a 50% reduction in phosphorus uptake by subterranean clover (*Trifolium subterraneum* L.) compared with daily watering. It also appeared that rapid P uptake occurred only at high moisture contents, and that uptake was proportional to the volume of soil brought close to the field capaicty and the length of time that it remained moist. It seems that plants were able to obtain their entire P requirements from the surface layer only when it was kept continuously mosit. Furthermore, the amount of P absorbed by the plants was directly proportional to the amount of water applied to the soil surface. This research finding is in direct contrast to that of Fawcett and Quirk [213], who finally concluded that the rate of P absorption and utilization by crop plants was not greatly affected by increasing water stress until the plants were subjected to wilting, at which point, absorption decreased markedly. However, the true meaning of this result [213] is uncertain, since groups of wheat plants were grown in small containers of soil (300–600 g) through which phosphate had been intimately mixed. Moisture depletion must have occurred very rapidly in such small containers, and so frequent remoistening would be necessary to avoid wilting. This experimental set-up and design was thus completely artificial, and it did not simulate the usual field situation in which phosphate is banded or layered in position separate from the location of the main soil moisture reserves.

Mouatt and Nes [219] have suggested that an adequate supply of phosphate can be maintained

Marcel Dekker, Inc.

only when there is a high level of available water in the growth medium. Of the several plants put under water stresses beyond the available moisture range, three had markedly lower concentrations of $H_2PO_4^-$ than other plants allowed to grow in the available moisture range. The reduction in the relative uptake of $H_2PO_4^-$ by maize seedlings was nearly linear with the soil moisture stress and decreased progressively from 100, 94, 80, and 54 to 35% of the control for water stresses of -0.3, -0.5, -1, -3, and -9 bar, respectively [220]. Regardless of water stress, P uptake by plants increased with increased P levels in the soil. Olsen et al. [221] observed that monovalent phosphate uptake depended on the soil P levels as much as on the magnitude of water stress. There was an increase in the concentration of P in alfalfa (*Medicago sativa* L.) and that of Ca, Mg, and Zn both in alfalfa and soinfoin (*Onobrychis viciifolia* Scop.) with decreasing soil moisture supply [222]. Compared with alfalfa, soinfoin had higher concentrations of P and Mg and lower concentrations of Ca, K, and Cu and a similar Ca/P ratio.

Nuttall [223] reported that increased soil moisture resulted in increased P but decreased S in alfalfa. Gomez-Beltrano [224] did not find any influence of moisture stress on P, N, and K concentrations. The P concentration was found to decrease at low leaf water potentials in pepper (*Capsicum annuum* L.) plants [225], and P deficiency appears to be one of the earliest effects of mild to moderate levels of water stress in soil-grown plants. The effects of water stress on P uptake depended on the magnitude and intensity of the water stress and on the concentration of P ion. Increasing the water stress from -0.4 bar to -5.5 bar had no effect on the accumulation of P or B in root cells or in xylem sap [226]. However, the absorption of $H_2PO_4^-$ was severely inhibited when water stresses were increased to -12 and -15 bar [227]. Nevertheless, translocation of P to the shoots was severely restricted even at a relatively low water stress condition [226]. Water stresses for the inhibition of P translocation in maize was about -5 bar, but for the inhibition of $H_2PO_4^-$ uptake, water stress had to be greater than -15 bar.

In experiments with elements at different concentrations in the uptake medium, the effects of water stress intensity on $H_2PO_4^-$ uptake in maize roots were greater at relatively high P levels (10^{-3} M or higher) than at lower levels [226]. Reports have indicated that at -10 bar, P absorption and translocation to shoots were inhibited with mannitol-induced water stress, but only P translocation was inhibited with PEG-induced water stress [226].

Under water stress, the uptake of K and Ca by maize plant increased [205]. Increased K uptake in maize suggests that, under stress conditions, K is absorbed preferably to N and P. Sinha [228] observed that drought-tolerant wheat varieties can accumulate more K than do the more susceptible varieties, and plants well supplied with K had a higher stomatal resistance, which resulted in a low transpiration rate. Furthermore, Maurya and Gupta [229] observed an increased water potential of wheat plants with increased K fertilization. Kuchenbuch et al. [230] have shown that low levels of soil moisture reduced both the root growth and the rate of K inflow per unit of root length of onion (*Allium cepa* L.) plants. It is, therefore, assumed that the water content of the soil influences the rate of K uptake by its effect on the transport of K from the soil to the root surface. Soil moisture content affects the availability of K in soil [231]. Van der Paauw [232] observed a positive relation between the number of days without rain in the growing season and the K response of grass, potato (*Solanum tuberosum* L.), and wheat. This indicates that soil moisture influences both the diffusion of K in the soil and plant root growth. This in turn is apparently the reason for the increasing rate of K uptake per unit of root surface and the total uptake of K with increasing soil moisture. In addition, variations in K uptake with moisture stress in sugar beet were such that under equally increased with water stresses, K increased in one variety and decreased in the other. The relative amounts of K, Ca, and Mg increased considerably more in barley than in rye when water stresses were imposed. It is suggested that nutrient uptake under water-stress conditions is influenced by the capacity of the roots to absorb nutrients.

An experiment [233] showed that drying of the upper layer of a siliceous soil profile strongly reduced the absorption of Mn by rye grass but that the uptake of Cu and Zn were relatively unaffected. It has been noted that an increased water-stress condition of a growth medium not only depressed the uptake and solubility of nutrient elements but also increased Ca/K and Ca/P ratios

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

in herbage. Calcium was depressed only slightly compared with P and K. The functional capacity of the plant root system may be reduced as a result of a shortage of soil moisture content. Furthermore, in a water-stress situation, the older roots surrounded by dry soil apparently lost their ability to function and the nutrients were supplied exclusively by the more active root tips. This led to a low uptake of anions and a greater uptake of bivalent cations compared with monovalent cations. The undesirable Ca/K ratios could develop in plants and cause other complications in the growth of the plants. Ratios of bivalent to monovalent cations were higher for dicotyledonous than for monocotyledonous plants [204]. In an experiment, Khan and Soltanpur [234] noted another anomaly in plants and suggested that high moisture levels could enhance P availability in the plant. This enahnced P availability could have caused the Zn deficiency that they observed in bean (*Phaselous vulgaris* L.) plants.

In general, the uptake of Cl^- was not affected immediately after the removal of roots from a water stress medium, but after 36 hs, the Cl^- uptake was only 2 μM/h compared with 7 μM/h for unstressed plants. In this same study, the plants subjected to water stress by decreasing the amount of the root system in solution transported less water after removal of stress than the unstressed plants. In addition, plants repeatedly subjected to water stress and then allowed to recover had enhanced rates of ion losses by leakage [227]. Greenway et al. [235] favorably suggested that the depressed uptake and accumulation of ions in water-stressed plants was caused by excessive leakage of ions from the cell membranes.

Numerous studies on water stresses have revealed that water stress, in most cases, restricted the uptake of nutrient elements by crop plants. Uptake of the ions from the growth media was closely related to plant water content, transpiration, and/or water flow. The length of time the plant roots could be exposed without permanent damage depended on the method used to impose water stress, the level of stress, and the plant species. Apparently the active transport systems of the crop plants were imparied or destroyed at high water stresses, and thereafter the various ions present in the growth medium responded differently.

CONCLUSIONS

The major types of stresses which potentially affect plant growth and nutrient uptake on a global basis are flooding, salinity, and water stress (drought). In addition, the other stresses which also potentially and perhaps simultaneously affect the normal growth of plants and ultimately the nutrient uptake scenario are, for example, seedbed preparation, plant population, planting time, types of soil properties, soil N, P, K, Ca, Mg, S, Fe, Mn, Zn, Cu, B, Mo, Co, Si, Cd, Cr, Se, and Al, nutrient imbalances and their interactions, soil organisms, diseases, weeds, toxic metals, air pollution, growth regulators, wind, hailstorms, water-table, and allelopathy.

Flooding is the saturation of the soil rootzone with water. The soil pore space, normally filled with air, is filled with water. Flooding (waterlogging) occurs when inundation persists as a result of inadequate surface and/or subsurface drainage and the aeration status of the soil system decreases below critical limits. Aerobic systems are oxygen sufficient, whereas anaerobic or anoxic systems are oxygen depleted. When soil is saturated, the concentration of O_2 available to the roots decreases rapidly, because it is consumed by roots and soil microorganisms. Anaerobiosis affects the plant metabolism and plant nutrient availability as a result of low oxygen concentrations in the rooting medium. Salinity is a condition of excess salts in the soil, which affects crop productivity by increasing the osmotic pressure of the soil solution interfering with the normal nutrient uptake and inducing ionic toxicity and associated nutrient imbalances. Salinity poses a severe threat for cultivation of crops. Water stress (drought) is also an important limitation to crop production. Reduction in photosynthetic activity and increases in leaf senescence are symptomatic of water stress and adversely affect crop growth. Other effects of water stress include a reduction in nutrient uptake, reduced cell growth and enlargement, leaf expansion, assimilate translocation and transpiration. Water stress also reduces the net CO_2 assimilation.

INTRODUCTION

The term *plant stress* is difficult to define because of several factors. The major factor, however, is the complex interaction between plants and the environment. If a stress is defined in terms of a plant's response in field conditions, then the stress cannot precisely be described, because the response of any individual stress factor is not easy to identify. In nature, it is almost impossible to find a condition where a single stress operates without the interference of other stress factors. In certain conditions, many environmental factors individually may not exhibit any stress effect but in different combinations can create a stressful environment for the plants. However, most of the studies in this area are conducted in defined conditions; the stress, therefore, is defined in a very general way as a biotic or abiotic factor that prevents plants from normal functioning and thus results in a reduction in their growth and reproduction [1]. Many environmental factors at their extremes have been recognized as stress factors. The threshhold level of different environmental factors exhibiting the stress response depends on many factors, including prehistoric growth and the structure of plants.

Since plants cannot flee from the stressful environment, they have developed various strategies during evolution to adapt to the changing environmental conditions and thus counter the stress effects. Plant adaptation involves three major events; namely, stress perception, transduction of stress signals, and the final response. In most stressful environments, plants can sense, correctly recognize stress signals, and use the signals as cues to bring specific changes at various levels, like alterations in morphological structures, physiological behavior, modification in biochemical pathways, and expression of stress-specific genes as a response for the adaptations.

In this chapter, the photosynthetic response of green plants to the environmental stress factors, including extremes of light, water, and temperature, are described. Some other factors, like heavy metals and nutrition stress, also are discussed in regard to their effects on photosynthesis. Emphasis

Marcel Dekker, Inc.

has been given to various pathways of transduction of stress signals and adaptive responses of chloroplasts experiencing these stresses.

STRESS SIGNALS, PERCEPTION, AND SIGNAL-RESPONSE COUPLING IN PLANTS

The mechanisms of recognition and perception of a stress signal followed by the conversion of the signal to a biochemical response in plants largely remain unclear. The perception of the stress signals and their initial interaction with the cells could be recognized by various physical perturbations that may include changes in cell volume, structure of biomembranes, ionic balance, total content, and composition of cellular solutes or alteration in protein-ligand interactions.

The bilayer lipid membrane, a boundary between the cell and its environment, is considered to be one of the major sites for perception of the stress signals [2,3]. In addition to the plasma membrane, the membranes of the nucleus, mitochondria, and chloroplast are well-organized structures that constitute not only lipids and proteins but also ions and various kinds of receptors that recognize both intrinsic and environmental signals. The stress-induced changes in the lipid structures and/or perturbations in lipoprotein complexes may subsequently be transmitted to various types of cellular responses through appropriate biochemical changes for developing adaptive mechanisms to counter the stress effect. The perception of stress signal that leads to changes in membrane fluidity and triggers a series of events, and the expression of genes for stress adaptation have recently been critically discussed by Murata and Loss [3].

The coupling of stress signals to the plant response appears to be very complex [3–5]. Different stress signals may have a common response. For example, the synthesis of many scavenging enzymes against the oxy free radicals in plants has been shown as a common response to most of environmental stresses. These stresses, however, may have different receptors and may produce the radicals in different biochemical routes. With some other environmental stress factors, the perception and initial transduction of stress signals may be similar, but the transduction of the signals at a later stage may diverge at the biochemical level, leading to individual stress-specific responses. This proposition is supported by the observation of expression of stress-specific genes as controlled by different regions of stress-specific promoters [6]. On the other hand, a single stress may induce different signal transduction pathways for stress adaptation. Abscisic acid (ABA) production and its role for expression of water stress–related genes are recognized as being a major signal transduction pathway, but there may be other signal transduction routes induced by the same stress independent of the hormone route [4].

Thus it appears that the stress signal transduction is complex in nature and is, therefore difficult to study. Second, most of the studies in this area are made at cellular levels. Such studies may be considered as models for predicting how the stress signals are recognized and transmitted through various cellular events and finally to the response in a whole-plant system. The signal transduction route, therefore, becomes much more complicated when discussed in the background of an integrated system with various tissue and cell types.

CHLOROPLAST AS THE MAJOR CELLULAR TARGET FOR PERCEPTION OF STRESS SIGNALS

Chloroplast, the Photosynthetic Organelle

Excellent reviews are available on the structure and function of chloroplasts [7–9]. The photosynthetic organelle consists of two major components (a) a lamellar network, collectively referred to as thylakoids, and (b) a stroma matrix with soluble enzymes of the Calvin cycle. The thylakoid membranes vary in their organization from simple structure in bacteria to a very complex organization in the chloroplasts of higher plants. The so-called light reactions comprizing the primary photo-

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

chemical reactions result in the formation of NADPH and ATP and liberation of O_2 from water. Thylakoid membranes, as classified to grana and stroma lamellae, consist of photosynthetic pigments like Chla, Chlb, carotenes, and xanthophylls in higher plants, where as different types of phycobilins constitute major light-harvesting pigments in cyanobacteria. The pigments associated with specific membrane-bound proteins form pigment assemblies for optimization of light energy absorption. The light reactions in the thylakoids are driven primarily by two photosystems which are coupled by an intersystem electron transport chain. The products of light reactions are subsequently utilized in the so-called dark reactions associated with the Calvin cycle for formation of sugar. The question that has been addressed in this section is how the chloroplast with these structural and functional features acts as the major sensor of environmental stress in addition to its major task of making organic food materials through the process of photosynthesis.

Why is the Chloroplast a Sensor of Stress?

Most of the environmental stresses when experienced by green plants bring about oxidative damage of cell structures and consequently a loss in the cellular activities. The transfer of electrons to O_2 and subsequent redox reactions in plant cells may generate various toxic O_2 species. In addition to the production of these highly toxic species, the redox reactions may lead to the formation of other kinds of oxidants with a high positive redox potential that can oxidize most of the essential cellular molecules. Under normal nonstressed conditions, the cellular environment tends to maintain a redox homeostasis which, however, is disrupted by various intrinsic and extrinsic factors. A shift of the redox steady state induced by various stresses creates an oxidative environment.

Chloroplasts in plant cells not only possess pigments which can absorb light and drive redox reactions of thylakoids, but the organelles also are the sites in the cell where O_2 is liberated from water. The availability of O_2 in the vicinity of the electron transport chain may lead to the formation of oxy free radicals in the cellular environment. Chloroplasts are also capable of producing strong oxidants associated with photosystemII (PSII) of thylakoids. Although these oxidants with high oxidizing potential are responsible for the splitting of H_2O molecules, they can oxidize pigments, proteins, and lipids of the thylakoid membranes as well. These special characteristics in fact make the photosynthetic organelle a major stress sensor in green plants.

The other important factor that makes the chloroplast sensitive to stress is the differential response of primary events associated with charge separation and enzyme-mediated electron transport systems of thylakoids. The primary photochemistry involved in the separation of charges within photosystem reaction centers is independent of temperature. The events like the transfer of energy and the subsequent oxidation of reaction centers occur in the time scale of the femtosecond to microsecond range. On the other hand, temperature-dependent redox reactions of the electron transport chain or fixation of CO_2 in the Calvin cycle mediated by enzymes are relatively slow processes that occur in the time range of a milisecond to minutes. A change in environmental factors, including a change in temperature, is likely to affect the electron transport efficiency and CO_2 fixation, the sink for energy utilization, without disturbing the light absorption and the initial events associated with charge separation at the reaction centers. This in turn may create a kind of excitation pressure on the photosystems of thylakoids. The excess quanta become harmful to the organelle in many ways, and they are discussed later in this chapter.

There appear to be two major events that regulate the induction of stress-signaling systems in chloroplasts. One event is the building up of excitation pressure on thylakoids because of high light stress, and the other event is the nonutilization of products of the light reaction in the Calvin cycle during CO_2 fixation. This situation is induced by stress factors other than high light stress and leads ultimately to generation of a redox back pressure on PSII of thylakoids. Both these events, however, are coupled under high light intensity and during operation of other environmental stress factors in the presence of light even at moderate intensity. The high light stress syndrome, therefore, could also be exhibited by the plants experiencing other abiotic stress conditions in the field where damage to any part of the electron transport chain of the thylakoid membrane or loss in the efficiency

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

of the Calvin cycle induced by these stresses may result in an imbalance between the amount of light absorbed and its utilization, leading to building up of the excitation pressure for the induction of photoinhibitory damage. The threshhold of light intensity for induction of such damage depends on the interaction of other stress factors operating in different combinations in the field.

Stress-Induced Alterations in the Structure and Function of the Photosynthetic Apparatus

The modifications of the chloroplast brought about by various environmental stresses are manifested at the levels of pigment composition, structural organizations of the lamellar network, primary photochemistry, and the CO_2 fixation efficiency of the organelle [10–12]. The major stress factors that are monitored either in the laboratory or in the field to examine their effects on the metabolism of chloroplasts include light stress [13–15], drought [15–19], temperature extremes [15,20–25], nutritional stress [26–29], heavy metals [30–32], ultraviolet light [33–39], ozone [40–43], and elevated CO_2 [44–46]. A quantitative loss of photosynthetic pigments, differential response of Chla and Chlb, and remarkable changes in carotenoid composition, particularly an alteration in the composition of xanthophyll cycle components induced by various environmental stress factors, have been widely reported [10–12,15]. These stresses are also known to result in structural modifications in general and electron transport complexes in particular [11,12,15]. The changes in pigments and membrane structures of thylakoids are accompanied by alterations in the rates of primary photochemical reactions associated with PSI and PSII and in the activity of the enzymes of the Calvin cycle [15]. A vast literature, however, is available on the susceptibility of PSII of the thylakoid membrane that has been reported to be a major target of stress [15,47]. This photosystem is known to be associated with various adaptational mechanisms and therefore has been well examined as a key component during the transduction of stress signals for the acclimation of the photosynthetic organelle.

PHOTOSYNTHETIC ADAPTATIONS

Short-Term Stress Adaptation

Although it is difficult clearly to distinguish between short- and long-term stress adaptations, a quick adaptational response of plants to stress is normally referred to as a short-term adaptation. This kind of adaptation may not necessarily need any specific stress-sensing receptors or de novo synthesis of new proteins. The signal transduction may involve a change in the concentration of certain metabolites, phosphorylation-dephosphorylation of proteins changes in protein conformation and dislocation, alteration in membrane-bound complexes, membrane fluidity, and membrane topology in general. Most of these changes are physicochemical in the sense that the changes may ultimately lead to reallocation of matter and energy which favor the chloroplasts to adapt efficiently to the stress. During short-term adaptation, plants without major changes in the synthesis of new proteins or other metabolites make a coordinated interaction between light-harvesting antenna and energy conversion as well as electron transport activities of thylakoid complexes and operation of the Calvin cycle so as to optimize the photosynthetic rate under the changing environment. These kind of short-term adjustments are mostly reversible. Movement and changes in size of the chloroplasts, quenching of excess energy by interconversion of the xanthophyll cycle components, and redistribution of excitons between the PSI and PSII are a few examples of short-term adaptation.

Long-Term Stress Adaptation

During long-term adaptation of chloroplasts, the stress signals lead to the synthesis of proteins, lipids, and pigments, which is sometimes accompanied by the degradation of already existing proteins and other metabolites. Excess or limited production of light-harvesting Chla/b protein (LHCII), DI pro-

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

teins of the PSII core leading to stoichiometric changes of photosystems of the thylakoids, and alterations in the quantity of Rubisco transcripts and its proteins are the stress-induced responses, considered to be in the category of long-term adaptation. The synthesis of stress-tolerant proteins like high light–induced, early light–inducible proteins (ELIPs), heat stress–induced heat-shock proteins (HSPs), and drought-induced dehydrin also is a typical example of the long-term adaptation of chloroplasts to environmental stress.

STRESS SIGNALS AND PSII PROTECTION

PSII Structure and Function

PhotosystemII of thylakoid has been recognized as the major target of environmental stress. A background description of the structure and function of PSII is necessary before various protective mechanisms adapted by the photosystem against different stresses are discussed.

The thylakoid of the photosynthetic organelle consists of several complexes, including PSI, PSII, the Cytbf complex, and ATPase. The primary photochemical events, including electron transport in the membrane, are mediated by these complexes. Since PSII initiates the first step of the photoelectron transport chain and is associated with the water-splitting complex, the photosystem has been extensively examined in different laboratories [13,47–50]. It is a multisubunit complex consisting of more than 25 different proteins. On the basis of their location on the membrane, some of the proteins are considered to be intrinsic and some others as extrinsic and are encoded by both plastid and nuclear genomes. The intrinsic proteins like D1 and D2 in addition to nonprotein components like the Chla dimer (P680), two additional Chla monomers, two pheophytins (pheo), quinone A (Q_A), and quinone B (Q_B), with a nonheme iron, constitute the core complex of PSII. The core complex is coupled to a cluster of 4 Mn and light-harvesting antennae like CP47 and CP43 [51]. Several extrinsic proteins, including a 33-kD Mn-stabilizing protein, are associated with the photosystem at the lumen side. The P680 acts as the primary electron donor and pheo as the primary electron acceptor. The photochemistry of PSII is initiated by charge separation that results in the formation of a $P680^+$ $Pheo^-$ primary radical pair. The Subsequent flow of electron from $Pheo^-$ to Q_A on D2 follows one electron gate pathway. Normally reduced Q_A is not protonated. On the other hand, Q_B on D1 has two electron gates, and after receiving the electrons gets protonated. The protonated Q_B is delocalized, moves to the lipid matrix, and transfers electrons to the Cytbf complex through a shuttling mechanism.

The donor-side electron transport component of PSII primarily consists of the oxygen-evolving complex (OEC) with the Mn cluster. The role of Mn in accumulating positive charges for evolution of O_2 is known [52,53]. The cluster is believed to be closely associated with D1 and D2 proteins. A number of amino acids in these proteins are suggested to be possible ligands for the metal binding. The ion like Ca^{2+} is reported to modulate the structure of OEC responsible for the splitting of H_2O molecules [54].

Chla/b binding proteins, namely LHCII, are known to be associated with PSII. Functionly active LHCII is formed when monomeric units are assembled at PSII in trimeric forms. Information is available on electron crystallographic structures [55] and the distribution of pigments in individual protein subunits of these complexes [56]. The arrangement of the structural components of PSII are shown in Figure 1.

Downregulation of PSII Photochemistry: An Adaptive Mechanism Against Stress

Downregulation of PSII is known as a major defense strategy of chloroplasts experiencing environmental stress. Two major signal transduction pathways induced by high light stress resulting in downregulation of photosynthesis are described below.

The Calvin cycle becomes a relatively poor sink when there is rapid electron transport activi-

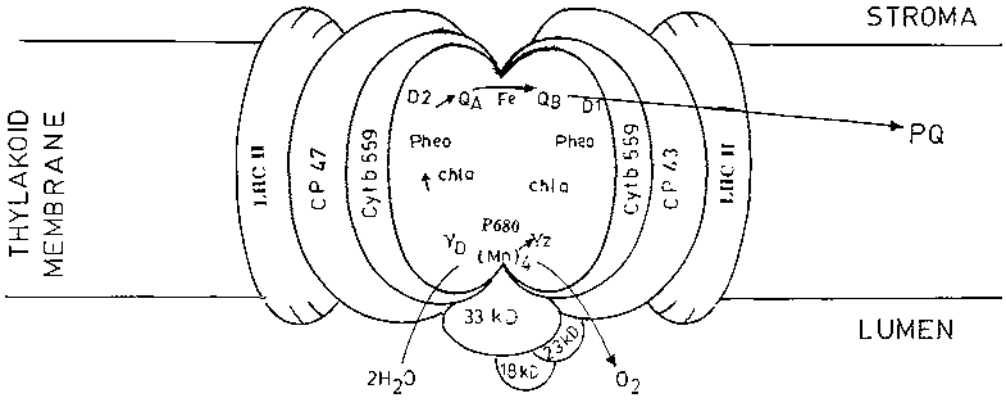

FIGURE 1 A scheme showing major polypeptides, donor and acceptor side components of PSII of thylakoids. The details for abbreviations and descriptions are given in the text.

ties induced by a high light condition. The mismatching between light and dark reactions generates a redox back pressure resulting in PSII inhibition. The inhibition is mostly mediated by overreduction of plastoquinones, particularly the double reduction of Q_A and the development of an acid pH of lumen. Both Q_A production and low lumen pH lead to downregulation of PSII through different mechanisms.

The overreduction of Q_A and its subsequent effects on D1 degradation are critically discussed below. The lowering of the lumen pH downregulates photosynthesis, primarily in two different signaling pathways, one by inactivating the OEC through the release of Ca^{2+} and the other through dissipation of light energy by the operation of xanthophyll cycle in light-harvesting antenna systems.

Inactivation of OEC and Reoxidation of Reduced Q_A

The Lowering of the lumen pH may lead to the release of Ca^{2+} from the OEC associated with PSII in the exchange of H^+ [57]. The release of the cations may cause an alteration in the specific geometry of the Mn cluster resulting in the inactivation of the water-splitting system, and consequently an accumulation and increased lifetime of $P680^+$ and YZ^+ [58]. Second, because of its potential for electrostatic interaction, released Ca^{2+} may bring certain changes in the core complex of PSII that possibly favor a charge recombination between $P680^+$ and Q_A^- and thus a decrease in back pressures. This recombination may lead to the formation of a triplet reaction center, which may degrade D1 protein, and thus have a control over turnover of the protein for photosynthetic adaptation. If the recombination follows a triplet-free route, the reoxidation of Q_A^- itself will decrease the back-pressure inhibition of PSII [58]. Both the signal transduction pathways, however, may be considered as the pathways for chloroplast adaptation against environmental stress.

Operation of the Xanthophyll Cycle

Induction of an acid lumen pH is the basic requirement for the operation of the xanthophyll cycle. Through dissipation of energy, the xanthophyll cycle protects chloroplasts against high-light stress. Since operation of the cycle dissipates excess light energy, it is therefore reported to minimize the requirement of D1 turnover, another adaptive response of PSII of chloroplasts against high-light stress [59]. The cycle basically involves the interconversion of violaxanthin to zeaxanthin through the formation of an intermediate (i.e., antheraxanthin). The enzymes involved for the interconversion are deepoxidase and epoxidase. The deepoxidase enzyme facing the lumen side is responsible for converting violaxanthin to zeaxanthin at low lumen pH induced by high light. On the other hand, the activity of epoxidase facing the stroma enhances the level of violaxanthin from zeaxanthin [15].

Although details of the characteristics of the enzymes are still not known, the violaxanthin deepoxidase has recently been purified as a 43-kDa protein. The gene for the enzyme has been cloned and sequenced [60]. The other enzyme, zeaxanthin epoxidase, has not been properly characterized yet. The pigments of the xanthophyll cycle are distributed throughout the thylakoid membrane mostly on small peripheral light-harvesting chlorophyll protein complexes [60].

Although considered primarily as being a response to high-light stress, the operation of the xanthophyll cycle can also be induced in other environmental stress conditions in the presence of varying light intensities. For example, a decrease in the chlorophyll content and the photosynthetic efficiency with a simultaneous increase in the dissipation of energy through the operation of the cycle have recently been reported by Verhoeven et al. [29] in higher plants under a limiting nitrogen supply. On the other hand, Biswal et al. [26,27] have observed a nitrogen deficiency–induced enhancement in the formation of zeaxanthin in a cyanobacterial system. The other stress factors like temperature extremes and drought may also result in a situation where absorbed light remains in excess and acts as a stress factor [14]. An enhancement in the level of zeaxanthin-antheraxanthin of the xanthophyll cycle may eventually be the response to these stress conditions. An increase in the level of zeaxanthin under a dehydration condition in *Chlorella* sp. to dissipate excess unutilized light energy as observed by Chen and Lai [61] supports this proposition. Similarly, a remarkable increase in the total pool of the xanthophyll cycle components and a relative enhancement in the level of zeaxanthin-antheraxanthin are found to be induced by low temperature even at moderate light conditions [62,63]. The operation of the xanthophyll cycle in a wide range of temperatures has been critically reviewed recently by Gilmore [64].

The signaling system for the induction of the operation of the xanthophyll cycle during high light intensity, low temperature, and drought conditions at moderate light appears to be the same with slight a difference. High light–induced rapid electron transport is known to induce an acid lumen pH, which is a prerequisite for the activation of deepoxidase for conversion of violaxanthin to zeaxanthin. On the other hand, a reduction in the primary photochemical reactions of thylakoids under drought and low temperature fails to develop low lumen pH by the same mechanism. These stress factors are likely to inactivate the function of the Calvin cycle and consequently a limited utilization of ATP molecules. The accumulation of unutilized ATP may prevent proper functioning of ATPase for H^+ transport. Hence, light-driven H^+ movement to the lumen becomes relatively more than its movement supported by ATPase from the lumen to the stroma and causing a low pH in the former. Thus, basically the mechanism of the signal transduction for dissipation of unutilized harmful quanta under high light and other abiotic stress conditions remains the same.

The exact nature of the signal transduction pathway with zeaxanthin as a major player during light stress is not clear. Different possible mechanisms are proposed to explain its role in the dissipation of light energy and the xanthophyll is extensively reported to be the effective quencher of excited singlet chlorophyll. The other major view on the mechanism is that the structural changes of light-harvesting systems induced by zeaxanthin result in the dissipation process. The light-induced lowering of the lumen pH may bring about specific structural changes of light harvesting Chl protein complexes through interconversion of violaxanthin to zeaxanthin. It is likely that a change in the structure may favor the aggregation of LHC and consequent dissipation of excess energy. It is also possible that the change in the structure of LHC could lead to the formation of Chl-carotenoid aggregates or specific, the aggregation of xanthophylls themselves. These pigment aggregates may directly serve as energy quenchers. However, the precise nature of the formation of these pigment aggregates is not known. It is possible that these aggregates are formed from the interaction between LHC trimers. The possibility of the protonation of LHC protein, and consequently aggregation also can not be ruled out [58]. Other possible explanation of energy quenching is the acid pH–induced protonation of amino acid residues of the LHC protein favoring not only the association of zeaxanthin to Chl but also the transfer of energy from singlet Chl to zeaxanthin [58]. The role of zeaxanthin in aggregating LHC with subsequent quenching of excess energy has been worked out in detail recently by Ruban et al. [65]. These investigators have clearly shown zeaxanthin-induced oligomerization of the major chla/b light-harvesting protein of PSII with a concomitant reduction in the

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

yield of Chla fluorescence. Violaxanthin inhibits the aggregation, and consequently there is a rise in the fluorescence yield. These data are indicative of the fact that the excess unutilized light that behaves as a stress signal is transduced through a kind of physical aggregation of light-harvesting units.

On the other hand, the possible role of zeaxanthin in quenching excess energy in different routes has been recently discussed by Eskling et al. [60]. They have proposed that the xanthophyll cycle protects membrane lipids against oxidation stress. The cycle also may modulate the membrane fluidity and blue light response. ABA-induced modification of the stress response through the regulation of the synthesis of the phytohormone by the xanthophyll cycle also has been proposed.

It appears that the signal transduction for the dissipation of excess light energy through the zeaxanthin route still remains unclear and thus needs further investigations.

D1 Turnover

The rapid turnover of D1 protein under high-light stress is an excellent adaptive mechanism that permits thylakoids to avoid complete disassembly of PSII and other subsequent damages. The degradation of D1 is therefore a prerequisite for protecting other components of PSII against photodamage. In addition to high light, light-dependent D1 turnover has been reported when plants experience water stress [66] and nutritional stress [67]. The details of D1 turnover, particularly the possible mechanisms of its degradation, have been critically described in a recent review by Andersson and Barber [13]. Both synthesis and degradation of the protein are dependent on light during the repair cycle of PSII, with the damaged D1 being replaced by its newly synthesized copy followed by reassembly of fully functional PSII on the thylakoid surface.

Although reports are available on the stress-induced degradation of both the D1 and D2 proteins of the PSII core complex [13], the degradation of D2 protein appears to be relatively slow compared with rapid degradation of the D1 protein under high-light stress. It is, however, believed that the D2 degradation is a secondary event followed by the degradation and removal of D1 from the core. The degradation of D2 may not contribute to the PSII repair cycle. The precise nature of the signal transduction associated with the D1 degradation induced by various environmental stresses still remains unclear. To illucidate the mechanism, the degradation of the protein has been investigated in different experimental conditions [13]. It is likely that the protein undergoes a kind of conformational alteration during transmission of the stress signal, and its altered conformation possibly makes it prone to proteolytic degradation. The nature of protease and its action on the degradation of the reaction center core proteins, however, are not yet known even though some information is available on the cleaved fragments of D1 proteins of its N- and C-terminal origins [13,68]. The stress signal transduction leading ultimately to D1 degradation is normally considered as an adaptive response only when the damaged D1 is immediately replaced by a new copy of the protein, otherwise the PSII disassembly becomes irreversible. It appears there is an effective and perfect signal coordinating system that integrates the degradation and synthesis of this crucial protein. A tight coupling between its degradation and synthesis in vivo has been proposed as one of the possible mechanisms operating in higher plants [13]. In fact, the process of D1 degradation becomes slow unless a newly synthesized DNA is available for immediate replacement of the damaged one [13].

The slow degradation of the D1 protein is explained in terms of its phosphorylation [69]. Under certain conditions, this could again be the strategy of the photosynthetic orgenelle to have a compatibility between the rate of its degradation and its synthesis [70]. Recently, Ebbert and Godde [71] have done extensive experimentation on D1 phosphorylation and PSII stability. They have suggested that there are two pools of PSII centers under a high-light condition. The pool of PSII with relative stability is located in the grana lamellae, and these PSII centers are dimers existing in phosphorylated forms. On the other hand, the other pool consisting of monomers of PSII centers is located in the stroma lamellae and are involved in the rapid turnover of the D1 protein. This is

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

the region where D1 is degraded and a new copy is inserted in place of the damaged one. The stability of dimeric and monomeric forms of PSII with reference to D1 degradation during the repair cycle of the photosystem has recently been described by Barber et al. [49].

STRESS-INDUCED SIGNAL TRANSDUCTION THROUGH THE CHANGES IN THE ELECTRON TRANSPORT SYSTEMS ASSOCIATED WITH PSII OF THYLAKOIDS

As discussed, one of the adaptive mechanisms of plants to environmental stress, particularly to high-light stress, is the rapid turnover of the D1 protein. This section briefly deals with how D1 degradation becomes a stress target by two different signal transduction pathways; namely, through the acceptor- and donor-side electron transport systems associated with the PSII reaction center which is believed to be the major victim of the stress. The degradation of the reaction center proteins is preceded by the acceptor- and/or donor-side inhibitions. The details of the components of the donor and acceptor sides are shown in Figure 1.

Signal Transduction Through the Donor-Side Route

The donor side of PSII with the OEC constitutes mainly a Mn cluster and two redox active tyrosine residues of D1 (Yz) and D2(YD) proteins. The Yz couples the Mn cluster to P680, the reaction center of PSII. When light is absorbed, coordinated action of these components at the donor side results in oxidation of water.

Light absorbed by P680 leads to separation of the charge with stable charge pairs like $Pheo^-$ and $P680^+$. The latter possibly extracts an electron from Yz resulting in the formation of Yz^+. Both $P680^+$ and Yz^+ are oxidants with a high oxidizing potential. Since OEC has a very delicate structure and is highly susceptible even to mild stress, which could initially trigger its damage and may result in an inability of the complex effectively to donate electrons to Yz^+ and $P680^+$. These oxidants consequently become long lived, and with a strong oxidizing capacity, they can oxidize pigments, lipids, and amino acids of proteins in the vicinity of PSII. Stress-induced destabilization of the OEC, inhibition at the donor side, and the possible locations of the inhibition have been critically discussed elsewhere [13,47]. The inactivation of the Mn cluster and the Yz may be the major stress-sensing signaling system operating on this side [13,47]. The events associated with the donor-side route may bring alteration in the D1 structure and its subsequent degradation. Jegerschold and Styring [72] have recently shown the damage of D1 protein by strongly oxidizing $P680^+$. They have proposed that with an inactivated Mn cluster, but with effective functioning of the acceptor side, $P680^+$ is the real oxidant that causes damage to the protein. The possible transduction of stress signals leading ultimately to the degradation of the D1 protein through the donor-side route of PSII is depicted in Figure 2.

Signal Transduction Through the Acceptor-Side Route

The transduction of a stress signal through changes in the electron flow of the acceptor side of PSII has been well investigated recently [13,47,73]. The signal transduction that results in the D1 structural change with subsequent proteolytic degradation could be initiated either by a low- or high-light condition in the presence or the absence of other environmental stress factors. The most important component of the pathway is the charge recombination process between Q_A^-/Q_B^- and the oxidized center of PSII. The charge recombination brings about the formation of $^3P680$ and the subsequent production of highly toxic $^1O_2$. Since the half-life of $^1O_2$ is short, its primary target therefore is PSII, particularly its D1 protein, which is known to degrade under this condition [74]. Different mechanisms are proposed to explain charge recombination processes in limiting excess-light stress

Marcel Dekker, Inc.

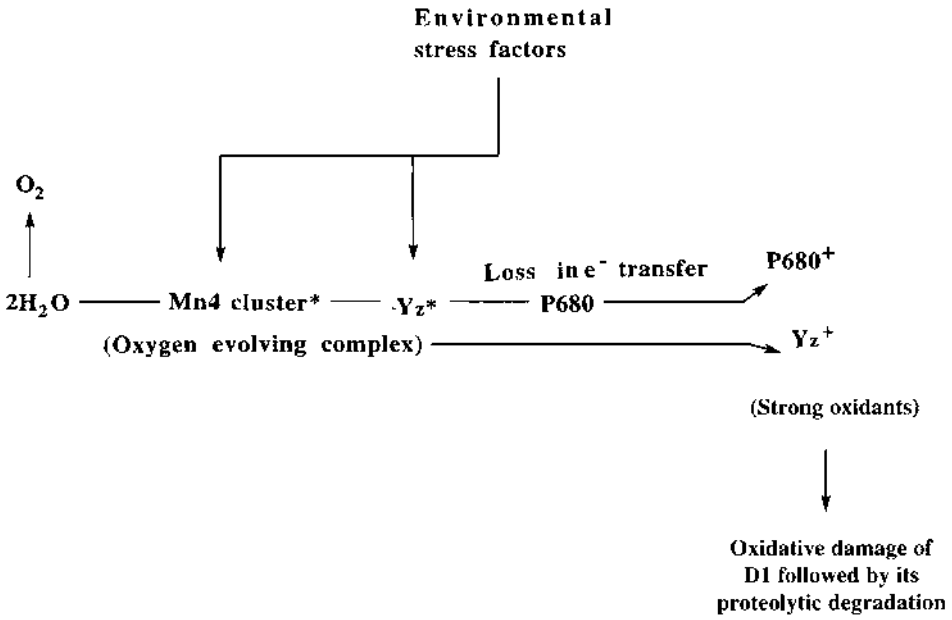

FIGURE 2 The possible mechanism of transmission of stress signals through the donor side of PSII. The stress factors are shown to affect the oxygen-evolving complex and thus reduce the flow of electrons from H_2O to P680, and there is a consequent accumulation of relatively long-lived Y_Z^+ and $P680^+$. These oxidants with high oxidizing potential can oxidize the D1 protein followed by its proteolytic degradation. * Indicates the possible targets of stress.

conditions resulting in the formation of $^1O_2$ via $^3P680$. In extreme low-light intensity, the rates of excitation may lead to a situation where Q_A^- and Q_B^- become relatively long lived. This makes the charge recombination between Q_A^-/Q_B^- of the acceptor side of PSII and the oxidized reaction centers at the donor side that favors formation of $^3P680$ and the subsequent formation of $^1O_2$ (Fig. 3). In extremely low irradiation, the charge recombination between Q_B^- and the oxidized center of PSII is possible before the double reduction of Q_B and its subsequent protonation to plastoquinol. Since this route does not operate in the anaerobic condition, it is $^1O_2$, not the oxidized species at the donor side, that is responsible for the D1 degradation [74]. In low irradiation conditions the possibility of the activation of any protective mechanism, including operation of the xanthophyll cycle or phosphorylation-dephosphorylation of PSII proteins normally induced by high-light conditions is less, the efficiency of low irradiation may therefore be higher than high-light stress for photodamage of PSII [74]. In high-light conditions, the basic mechanism of the signaling system for PSII damage, however, appears to remain the same; that is, through the charge recombination between Q_A^- and the oxidized centers of PSII. The signal transduction through the acceptor-side route resulting in D1 degradation is shown in Figure 3.

Whether it is the acceptor- or the donor-side route, the stress-induced inhibition results in the conformational alteration that signals the proteolytic degradation of the D1 protein [13], although the degradation pattern of the protein by the donor-side and acceptor-side inhibition may be different [68]. The acceptor-side or the donor-side signal transduction path may be induced by other stress factors in the presence of light. For example, drought, extremes of temperature, and other abiotic factors are known to affect CO_2 fixation in the Calvin cycle and thereby modulate electron transport efficiency at the acceptor side leading to excitation pressure at PSII [47] where photoinhibition takes over the rest of the damage, including D1 degradation (see Fig. 3).

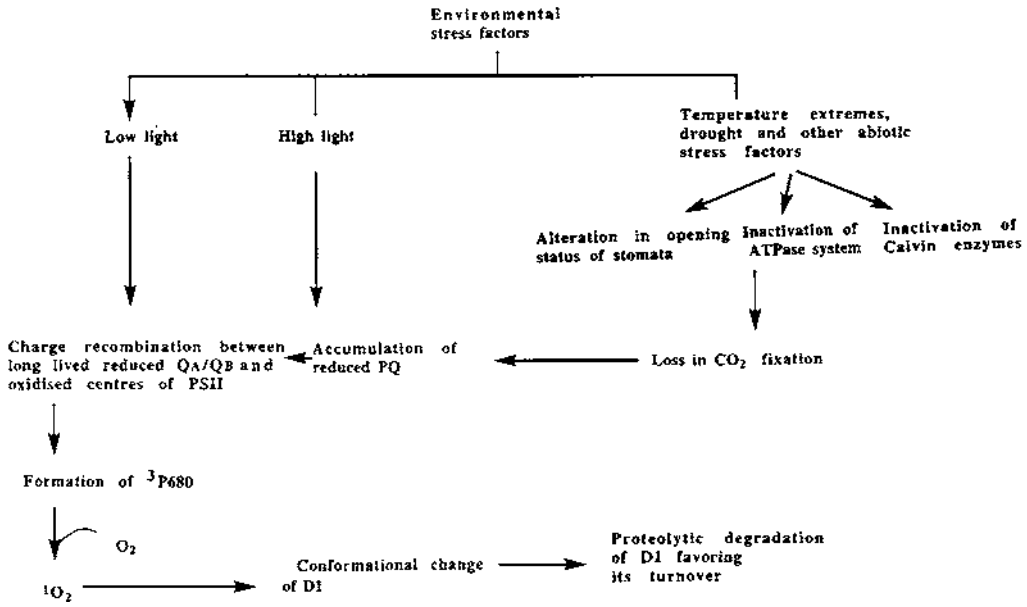

FIGURE 3 The possible stress-signaling system operating through the acceptor side of PSII. Various stress factors may cause closing of stomata, inactivation of enzymes for ATP synthesis, and CO_2 fixation in the Calvin cycle which as a consequence bring about saturation of the reduced PQ pool. The reduced pool leads to recombination of charges between Q_A^-/Q_B^- and oxidized centers of PSII and forms $^1O_2$ which finally degrades the D1, possibly through a protease. The figure also shows the production of $^1O_2$ through charge recombination processes that occur both in low- and high-light conditions.

MOLECULAR BIOLOGY OF STRESS AND CHLOROPLAST ADAPTATION: FROM STRESS PERCEPTION TO GENE EXPRESSION

In most of the stress adaptations, biochemical and physiological responses find their origin from the expression-repression of stress-related genes. The characteristics of such modifications are, however, determined by the interaction of genes with the stress within the genome limit of the plants. However, the question regarding the mechanism of the cellular perception of stress signals, and the subsequent induction of the signal transduction pathway leading to gene regulation has not been clearly answered [3,4,15].

There are three basic categories of stress-induced gene regulations. One of them is related to either overexpression or underexpression of certain genes, and the gene products may not necessarily be stress-specific proteins. The stress-induced changes may require quantitative readjustment of the existing chloroplast components, and depending on the nature of adjustment, underproduction or overproduction of structural proteins-enzymes becomes necessary as an adaptive response. The regulations for such readjustments are therefore considered to be nonspecific to stress. The genes expressed in response to stress in the second category are stress specific, and the gene products may not necessarily be related to the normal cellular activity. The third category of gene regulation involves the expression of genes for the synthesis of scavenging enzymes against oxy free radicals induced by almost all environmental stresses.

Stress-Sensing Signals and Regulation of Nonspecific Genes: Quantitative Readjustment of Chloroplast Components

An extensive literature is available on stress-induced overexpression or underexpression of genes for quantitative alterations of various components of the thylakoids and stroma of chloroplasts [15,75]. The differential regulation of cab gene expression for the synthesis of LHCII at varying light intensities by a redox signaling system is a well-studied example of this category [76]. The cab genes are nuclear genes, and the experiments on the run-on transcription and stability of mRNA clearly suggest that the light intensity, low or high, may act at the level of transcription through a signaling system generated by the redox status of the plastoquinone pool of PSII [77]. It is important to note that this redox-sensing signaling system is not only induced by high light alone but also by other stress factors which could reduce the capacity of the chloroplasts effectively to utilize light energy absorbed by the photosynthetic pigments. In addition to light, the extremes of temperature and water stress may result in a situation where the amount of light absorbed becomes more than its utilization in CO_2 fixation in the Calvin cycle [47]. This may lead to a redox pressure on PSII, a high-light syndrome, and thus generates the same kind of signaling system with the reduced plastoquinone pool as the sensor of these stresses (Fig. 4).

The proposition that the redox status of the plastoquinone pool as the stress-sensing system regulates cab gene expression is supported by the observation of the changes in the transcription of the gene by modulating the redox status of the pool with different types of inhibitors [75]. Escoubas et al. [75] propose that the signal generated by the redox status of plastoquinone from the chloroplast to the nucleus is mediated by a kinase-phosphatase cascade. High-light intensity that is capable of overreducing the plastoquinone pool may result in the phosphorylation of a chloroplast protein by redox-sensing kinase that may activate a protein kinase in the cytoplasm. The cytoplasmic

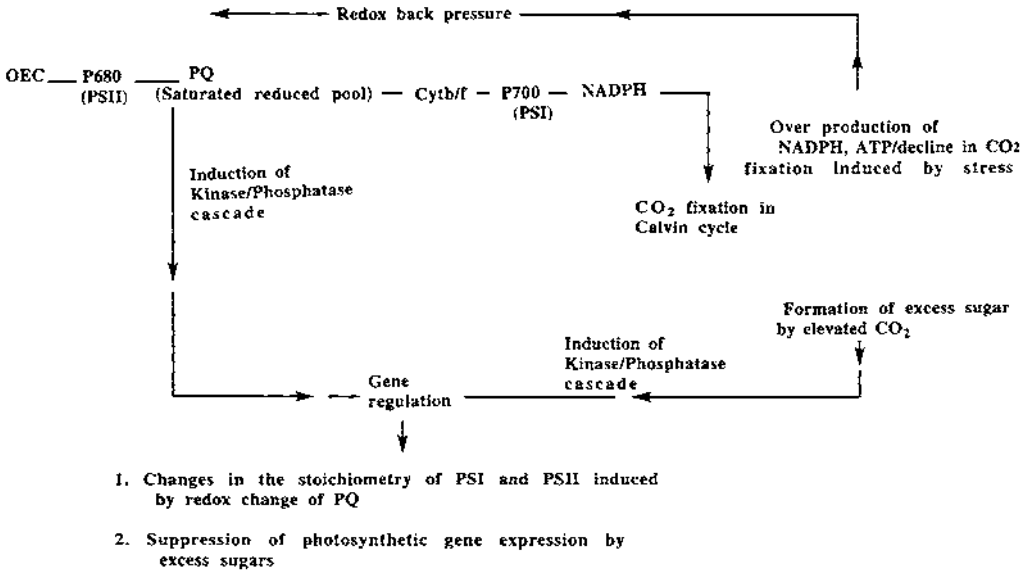

FIGURE 4 A scheme showing overexpression/underexpression of photosynthetic genes during varying environmental conditions. The figure exhibits the possible signal transduction paths of gene regulation for the synthesis of light harvesting and core proteins of photosystems of thylakoids induced by stress through a reduced pool of PQ and suppression of photosynthetic genes by excess sugar, possibly through hexokinase. The details of the stress-signaling systems operating through these paths are described in the text.

protein kinase possibly phosphorylates the cab gene repressor factor, which moves to the nucleus in its phosphorylated form, binds to cab gene promoter, and represses it [75]. In a low-light condition, the plastoquinone pool associated with PSII largely remains in the oxidized form that results in poor activity of the protein kinases and hence switches off this signal transduction pathway. These experiments clearly link a stress-induced signaling system generated through the changes in the rate of primary photochemical reactions and alteration in nuclear gene expression, an adaptive response of the photosynthetic organelle [76]. The signal of the changes in the light intensity not only affects the level of LHC of PSII, but the variation in the intensity could also lead to overexpression or limited expression of genes for core proteins of the photosystem. A high-light intensity is reported remarkably to enhance the level of the D1 protein [78] and the level, on the other hand, goes down when plants experience relatively low-light intensity [79]. It appears that the perception of the light stress, its recognition, and subsequent transduction are so perfect that plants can sense the right mode of the signal transduction pathway when the intensity of a single stress changes.

Another example of the regulation of photosynthetic genes induced by an elevated level of CO_2 is considered here. The production of excess sugar induced by elevated CO_2 as a stress factor leads to a kind of feedback inhibition of photosynthesis, and the inhibition is believed to be controlled at the level of genes [46]. This situation arises when the rate of photosynthesis is relatively high and the sugar-utilizing sinks are saturated. An elevated CO_2 level causes a remarkable loss in the amount of both large and small subunits of Rubisco in addition to the loss of thylakoid proteins like D1 and D2 of PSII core complex and the A1 protein of the PSI core [44,45]. Similar findings on the decline in the level of transcripts for the small subunit of Rubisco induced by excess sugars have been observed recently by Lee and Daie [80]. Although the nature of the signaling system that senses the excess sugar is not properly understood the phosphorylation of sugars mediated by hexokinase is considered as a possible component of the signal transduction pathway [46,81]. The proposition of this kind of signal transduction through hexokinase is supported by the observation of photosynthetic acclimation to a high CO_2 level by overexpression of the enzyme [46]. Different types of sugar-sensing signaling systems and possible mechanisms of the transduction of the signals have recently been discussed by Smeekens and Rook [5] and Ehness et al. [82].

These elegant experiments relating to the photosynthetic response to the changes in the level of light or CO_2 clearly suggest the operation of signaling systems that could rightly sense and recognize the variation in the intensity of a single stress and thus regulate overexpression-underexpression of genes as per the desired readjustment of the photosynthetic components during chloroplast acclimation (see Fig. 4).

Regulation of Stress-Specific Genes

Recently, many stress-responsive genes, particularly some of the genes relating to drought, chilling temperature, heat, and light stress have been isolated, cloned, and characterized. Because the accumulated data during the last 5 years is so vast, this chapter has limited the scope in describing them in detail. Attempts have been made to generalize and to discuss only a few of the major findings.

Induction of ELIP Synthesis: A Response to High-Light Stress

The ELIPs are nuclear encoded proteins that have structural similarities with the light-harvesting complex. These proteins are so named because they were initially thought to be synthesized during the early development of the photosynthetic organelle. However, it now has been established that these proteins accumulate as an adaptive response to high-light stress. Although the precise function of the protein has not been clearly worked out, these proteins may provide a surface for binding and the subsequent stability of free pigments which are released because of the high-light–induced degradation of Chl binding proteins of PSII. Since ELIPs are believed to be Chl binding proteins with four molecules of Chla, two luteins, and few other carotenoid species [83], they may function

as nonphotochemical quenchers of fluorescence and thus protect the photosynthetic organelle against high-light stress by dissipation of energy [84]. Under varying light conditions, a kind of inverse relationship is reported to exist between the accumulation of ELIPs and LHC. The induction of the accumulation of ELIPs with a concomitant decrease in the LHC antenna system may suggest an adaptive response of plants to high-light stress [85]. The details of structure, photoprotective functions, the regulation of synthesis, and the subsequent assembly of these proteins in thylakoids have been recently reviewed by Adamaska [86]. The high-light stress is reported to enhance the level of its transcripts by five- to eightf [85]. Both the transcripts and the proteins of ELIPs remain stable in relatively high- than in low-light conditions [15]. The induction of ELIPs and their regulation both at the transcription and posttranscription levels have been examined by Montane et al. [85] in varying light and temperature conditions.

The mechanism of a high-light–sensing signaling system responsible for the accumulation of ELIPs has not been worked out. In most of the cases, the turnover of the D1 protein induced by high-light stress is linked to the induction of ELIP transcription [86–88]. The stress-induced changes in the redox status of some component(s) of the electron transport chain associated with thylakoids may generate a signal for upregulation of ELIP transcription and translation [85]. Further studies in this direction may provide clues on that signal transduction pathway for the induction of this group of stress-responsive proteins.

Gene Expression and Synthesis of Specific Proteins Under Water and Salt Stress

Our knowledge on the perception of water stress signal, its transduction leading to specific gene expression, and finally processing of the gene products is still limited. It appears there are multiple pathways of signal transduction systems operating at the cellular level for gene regulation. The loss of water from the cells, one of the initial events of water deficit, may affect turgor and changes in size and membrane properties. Although the precise nature of signal-sensing mechanisms is not clearly understood, a few osmosensers associated with the membrane may transmit the signal through a cascade of phosphorylation-dephosphorylation leading to expression of specific genes [4].

Although the components of the signal transduction pathway are difficult to identify, ABA is well known as one of such components acting in one of the signal transduction pathways [4,89]. Experiments conducted so far clearly indicate ABA-dependent and ABA-independent pathways for the induction of stress-related genes. Participation of different elements of DNA regulating stress induction of gene expression supports this proposition [4].

In addition to the expression of genes for the production of late embryogenesis–abundant (LEA) proteins, including dehydrin, a set of stress-specific proteins synthesized as a response to water deficit [4], the stress has recently been reported to induce a chloroplastic lipoxygenase. The cDNA of the gene has been isolated, sequenced, and characterized [90]. The stress is also reported to induce two important chloroplastic proteins with a molecular weight of 32 and 34 kDa, which have been well characterized recently [91]. The 32-kDa protein is located in the stroma, and its synthesis is likely to be induced by a high osmolarity–related signal. On the other hand, stress-induced synthesis of a 34-kDa protein located in the thylakoids is mediated by an ABA-related signaling system. This protein may be involved in the reorganization of the thylakoid structure in order to tolerate the stress, and the 32-kDa protein may regulate the osmolarity of the stroma. Although synthesis of both the proteins is induced by water deficit, this signaling system for induction of their synthesis appears to have two different routes. It is interesting to note that the synthesis of the 34-kDa protein is induced not only by drought stress but also by low temperature and high salinity [91], which may suggest a single channel for transduction of signals generated by all the three kinds of stresses. But the drought stress resulting from low temperature and salinity and then operating in the channel cannot be ruled out.

It is well known that salt stress in addition to an ionic effect also results in dehydration.

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

Therefore, salt stress–induced signal transduction is likely to have common routes with the signaling systems that are operative during drought and other environmental stresses causing dehydration. One of the pathways is mediated by the accumulation of osmolytes or compatible solutes, including sugars, amino acids, and proteins. These solutes maintain a kind of osmotic balance and then protect the cells-organelles against dehydration [4]. *Glycinebetaine*, a quaternary ammonium compound, is known to stabilize OEC [92], Rubisco [93] and against salt stress [94]. The codA gene responsible for the synthesis of choline oxidase and converts choline to glycinebetaine has already been cloned and characterized. The transgenic plants with overexpression of the gene have already been found to protect PSII activity in chloroplasts. Recently, the details of the gene regulation of the accumulation of proline, one of the major osmolytes induced by osmotic stress, have been critically reviewed by Yoshiba et al. [95]. A desired level of proline accumulates as a response to the stress by the regulation of genes activating the synthesis and inactivating the degradation of proline. A tilting of balance toward its synthesis may lead to overproduction of the osmolyte, and thus plants develop salt- or water-stress tolerance. However, the specific role of proline for photosynthetic acclimation still remains unclear.

Temperature Stress and Gene Expression

Reports are available on low temperature–induced gene expression in plants experiencing temperature stress [2,96–99]. Some of the genes relating to the stress also have been cloned and characterized [100]. However, the nature of the signaling system for gene expression and the mechanism of the photosynthetic adaptation are still not clearly understood.

The expression of two low temperature–induced genes (cor15a and cor15b) encoding for two proteins of a 15-kDa molecular weight each has been reported by Lin and Thomashow [101] and Wilhelm and Thomashow [102]. These proteins are targeted to the chloroplast. Since the induction is mediated by exogenous ABA [102], it is possible that the signal may be transmitted through the ABA route. The accumulation of compatible solutes like betaine in the cold-induced signal transduction pathway has recently been worked out both in cyanobacteria [103,104] and higher plants [94]. These investigators have shown expression of genes induced by low temperature followed by the accumulation of betaine that protects the photosynthetic organelle against the stress.

Extensive reports are available on the induction of gene expression by heat-shock treatments. The plastid-specific heat-shock proteins are linked to the protection of the photosynthetic organelle during light and heat stress [15].

The nature of the signal transduction system associated with the gene expression induced by heat shock and posttranscriptional as well as posttranslational modifications are not known, and the function of heat-shock proteins to protect chloroplasts is not clear. However, Debel et al. [105] have recently observed the accumulation of a 23-kDa nuclear encoded heat-shock protein in the mitochondria under light stress. High light, because of the production of heat, may result in the induction of heat-shock proteins. Debel et al. have proposed that under high-light conditions, the stress signal transduction for chloroplast proteins is very complex. A possible coupling of the chloroplast and mitochondrial functions through photorespiration under high-light conditions has been proposed. Since photorespiration is known to protect the chloroplast against photoinhibition, it is likely the response induced by heat-shock proteins in the mitochondria may have a link for photoprotection of chloroplasts through photorespiration, thus resulting in a long route signal transduction pathway involving two important organelles of the cell.

The studies on the expression of specific gene products relating to the stress factors other than light stress, drought, and temperature extremes are scanty and therefore are not discussed in this chapter.

Oxidative Stress and Regulation of Defense Genes

As discussed earlier, the excess light not utilized in the photochemical reactions of chloroplasts causes photodamage of the organelle. However, plants develop different kinds of adaptive mecha-

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

nisms to counter this stress effect in different ways which have also been discussed. In spite of these defense strategies, there is a possibility of stress-induced disorganization of the thylakoid complexes and leakage of electrons to O_2 which results in the formation of various toxic O_2 species. The damage to the photosynthetic organelle induced by the formation of oxy free radicals is well known [106]. The plants therefore develop a second line of defense mechanism against these toxic O_2 species, including $O_2^{\cdot -}$, H_2O_2, $^{\cdot}OH$, and $^1O_2$. The stress-induced formation of these toxic species is reported to induce the expression of the genes responsible for the synthesis of superoxide dismutase, ascorbate peroxidase, and glutathione reductase that effectively scavenge these harmful species and thus protect plants in general and chloroplasts in particular against oxidative stress. The details of the regulation of the gene expression for the synthesis of these scavenging enzymes in plants experiencing drought, chilling, and salt stresses in different plant systems have been recently reviewed by Eshdat et al. [107] and Alscher et al. [108]. The induction of an oxidative environment is normally considered as a secondary event created by many abiotic and biotic stress factors that plants experience. The molecular mechanism of signal transduction induced by the events associated with oxidative stress resulting in the genetic response still remains unclear. However, two major components in the signal transduction pathway, namely, thiol-disulfide exchange reactions involving the glutathione pool and the production of H_2O_2, are proposed to be crucial for gene regulation [109]. Both thiol-disulfide exchange reactions and H_2O_2 are reported to couple the stress to the expression of genes for defense against O_2 free radicals [109]. Among the reactive O_2 species, H_2O_2 is considered to be the most stable one, and its production through the electron transport chain of thylakoids is well known. H_2O_2 as a possible stress-signaling molecule, acting at the level of genes, is supported by the observations of the induction of proteins reported to cause low-temperature tolerance on its exogenous application to higher plants [109]. Recently, Karpinski et al. [110] have shown a novel type of long route signal transduction path induced by O_2 free radicals under high-light conditions. High light–induced alteration in the redox status of the plastoquinone pool has been suggested to act as a light-sensing mechanism and is linked to the production of H_2O_2. The stress-induced event results in a remarkable increase in the transcripts of two ascorbate peroxidase genes. These enzymes are cytoplasmic and are involved in regulating the redox level of the glutathione pool. The unique feature of this signal transduction for the expression of genes to counter the oxidative stress is that the gene products do not participate directly in chloroplasts, although the initial signal is generated by redox reactions associated with the thylakoids of the organelle. The signal-induced expression of genes prevents photooxidative damage through scavenging of H_2O_2 produced by thylakoids but is located in the cytoplasm [110].

The literature on the induction of scavenging enzymes as a response to stress is rich, but the picture of the stress-induced signal transduction path leading to gene expression still remains hazy. There is no unambiguous experimental proof to accept H_2O_2 and the thiol pool as the stress-sensing components for gene regulation. This needs further clarification.

CONCLUSIONS AND PERSPECTIVE

Our knowledge of the plant response to environmental stress has remarkably progressed in the last two decades because of the availability of highly sophisticated techniques and the rapid expansion of our knowledge in plant science, particularly in the field of molecular biology. The literature on the molecular biology of the chloroplast is very rich. The organelle genome is well characterized, and information is available on the regulation of most of the photosynthetic genes. The response of some of the genes to stress also have been reported. But the central question of the recognition of the stress signal by the cell, its transduction for gene regulation, and photosynthetic modifications by gene products is not fully answered.

This chapter has focused primarily on the response of the chloroplast with particular reference to the photosynthetic acclimation in the background of the operation of possible stress-signaling systems. The field is so complex and our knowledge is so limited, we have been compelled to address some of the fundamental unanswered questions in this section.

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

1. As discussed earlier, although the presence of green pigments and the potential of producing strong oxidants, make plants capable of splitting H_2O molecules for the liberation of O_2, this make them prone to environmental stress. Because of the association of the production of strong oxidants with PSII, the photosystem plays a key role in the stress-signaling system during photosynthetic acclimation. The stress response of PSII has, therefore recently become the major area of research. This chapter also reflects this view. However, the interpretation of most of the data is made on the background of PSII structure and function, which are extrapolated mostly from our knowledge of reaction centers of bacterial systems. Although O_2 evolution by green plants was discovered more than two centuries ago, the knowledge we have gained so far does not add to a clear understanding of the mechanism of H_2O splitting during photosynthesis. We do not know the precise topology of Mn in PSII, but the Mn cluster in the vicinity of the photosystem has been recognized as a major stress-sensing system. Unless we get a clear picture of the geometry of the Mn protein complex of PSII, it will be difficult to explain the mechanism of the transmission of the stress signal associated with it.

2. Most of the signal transduction pathways during photosynthetic acclimations are discussed with the kinase-phosphatase cascade as the stress-signaling system as reviewed in this chapter. But the details of the mechanism of protein phosphorylation leading to its conformational modifications have not been worked out. Again, the induction of nuclear gene regulation by protein phosphorylation in the chloroplast has to be explained in terms of transmission of the signal between these organelles. A clear understanding of the integration and coordination of the stress-signaling systems in the cellular environment during photosynthetic acclimation needs extensive experimentation.

3. This chapter has focused on the D1 turnover in PSII as a crucial event for chloroplast adaptation during light stress. But the nature of the degradation of the protein by the stress largely remains unclear. The stress-inducing signaling system involving charge recombination between Q_A^-/Q_B^- and the oxidized centers of PSII is reported to generate $^1O_2$ which is believed to bring oxidative damage to the D1. But the precise nature of the damage of the protein that makes it prone to proteolytic degradation is still obscure. The nature of so-called protease also remains ambiguous.

Similarly, stress signal transduction through the operation of the xanthophyll cycle has been considered as a photosynthetic adaptation. The mechanism of quenching of excess harmful quanta by zeaxanthin, however, remains rather controversial and needs further clarification.

4. The expression of the genes responsible for the synthesis of stress-specific proteins, including ELIPs, HSP, and LEA, in response to environmental stresses, has extensively been investigated. Most of these stress-responsive genes have been isolated, cloned, sequenced, and well characterized, but their precise functions in stress adaptation, particularly during photosynthetic acclimation, are not clearly understood.

We have several such unanswered questions in this area of research, but we have, at the same time, sufficient optimism to find answers to them in the near future because of our access to new technology and also because of our commitment and compulsion to study photosynthesis relating to stress, because the study is directly linked to plant productivity.

Effect of High-Temperature Stress on the Photosynthetic Apparatus

Robert Carpentier
Université du Québec à Trois-Rivières
Trois-Rivières, Québec, Canada

INTRODUCTION

The action of physiological stresses on plants has been a subject of numerous studies. Plants are able to survive and grow even under unfavorable environmental conditions. Living organisms can hardly survive below −3°C, because most of the biochemical reactions are hampered owing to the high content of water in the living tissues. Some plant species can grow under desert conditions and relatively high temperatures, but most species are sensitive to a variation of a few degrees below or above their normal growth temperature. In the higher temperature zone (37–47°C), tolerance mechanisms may allow some extent of adaptation. Hence, photosynthetic organisms can tolerate temperatures above their normal growth temperature. The latter may be very high for desert plants but relatively lower for other species. Each species has its own optimal temperature and its lower and higher temperature limits. When exposed to changing temperatures, various structural modifications are known to happen at the molecular level. Such modifications include changes in the rate of metabolic reactions as well as modifications of subcellular structures. A heat shock is induced when a plant is brought near to its higher temperature limit for growth. Of course, even a relatively weak temperature variation can alter the normal cellular biochemical processes which could be considered as a heat stress. However, an increase of 10–15°C above normal growth temperature will cause a deeper modification of growth without being necessarily lethal. Those changes involve protein denaturation, enzyme inactivation, and more specifically a reduction in the chloroplast's photosynthetic activity.

In this chapter, the action of high-temperature stress at the level of the photosynthetic apparatus will be examined. Heat stress induces significant modifications in the composition of the chloroplast membrane lipids and proteins together with structural changes of the thylakoid membranes. Those changes greatly affect the activity of the photosystems. However, some adaptation mechanisms can prevent excessive damage if plants are preexposed to high temperature. Acclimation

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

mechanisms may involve some changes in the chloroplast membrane fluidity and lipid composition as well as the synthesis of heat-shock proteins.

DAMAGING EFFECTS OF HIGH TEMPERATURE ON THE PHOTOSYNTHETIC MEMBRANE

Heat stress results in a progressive decline of photosynthetic activity in terms of electron transport and CO_2 fixation [1–3]. In general, the photosynthetic activity remains stable up to 30°C but sharply decreases above this temperature to reach a complete inhibition at about 40°C [2]. Thylakoid membranes inside the intact chloroplast are somewhat less sensitive to heat in comparison with the isolated counterpart [4]. This is explained by the protective effect of stromal solutes [4]. Further, thermal damage to the thylakoid membrane in the intact chloroplast arises at a lower temperature in comparison with the chloroplast envelope membrane that is affected only between 53 and 57°C [5].

Alteration of Lipid and Protein Composition

The action of high temperature is not followed by major chemical modification of chloroplast membrane lipids such as the oxidation of unsaturated fatty acids. A 3-min exposure (in vivo or in vitro) at 48°C did not significantly influence the composition in fatty acids of the lipids in the thylakoid membranes in comparison with controls treated at 20°C [6]. However, the level of free fatty acids in the thylakoid membrane may increase by up to two- to threefold after incubation of the isolated membranes at high temperature. The most abundant fatty acids generated are the unsaturated ones such as linoleic acid and hexadecatrienoic acid [6]. Thylakoid membranes mainly contain monogalactosyl diacylglycerol (MGDG), digalactosyl diacyglycerol (DGDG), sulfoquinovosyl diacylglycerol, and phosphatidylglycerol. MGDG and DGDG are composed of a large proportion of highly unsaturated fatty acids. Thermal stress was also shown to induce a decrease in the MGDG/DGDG ratio and an increase in the incorporation of DGDG with saturated fatty acids into the thylakoid membrane [7].

It must be emphasized that even weak quantities of unsaturated fatty acids such as linoleic acid in the thylakoid membranes contribute to an increased sensitivity to thermal stress at 30°C [6]. It is suggested that endogenous lipases activated by thermal exposure may increase the content of free fatty acid with a resultant increase in polar interactions at the membrane surface which reduces the thermostability of the membrane structure. Thus, the formation of free fatty acids during heat stress could be an important mechanism leading to thermally induced damage. High-temperature treatment produces a raise in membrane fluidity and lateral diffusion of membrane lipids [8]. It was also suggested that membrane permeability increases during treatments at high temperature which resulted in a decrease in proton gradient formation across the thylakoid membrane [3]. The decreasing proton gradient formation as temperature is raised above 30°C is also suggested from the inhibition of the energy-dependent nonphotochemical fluorescence quenching qN at those temperatures [9,10].

It was shown by autoradiography that the synthesis of several thylakoid membrane proteins was strongly reduced during exposure at elevated temperatures [7]. This reduced synthesis includes the apoprotein of the reaction center of photosystem II (P680), subunits α and β of ATPase synthetase, cytochrome *f*, cytochrome *b*559, and the apoprotein of the core antenna complex CP47 [4]. All these polypeptides are coded by the chloroplastic genome. On the other hand, the light-activated protein kinase of the thylakoid membrane remained active as demonstrated by the phosphorylation of six-membrane polypeptides (9.0, 25.5, 26.0, 32.0, 33.0, and 43.0 kDa) during heat treatment at 50°C [7]. It was also noted that the small subunit of rubilose bisphosphate carboxylase and some polypeptides of the light-harvesting complex of photosystem II that are imported into the chloroplast in an ATP-dependent process are still accumulated even after inactivation of the ATPase synthetase.

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

It is suggested that the conformational changes of the chloroplast membrane that occur during heat stress improved the membrane permeability for cytosolic ATP.

Structural Changes

Important structural changes modify the thylakoid membrane integrity following exposure at elevated temperatures [11,12]. The first changes appear in the 35–45°C interval as a decreased membrane stacking and a general reorganization of the thylakoid membranes. Above 45°C, a transformation of membranes into vesicles is observed. Freeze-fracture experiments have indicated the dissociation of the major light-harvesting complex of photosystem II from the core complex [13,14]. This dissociation is supposed to coincide with the decreased membrane stacking with the consequent formation of antenna-depleted photosystem II in the nonappressed region of the thylakoid membranes. A careful analysis of the protein composition of barley thylakoid membranes during heat stress at 46°C has also shown that the photosystem II core complex dissociates from a dimeric to a monomeric form, whereas the major light-harvesting complex is fractionated from a trimeric to a dimeric aggregate [15]. The above dissociations can be attributed to the increased fluidity of the thylakoid membrane mentioned in the previous section and to the modification in the hydrophylic and hydrophobic interactions.

Photosystem II cores with their full complement in light-harvesting complex were denoted as PSII-α, whereas the depleted photosystem II cores formed during heat stress were found to be similar to PSII-β located in the stromal lamellae [16,17]. An increase in PSII-β with increasing temperatures was recently confirmed from measurements of fast-induction chlorophyll fluorescence [18]. Heat treatment at 45°C thus results in an increased photosystem II/photosystem I ratio in the nonappressed region [16]. This progressive process is reversible up to 45°C; at this temperature, irreversible modifications are produced.

Changes in the antenna size of photosystem II units during heat stress also result in a modification of the distribution of absorbed energy between photosystem I and photosystem II. The reversible effects of moderately elevated temperature on excitation energy distribution are similar to the formation of state II, a state where the absorbed energy is preferentially redistributed toward photosystem I in contrast to the opposite state I [16,19,20]. This change in energy distribution could protect photosystem II against excessive damage caused by strong illumination (photoinhibition) that usually prevails simultaneously with high temperature in the environmental conditions [16,19]. It was shown that heat stress up to 42°C did not affect the possibility of state transition in the thylakoid membranes, which is however abolished at 47°C [9]. Thermal unstacking of the thylakoid membrane at this latter temperature should rather imply randomization of the protein complexes independently from state transition. It is proposed that the phosphorylated light-harvesting complexes of photosystem II move away from the photosystem and that photosystem II core complexes (PSII-β–like) migrate to the unstacked regions of the thylakoid membranes leaving the light-harvesting complexes in the grana region [21]. This reorganization does not necessarily imply an increased antenna size for photosystem I.

Inhibition of Photosynthetic Activity

Photosystem II

It has been known for some time that the process of oxygen evolution constitutes the most sensitive reaction to heat stress in photosynthesis and that photosystem II is much less resistant to heat in comparison with photosystem I [3,22]. Thus, artificial electron donors to photosystem II such as 1,5-diphenylcarbazide can reconstitute the electron transport activity after heat deactivation [22]. Experiments in the presence of ethylenediaminetetraacetic acid (EDTA) have shown that thermal inactivation is due to the extraction of divalent cations (Ca^{2+} and Mn^{2+}) from the oxygen-evolving complex of photosystem II [23]. Other studies have shown that inactivation of photosystem II was

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

accelerated in the absence of Cl^- [24]. It was demonstrated that the addition of 1 mM Mn $(CH_3CO_2)_2$ decreases the temperature of half-inactivation by 2°C in isolated membranes enriched in photosystem II and fully complemented with Cl^-, whereas in the absence of Cl^-, this parameter decreased by 7–8°C [24]. This acceleration of the thermal inactivation was specific for Mn. Heat treatment also produced the release of three extrinsic polypeptides (18, 24, and 33 kDa) and half of the Mn associated with the oxygen-evolving complex from the membranes [24]. It was alternatively suggested that thermal inactivation of oxygen evolution was not specifically due to the release of Mn from the oxygen-evolving complex but rather to the dissociation of the 33-kDa extrinsic polypeptide that is involved in the stabilization of the Mn cluster [25].

The antenna complex of photosystem II is also sensitive to heat stress. Thus, chlorophyll fluorescence from chloroplasts decreases progressively with elevated temperature from 20 to 48°C [1]. Thermal inhibition of photosystem II is accompanied by a decrease of the variable portion of chlorophyll fluorescence associated with the photochemical activity of the photosystem and the so-called photochemical fluorescence quenching, qP [9,10,26,27]. This decline arises from a quenching of the maximal level of fluorescence, Fm, and an important increase of the minimal level, Fo, especially above 40°C [28]. The increase of Fo is either explained by the accumulation of reduced Q_A [29,30], or by the disconnection of the major light-harvesting complex from the photosystem II core [13,14]. However, a recent study using time-resolved fluorescence measurements in heat-treated leaves has shown that the major portion of the increase of Fo above 40°C is related to the disconnection from the photosystem II core of a protein complex containing only a small portion of the total antennae chlorophyll molecules [31].

The inhibition of photosystem II activity in intact leaves was shown to be largely attenuated if heat stress at 40°C was performed during illumination under low-light intensity [32,33]. However, this effect was attenuated by far-red light [32], and strong illumination accelerated the damaging process [34–36]. Photosystem II complexes devoid of the extrinsic proteins and of Mn involved in the process of oxygen evolution can be reassembled into an active complex by weak illumination in the appropriate medium. It is postulated that low light prevents thermal inactivation through a process of photoactivation that counterbalances the light-induced dissociation of the oxygen-evolving complex [37].

Photosystem I

Photosystem I is more resistant to heat stress and on inactivation of photosystem II in potato leaves, photosystem I catalyzes electron flow from endogenous stromal reductants [38] and may also retain its cyclic electron transport activity in leaves [39]. Optimal activity of electron transport from 2,6-dichlorophenolindophenol ($DCIPH_2$) to methylviologen was reported after incubation of thylakoid membranes at a temperature of 50°C [40]. Photosystem II activity is fully inhibited under such conditions [41–43]. A hypothesis to explain the above heat stress–stimulated electron transport rates is that new reduction sites or greater affinity for the artificial electron donors used in activity measurement was created at the level of the cytochrome b_6/f complex following membrane reorganization during heat stress [40,44,45]. This interpretation was based on the loss of the increased activity at 50°C in the presence of KCN or $HgCl_2$, two inhibitors affecting electron transport between the cytochrome b_6/f complex and the photosystem I reaction center complex. Further, the inhibitor 2,5-dibromo-3-methyl-6-isopropyl-p-benzoquinone (DBMIB) that binds to a site prior to the cytochrome b_6/f complex presented no effect on the enhanced activity. The new reducing sites would be created owing to changes in lipid-protein interactions induced by the temperature treatment.

Another hypothesis to explain the high photosystem I electron transport activity after exposure to a temperature of 50°C concerns the dissociation of the antenna complex of photosystem II during heat stress. It was suggested that the dissociated light-harvesting complex could become associated with photosystem I [12,13] and reversibly increase its activity at elevated temperature in favor of the development of state II [46]. However, further experiments have shown that the enhanced activity at 50°C is also observed in isolated photosystem I-enriched submembrane fractions which demonstrate that dissociation of the light-harvesting complex from photosystem II is not required [47]. It was also proposed that this effect could be due to thermal uncoupling of ATP synthesis owing to

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

a decreased proton gradient following an increased membrane fluidity after heat stress [12]. However, it was later shown that no enhancement was produced if the electron donor N,N,N′,N′-tetramethylphenylenediamine (TMPD) was used in place of $DCIPH_2$ [40,44,47].

The heat-induced stimulation was also lost when $NADP^+$ was used as the final electron acceptor instead of methylviologen [48]. It was deduced that the activity of the membrane-bound superoxide dismutase (SOD) decreases at elevated temperatures which would be at the origin of the activation of photosystem I activity. However, a more complete study using various electron donors in a photosystem I-enriched submembrane fraction [49] has shown that the stimulation was independent from the redox potential of the electron donor and from conformational changes at the level of the cytochrome b_6/f complex. Instead, thermal stress was suggested to release the membrane-bound SOD from the thylakoids, thus allowing artificial electron donors with appropriate properties such as hydrophobicity and capability to donate protons, directly to reduce superoxide radicals to hydrogen peroxide at the expense of the usual disproportionation of superoxide into oxygen and hydrogen peroxide with a resultant enhancement of oxygen-uptake activity [49].

Independently from the reactions involving oxygen uptake, higher rates of light-induced P700 oxidation were obtained after incubation of thylakoid membranes above 40°C with an optimal effect at 50°C [46,50]. This increased activity in whole thylakoid membranes was associated with a greater antenna cross-section in photosystem I after heat stress [50]. An increase in the fluorescence ratio F735/F685 measured at 77 K in the stromal portion of heat-stressed thylakoid membranes (50°C) was connected with changes of interaction between photosystem I and PSII-β that would favor energy distribution toward photosystem I [51].

ACCLIMATION TO HIGH TEMPERATURE

Changes Related to Membrane Fluidity and Structure

Plants can become adapted to elevated temperatures if they are exposed to moderately elevated temperature during their growth, with this property being dependent on their physiological state [52]. For example, senescent plants can hardly become adapted, because they are more sensitive to heat stress. Such thermal adaptation is associated with thylakoid membrane reorganization leading to better stability against further exposure to heat stress [8].

Isolated thylakoid membranes can be stabilized and better protected against elevated temperatures by immobilization in various media such as an albumin-glutaraldehyde cross-linked matrix or in polyvinylalcohol films [53,54]. Alternatively, the membrane stability under heat stress can be improved on addition of various solutes in the media. For example, glycinebetaine, glycerol, and sucrose were shown greatly to stabilize the oxygen-evolving function of photosystem II in thylakoid membranes or photosystem II-enriched membranes exposed to heat stress [55–57]. The temperature for inactivation of primary electron transport reactions in photosystem II-enriched membranes was also greatly reduced in the presence of glycinebetaine or sucrose [58]. Osmolytes are also present in plant cells, and osmotic pressure has been suggested to increase tolerance of the photosynthetic apparatus against heat stress [52]. Hence, desert plants increase their resistance by six- to ninefold at the end of their summer season owing to an increase in the cellular concentration of small molecules [52].

Transfer of photosynthetic organisms from 20 to 45°C results in a rapid modification of membrane fluidity [59]. There is no phase transition affecting the molecular order of membrane lipids during thermal adaptation; rather the changes are due to some modifications in the hydrophylic and hydrophobic forces. After adaptation, there is a significant accumulation of DGDG, and, more specifically, 16% of the molecular mass of DGDG is composed of saturated (18:1/16:0) fatty acyls. Also, the MGDG/DGDG ratio decreases from 1.3 to 0.9 [7,60]. The protective action of DGDG may be associated with its capability to form bilayers in contrast to MGDG [7,60]. Using homogeneous catalytic hydrogenation of thylakoid membranes, it was shown that saturation of *cis* double bonds of lipid alkyl chains resulted in a significant increase in the thermal stability of photosystem II and of general membrane structure [61]. Along those lines, mutants of *Arabidopsis thaliana* with

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

reduced levels of polyunsaturated lipids presented a significant decrease in membrane stacking resulting from a decreased amount of thylakoid membranes per chloroplast and from an increased stability of photosynthesis toward heat stress [62,63]. However, recent studies using *Synechocystis* PCC6803 and *Anacystis nidulans* R2-SPc with modified desaturases demonstrated that elimination of dienoic lipids molecules, but not trienoic lipids molecules, produced some extent of decrease in heat tolerance [64,65]. It was concluded that an increase in the unsaturation of membrane lipids reduced sensitivity to chilling stress but not to heat stress [65]. Adversely, using a mutant of *Chlamydomonas reinhardtii* impaired in chloroplast fatty acid desaturation and which indeed presented a reduced level of unsaturation of thylakoid membrane lipids, it was shown that a lowered unsaturation level contributes to the high-temperature tolerance of photosystem II [66].

A role of the carotenoid zeaxanthin in the acquisition of thermostability has been suggested from experiments in which potato leaves or whole plants were exposed to a temperature of 35°C [67,68]. Elevated temperatures would promote the dissociation of violaxanthin molecules from the surface of the light-harvesting complexes which make this xanthophyll accessible for deepoxidation into zeaxanthin molecules by the membrane-bound xanthophyll deepoxidase [68]. Accumulation of zeaxanthin in the thylakoid membrane has been shown to reduce membrane fluidity [69]. It is thus proposed that the formation of rigid carotenoids such as zeaxanthin preserves membrane permeability and photosynthetic activity during heat stress [68,70].

Protein phosphorylation of the thylakoid membranes is less pronounced in thermotolerant plants. The lower phosphorylation state of the major light-harvesting complex may prevent its abusive dissociation from the core complex of photosystem II, with the phosphorylation being required for the migration of the light-harvesting complex [7]. Because the protein kinase remains active in plants exposed to a thermal stress, severe inhibition of the phosphoprotein phosphatase or possibly a conformational change of phosphoproteins of photosystem II that would decrease their accessibility to phosphorylation would be responsible for the low phosphorylation state of acclimated plants [7]. The light-harvesting complex is suggested to present a structural and stabilizing role in photosystem II under heat stress maintaining the oxygen-evolving complex in a functional state [37,71].

Finally, in the cyanobacterium *Synechoccus*, it was proposed that the presence of the low potential cytochrome *c*550 is responsible for the heat stability of oxygen evolution [72]. This cytochrome is supposed to be membrane bound to the lumenal side of the thylakoid membrane near the oxygen-evolving complex, but its mode of action remains unknown [72].

Synthesis of Heat-Shock Proteins

Synthesis of heat-shock proteins (HSPs) in plant species adapted to a temperate environment occurs mostly at temperatures above 32°C but is maximal at around 39–40°C for most species [73,74]. A large number of HSPs were initially found in the chloroplast. In fact, 19 proteins were reported to accumulate during heat stress and were detected in the soluble fraction of the chloroplast [7]. However, experiments using purification of the chloroplast fraction in Percoll gradients have shown three high molecular weight HSPs (96, 74, and 67 kDa) and 6 low molecular weight HSPs (26, 24, 22, 21, 19, and 17 kDa), and isolation with a sucrose density gradient resulted in the detection of only 7 HSPs [75].

Heat-shock proteins are synthesized in the cytosol and transported in the chloroplast. Indeed, although the synthesis of most proteins was inhibited by cycloheximide, an inhibitor of cytosolic ribosomes, the profile of synthesized HSPs remained unchanged in the presence of chloramphenicol, which affects the synthesis of proteins on organelle ribosomes [76]. It was shown that the most abundant HSPs imported have molecular masses of 22 and 25–27 kDa [76,77].

Fractionation of the soluble fraction from the membrane fraction of the chloroplast indicated that some of the HSPs may be associated with the thylakoid membranes [75,77,78]. Such association with the thylakoid membranes was found to be optimal between 36 and 40°C [77,79]. It was suggested that interactions of the proteins with the thylakoid membranes are facilitated at those temperatures owing to modifications of protein and lipid structure in the membrane. It has been shown that

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

HSPs are stored in aggregated oligomeric forms of 200–800 kDa with mRNA. The formation of these grains is thought to constitute a mechanism for the protection of the mRNA against thermal denaturation during heat stress [80,81]. Heat-shock grains (HSGs) were also detected in the chloroplast [82,83]. The grains dissociate when the temperature returns to normal conditions [81]. Thus, it was also argued that the presence of HSPs with the membrane fraction is not due to direct association with the membrane but to the formation of HSGs that sediment with the membrane fraction [76,84].

The synthesis of HSPs is associated with resistance to heat stress, although it has not been demonstrated that they are directly involved. Several studies have shown a close correlation between the kinetics for synthesis of HSPs and thermotolerance [85–87]. Also, inhibition of the de novo synthesis of cytosolic proteins results in a strong decrease of photosystem II function after heat shock [88]. Localization of chloroplasts HSPs of 22 kDa has been suggested in the grana fraction [89], and reports of the light-controled synthesis and accumulation of this protein argue in favor of its implication in the protection of the photosynthetic apparatus [90–92]. HSPs of the family of 60, 70, and 90 kDa are known as ''chaperons.'' This type of polypeptide is involved in the transport and folding of some specific proteins. The polypeptides of the HSP70 family are involved in helping the formation of tertiary or multimeric structures or to translocate proteins across mitochondrial or chloroplastic membranes [93–95]. Polypeptides of the HSP70 family were also found in the chloroplast stroma and envelope [96,97]. To date, two chloroplastic functions of HSP70 homologues were suggested; namely, association with Cpn60 into the maturation of newly imported ferredoxin-$NADP^+$ reductase and integration of the apoprotein of the light-harvesting complex of photosystem II into the thylakoid membrane [98,99]. Interestingly, there has been reports of the ability of small HSPs (HSP20 family) and α-crystallins as well to inhibit aggregation and facilitate refolding of thermally denatured proteins [100–102]. However, the mode of action of HSPs in thermotolerance is still awaiting elucidation. A plausible hypothesis is that they may be involved in maintaining the tertiary structure of polypeptides to counterbalance the deleterious effects of heat.

CONCLUSIONS

Exposure of plants to temperatures above their usual environmental conditions results in reversible and irreversible modifications of the thylakoid membrane structure and composition that strongly alter photosynthetic efficiency, with photosystem II being very sensitive to high temperatures. Plants thus try to cope with temperature stress by controlling membrane fluidity and by the synthesis of heat-shock proteins. That these changes are directly involved in protection against elevated temperatures has not been demonstrated, although a correlation with an increased tolerance to heat stress has been fully documented. A better knowledge of plant adaptation mechanisms to heat stress may be useful in applying molecular engineering to the task of improving crop productivity.

Altered Nitrogen Metabolism Under Environmental Stress Conditions

ETIENNE RABE
University of Stellenbosch
Matieland, Republic of South Africa

INTRODUCTION

Specific nitrogen-containing compounds (NCCs) accumulate in plants subjected to specific environmental stress conditions. Books and review articles detailing the effects and consequences of environmental stress conditions are numerous [1–6]. Larcher [7] approached stress in plants from a somewhat philosophical viewpoint, defining it as the internal pressure reaction resulting from (usually) external forces. He also detailed the dynamics of the stress reaction into three phases: the ''alarm'' phase, characterized by a reduction in ''vitality''; a ''resistance'' phase (in response to prolonged stress), in which the plant can adapt and return to nearly normal functioning; and an ''exhaustion'' or ''depletion'' phase, in which the adaptive capacity is overstretched, leading to metabolic disturbances and sometimes death of the plant. Various proposals have been advanced that attempt to assign a biochemical role to the accumulation of NCCs during stress. Rabe [8] reviewed the relevant literature and attempted to provide a plausible, unified hypothesis to explain the accumulation of NCCs during stress conditions. This chapter revisits the evidence supporting the hypothesis advanced by Rabe [8] and elaborates on the practical significance of NCC accumulation, whether negative or positive. Not all the literature is recited, nor is the specific detail of NCC accumulation in a specific species in response to stress detailed again. The reader is therefore referred to Rabe [8] for additional information.

The specific environmental stress conditions to be discussed include mineral deficiencies—macronutrients (K, P, Mg, S, Cl, and Ca), and micronutrients (Fe, Mn, Zn, and Cu), some heavy metal toxicities, drought and salinity stress, temperature extremes, and disease infection (nematodes, root rot fungi, viruses, and bacteria). Documented evidence with respect to the physiological consequences of acid stress, anoxia, and externally induced NH_3-NH_4^+ toxicity is somewhat sparse but is briefly addressed.

ACCUMULATION OF SPECIFIC NITROGEN-CONTAINING COMPOUNDS

The NCCs that normally accumulate during stress conditions include (a) protein amino acids (e.g., arginine, proline, lysine, histidine, glycine, and serine), (b) nonprotein amino acids (e.g., citrulline and ornithine), (c) the amides (glutamine and asparagine), and (d) diamines (e.g., agmatine, *N*-carbamoylputrescine, and putrescine) and polyamines (e.g., spermine and spermidine).

Characteristics general to plants subjected to stress are the increased levels of total free amino acids [9–16]. Reduced rates of protein synthesis or decreased protein levels also occur during stress [9–12].

In general, it seems as though the nature of the stress and the plant type govern which NCC accumulates (Table 1), because (a) during conditions of mineral deficiency, it is usually the amides, glutamine and asparagine, the basic amino acid arginine, and the diamine, putrescine, that accumulate; (b) stress related to altered water relations usually causes proline and putrescine to accumulate; and (c) disorders of a pathological nature increase arginine and proline levels. Details about which NCCs accumulate during various stress conditions are provided in Table 1. The reader is also referred to Rabe [8] for additional information on how specific crops are affected.

The NCCs accumulating during stress conditions all contain at least one amino group. The most frequently accumulating NCCs, that is, the basic amino acids and amides (arginine, citrulline, ornithine, glutamine, and asparagine) and the diamine, putrescine, contain two or more amino groups. The so-called N efficiency of these compounds is important in explaining why they preferentially accumulate under stress conditions. The close biochemical interrelationship between the NCCs accumulating during stress, either products or precursors of one another, is outlined in Figure 1.

CELLULAR FUNCTIONS OF NCCs

The functions attributed to some of the accumulating NCCs are quite diverse. For instance, during K deficiency, when excess organic acids are synthesized, putrescine has been reported to maintain the ionic balance of cells [24,68]. The role of proline accumulation is widely described as that of acting as cytoplasmic osmoticum (as is the case with betaines and related compounds, not discussed in this chapter; refer to Wyn Jones and Storey [83]), lowering cell water potential during periods of drought stress or under saline conditions. This enables the plant to take up moisture against external gradients [84]. Aspinall and Paleg [84] also list some other functional aspects of proline accumulation. These may include the hydration of biopolymers, serving as a readily utilizable energy source (carbon skeleton) and as a storage form of N during periods of nonoptimal growth conditions. Several papers also suggest that arginine and the amides can serve as N storage compounds during stress periods and resultant nonoptimal growth [40,45,46]. The synthesis of asparagine, glutamine, and arginine is expensive in terms of energy input [46]. The same applies to proline synthesis, if it solely acts as a carbon and nitrogen-storage form. This is energy that can be anabolically utilized in the process of normal protein synthesis rather than the accumulation of specific amino acids. Mertz et al. [46] did not explain why, under stress conditions, energy would be diverted to NCC synthesis at the expense of protein synthesis and continued growth, or why N would be stored when the growth rate is in any case impeded. Research results from Rabe and Lovatt [37] on the mechanisms underlying the accumulation of arginine during P deficiency may provide a possible explanation of this question. The mechanism proposed may be of general application and is discussed in more detail in the next section.

METABOLIC RESPONSE TO STRESS CONDITIONS

Response to Mineral Deficiencies

Arginine accumulation during phosphorus deficiency [37] is due to increased de novo synthesis rather than reduced catabolism or increased protein degradation. The increased activity of the argi-

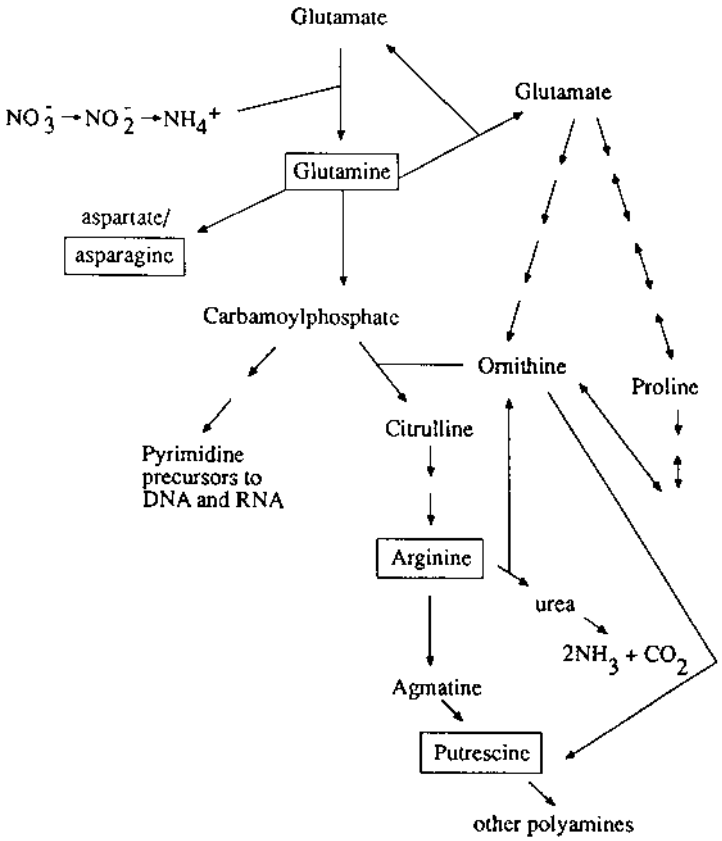

FIGURE 1 Biochemical interrelationship between NCCs that accumulate during stress conditions.

nine de novo biosynthetic pathway is an early response to P deficiency, within 10 days in squash (*Cucurbita pepo* L.) and 6 weeks in rough lemon seedlings (*Citrus limon*) in plants of two diverse families, that is, the Cucurbitaceae, an herbaceous annual, and a woody perennial, Rutaceae (Table 2) [38]. These workers also demonstrated that ammonia accumulated during P deficiency and that the amount of accumulated ammonia increased with the increasing severity of P deprivation. The source of ammonia appears to be twofold: conversion of accumulating nitrate and degradation of amino acids normally incorporated into protein. Phosphorus deficiency thus resulted in ammonium toxicity.

Rabe and Lovatt [38] hypothesized that any stress causing glucose depletion and/or reduced growth results in ammonia accumulation early in the stress period.

Arginine accumulation has also been recorded during Mg, K, S, Cl, Ca, Fe, Mn, and Zn deficiencies (refer to Table 1 for references). Many other NCCs accumulated during mineral-deficient situations (see Table 1).

Response to Other Environmental Stress Conditions

Elevated arginine levels have been recorded during osmotic stress [55–58], acid stress [68], stress arising from excess exogenously supplied ammonia [42,71,72], and certain pathological disorders

TABLE 2 Effect of P Deprivation on De Novo Arginine Biosynthesis in Young, Fully Expanded Leaves from Squash (*Cucurbita pepo* L.) and Rough Lemon (*Citrus limon* L.)

Plant	Treatment duration	De novo arginine biosynthesis[a]	
		P sufficient	P deficient
Squash	10 days	35 ± 3	78 ± 7 (7)[b]
Rough lemon	6 weeks	15 ± 3	149 ± 13 (6)
	12 weeks	15 ± 3	161 ± 17 (3)

[67,81]. Proline accumulation has been reported to occur during water-deficit stress [84], following exposure of plants to high or low temperature [76], during salinity stress [58,84], during nutrient deficiency [5,85], and under pathological conditions [80]. Apart from arginine and proline, many other NCCs accumulate during the specific environmentally induced stress conditions described here (see Table 1). Elevated levels of ammonia were demonstrated during water stress [86] and low temperatures [87] in *Citrus* species.

MORPHOLOGICAL AND ANATOMICAL ASPECTS ASSOCIATED WITH ALTERED N METABOLISM

Symptoms of P deficiency seem to be identical to those induced by ammonia toxicity. In both cases, lesions appear on the blade of the leaf as darkened, water-soaked areas that later become necrotic [38]. The leaf margins of P-deficient *Citrus* plants appear burned [38], as was described for tomato [88]. The symptoms and metabolic changes associated with P deficiency could be duplicated via ammonia feeding [38]. Ammonia toxicity has been shown structurally to alter tomato chloroplasts [89], in which the chlorophyll and grana disappear.

Puritch and Barker [89] speculated that the disruption of the membrane structure may be due to chlorophyll loss or abnormal protein synthesis (e.g., short half-life of chloroplast proteins and low rate of synthesis). Chloroplast abnormalities similar to those shown for ammonia toxicity have also been shown for manganese-deficient spinach [90]; others [14] have reported that manganese deficiency, in addition to causing NCC accumulation, results in high endogenous ammonia levels (see Table 1).

NCC ACCUMULATION: A DETOXIFICATION MECHANISM?

The evidence of increased arginine levels and accelerated biosynthesis, discussed earlier with respect to the P-deficiency effects, is consistent with the hypothesis that the increased activity of the arginine biosynthetic pathway during P deficiency provides a mechanism for detoxifying leaf tissue of excess ammonia. This interpretation is supported by results obtained from ammonia-feeding experiments that resembled the P-deficiency symptoms or, stated differently, provided symptoms similar to those in plants deficient in P [38]. The incorporation of labeled bicarbonate into arginine plus urea also increased as the concentration of exogenously supplied ammonia or the length of exposure increased

(Table 3). The elevated ammonia levels during water stress [86] and low temperatures [87] in *Citrus* species are additional evidence of altered N metabolism during stress.

The de novo arginine biosynthetic pathway is expensive in terms of ATP and carbon, causing additional stress to a plant that is ''functionally'' carbohydrate depleted. Thus, during P deprivation, the pathway should logically be prone to inhibition. This is not the case, however, supporting the argument that the de novo arginine pathway is important in detoxifying P-deficient leaf tissue of accumulating ammonia.

If the NCCs accumulate during P deficiency (arginine [9–11,17,34–40], asparagine [20,22,36,41], glutamine [10,36], proline [15], lysine [15], histidine [15], the amine, agmatine [26], and others [15,17]) as a response to high ammonia levels, is it true for NCC accumulation under other mineral or environmental stress conditions? First, I discuss the accumulation of proline. If it is assumed that proline accumulation is due, in each of the cases discussed earlier, to the same fundamental mechanism, then one should enquire about the features common to these seemingly disparate stress conditions. Proline accumulation in response to temperature extremes and salinity stress could be due to a disturbance in tissue water status comparable to that observed during drought stress [84]. Does this, however, fully explain proline accumulation during other stress conditions (e.g., nutrient deficiencies)? A more common denominator among all these stress conditions may be that they result in a general reduction in growth rate, as is the case with P deficiency, when arginine accumulates. There is no feedback inhibition for N uptake and nitrate reduction [91], but the lack of anabolic processes (protein synthesis and growth) leads to ammonia accumulation and subsequent detoxification by sequestering ammonia into NCCs (e.g., proline in this case). It is thus submitted that, based on evidence from the literature that NCCs accumulating during normally encountered environmental stress conditions can serve in detoxifying the cell of ammonia, as has been demonstrated for P deficiency in *Citrus* and cucurbits, this led to arginine accumulation. However, this does not exclude the possibility that in given situations these NCCs may indeed sometimes be a storage form for N and/or carbon or serve some other biochemical role.

We have discussed the endogenous generation of ammonia and the NCC accumulation response. How do plants react to high exogenous ammonia or nitrogen levels? Growing plants need to assimilate N ultimately in the fully reduced form. High exogenous concentrations of NH_3-NH_4^+ are toxic to plants, although the biochemical aspects of the toxicity are not always clear [89,92,93]. Bennett and Adams [94], in one of a few studies in which the concentration of exogenously supplied ammonia leading to incipient ammonia toxicity was quantified, concluded it to be between 0.15 and 0.20 mM ammonia in Sudan grass and cotton. Givan [95], in a review on the subject of metabolic

detoxification of ammonia in tissues of higher plants, where he mainly addressed externally induced toxicity, offered two ways in which plants may be able to assimilate and dispose of high concentrations of ammonia: detoxification of excess ammonia by simply accelerating the rate of N assimilation via the usual pathway or supplementing the normal pathway by additional ammonia-utilizing reactions, initiated only at times when the plant is subjected to excessive levels of ammonia. Both these mechanisms seem to be operative during certain nutrient deficiencies and environmental stress conditions with the ''additional ammonia-utilizing reactions'' being particularly important during NCC accumulation.

The effect of the N form in the nutrient solution on the amino acid composition can be quite significant (Table 4). Levels of asparagine, glutamine, serine, arginine, and histidine were elevated between two- and sixfold when NH_4^+ N was applied instead of NO_3^- N to sand-cultured tomato plants [71]. The same was found when the different N forms were supplied to plants grown in vermiculite, peat, or solution culture.

The de novo arginine biosynthetic pathway was accelerated significantly when subjecting excised leaves of both squash (*Cucurbita pepo* L.) and rough lemon (*Citrus limon* L.) to ammonia-containing solutions. The level of activity increased with increasing ammonia concentration or increased length of exposure [38].

Both free and bound putrescine and spermidine increased significantly when half of the NO_3^- N was substituted by NH_4^+ in sulfur-fumigated pea plants [72]. Amine levels were also increased in unfumigated, NH_4^+-supplied plants relative to exclusively NO_3^--supplied plants. Since both sulfur pollution and NH_4^+ nutrition increase the hydrogen ion concentration of the cells and cause a shift in the cation/anion ratio, it was concluded that both result in amines being synthesized to bind these hydrogen ions and to compensate for the relative cation deficit [72]. However, it should be investigated whether acid stress in itself does not also lead to elevated endogenous ammonia levels.

Increasing the supply of ammonia to tomato plants in sand culture resulted in a massive accumulation of glutamine in both the roots and shoots (within 8 h in the root [70]). It was suggested that this time course is probably too short for any ionic imbalance to initiate such a drastic response, especially since the glutamine levels started to decrease after 48 h and that one would have expected the ammonia nutrition to increase the solution acidity even further. Le Rudulier and Goas [74] and Klein et al. [31] also recorded increased putrescine levels in response to ammonium nutrition in soybeans and peas, respectively. Again, a reduction in cellular and exogenous pH was implicated as the cause of the putrescine accumulation [31]. The increase in endogenous ammonia concentration because of exogenous application, however, was not submitted as a possible reason for the accumulation of the NCCs.

TABLE 4 Levels of Certain Free Amino Acids in Shoots of Tomato Plants as Influenced by N Form and Growing Media (μmol g^{-1} dry weight)

	Solution		Sand		
Amino acid	NO_3^-	NH_4^+	NO_3^-	NH_4^+	5% LSD
Asparagine	32.5	42.0	22.5	61.5	16.1
Glutamine	8.8	26.0	8.6	49.1	3.9

The combined direct and indirect evidence from the literature of ammonia accumulation, accelerated arginine biosynthesis, NCC accumulation, and reduced anabolic processes like protein synthesis and growth during various environmental stress conditions all support the hypothesis that it is a mechanism of sequestering potentially toxic levels of free cellular ammonia.

POSSIBLE PRACTICAL SIGNIFICANCE OF ALTERED NITROGEN METABOLISM DURING STRESS

The stress-induced ammonia response of plants may have practical implications. Stress, albeit environmental, physiological, or mechanical, is not always detrimental to commercial agriculture. In fact, in an excellent review article, Grierson et al. [96] listed various stress conditions that are utilized to the benefit of agriculture, for example, pruning and bending in deciduous fruit, viroid inoculation for tree size control in *Citrus* species, and cold storage and modified-atmosphere storage of fruit for longer shelf life. Rabe [97] lists a number of advantageous and problematical side effects of stress in fruit culture. These include, among others, the use of dormancy-breaking chemicals for an even blossom, fruit thinning by various chemicals for fruit size improvement, and water-induced and low temperature–induced flowering response in various species. A few practical aspects are discussed in more detail.

Luxurious Nutrition Regimens

Most, or all, plants do not regulate N uptake. This is consistent with the fact that land plants evolved under conditions in which N was limited. Thus, there was little selection pressure for regulating nitrogen uptake or reduction [91]. In modern agriculture, the tendency is to stimulate vegetative growth, at least in the initial years after establishment of perennials, by applying excess N to the extent that the anabolic processes of the plant may not adequately cope with it.

Predisposition to Disease

The relative cost of ammonia-based versus nitrate-based fertilizers makes the former a much more attractive source of N. There is evidence, however, that the continual or excessive use of ammonium-based fertilizers can be a predisposing factor in increasing disease susceptibility. For instance, most root and cortical diseases are stimulated by N applied in the form of ammonium compared with nitrate [98]. Ammonium nutrition increases the incidence of *Fusarium* [99] and *Phytophthora* [100] rots in citrus. Furthermore, the deleterious effects of any environmentally induced stress condition are probably aggravated by high exogenous levels of ammonia, as was demonstrated by Lewis et al. [101] in both wheat and maize, in which the ammonium-grown plants were much more sensitive to salinity toxicity than nitrate-grown plants. Whether high exogenous levels of ammonia and high endogenously generated ammonia levels are ultimately equally harmful to the plant is uncertain. The indications are that it does not matter how the excess is attained. The relative P dependence of citrus rootstocks [102] and hence differences in the rootstock ability to metabolize excess ammonia levels [39] parallel the susceptibility to infection by the citrus nematode [103]. There are also indications that citrus rootstock species with different levels of endogenous ammonia during P deficiency (high in rough lemon versus low in trifoliate) [39] are correspondingly susceptible to *Phytophthora* infection (rough lemon being more susceptible; personal observation).

Tolerance to Stress Conditions Between Selections in the Same Genus and Species

Different genera in the same family (e.g., *C. limon* and *Poncirus trifoliata* in *Rutaceae*) have been shown to differ in their ability to cope with P deficiency [39]. This differential response was linked

to differences in N metabolism or leaf tissue ammonia levels. As just indicated, the correlation seems to be extended to differential disease susceptibilities. There may be other instances, other than in *Citrus*, in which this may be true. For instance, it would be of interest to determine how the mechanism of the differential tolerance of various tomato strains to P deficiency [104,105] is linked to differences in N-uptake characteristics and metabolism. Since cultivars, and selections within cultivars, have been shown to differ in terms of salinity tolerance, it is conceivable that the same differences may exist as far as the ability to detoxify the cell of excess levels of ammonia is concerned.

Manipulation of Flowering

Stress conditions are usually a prerequisite for flowering in many commercial species, including *Citrus*: water and low-temperature stress [106–111], girdling [108,112], restriction of root volume [113], and root pruning [80,108]. Some of these flower-inducing stress conditions have been demonstrated to increase the level of endogenous ammonia [86,87,106]. The water-deficit and low-temperature stress conditions were correlated with ammonia accumulation and flowering intensity in *Citrus* under greenhouse conditions [106]. Furthermore, the leaf ammonia content increased in a manner that paralleled the duration of the stress [114], establishing a cause-and-effect relationship between tree ammonia status and floral intensity. Raising the ammonia content of the trees artificially by foliar urea application of low-biuret urea increased leaf ammonia content and floral density without affecting the number of vegetative shoots produced. Utilizing these findings to economic benefit, Lovatt et al. [114] demonstrated yield increases in N-sufficient Washington navel orange trees in 3 years successively without a reduction in fruit size with winter applications of foliar urea. In our own field trials, we obtained positive yield responses to preblossom urea sprays in four different citrus cultivars [115]. Significant yield increases were obtained only in orchards with below optimum N status, however, suggesting that the urea sprays acted in supplementing the N nutrition of the tree. Edwards [116] reported similarly promising results with respect to increasing floral intensity with the application of ammonia, arginine, and polyamines on apple trees.

Stress Effect in Dormancy Release in Deciduous Fruit

Many deciduous fruit-growing areas traditionally do not have enough winter chilling to allow the natural release of buds from dormancy. Saure [117] reviewed this topic. Most of the chemical treatments being used are effective at concentrations very near the lethal point. Among these chemicals are the mineral oils, which alone or in combination with such chemicals as dinitroorthocresol (DNOC) or cyanamide (H_2CN_2) can effectively ''normalize'' bud break under conditions of inadequate winter chilling. Thiourea (TU) has also been shown to be effective as a rest-breaking chemical [118]. Interestingly, Terblanche et al. [119,120] found that a late autumn urea foliar spray increases the efficiency of the DNOC rest-breaking spray. The physiological basis for this is still not fully understood. Preliminary findings (unpublished data) point to a significant increase in the levels of a number of free amino acids during the early phase following the rest-breaking spray. We are currently devoting research efforts to this phenomenon.

NCC Analysis as an Early-Warning System

It has been demonstrated here that NCC and ammonia accumulation in response to environmental stress is correlated with general plant health. Although ammonia is known to be toxic to plants, an upper threshold tolerance value for leaf ammonia concentration has not yet been determined for any plant species. If this value were known, leaf ammonia content might provide a good indicator of plant health. Rabe and Lovatt [39] also suggested that leaf arginine could be used to monitor plant stress. Other possible compounds that could be determined for stress analysis include levels of total free amino acids or certain amines. Since these metabolic abnormalities occur before any

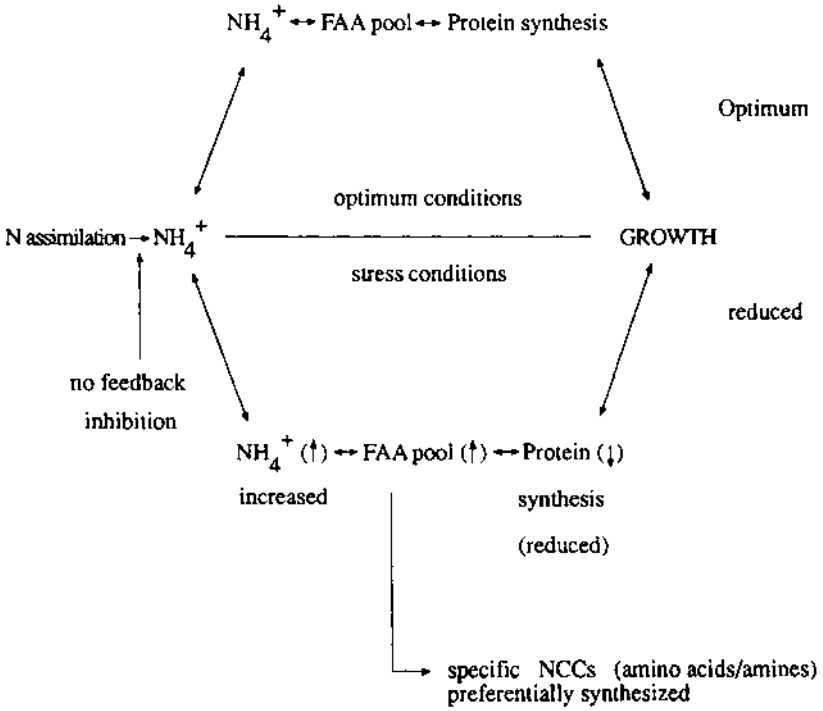

FIGURE 2 Schematic outline of the hypothesis.

visible symptoms of stress are evident, they may provide an early warning system on which to react before economic damage is suffered.

CONCLUSIONS

A schematic outline of the effect and consequences of optimal and nonoptimal conditions on N metabolism is presented in Figure 2. The lack of feedback inhibition on N uptake and reduction during periods of reduced growth or reduced protein synthesis causes NH_3-NH_4^+ accumulation and preferential synthesis of specific amino-containing compounds.

Protein Synthesis by Plants Under Stressful Conditions

R. S. Dubey
Banaras Hindu University
Varanasi, India

INTRODUCTION

Environmental stresses present major challenges in our quest to achieve sustainable food production. The reactions of plants to environmental stresses are complex and involve many kinds of physiological and biochemical responses. Such reactions are initiated by plants growing in stressed environments to overcome, avoid, or neutralize the effects of stress. Tolerance or sensitivity toward a particular stressful condition depends on the genetic and biochemical make-up of the species. Much attention has been focused during recent years to evolve crop species with adaptibility built into their genetic and biochemical make-up toward various stressful environments.

Plants are unable to express their full genetic potential for production when subjected to stressful environments [1]. Various environmental stresses cause important modifications in gene expression in plants [2]. Such modifications may lead to the accumulation or depletion of certain metabolites, alterations in the behaviors of many enzymes, overall changes in protein synthesis, and, of particular interest, synthesis of new sets of proteins which are specific to the particular type of stress [3]. It has been shown that different environmental stresses induce the synthesis of new proteins in plants, which possibly provide evolutionary value to the plants for enhanced survival under adverse environmental situations. The synthesis of such stress-induced proteins has been well documented under salinity stress [4–10], osmotic stress [6,11–17], heat shock [2,18–21], low-temperature treatment [22–26], anaerobiosis [27–29], infection with pathogens [30–35], wounding [34–38], gaseous pollutants [39], and ultraviolet (UV) radiation [38–40].

The main idea underlying studies of stress-induced protein synthesis in plants is that the different sources of stress, their duration, and severity lead to differential expression of genetic information, resulting in changes in gene products, including mRNA and proteins. Such newly synthesized proteins are specific to the particular type of stress and possibly confer enhanced survival value to the plants [7]. In most cases, the stress-induced proteins have been identified by biochemical and molecular biology techniques from different organs of plants and are well characterized. Physicochemical parameters such as molecular weights and pI (isoelectric point) values of these proteins have been deduced [7,13,21,28], and in many cases data regarding association characteristics and

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

amino acid sequences have also been reported [6,8,17,41]. Although these proteins are synthesized in plants when they are subjected to stress and can be revealed in tissues of plants adapted to stress, specific metabolic functions for most of these proteins have not been established as to how they confer adaptability toward stress [7,42]. Particularly, under anaerobic stress, the polypeptides which are synthesized have specific functions and belong to the enzymes of sugar phospate metabolism [27]. Heat-shock proteins, which are synthesized under heat stress, possibly assist in protein folding, protein-protein interactions, and the translocation of proteins across cellular compartments, and they have a possible role in protecting the organism from heat stress [20]. Similarly, the pathogenesis-related proteins do act in the defense of the plant and have a putative role in pathogen resistance [42]. Under salinity stress, it is suggested that the newly synthesized proteins, together with amino acids and soluble nitrogenous compounds, act as components of a salt-tolerance mechanism. These might function as compatible cytoplasmic solutes in osmotic adjustment in order to equalize the osmotic potential of the cytoplasm with the vacuoles in adverse conditions of salinity [43,44].

Studies related to the stress-induced synthesis of proteins have been performed using cultured plant cells [4,6,7,12], seedlings [10,18,23,45] excised plant organs [46], and intact plants [31,47–49]. Among these systems, cultured plant cells have proven to be superior to other systems, as they show uniform response and are under better controlled enviornmental parameters [7,50]. Cell cultures from tobacco, cowpea, potato, citrus, and many other plant species have been used to identify and characterize newly synthesized proteins under salinity, heat-shock, freezing, osmotic, and heavy metal stresses [2,6,7,8,50].

Besides the identification of stress-induced specific proteins, several investigators have tried to quantify the overall metabolic status of total and soluble proteins (including enzymes) of different metabolic pathways in stressed plant parts in order to evaluate the impact of stresses on various aspects of plant growth and metabolism [36,37,44,51,52]. Environmental stresses generally are detrimental to plant growth, adversely affect the metabolism of plants, and cause an imbalance in the level of protein as a result of their effects on the synthesis and hydrolysis of proteins [52–55]. In salt- and water-stressed plant parts, the protein content decreases owing to the decreased rate of protein synthesis and the increased rate of proteolysis [16,52,56]. In seeds germinating under salinity or moisture stress, however, an increase in the protein level is observed. This increase can best be explained by the fact that in germinating seeds, stress causes decreased proteolysis in endosperms resulting in the slower depletion of reserve proteins. This reflects an apparent increase in the endospermic protein level under stress, which is not a result of enhanced protein synthesis [52,56,57].

Stress tolerance is dependent on the genetic and biochemical characteristics of the species. Therefore, attempts have been made by certain investigators to differentiate stress-tolerant and stress-sensitive genotypes of crops on the basis of profiles or levels of soluble proteins, specific enzymes in germinating seeds, and growing plant parts [16,44,52,54]. The results of these attempts indicate that different levels of soluble proteins and many enzymes exist in the two sets of genotypes differing in stress tolerance.

Studies conducted so far indicate that stressful conditions adversely affect the protein metabolism in plants and that in all different types of environmental stresses, such as salinity, drought, heat, chilling, anaerobiosis, pathogenesis, wounding, heavy metal toxicity, and gaseous pollutants, new stress-specific proteins are synthesized. An overview of protein synthetic responses in plants and an alteration in the levels of key enzymes under various stresses is presented in Figure 1. This chapter presents the current knowledge about the effects of various environmental stresses on the overall aspects of protein synthesis in plants and the possible role of stress-specific proteins in confering an enhanced survival value to the plants against various environmental stress situations.

STRESSED ENVIRONMENTS AND PROTEIN SYNTHESIS

The major types of stress to which plants are exposed include salinity, drought, flood, heat, cold, anaerobiosis, infection by pathogens, metal toxicity, gaseous pollutants, and UV radiation. Plant

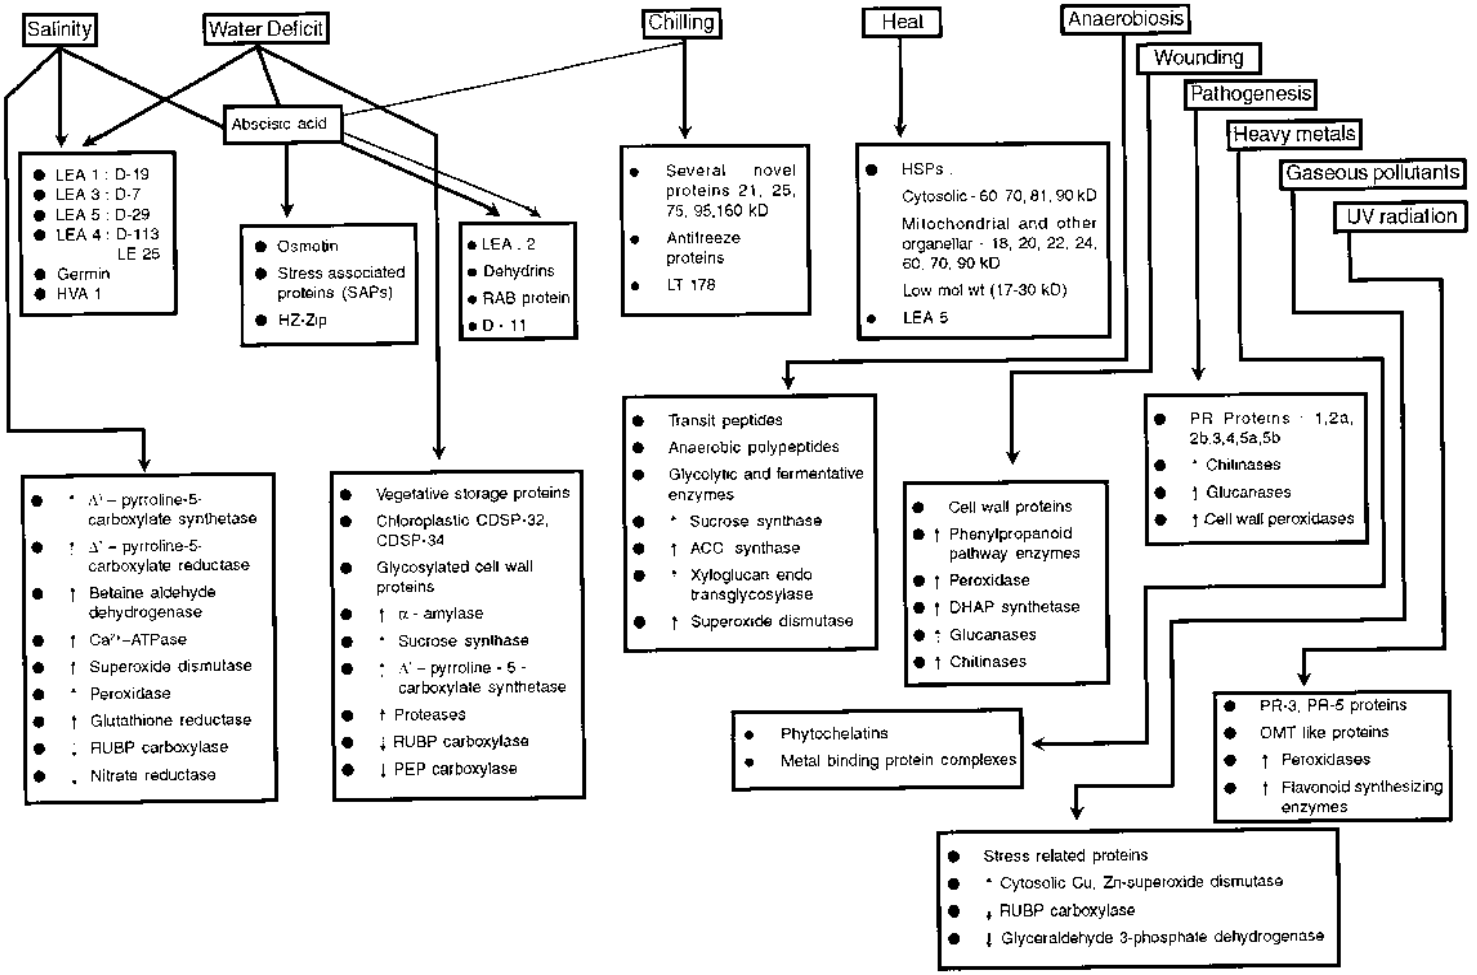

FIGURE 1 An overview of stress-induced protein synthetic responses in plants. Different stresses induce the synthesis of various groups of proteins and cause either elevation (↑) or decline (↓) in the levels of enzymes. Some of the responses of salinity, water deficit, and chilling are common and are mediated via elevated levels of abscisic acid. For details, see text.

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

metabolism and, more specifically, protein synthesis are adversely affected under these conditions. The effect of stress depends on the developmental stage of the plant and genotypes of the plant species as well as the intensity and duration of the stress. In this chapter, recent progress toward understanding the impact of different types of environmental stress on protein synthesis is summarized.

Salinity

Soil salinity is a major environmental stress that drastically affects crop productivity. Salinity poses a severe threat for the cultivation of crops in arid and semiarid agricultural lands. Because of the continuous build-up of salinity in the soil, millions of hectares of usable lands have now become unsuitable for cultivation. It is estimated that every year more than a million hectares of land are subjected to salinization. Soil salinity is thus threatening our civilization by persistently reducing the area for crop cultivation. Salinity not only causes great losses in crop yields but also has an impact on other economic, environmental, social, and political problems in the affected countries. Progress in developing salt-tolerant crop varieties has been very slow because of our incomplete knowledge of the mechanism of salt damage and the complex nature of salt tolerance. Even different varieties of a particular species may exhibit different tolerance behaviors. Salinity affects seed germination, plant growth, nutrient uptake, and metabolism owing to the osmotic inhibition of water availability, toxic effects of salt ions, and nutritional imbalance caused by such ions [58].

Salinity promotes the synthesis of salt stress–specific proteins [5–7,42], causes either decreases [49] or increases [57,59] in the level of total and/or soluble proteins, depending on the plant parts studied, and leads to increased activity-synthesis of many enzymes [10,52,60–63].

Salt-Induced Protein Synthesis

Plants growing in saline environments show distinct changes in the pattern of synthesis and accumulation of proteins. Most of the experiments to study the salinity-induced synthesis of proteins have been conducted using plants cell cultures. Cell cultures rather than whole-plant systems have proven to be more advantageous for such studies, because, in cell cultures, environmental parameters can be better controlled and the stress-tolerant cell lines generated can be readily selected and assayed for newly synthesized proteins.

Several investigators have shown the synthesis of new proteins in cultured plant cells when subjected to salinity stress [4,6,7,42,59]. The levels of proteins differ in salt-tolerant and salt-sensitive genotypes when they are subjected to salinity stress [44,54]. Although it is well established that salt tolerance and sensitivity depend on the genetic and biochemical composition of the species, it has been difficult so far to specify the exact genetic domain responsible for salt-adaptation expression leading to the synthesis of these proteins in salt-adapted plants. These specifically synthesized proteins under salt stress appear to have a role in providing tolerance or adaptation to the plants. However, the overall mechanism of how these proteins could provide adaptation is not clearly understood.

To understand the mechanism of salt resistance in cultured tobacco cells, Ericson and Alfinito [4] examined the protein patterns of NaCl-adapted as well as NaCl-nonadapted cell lines of tobacco (*Nicotiana tabacum* L.). Their results indicated that cells adapted to a medium containing NaCl showed two protein bands of 32 and 20 kDa in more abundance than unadapted cells. Further, in the salt-adapted cells, a unique protein of 26 kDa appeared that was specific for these cells and was not present in unadapted cells or cells growing without NaCl. These investigators suggested that the three proteins synthesized in salt-adapted cells might be involved in a salt-adaptation process.

According to Singh et al. [64], in cultured tobacco cells, the process of cellular adaptation to osmotic stress in a saline environment involves the specific alteration in gene expression of salt-adapted cells leading to the synthesis of several novel proteins, including the predominant 26-kDa protein. Since 26-kDa protein is specifically synthesized and accumulated in cells undergoing os-

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

motic adjustment to salt or dessication stress, this protein has been named ''osmotin'' [6]. Osmotin is regarded as a unique protein associated with NaCl-adapted tobacco cells [6]. Interestingly, the synthesis of osmotin is not induced by osmotic shock but starts only when cells are adapted to NaCl or polyethylene glycol [64]. In salt-adapted cells, osmotin constitutes about 10–12% of the total protein in the cell [64]. It is believed that the role of osmotin is in providing osmotic adjustment to the cells either by facilitating the accumulation of solutes or by providing certain metabolic alterations in the cell, which may be helpful in osmotic adjustment[6].

Similar to tobacco cells, the synthesis of salt-induced proteins has also been shown in maize[65], barley [5,49], citrus [7,8], tomato [7,59], rice [9], and finger millet [66]. Barley plants, when subjected to short-term NaCl shock or a long-term NaCl treatment for a period of 8 days, show marked quantitative and qualitative changes in protein profiles compared with nonstressed plants [5,49]. Maize callus tissue [65] shows predominantly accumulation of a 26-kDa protein under saline stress. In potato plants, high salinity leads to the increased synthesis of 32- and 34-kDa proteins in the thylakoids [67]. A comparison of the protein profiles of nonadapted and NaCl-adapted cell lines of citrus and tomato indicates that, in citrus, the level of most proteins is suppressed, whereas, in tomato, it is enhanced under salt stress [7]. Tomato cell cultures when grown in a medium with 25 mM NaCl and proline synthesize extra polypeptides of 190-, 58-, 45-, and 26-kDa, and with the further increase of NaCl in the medium, a new 67-kDa protein is accumulated [59]. In tobacco cells, enhancement in the level of certain proteins and a decrease in the level of others is observed when cells are adapted to NaCl [6]. This indicates that salt-induced changes in proteins are species specific and that different proteins are associated with salt tolerance in different species.

In certain plant species, such as rice (*Oryza sativa* L.) and Shamouti orange (*Citrus sinensis* L. Osbeck), it has been shown that salt-sensitive and salt-tolerant genotypes have different patterns of protein profiles whether grown in the absence or the presence of NaCl. Salt-tolerant genotypes of rice possess a 28-kDa protein in shoots which is absent in salt-sensitive genotypes, and the level of this protein is further elevated when the rice seedlings are raised in saline medium [68]. This shows that the presence of the additional 28-kDa protein band is associated with salt-tolerance characteristics in rice. In salt-sensitive rice species, some of the major preexisting proteins disappear and certain new proteins appear with an increase in salinity. Ten-day-old seedlings of rice cv Nona bokra, Basmati, IR 28, and IR 29 when treated with 2% NaCl for 8 h show a synthesis of two new proteins of 27.0 and 25.5 kDa [9], whereas seedlings of certain rice cultivars when exposed to salinity stress accumulate 87- and 85-kDa stress-associated proteins [69]. Similar to rice, in citrus (*Citrus sinensis* L. Osbeck), a 25-kDa protein has been shown to be associated with salt tolerance [7]. This protein appears to be a constitutive protein in salt-tolerant citrus cells and is present whether cells are grown in the absence or the presence of NaCl. The level of this protein is enhanced when cells are grown in saline medium. Enhancement can be readily observed by growing the cells in the growth medium containing 1% NaCl.

Since the synthesis of constitutive proteins associated with salt tolerance in rice or citrus does not depend on the presence of salt in the growth medium, it appears that the salt-tolerance trait is stable in these species. Salt-tolerant lines in these species show synthesis of such constitutive proteins up to many generations when grown in either the presence or the absence of NaCl. Similar constitutive proteins have also been shown to be associated with sensitive or tolerant genotypes of finger millet. Among finger millet (*Eleusine coracana* Gaertn.) genotypes differing in tolerance to NaCl, a 200-mM NaCl treatment causes the synthesis of many stress-induced proteins with molecular weights of 70–72, 52, 37, 24, and 23 kDa in all genotypes. But in tolerant genotype GE-415, the synthesis of a 54-kDa protein occurs under NaCl treatment, which is not observed in the salt-sensitive genotype VL-481 [66]. This suggests that the synthesis of NaCl-induced proteins in finger millet is correlated with the differences in salt tolerance of the genotypes. In a species of citrus, either in cell suspension or when seedlings are grown in the presence of 0.2M NaCl, the steady-state level of a citrus-LEA5 (C-LEA5) protein increases [8].

In many plants species, certain hydrophilic proteins and their mRNAs have been reported to

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

be synthesized de novo in response to salt stress. Some of these proteins and mRNAs are also inducible by water deficit or treatment with abscisic acid (ABA) [42]. Such proteins have been grouped in different classes based on DNA sequences of their genes and/or predicted functions of the proteins [70]. In most of the cases, the functions of the inducible proteins have not been clearly established, and predicted functions have been proposed based on deduced amino acid sequences [70]. Salinity imposition during the period of seed development following maturation leads to the synthesis of late embryogenesis–abundant (LEA) proteins in cotton, carrot, barley, and maize [71]. In vegetative organs of many other plant species, salinity-induced proteins have been identified which share significant amino acid sequences with the LEA proteins of cotton. Thus various groups of LEA proteins have been identified which have been classified based on notable structural domains predicted by amino acid sequences [70]. LEA group 1 proteins include the Em family of proteins which are devoid of cysteine and tryptophan. Such proteins have been identified in many monocots and dicots, and it is suggested that these proteins function in a water-binding capacity creating a protective aqueous environment [70]. LEA group 2 proteins include dehydrin, RAB (ABA-responsive), and D11 proteins which have characteristic lysine-rich regions and are also expressed owing to treatment with ABA [70]. LEA group 3 and group 5 proteins are represented by D7 and D29 from cotton, respectively, and contain repeated tracts of 11 amino acids [70]. Citrus cell suspensions grown in the presence of 0.2 M NaCl or leaves of citrus plants irrigated with NaCl accumulate a protein (C-LEA5) which has high similarity with the cotton LEA5 protein [8]. LEA group 4 protein represents D113 protein, the synthesis of which is induced in drying cotton seeds, and this protein has a homologue in tomato LE25 [70].

In addition to the inducible proteins which have predicted functions, there are many salt-induced proteins which have no specified functions. A protein, RD22, is induced early during seed development in *Arabidopsis* and has homology to an unidentified seed protein from *Vicia faba* [70]. In the roots of salt-stressed barley plants, a ''germin''-like protein has been identified [70]. Germin is a protein which accumulates during the early growth of wheat plants and has no specified function.

The most extensively studied proteins from many plant species that accumulate in response to dehydrative forces like salinity, water stress, and low temperature are dehydrins (LEA-D11 family), which are composed of several typical domains joined together in a few characteristic patterns with numerous minor permutations [72]. Although the fundamental biochemical mode of action of dehydrins has not been demonstrated, dehydrins regarded as are surfactants which are capable of inhibiting the coagulation of a range of macromolecules and thereby preserving structural integrity [72].

Transgenic rice plants expressing a LEA protein gene (HVA1) from barley showed accumulation of HVA1 protein in both roots and leaves, and such plants showed increased tolerance to salinity [73]. These observations suggest that LEA proteins play an important role in the protection of plants under salt-stress conditions, and that LEA genes hold considerable potential for use as molecular tools for genetic crop improvement toward salinity tolerance [73].

Protein Level in Salt-Stressed Plants

Protein synthesis in plants growing in saline environments is adversely affected. Salt stress results in a general decrease in protein synthesis with a loss of polyribosomes [42]. In germinating seeds, as well as during later growth stages of plants, salinity causes impairment in synthesis as well as degradation of proteins. To access the general impact of salt damage on plant growth and metabolism, various investigators have attempted to study the overall status of total proteins and soluble proteins and the pattern of protein synthesis in different parts of plants growing under salinity stress. Salinity in the majority of cases lowers the level of protein in salt-stressed plant parts as a result of the decreased synthesis of protein as well as the increased activities of protein-hydrolyzing enzymes. In certain cases, however, an increased protein level is noticed under salinization, possibly due to the increased synthesis of new salt-induced proteins or the decreased activities of proteolytic enzymes.

The process of protein synthesis has been shown to be salt sensitive, as observed in wheat germ and *Suaeda maritima* [43]. Under in vitro conditions, a protein-synthesizing system extracted

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

from these species is more sensitive to Na^+, K^+, and Cl^- than under in vivo conditions, as revealed by amino acid incorporation data. A salt-tolerant species like *S. maritima* can maintain optimum growth at a high salt level of 500 mM NaCl, whereas the enzymes extracted from this plant are sensitive to a low level of NaCl (170 mM). This suggests that, under in vivo conditions, soluble enzymes as well as enzymes of protein-synthesizing mechanisms are comparatively less sensitive to NaCl than isolated enzymes under in vitro conditions. Although studying the effects of salts on protein synthesis in *S. maritima*, Hall and Flowers [74] observed that, in this species, protein synthesis is sensitive to salts and that amino acids incorporation decreases under in vitro conditions when KCl concentration in the medium exceeds 50 mM.

In various crop species, a decrease in the protein level in salt-stressed plant parts is attributed to a decrease in protein synthesis, the decreased availability of amino acids, and the denaturation of the enzymes involved in amino acids and protein synthesis [49,74,75]. In pea roots, sodium salts inhibit the synthesis as well as hydrolysis of basic proteins. Thus, there is a decrease in the protein level as observed in roots of pea plants growing under saline stress [75]. In chickpea (*Cicer arietinum* L.), one of the major legume crops for semiarid tropics, a salinity treatment with 100 mM NaCl in nutrient solution caused a marked decrease in the level of proteins in developing seeds when plants were raised in sand cultures [76].

When rice (*Oryza sativa* L.) seeds were germinated under increasing levels of NaCl salinity, a decrease in total as well as soluble protein level was observed in the embryoaxes [52]. A greater decrease in protein level was observed in the embryoaxes of salt-sensitive cultivars than tolerant cultivars under similar level of salinization. Dubey and Rani [52] observed that under 14 dS m^{-1} NaCl salinity, the soluble protein level of embryoaxes of salt-sensitive rice cultivars Ratna and Jaya was reduced to almost one-third compared with nonsalinized seeds at 120 h of germination. A moderate salinity level of 7 dS m^{-1} NaCl had virtually no effect on the change in total and soluble protein levels in embryoaxes of germinating seeds of salt-tolerant rice cultivars CSR-1 and CSR-3, whereas a higher salinity levels caused a marked decrease in the protein level in the embryoaxes of these cultivars [52]. In barley plants, imposition of NaCl stress leads to a decrease in the leaf protein content and induces marked quantitative and qualitative changes in the polypeptide profiles affecting mainly the proteins with approximately equal mobility [49].

Although salinity causes decreased protein synthesis and increased proteolysis in various plant species, in many cases increased protein levels are observed under salinization in germinating seeds [52], growing seedlings [44], and different plant parts [54]. In germinating seeds, endospermic protein hydrolysis is suppressed under salinization. When seeds of rice cultivars differing in salt tolerance are germinated under increasing levels of NaCl salinity, it has been observed that salt treatment suppresses protein depletion from the endosperms of all cultivars, with greater suppression in the salt-sensitive cultivars than in the salt-tolerant cultivars [52]. A lower salinity level of 7 dS m^{-1} NaCl has virtually no effect on the change in the endospermic total and soluble proteins compared with seeds germinating without NaCl, whereas a higher salinity level of 14 dS m^{-1} NaCl caused a marked suppression in endospermic protein depletion in the salt-sensitive rice cultivars Ratna and Jaya [52].

An apparent increase in the protein level in the endosperms of germinating seeds is observed with an increase in salinity. This can be explained as a result of decreased proteolysis caused by salinity leading to slower depletion of reserve proteins, not as a result of enhanced protein synthesis [52]. The NaCl salinity caused a delay in the breakdown of endospermic proteins as well as inhibition in translocation of hydrolyzed products from endosperms to growing embryoaxes [57]. The obvious implication is that inhibition of seedling growth under salinization can also be partly attributed to delayed mobilization of reserve proteins, because proteolysis is probably the primary, but essential, step toward synthesis of new proteins for seedlings growth [77].

When raised under increasing levels of NaCl salinity, rice seedlings, show an increased level of total as well as soluble proteins compared with nonstressed seedlings [44]. During a 5- to 20-day growth period, when two sets of rice cultivars differing in salt tolerance were examined for the metabolic status of proteins in roots and shoots, it was observed that at a salinity level of 14 dS m^{-1} NaCl salt, stressed seedlings of tolerant cultivars maintained higher levels of total as well as

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

soluble proteins compared with the seedlings of the sensitive cultivars [44]. The increased soluble protein level in rice seedlings became more significant when the salinity level was raised from 7 to 14 dS M^{-1} NaCl [44].

Similar to rice, in cowpea (*Vigna unguiculata* L.) seedlings, pea (*Pisum sativum* L.), and *Cajanus Cajan* plants, as well as in soybean callus cultures, NaCl salinity caused an increase in the protein content [59,78–80]. The increased protein level under salinization as noted in these cases appears to be due to the increased synthesis of preexisting as well as certain new sets of proteins [44]. The increased synthesis of certain specific proteins has been noticed in plants subjected to saline stress, but whether this increased synthesis is responsible for a net increase in the total and soluble protein level of stressed plants remains to be investigated.

To understand the mechanism of salt tolerance in crops, various investigators have studied the metabolic status of proteins and amino acids in germinating seeds and seedlings using cultivars differing in salt tolerance [44,52–54]. Especially in rice (*O. Sativa* L.), a staple food crop for the majority of the world population, salt-tolerant cultivars are characterized by a higher value of protease-specific activity as well as a higher total and soluble protein content in germinating seed parts under control and salt treatments compared with sensitive cultivars [44]. Further, tolerant rice cultivars maintain a higher level of total as well as soluble proteins in salt-stressed seedlings compared with sensitive seedlings [44]. This shows the salt-tolerance ability to be associated with a possible higher protein level in rice, seemingly endogenous proteins that are either not found or are very poorly expressed in sensitive cultivars.

Using a salt-tolerant rice variety, Pokkali, and a salt-sensitive variety, Taichung N1, a cDNA clone *oslea 3*, encoding a group three LEA proteins, was identified that accumulated to higher levels in the salt-tolerant variety compared with the sensitive one on imposition of salt stress [53]. Further, this stress-induced protein and its mRNA declined less rapidly on sustained salt shock in tolerant cultivars than the sensitive ones. Such observations indicate that the differential regulation of protein expression is associated with varietal differences in salt-stress tolerance [53].

Soybean (*Glycine max*) cultivars differing in salt tolerance show different levels of proteins and amino acids when grown in the presence of NaCl [54]. Salt-tolerant soybean cultivars Clark and Forest accumulate higher levels of soluble proteins, whereas sensitive cultivar Kint shows a decrease in the soluble protein level when grown in saline soils [54]. Such observations indicate that, in rice and soybean plants, the salt-tolerance ability is associated with a higher level of proteins, which are seemingly endogenous proteins that are either not found or are very poorly expressed in sensitive cultivars on imposition of salinity.

Enzyme Levels in Salt-Stressed Plants

Salinity induces changes in the activities of proteolytic [52,56,57], amylolytic [57,81,82], nucleolytic [83], phosphorolytic [60,62,84–86], oxidative [63], antioxidant [87], photosynthetic [49], and nitrogen assimilatory enzymes [88], in germinating seeds and in growing plants. Salinity causes either an increase or a decrease in the activity of enzymes, depending on the nature of the enzymes, extent of stress, the plant parts studied and the genotypes of plant species differing in salt tolerance.

In endosperms of germinating rice seeds, salinity causes a decrease in the activities of hydrolytic enzymes, including α-amylase, protease, RNase, phosphatase, and phytase [52,57,81,83]. The decrease is more in salt-sensitive than in salt-tolerant varieties. In growing seedlings of rice, salinity enhances the activities of nucleases [83], proteases [56,83], peptidases [56], phosphatases [60,62,84], and oxidases [61]. Genotypes of rice species differing in salt tolerance maintain different levels of salinity-induced activities of enzymes.

Barley plants grown in presence of 200 mM NaCl show stimulation in β-amylase activity in leaves [82]. β-Amylases are regarded as stress-induced proteins in barley [82]. Certain enzymes involved in the synthesis of osmolytes show a marked increase under salinity stress [71]. The enzymes of proline biosynthesis, Δ^{-1}-pyrroline-5-carboxylate synthetase and Δ^{-1}-pyrroline-5-carboxylate reductase, the penultimate enzyme of betaine biosynthesis, betaine aldehyde dehydrogenase, and the enzyme of sorbitol biosynthesis, aldose reductase, show increased activity in many plants subjected to salt stress [10,71]. Plant genes that code for key enzymes involved in osmolyte biosynthesis

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

have been isolated from barley, spinach, sugar beet, soybean, and rice plants [71]. Salt-tolerant varieties of rice show a higher level of expression of the enzyme Δ^{-1}-pyrroline-5-carboxylate synthetase and its mRNA compared with salt-sensitive varieties when grown in saline medium [10]. The enzymes involved in membrane transport, such as plasma membrane–ATPase in cotton seedlings [86] and Ca^{2+}-ATPase in tomato plants [71], show a higher level of activity under salinization. An increased turnover of the tonoplast H^+-ATPase has been observed in leaves of *Citrus sinensis* plants under salinity stress [85].

The activities of the oxidative enzymes polyphenol oxidase and indole-3-acetic acid oxidase increase in the seedlings of salt-tolerant as well as salt-sensitive rice cultivars under salinization, and the extent of the increase differs in the two sets of cultivars [63]. Similarly, phosphohydrolases show varying behavior under salinity in rice plants of differing salt tolerance.

The changes in the activity behavior of the enzymes acid phosphatase, alkaline phosphatase, and ATPase isolated from the chloroplasts of two sets of rice seedlings differing in salt tolerance, when grown under increasing levels of NaCl salinity, are shown in Table 1. As it is evident, acid phosphatase activity was more inhibited owing to salinity in salt-sensitive cultivars compared with the salt-tolerant ones, whereas the activity of alkaline phosphatase increased in the salt-sensitive seedlings but not in the salt-tolerant ones. Further, salinity caused enhancement of ATPase activity in both sets of rice seedlings, with greater enhancement in tolerant cultivars than the sensitive ones. The activity of the antioxidant enzymes superoxide dismutase, peroxidase, and glutathione reductase increase in callus cultures of *Citrus limon* [87], *Oryza sativa* [59], and *Medicago sativa* [89] grown in the presence of NaCl. In soybean callus cultures, an increase in glutathione reductase activity in response to NaCl constitutes an adaptive response of callus tissues to NaCl [59].

The level and activity of the key enzyme of photosynthesis in C_3 plants, ribulose-1,5-bisphosphate carboxylase, decrease in barley plants on imposition of NaCl stress [49]. The prime enzyme of nitrate assimilation, nitrate reductase (NR), has been extensively studied for its behavior in different plant species under salinization [58,88]. Salinity effects on NR activity are varied and depend on the type and extent of salinity as well as genotypes of the plants studied. In intact tissues of wheat, lentil (*Lens esculanta* Moench), mulberry (*Morus abla*), sorghum, and tobacco plants, NR activity decreases owing to NaCl salinity [88], whereas in rice plants the behavior of NR varies in genotypes differing in salt tolerance when raised under NaCl salinity [90]. The salt-sensitive rice cultivars Ratna and Jaya show a decrease in NR activity in the shoot and root, whereas salt-tolerant

T and S in parentheses indicate tolerant and sensitive rice cultivars, respectively. Enzyme units are expressed as μmol substrate hydrolyzed h^{-1} mg^{-1} protein.

cultivars CSR-1 and CSR-3 show increased activity of the enzyme in both of these tissues under salinization [90].

Isoenzyme profiles of many enzymes are influenced by salinity. In certain cases, some of the molecular forms of enzymes present in nonsalinized plants disappear in stressed plants, whereas in other cases certain new molecular forms of enzymes appear under salinization. In shoots of 15-day-old nonsalinized rice seedlings, four acid phosphatase isoenzymes were observed, whereas when seedlings were raised at a salinity level of 14 dS m^{-1} NaCl, only one isoenzyme remained detectable [84]. The decreased number of acid phosphatase isoenzymes at a higher level of salinization paralleled the decreased activity of the enzyme under such conditions [84].

In the young embryoaxes of germinating seeds, certain new molecular forms of acid phosphatases appear under salinization. When acid phosphatase isoforms from the embryoaxes of germinating seeds of the salt-sensitive rice cultivar Jaya and the salt-tolerant cultivar CSR-1 were compared at 48 and 96 h of germination under increasing levels of NaCl salinity, it was observed that certain new isoenzyme forms appeared in both sets of cultivars under salinization [60]. Further, a greater number of isoenzymes were observed in the embryoaxes of salt-tolerant rice varieties than salt-sensitive varieties under both controls as well as salt treatments [60]. Therefore, under salinization, certain isoforms of acid phosphatase are not synthesized, whereas the synthesis of certain new isoforms is induced depending on the plant parts and the genotypes studies. It has been shown that salt tolerance is associated with the presence of a large number of acid phosphatase isoenzymes [60].

The specific activities and patterns of peroxidase and superoxide dismutase isoenzymes are altered significantly in plants subjected to salinity stress. When rice seedlings were raised under an increasing level of NaCl salinity, certain new isoforms of peroxidases appeared, and the intensities of some of the preexisting isoenzymes increased, especially in the salt-sensitive varieties [61]. Different patterns of peroxidase isoenzymes were observed in the two sets of rice cultivars differing in salt tolerance. In 15-day-old seedlings of a salt-tolerant rice cv CSR-1, three isoenzymes were observed in roots and five in shoots, whereas in a salt-sensitive cv Ratna, six isoenzymes were observed in the roots as well as in the shoots [61]. Salt-tolerant embryonic callus cultures of lemon (*Citrus limon* L. Burm) exhibited an increase in the activity of antioxidant enzymes involved in oxygen metabolism with an increase of peroxidase activity and with the induction of a new superoxide dismutase isozyme [87]. These studies and other similar studies suggest that peroxidase and superoxide dismutase isoenzymes can serve as useful markers in the analysis of gene functions and metabolic regulations, including salt-tolerance characteristics [61].

Like acid phosphatases and peroxidases, isoenzyme profiles of ribonucleases [91] and α-amylases [81] are also influenced under salinization. The presence of different isoenzyme patterns of phosphatases, peroxidases superoxide dismutase, and ribonucleases in salt-sensitive and salt-tolerant genotypes of crops strengthens the view that salt tolerance or sensitivity depends on the genetic and biochemical make-up of the species. Also, specific molecular froms of the isoenzymic proteins, which appear to be constitutive proteins, are possibly associated with the salt tolerance or sensitivity characteristics. However, the mechanism of the expression of intrinsic isoenzyme proteins related with sensitivity or tolerance and of those isoenzymic proteins that specifically appear under salinization remains to be investigated.

Water Stress

Water is the Earth's most distinctive constituent and is an essential ingredient of all life. Its deficit is one of the most common environmental factors limiting crop productivity. Drought is a natural calamity and has devastating effects on crop yields. Crop plants are frequently subjected to water stress during the course of their lifetimes. However, certain stages, such as germination, seedling, and flowering, are the most critical for water stress damage. Stress imposed during these stages drastically affects crop yields. Water stress reduces plant growth and manifests several morphological and biochemical alterations in plants ultimately leading to massive loss in yield. A reduction in

Marcel Dekker, Inc.

the efficiency of key processes including protein synthesis, photosynthesis, respiration, and nucleic acid synthesis are among the biochemical manifestations of water stress. Water stress inhibits protein synthesis, induces the synthesis of small sets of stress-specific proteins, promotes important modification in gene expression, causes activation or inhibition in activities of many enzymes, and leads to changes in the ultrastructures of tissues. A considerable amount of work has been done by various groups of investigators in the last few years to understand the mode of protein synthesis in plant parts under water-stressed environments [11,14,17,19,72,92,93], the level of proteins in stressed plants [94,95], and the activities of key enzymes influenced under water stress [10,96,97,98].

Water Stress–Induced Proteins

Water stress causes an alteration in gene expression in plants leading to an inhibition of protein synthesis as well as enhanced synthesis of certain stress-specific proteins. Quantitative and qualitative changes occur in the synthesis of proteins in plants in response to water deficit. It is well documented that, in various crops, water stress causes tissue- and organ-specific differential genomic expression which results in changes in the patterns of protein synthesis in cells [11,19,92]. Plants growing in a water-stressed environment or cells undergoing adaptation to water stress show both a decrease as well as an increase in small sets of cellular proteins. Many of these proteins which are specifically synthesized under water stress have been isolated and well characterized [6,72,93,99].

Mild to moderate water stress decreases the efficiency of protein synthesis in plants, but such plants recover and their protein synthesis returns to normal when stress is reversed or plants are rewatered [11]. Imposition of water stress alters the status of the protein-synthesizing complex polyribosomes in the tissue. The content of Polyribosomes decreases with one type of water stress, and the extent of such a decrease varies among different plant species and even in different organs of the same plant [11,100]. Studies in maize [11] and wheat [100] have indicated that increasing the level of water stress causes a decrease in the polyribosome level. Plant species which can survive under water stress show a greater capacity to produce polyribosomes in the tissues.

Various investigators have demonstrated the synthesis of water stress–specific proteins in different crops [6,14,17,19,72,92,93,99]. Many of these proteins also appear in response to the application of abscisic acid (ABA), suggesting that ABA is a signal in the stress response. Genes encoding these proteins have been isolated and studied using DNA probes. Like salinity stress, water stress–inducible proteins have been grouped in several families depending on the DNA sequences of genes, their expression characteristics, and their predicted functions.

Major families of water stress–induced proteins have been described as LEAs (late-embryogenesis abundant), RABs (responsive to ABA), dehydrins, and vegetative storage proteins [42]. LEA proteins have been further subdivided into several group: group 1 (D19 protein from cotton), group 2 (D11 from cotton), group 3 (D7 from cotton), group 5 (D29 from cotton). Many of these proteins are hydrophilic and are soluble on boiling, and are therefore expected to be located in the cytosol. It is predicted that most of these proteins are involved in protecting cellular structures and components from dehydration associated with water deficit.

Among proteins that accumulate in plants in response to dehydrative forces or water deficit, dehydrins have been the most commonly observed. Barley, maize, pea, and *Arabidopsis* plants show increased synthesis of dehydrins under osmotic stress [71]. Dehydrins are composed of several typical domains joined together in a few characteristic patterns with numerous minor permutations. Dehydrin polypeptides are made up of less than 100 to nearly 600 amino acid residues [72]. Although the fundamental biochemical mode of action of dehydrins has not been demonstrated, it is believed that dehydrins are surfactants and thereby they inhibit the coagulation of a range of macromolecules and preserve the structural integrity of the cell [72]. Genes encoding dehydrins also are ABA regulated. In dehyrated leaves of tomato, maize, and *Arabidopsis* plants, endogenous ABA levels increase with the simultaneous increase in dehydrins and its mRNA [70]. Dehydrins are localized primarily in the cytoplasm of root and shoot cells [70].

In certain plant species, synthesis of dehydrin-like proteins has been observed under osmotic

stress or under treatment with ABA. In *Stellaria longipes* the synthesis of a dehydrin like protein is induced as a result of treatment with ABA or under osmotic stress [17]. Sequence analysis of this protein indicates that it shares some similarity in structural features with dehydrins of other plants and also exhibits certain unique characteristics [17]. In castor bean, the synthesis of dehydrin-like proteins is tissue specific and is dependent on the physiological stage of the seed. Patterns of water deficit–induced dehydrin-related polypeptides in endosperms differ from those induced during late seed development [45]. In drought-stressed roots and shoots of *Lathyrus sativus*, dehydrin-like transcripts accumulate, which are also expressed in unstressed seedlings owing to ABA treatment [101]. A novel protein with 40-KDa molecular weight has been detected in pea plants under dessication. The deduced amino acid sequence of this protein indicates two lysine-rich blocks; however, the remainder of the sequence differs markedly from other pea dehydrins [13]. By analogy with heat-shock cognate proteins, this protein has been designated as dehydrin cognate [13].

Like dehydrins, the RAB and D11 (group 2) family of proteins are also ABA regulated and possess a characteristic lysine-rich region with consensus amino acid sequences repeated at least two times. Proteins of this family have been identified in many plant species, including maize, tomato, wheat, alfalfa *Arabidopsis*, rice, and castor [45,70,71,102]. LEA group 1 (D19) proteins, which are devoid of cysteine and tryptophan, have been detected in cotton, barley, and carrot under water deficit [71]. It is suggested that LEA group 1 proteins function in a water-binding capacity creating a protective aqueous environment [70]. LEA group 3 and group 5 proteins, which are represented by D7 and D29 proteins, respectively, from cotton contain a repeated tract of 11 amino acids. These proteins have been isolated from dessicating mature cotton embryos, chloroplasts of *Craterostigma plantagineum*, and citrus seedlings exposed to drought [8,70]. A citrus cell suspension in response to salt stress, leaves of citrus plants irrigated with NaCl, or seedlings exposed to drought lead to an osmotic stress–induced elevated level of LEA5 protein and its mRNA [8]. Another group of LEA proteins, group 4, is represented by D113 protein, which has a homologue in tomato and is expressed in drying cotton seeds [70,71].

Using a transgenic approach, it is suggested that LEA proteins play an important role in the protection of plants under water stress. Expression of the barley (*Hordeum vulgare* L.) LEA protein gene, *HVA1,* in rice cell suspension leads to a high level of accumulation of this protein, and such plants slow an increased tolerance to water deficit [73]. Osmotin, the 26-kDa protein which is synthesized and accumulated in cells undergoing osmotic adjustment to NaCl, also accumulates in cells undergoing osmotic adjustment to polyethylene glycol [6]. ABA, which is known to induce osmotic adjustment in cells, also induces the synthesis of osmotin. Osmotin synthesis is regulated by ABA, but its accumulation is dependent on the extent of water stress and the adjustibility of the cells to stress. Like dehydrins, osmotin also is the much extensively studied protein which accumulates under water and salinity stresses in several plant species like tobacco, triplex, tomato, and maize [71]. An osmotically regulated glycine- and threonine-rich protein was identified in rice by Mundy and Chua [102]. This protein is a product of an ABA-responsive gene *rab* 21. Osmotic stress imposed by polyethylene glycol or dessication leads to an increase in the level of ABA, and in turn the *rab* 21 gene is induced and expressed to synthesize this protein in rice tissues.

From rice cv *Tainchung* native 1, a 15-kDa protein that accumulates in the sheaths and roots of mature rice plants and seedlings when subjected to either osmotic stress or treated with ABA has been isolated and characterized [99]. Rice varieties show considerable differences in sensitivity to drought, however, in many of the varieties examined, water-deficit created as a result of PEG (polyethylene glycol) led the induced synthesis of one 26-kDa protein with a pI of 6 [16]. In certain varieties of rice, water stress causes accumulation of 87-and 85-kDa proteins, called stress-associated proteins (SAPs), that also accumulate under salinity and high and low temperatures [69].

A boiling-stable protein (BspA) has been shown to accumulate in shoots of *Populus popularis* plants under water stress [93]. In addition to BspA, plants also show accumulation of the water stress–related protein dehydrin (dsp-16) and sucrose synthase under water deficit [93]. In a highly drought-tolerant legume, cowpea (*Vigna unguiculata*), which shows about 160 times higher accumu-

Marcel Dekker, Inc.

lation of ABA in drought-stressed conditions compared with unstressed plants, two cDNA clones, CPRD 8 and CPRD 22, which encode putative proteins that are related to old yellow enzyme and group 2 LEA proteins, respectively, were identified in drought-stressed plants [103]. However, in 10-h dehydrated cowpea plants, two additional cDNA clones, CPRD 12 and CPRD 46, were identified which encode putative proteins related to nonmetallo–short-chain alcohol dehydrogenase (CPRD 12) and chloroplastic lipoxygenase (CPRD 46). These genes are also induced under salinity stress [104].

Exposure of *Arabidopsis thaliana* to drought stress results in the accumulation of the RAB18 protein, and such plants develop enhanced freezing tolerance [15]. Progressive water deficit in whole *Solanum tuberosum* plants leads to about a 2.5-fold increase in leaf ABA content and the synthesis of two chloroplastic proteins of 32 and 34 kDa, named CDSP 32 and CDSP 34, which are synthesized in the stroma and in the thylakoids, respectively [67]. A 65-kDa protein with pI value of 5.2 has been shown to accumulate gradually in tomato leaves during water stress [105]. Quantification of this protein by gold labeling indicates that synthesis of this protein occurs in nuclei and chloroplasts as well as in some cytoplasmic regions of the cells in drought-stressed plants [105].

Certain additional families of proteins and their genes which are induced by water deficit have been identified in specific plant species. In *Arabidopsis*, 77.9- and 64.5-kDa hydrophilic proteins accumulate under water stress, and their genes, which are adjacent to each other in the genome, have been characterized from different laboratories [70]. Synthesis of these proteins also occurs with ABA application. Similarly, a family of genes and their products, glycine-rich proteins, which are hydrophilic and ABA responsive, have been identified in alfalfa plants under water stress [70]. However, no specific predictions about the functions of these *Arabidopsis* and alfalfa proteins have been made under stressful conditions.

A gene named ATHB-7, which belongs to a class of recently discovered homeobox genes found as yet only in plants, has been characterized in all organs of *Arabidopsis thaliana*. Expression of this gene and the synthesis of its proteins, called homeodomain-leucine zipper (HD-Zip) proteins, is induced severalfold under water deficit as well as by exogenous treatment with ABA [106]. It is suggested that ATHB-7 is transcriptionally regulated in an ABA-dependent manner and may act in a signal transduction pathway mediating a drought response [106]. Besides cytosolic and organellar proteins which are induced under water stress, in cell walls of bean (*Phaseolus vulgaris*) seedlings, two proteins, 36- and 33-kDa, have been identified that are glycosylated and accumulate when plants are subjected to the gradual loss of water [107].

Studies conducted by various investigators related to the effects of water stress on protein synthesis in many important crops suggest that water stress severely affects protein synthesis, alters gene expression and protein profiles in stressed tissues, and induces the synthesis of stress induced–specific proteins. Many of these proteins are hydrophilic and belong to specified families and have predicted functions in protecting the cells from water stress. Some of the stress-induced proteins appear to be tissue specific, whereas others appear not to be specific for any particular tissue or organ. Genetic expression studies reveal that among the stress-induced proteins which are well characterized, the majority are the product of ABA-responsive genes. How stress conditions signal an increased production of ABA, how ABA modulates the expression of these genes, and what is the functional role of stress-responsive proteins in dehydration tolerance, such as osmoprotectants, radical scavengers, protectants of subcellular organelles and macromolecules, or as regulatory proteins, remains yet to be investigated in detail.

Protein Level in Water-Stressed Plants

The levels of total as well as soluble proteins are altered in plants growing under water-stressed environments compared with plants growing under nonstressed conditions. Various workers have observed either a decrease [51,94,108,109,110] or an increase [94,95] in the levels of total or soluble proteins in different organs of plants subjected to water stress. The increased or decreased levels of proteins depend on the plant species and organ studied as well as the severity of the stress.

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

Shah and Loomis [111] observed decreased contents of soluble and total proteins in sugar beet leaves from data recorded on a per gram of dry weight basis when the plants were subjected to progressive water stress. These investigators observed that the response to water stress was quick and could be reversed by rewatering the plants. This indicates that water-stress effects are reversible to a certain extent. According to Hsiao [108], the rapid response of plants under water stress and its quick reversibility by rewatering suggest that water stress affects protein synthesis mainly at the translation level. When Bermuda grass plants were subjected to increasing water stress, a decrease in the soluble protein level was observed [109]. In whole chloroplasts as well as chloroplast membrane fractions isolated from drought-resistant as well as drought-sensitive genotypes of water-stressed wheat plants, a decrease in the protein content was observed compared with nonstressed plants [112]. Mung bean seedlings differing in water stress tolerance, when raised under increasing water deficits, show a decrease in the protein level in the axis [94].

In *Lycopersicon chilense* plants as well as cell suspensions, water stress leads to the decreased synthesis of a proline-rich 12.6-kDa protein in the cell walls [110]. This is possibly attributed to the downregulation of its gene, designated PTGRP under dessication. In nodules of water-stressed (−2.03 MPa) pea (*Pisum sativum* L. cv Frilene) plants, about 30% decline in soluble protein level is observed compared with well-watered plants [51]. When rice varieties differing in water stress tolerance were examined for changes in the protein profiles in different organs due to water stress, it was observed that in the two cultivars, Sinaloa and IR 10120, the synthesis of several polypeptides decreased owing to PEG-induced water stress [16]. It is suggested that in rice, the extent of the decrease in the levels of proteins or changes in protein profiles in different organs due to water deficit are cultivar specific [16].

A decreased level of the total as well as the soluble protein contents in water-stressed tissue [94] appears to be due to more degradation of proteins as well as the overall inhibition in protein synthesis under water stress. It has been observed that water-stressed plant parts show a high protease activity compared with nonstressed plants [113]. The high activity of protease in water-stressed plants appears to be of adaptive significance, because it leads to the accumulation of free amino acids as a result of the degradation of proteins. Increased levels of free amino acids together with organic acids and quaternary ammonium compounds serve as compatible cytoplasmic solutes to maintain the osmotic balance between the cytoplasm and the vacuole under conditions of water stress [109].

Genotypes of crop cultivars differing in water-stress tolerance, when raised under increasing levels of water stress, show different levels of proteins as well as a specific activity of protease in the two sets of cultivars. Seedlings of drought-tolerant Mung bean genotypes show a higher protein content in embryoaxes as well as cotyledons compared with drought-sensitive genotypes when raised at a −10.0 bar moisture stress level [94]. Similarly, drought-resistant maize (*Zea mays* L.) cultivars show a high protease activity at higher levels of water stress, whereas inhibition in protease activity is noticed under higher water-stress levels in sensitive cultivars [113]. While comparing the total protein and free amino acid pool size in drought-resistant and drought-sensitive cultivars of *C. arietinum* and *Z. mays*, Rai et al. [95] observed that resistant plants are characterized by an increase over nonstressed plants in total protein and free amino acid levels.

Certain investigators have observed an increase in protein levels in plants subjected to water stress [94,95]. Genotypes of *C. arietinum* cultivars, differing in water stress tolerance, when raised under increasing osmotic potential levels, show increased protein levels in shoots compared with nonstressed plants [95]. A drought-resistant *Cicer arietinum* cv C-214 showed an increase of 60% protein over control at an osmotic potential of −3 atm, whereas a sensitive cultivar, G-130, showed a 15% increase over control under similar conditions of stress [95]. Similarly, when drought-resistant *Z. mays* cv Ageti-76 plants were grown under increasing osmotic potentials in the range of 1 to 10 atm, an increase in protein content was noticed, reaching 190% of control [95]. Similarly, in cotyledons of germinating mung beans under water stress, an increased protein level was noticed when they were compared with nonstressed germinating seeds [94]. These observations indicate that water stress has varying effects on the level of proteins in different crop species, and the stress-induced

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

response depends on the species of crop examined, and it may vary even in different organs within the same species.

Enzyme Levels in Water-Stressed Plants

The normal metabolism of plants growing under water-stress conditions is adversely affected with a concomitant disturbance of the enzymatic constitution of the plants. Water stress lowers the level of many enzymes in the tissues [51,96,98,113–115]. The activities of certain enzymes increase as a result of water stress [10,70,97,108,113]. Nitrogen assimilation and photosynthetic efficiency are reduced in water-stressed plants mainly owing to the decreased activities of the key enzymes involved in these processes. Nitrate reductase (NR), the prime enzyme in the N-assimilation process, is markedly inhibited by water stress [108]. The effect of mild (−0.5 MPa) levels of water stress on the level of protein and the activities of enzymes NR, glutamine synthetase (GS), alanine aminotransferase (AlaAT), and aspartate aminotransferase (AspAT) in roots and shoots of 20-day grown followed by 24-h water-stressed rice plants is in Table 2. As it is evident from Table 2, water stress causes a drastic decline in the protein levels as well as in the activities of the enzymes of NO_3^- assimilation, NR and GS, whereas the key enzymes of amino acid metabolism, AlaAT and AspAT, show increased activity under a mild water stress level; however, under a moderate water stress level of −2 MPa, a pronounced inhibition in the enzyme activity is noticed. The nitrate reductase activity is directly associated with protein synthesis and plant growth, and both of these processes are adversely affected by water stress [116].

The photosynthetic apparatus is sensitive to dehydration. Water stress has a direct effect on carboxylating enzymes. The activities of the enzymes RuBP carboxylase and PEP carboxylase decreased in the leaves of plants subjected to water stress [114,117]. In sugar cane leaves, a decrease in the leaf water potential up to −0.37 and −0.85 MPa led to about a two to nine times decrease in the activities of RuBP carboxylase, PEP carboxylase, fructose- 1,6-bisphosphatase, NADP malic enzyme, and orthophosphate dikinase leading to an overall decreased rate of photosynthesis [114]. Water stress alters carbon partitioning in plant parts owing to an alteration in the activities of sugar-metabolizing enzymes. In leaves of sorghum plants, water stress reduces sucrose formation owing to an inhibition in the activities of fructose 1,6-bisphosphatase and sucrose phosphate synthase [115]. However, in potato tubers, moderate water stress leads to an activation of sucrose phosphate synthase and stimulation of sucrose synthesis [98]. More extreme water stress in potato tubers leads to a further alteration in carbon partitioning, because it inhibits the activities of one or more of the enzymes involved in the terminal reactions of starch synthesis [98].

Water stress leads to oxidative damage in plants by inducing the production of active oxygen species and decreasing the activities of the antioxidant enzymes catalase, peroxidase, and superoxide dismutase [51,96]. An examination of the involvement of activated oxygen in the drought-induced damage of pea nodules indicates that water stress (−2.03 MPa) caused a decrease in the activities of catalase (25%), ascorbate peroxidase (18%), dehydroascorbate reductase (15%), glutathione reductase (31%), and superoxide dismutase (30%) with a simultaneous decrease in the contents of ascorbate (59%), reduced glutathione (57%) and oxidized glutathione (38%) [51]. The overproduction of antioxidant enzymes provides an elegent approach to engineer plant species genetically for water-stress tolerance. Transformed alfalfa plants expressing Mn superoxide dismutase cDNA from *Nicotiana plumbaginifolia* have been shown to be more resistant to drought stress [118].

Levels of many enzymes increase under water stress. Many hydrolytic enzymes show an increased activity in water-stressed tissues. The α-amylase activity increased under water stress, which was responsible for increased starch hydrolysis in vivo, leading to increased levels of sugars and a decreased level of starch, as observed in water-stressed tissues [108]. Proteases have been shown to be induced under water stress. A thiol protease in pea and two cysteine proteinases in *Arabidopsis* have been identified which are induced under water deficit [70]. Certain hydrolytic as well as oxidative enzymes show different behaviors in the crop cultivars differing in water-stress tolerance. While investigating the behavior of drought-resistant and drought-sensitive *Z. mays* culti-

vars for protease activity under water stress, Thakur and Thakur [113] observed an increasing trend in protease activity with an increasing osmotic potential in resistant cultivar Ageti-76, whereas in the sensitive cultivar Vijay, they observed a decreased protease activity under severe water stress. While studying the behaviors of certain hydrolytic and oxidative enzymes in the leaves of water-stressed rice plants of the two genotypes differing in stress tolerance, Goyal and Kochhar [119] observed that protease, ribonuclease, peroxidase, and IAA (indole acetic acid) oxidase activities were inhibited by water stress. However, the activity of ascorbic acid oxidase increased in the both sets of cultivars. Different responses for these enzymes were observed for the two sets of cultivars differing in stress tolerance.

In certain plant species, the increased synthesis of sucrose [93] and proline [58] occurs under water stress owing to a stress-induced increase in the activities of the enzymes synthesizing these metabolites. In *Populus popularis* plants, the accumulation of sucrose accompanied by the increasing activity of its synthetic enzyme sucrose synthase occurs under water deficit [93]. The activity of the enzyme Δ^{-1}-pyrroline-5-carboxylate synthetase (P5CS), which is involved in the biosynthesis of proline, increases in rice seedlings under dehydration [10].

Different behaviors of certain oxidative enzymes have been observed depending on the different methods of creating water stress as well as the plant parts studied. The activities of IAA oxidase and peroxidase increased in etiolated water-stressed seedlings of winged bean (*Psophocarpus tetragonalobus* L.) and amaranthus (*Amaranthus caudatus*) plants, whereas the decreased activities of two enzymes were observed in water-stressed green seedlings [120]. The higher activities of oxidative enzymes under water stress is possibly due to a gradual shift of reductive metabolism to oxidative metabolism under these conditions. While studying oxidative processes in rice plants differing in water-stress tolerance, Lodh et al. [97] observed an increased activity of peroxidase in drought-tolerant cultivars Lalnakanda-41 and T(N) 1 × T.65 as well as drought-sensitive cultivar CO-13. These investigators observed an increased catalase activity in drought-sensitive rice cultivar CO-13 but not in the drought-tolerant cultivars. Polyphenol oxidase activity has been reported to increase in leaves and roots of drought-sensitive rice cultivar CO-13, whereas, in drought-tolerant cultivars Lalnakanda-41 and T(N) 1 × T.65, the activity of the enzyme decreased in the leaves as well as the roots under water stress [97]. These observations suggest that water stress leads to changes in the levels of various enzymes in stressed plant parts and that the effects of stress depend on the properties of enzymes, severity of the stress, and organs of the plants studied.

Heat Stress

High-temperature or heat stress adversely affects plant growth and yield in many areas of the world. Some plants can survive when the temperature exceeds even 20°C above ambient, whereas in most of the field crops, temperatures above 40°C cause heat injury, severely limit photosynthesis, and alter protein metabolism by causing protein breakdown, protein denaturation, enzyme inactivation, and other effects.

When plants are subjected to heat treatments beyond optimum growth temperatures, the normal protein synthesis declines owing to a coordinate loss of translational efficiency of most mRNAs and the enhanced synthesis of a small set of proteins known as heat-shock proteins (HSPs) occurs. It is believed that heat tolerance in plants is associated with the synthesis of HSPs, which protect plants from otherwise nonpermissive temperatures and provide them with an endogenous protection system for thermotolerance. The phenomenon of heat-shock response (HSR) is conserved among all biological organisms. Although HSPs provide the molecular basis for thermotolerance, but whether they act directly in signal transduction or induce the synthesis of secondary agents involved in protection is not yet clear. The synthesis of HSPs occurs in diverse plant species when they are exposed to temperatures 10–15°C above growing temperatures [18–21,48,121–123].

Crop plants, such as maize, soybean, cowpea, and wheat, start synthesizing HSPs in the tissues with a rise in tissue temperature beyond 32–33°C [2]. The induction of HSP synthesis parallels the increase in temperature. It has been observed that exposure of plants to higher temperatures of heat

shock leads to the stability as well as the rapid induction of specific mRNAs related to specific HSPs [124].

Synthesis of Heat-Shock Proteins

The synthesis of HSPs occurs in plant cell cultures undergoing thermoadaptation or intact plants subjected to heat stress [2]. It has been shown that not only heat stress but other conditions, such as treatment with arsenite, heavy metals, ethanol [2], ABA, water stress, and wounding [19],induce some of the HSP mRNAs and lead to the expression of HSPs in plants. This shows that the synthesis of HSPs can be induced even in the absence of heat stress and high temperature protection can be provided without prior heat shock.

Cytoplasmic distribution and subcellular localization of HSPs indicate that they remain either specifically associated with various subcellular organelles, such as nuclei, chloroplasts, mitochondria, plasma membrane, or as cytoplasmic aggregates distinct from ribosome granules [2,18]. When the tissue temperature exceeds 32–33°C, HSPs are typically seen. The appearance of these proteins has been positively correlated with enhanced thermotolerance, and, as well, it also provides a certain level of cross protection to other kinds of stresses [42].

In carrot cells, heat-shock treatment causes an inhibition of protein synthesis with the simultaneous appearance of new proteins [125]. In carrot cells, patterns of these newly synthesized proteins become different depending on the growth stages of cells and culture conditions. It was shown by Kanakus et al. [122] that tobacco cell suspensions synthesize HSPs in different phases of the growth cycle. When maize tissues are exposed to heat shock, they show the induction of heat-shock protein mRNA and synthesis of a set of 10 HSPs [19,121]. Different tissues of the same plant, as well as different developmental stages of the tissues, show different pattern of HSPs [47].

In field-grown cotton (*Gossypium hirsutum* L.) plants, when the temperature reaches 40°C for a few weeks, synthesis of eight unique polypeptides of 100, 94, 89, 75, 60, 58, 37 and 21 kDa occurs [47]. These polypeptides accumulate in dryland plants that have a canopy temperature of 40°C and are absent in irrigated plants that have a 30°C canopy temperature. A group of 11 newly synthesized polypeptides accumulated in laboratory-grown heat-shocked cotton plants, as revealed by autoradiography of radiolabeled polypeptides. Of these 11 polypeptides, 8 appear to be similar to those of heat-shocked field-grown cotton plants [47]. These results suggest that dryland crops synthesize HSPs in substantial levels in response to high temperatures.

Many desert succulent plants have been shown to accumulate HSPs when day and night air temperatures are raised from 30 and 20°C to 50 and 40°C [48]. The pattern of accumulation of HSPs is species specific in these plants; however, a unique 25- to 27-kDa protein accumulated in all species examined, which appeared to be associated with thermotolerance in these plants [48]. Elevation of the culture temperature to 32°C for 8 h leads to irreversible de novo synthesis of a number of HSPs of a 70-kDa class: HSP68 and HSP70 in *Brassica napus* [20]. Five-day-old rice seedlings, when subjected to a temperature stress of 45°C for 1–2 h, synthesized and accumulated a 104-kDa polypeptide, which constituted about 0.4% of the total soluble protein fraction [123].

Among the wide range of HSPs which accumulate under heat shock, some are specifically associated with organelles, including the nucleus, nucleolus, chloroplast, mitochondria, and plasma membrane. Certain other HSPs are found to be associated with ribosomes or they remain as aggregates in the cytoplasm [18]. In pigeon pea (*Cajanus Cajan*) plants, heat-shock proteins of 18, 20, 22 and 24-kDa are found to be associated with mitochondrial and membrane fractions, whereas the 60-, 70-, and 81-kDa proteins are found in the soluble fraction [126]. In mitochondria of pea plants, a novel 22-kDa protein accumulates in the matrix when normal growth temperature is shifted from 25°C to 40°C [127].

Types of Heat-Shock Proteins

Heat shock induces the synthesis of a wide range of HSPs in plants. A general system of classification for these proteins is based on their molecular weights and their localization in the cell. Some of

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

the common HSPs synthesized in plants include HSP70, HSP60, low molecular weight HSPs, and high molecular weight HSPs. Many HSPs, like HSP60, HSP70, and HSP90, are present as constitutive proteins in the cytoplasm as well as other organelles like mitochondria and chloroplasts of plants in nonstressed conditions and their level increases under heat shock. Studies indicate that HSPs function in a fashion similar to molecular ''chaperons'' and assist the self-assembly of nascent polypeptides into their correctly folded tertiary structures and also prevent the formation of an aggregation of nonfunctional proteins resulting from heat denaturation [42]. Especially small HSPs which range in size from 17 to 30 kDa and are encoded by six nuclear gene families, accumulate to high levels in response to heat stress and bind partially denatured proteins, preventing irreversible protein inactivation and aggregation, and thus contribute to the development of thermotolerance [21]. According to Harrington et al. [128], HSPs have a possible function in signal transduction involving protein kinases and heat shock–induced calmodulin-binding proteins.

Chilling

Chilling is one of the most severe constraints limiting crop productivity. Low environmental temperatures lead to chilling injury in plants and result in the loss of plasma membrane integrity, irreversible and proportional loss of proteins from the cell, and ultimately the death of the cell [46,129]. According to Levitt [129], freezing-induced dehydration within the cell leads to aggregation of proteins owing to the formation of disulfide bonds as well as the denaturation of soluble proteins. Synthesis of many key enzyme-proteins decreases when plants are exposed to low temperatures [24,25], and synthesis of certain specific proteins is induced [26].

Many enzymic proteins, especially of those carbon assimilation, are extremely sensitive to chilling. The key photosynthetic enzyme of C3 plants, Rubisco, which constitutes about 60% of soluble proteins, undergoes changes in structure, conformation, and properties at low temperatures [24,46]. In *Zoysia japonica* plants, a drastic decline in the level of C_4-cycle enzymes phosphoenolpyruvate carboxylase (PEPC) and phosphoenolpyruvate carboxykinase (PCK) takes place during exposure to low temperature. In *Lycopersicon esculentum* and *Zea mays* plants, chilling stress results in an irreversible loss of Rubisco activity and stromal fructose-1,6-bisphosphatase activity [24]. In the conifer *Pinus sylvestris*, the contents of D1 protein of the photosystemII (PSII) reaction center and of the PSII light-harvesting complex (LHCII) proteins decline under low-temperature stress [130]. Similarly, the —SH-rich enzyme glutathione reductase becomes partially inactivated by freezing [131]. It is suggested that the activity loss of many enzymes on chilling is as a result of a modification of sulfhydryl groups or other side chains of the protein [24].

In many plant species, chilling injury leads to build-up of reactive oxygen species, oxidation of proteins, and decline in the activities of catalase, ascorbate peroxidase, and glutathione reductase [132]. The tolerance of rice cultivars to chilling injury is closely linked to the cold stability of catalase and ascorbate peroxidase [132].

Cold Acclimation

When plants are exposed to low nonfreezing temperatures for a few hours or day, certain new sets of proteins are synthesized and these plants develop the capacity to adapt to a subsequent chilling or freezing temperatures. Such a mechanism of adaptation is known as cold acclimation (CA). Generally temperatures from 4 to 15°C are considered to be chilling, whereas a temperature below 4°C, is considered to be freezing [42]. CA results in altered gene expression leading to synthesis of specific proteins and certain enzymes which are responsible for the development of freezing tolerance [26,133,134]. Several preexisting proteins abundant in the tissues of plants grown under normal temperature decline on exposure to low temperatures. However, many new transcripts and polypeptides are synthesized [22,26,135], which appear to play a major role in acclimation of plants to freezing temperatures [26].

Plants differ in their capacity to tolerate low temperatures. In many crop plants, freezing

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

tolerance can be induced by exposure to low nonfreezing temperatures. Freezing-tolerant or cold-acclimated plants possess new proteins which are not present in normal or nonacclimatized plants. Uemura and Yoshida [136] while studying cold acclimation in winter rye (*Secale cereale* L.) seedlings, observed that more than 20 proteins disappeared in the plasma membrane during acclimation, and the concentration of 11 proteins increased, whereas 26 new proteins were synthesized.

In young rapeseed *Brassica napus* seedlings, a 48-h exposure to nonchilling temperatures induces important changes in gene expression. The synthesis of specific polypeptides is increased with a concomitant increase in respective mRNA levels, whereas the synthesis of six polypeptiedes is suppressed with degradation of their corresponding mRNAs [22]. Transcripts of a gene encoding a putative cell wall plasma membrance linker proline-rich protein has been isolated by Goodwin et al. [137] form *Brassica napus* leaves, which are specifically expressed in leaves on exposure to low temperature. This indicates that an increase in the level of specific mRNA transcripts and their corresponding proteins is correlated with improved freezing tolerance [22]. The CA of rapeseed seedlings leads to a decreased level of mRNA for the Rubisco small subunit as well as the reduced synthesis of this protein [22]. In cold-sensitive rice (*Oryza sativa* L.) plants, CA leads to suppression as well as induction in gene expression resulting in a decreased level of certain proteins and the increased synthesis of other specific proteins as well as corresponding mRNAs [23]. Hahn and Walbot [23], while studying the effect of cold treatment on the pattern of protein synthesis in rice leaves, detected several novel proteins of 95, 75, 25, and 21 kDa that were synthesized during 1–7 day of 11 and 6°C cold treatment. These proteins were cold specific; other stresses, such as water stress, salinity, and acid treatment, could not induce the synthesis of such proteins.

In freezing tolerant cereal plants, such as rice, wheat, and barley, antifreeze proteins are synthesized during CA, which play significant role in increasing freezing tolerance [26,134]. Six antifreeze proteins which have the unique ability to absorb onto the surface of ice and inhibit its growth have been isolated from the apoplast of winter rye leaves where ice forms at subzero temperatures [26]. Among the rye antifreeze proteins, two are endoglucanase-like, two chitinase-like, and two thaumatin-like proteins [26]. The accumulation of antifreeze proteins is not a general response to all plants, but it is a specific response that is important in the freezing tolerance in certain plants.

In certain plants, such as citrus [138] and some herbaceous species [139], a very high molecular weight protein has been identified that is specifically synthesized under CA. Durham et al. [138], while comparing polypeptide patterns resulting from in vitro translations of total RNA isolated from cold-acclimatized and non–cold-acclimatized leaf tissues of cold-sensitive *Citrus grandis* plants, observed a 160-kDa polypeptide in cold-acclimatized leaves that was not present in non–cold acclimatized citrus leaves. This 160-kDa unique polypeptide has also been detected in cold-acclimatized spinach and sweet orange, *C. sinensis* [139].

In *Arabidopsis thaliana*, two glycine-rich proteins, MSACIA and MSACIB, accumulate during CA. Timing and localization of the expression of these two proteins are different and the differential expression involves both transcriptional and posttranscriptional events [140]. Comparisons among different cultivars of *A. thaliana* suggest that low freezing tolerance is associated with the failure to accumulate these proteins. Mantyla et al. [15] have shown the accumulation of ABA-responsive RAB18 and LT178 proteins in *A. thaliana* plants under CA. In floral buds of a woody perennial blueberry (*Vaccinium*), three different dehydrin-like lysine-rich proteins of 65, 60, and 14 kDa accumulated in response to chilling [141]. Accumulation of high levels of dehydrin transcripts has also been observed in field-grown freezing-tolerant bromegrass (*Bromus inermis* L.) and rye (*Secale cereale*) plants [142]. Field-acclimated plants accumulating high levels of dehydrin transcripts have been regarded as being more freeze tolerant [142].

There does not appear to be any uniform pattern of protein synthesis among various plant species during CA. This implies that CA-induced proteins are not highly conserved as heat-shock proteins. A characteristic feature of CA-induced proteins is that some of the synthesized proteins are transient, whereas others are stable, the synthesis of which continues for weeks [135].

The inheritance of freezing tolerance appears to be a multigenic phenomena, and the precise function of the proteins encoded by these genes is not fully known. Both transcriptional and posttranscriptional controls have been shown to be involved in the expression of these genes [143].

Abscisic Acid and CA

It has been observed that exogenous ABA induces freezing tolerance in many plant species [133,144], although the physiological basis of this phenomena is poorly understood. In certain plants, an increase in the endogenous ABA level is observed following CA [42,144]. Plantlets of potato (*Solanum commersonii*) stem culture, when treated with ABA for 14 days, develop cold tolerance with the concomitant induction of 30 polypeptides [144]. Several specific translatable mRNA populations and their in vitro translation products have been identified following ABA treatment of potato plantlets [142]. It is suggested that ABA alters gene expression leading to the development of cold hardiness [145] by the synthesis of certain specific polypeptides that are similar to some of the polypeptides synthesized during CA [15,144]. The ABA has been shown to induce the synthesis of certain polypeptides that are not synthesized in CA tissues [144]. A comparative study of CA-induced proteins and ABA-induced proteins suggests that both CA and ABA induce the synthesis of specific and certain common proteins. This also suggests that the full development of cold tolerance requires the synthesis of complete sets of CA-induced proteins, because certain genes, in addition to those responsive to ABA, are involved in the development of maximum freezing tolerance [133].

Anaerobic Stress

Anaerobic stress is generally caused by excessively wet soil or flooding conditions. Anaerobiosis affects plant metabolism as a result of a low oxygen concentration in the rooting medium. Plants adapting to anaerobic stress switch from oxidative to fermentative carbohydrate metabolism [27]. Under anaerobic stress, normal protein synthesis is suppressed, associated with the loss of polysomes, and gene expression alters leading to synthesis of specific sets of novel polypeptides commonly known as transition polypeptides (TPs) and anaerobic polypeptides (ANPs). Repression of preexisting aerobic proteins and the synthesis of new proteins appear to be the immediate biochemical response of anaerobiosis [145]. Most of the studies related to protein synthesis under anaerobic conditions have been performed in maize [146], rice, [27] and *Arabidopsis* [147]. Transient polypeptides are translated primarily during the first 5 h of anoxia, and they are stable and last long after their synthesis declines, whereas ANPs appear approximately after 90 min of anoxia, and their synthesis continues for several days until cell death [42].

In maize, an anaerobic response causes de novo synthesis of about 20 ANPs [146]. Because of an anaerobic conditions in maize, initially the rapid synthesis of four 33-kDa transition polyeptides takes place, whereas after 90 minutes of anoxia, the selective synthesis of an additional 20 polypeptides occurs [28,146], which represent about 70% of the total proteins synthesized during anaerobiosis [146]. Anaerobic stress–induced proteins are different from heat-shock proteins except for a few that are common to both types of stresses [28].

Most of the ANPs are apparently involved in maintaining ATP levels in the cells. Many of these are enzymes involved in glycolysis or fermentative processes such as alcohol dehydrogenase (ADH), lactate dehydrogenase (LDH), aldolase, enolase, glucose-phosphate isomerase, glyceraldehyde-3-phosphate dehydrogenase, pyruvate decarboxylase, and sucrose synthase [28]. Among these enzymes, ADH is the best characterized. In several tissues of maize examined, *ADH* gene expression is maximal with anoxia [42]. Similarly, in *A. thaliana*, two *ADH* genes exist; one set is strongly induced by low oxygen stress mainly in roots, whereas the other set is expressed constitutively in both roots and leaves [147]. In maize seedlings during several days of hypoxic induction, LDH activity increases up to 3.5-fold. This increased activity is the result of increased protein levels, which can be correlated with the induction of 2 *ldh* transcripts of 1.3 and 1.7 kb [29].

Ricard et al. [27] observed a significant increase in the level of sucrose synthase with a concomitant increase in its mRNA level in rice seedlings subjected to anaerobiosis. Unlike maize, only one sucrose synthase protein exists in rice. Its synthesis is enhanced with a concomitant increase in mRNA levels under anaerobiosis [27] that indicates that its level of control is possibly transcriptional.

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

Two enzymes, which have different functions than ANPs, have been identified, the level of which increases in response to hypoxia. These are 1-aminocarboxylate-1-cyclopropane synthase (ACC synthase), which catalyzes the rate-limiting step in the synthesis of ethylene, and the other is xyloglucan endotransglycosylase, which is possibly involved in aerenchyma formation during flooding [28,42].

In maize seedlings, it has been observed that treatment with ABA increases tolerance to anaerobic conditions [148]. Such an induction of tolerance is partly attributed to the synthesis of new proteins. It was shown by Hwang and Van Toai [148] that cycloheximide, when added together with ABA, reduced the survival rate of maize seedlings. However, ABA-induced tolerance appears to be species specific, because results similar to those with maize are not observed in other crops.

Pathogenesis-Related Proteins

When plants are infected with pathogens, such as bacteria, viruses, and fungi, certain novel proteins are synthesized. These host-coded proteins, which are induced by a wide range of pathogens, are commonly known as pathogenesis-related (PR) proteins. Many of the PR proteins are also induced by abnormal concentrations of plant hormones, or they are due to the presence of pollutants such as heavy metals [38]. Since these proteins are synthesized during infection, they appear to have a possible role in inducing resistance against further infection by the pathogen [33].

The PR proteins form a heterogeneous family of plant proteins and have been grouped into different classes: 1, 2a, 2b, 3, 4, 5a, and 5b [42]. However, the functions of classes: 1, 4, and 5b PR proteins are not fully known, but it is believed that they are involved in the defense of the plant. Class 5a PR proteins have a possible role in pathogen resistance, whereas classes 2 (a and b) and 3 have been extensively studied and identified as β-1,3 glucanases and chitinases, respectively [42]. Class 5a PR proteins include thaumatin-like proteins. Osmotin, a 26-kDa protein, initially described in tobacco suspension cultures under salinity stress, belongs to the family of class 5a PR proteins, and it has antifungal activity [42].

Chitinases and β-1,3-glucanases are the best characterized PR proteins. Chitinases hydrolyze β-1,4-acetyl glucosamine linkages of chitin polymers, which are primary constituents of fungal cell walls; whereas glucanases hydrolyze β-1,3-glucan residues present in fungal cell walls [42]. The overexpression of chitinases and/or β-1,3-glucanases in transgenic plants provides considerable protection against fungal pathogens. Chitinases show an increased level in many plant species, including *Arabidopsis* [149], tobacco, wheat [150], pepper [151], tomato [152], and *Phaseolus vulgaris* [153], in response to infection by fungal pathogens or viruses. Three classes of plant chitinases—I, II, and III—have been described based on their basic or acidic properties as well as their localization within or outside the cell [149]. Chitinases I and II, which are basic and acidic proteins, respectively, are expressed in an organ-specific and age-dependent manner in uninfected plants. Class III chitinases are mainly extracellular cucumber chitinases which are induced and accumulate in the extracellular space after pathogen attack [149]. Chitinases have potent antifungal activity [150]. Four isoenzymes of chitinase (26, 27, 30, and 32 kDa) are induced in tomato plants on infection by the fungus *Alternaria solani* [152]. It is suggested that a higher constitutive level of chitinase and β-1,3-glucanase and the induction pattern of a 30-kDa chitinase isoenzyme in early blight–resistant breeding lines is related to genetically inherited resistance of tomato to *A. solani* [152].

Two class 1 PR proteins, designated as acidic PR-1 protein (PR1a1) and basic PR-1 protein (PR1b1), which are low molecular weight proteins and are encoded by two closely related genes, have been characterized in tomato plants [33]. The expression of these two proteins is also induced by salicylic acid and ethylene. In transgenic tobacco plants infected with tobacco mosaic virus (TMV), the PR1b1 gene is strongly activated locally in tissues undergoing an hypersensitive response but not systemically in uninoculated tissues [33]. In the primary leaves of *Phaseolus vulgaris* plants following infection with southern bean mosaic virus (SBMV), 10 acidic and 8 basic PR proteins have been identified, which include 4, 17-kDa serologically related, acidic proteins of unknown functions; 2 chitinases, 1 acidic (29 kDa) and 1 basic (32 kDa) possessing antifungal activities; and 4 (21, 28, 29 and 36 kDa) serologically related, acidic glucanases [154].

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

Different isoforms of β-1,3-glucanases have been characterized in the infected tissues. Infection of groundnut leaves with the early leaf spot pathogen, *Cercospora arachidicola*, leads to a marked increase in the extracellular β-1,3-glucanase activity with the synthesis of its three isoforms [155]. In pepper (*Capsicum annum*) plants, it has been suggested that the glucanase activity is involved in the mechanism of resistance to cucumber mosaic virus in tolerant cultivars [151]. Osmotin-like proteins, which are class 5a PR proteins, have been shown to be encoded by at least six members of a multigene family in *Solanum commersonii* after infection by *Phytophthora infestans*. The expression patterns of two osmotin-like proteins in *Solanum commersonii* plants suggests their dual function in osmotic stress and plant pathogen defense [156].

Some of the PR proteins are present in healthy tissues and are differentially expressed by signals involved in flowering and reproduction. This implies that they are involved in the normal physiological processes of the plants in addition to plant defense [149]. According to certain investigators, salicylic acid is involved in the signal transduction pathway leading to a resistance to pathogen infection and the synthesis of PR proteins [140]. The salicylic acid level increases in plants following pathogenic attack [149]. In barley leaves, salicylic acid treatment induces the accumulation of two PR proteins and one salicylic acid–specific protein [157]. In tobacco plants, salicylic acid acts as an endogenous signal for the expression of acidic PR-1 proteins [158]. However, using transgenic tobacco plants accumulating high levels of soluble sugars due to the cytosolic expression of an inorganic pyrophosphatase from *Escherichia coli*, the possible role of soluble sugars in the induction of PR proteins has been suggested [32,41]. Such an induction appeared to be salicylic acid independent in the source leaves of tobacco plants [32]. According to Malamy et al. [159], multiple pathways exist that lead to defense response in plants, one of which appears to be independent of salicylic acid. More evidence is required to address the signal transduction pathways leading to the synthesis of PR proteins and the function of PR proteins in plant defense.

Wounding

Wounded plants manifest increases in the activities of many enzymes and the levels of proteins [34,35,160]. Enzymes and proteins that show an increased level in response to wounding include enzymes of the phenylopropanoid pathway, peroxidase DHAP synthetase, glycine-rich and hydroxyproline-rich cell wall proteins, protease inhibitors, and 1-aminocyclopropane-1-carboxylate synthase [160,161]. It is believed that some of these enzymes and proteins are involved in a lignification process and thus form a wound periderm to limit pathogenic attack [161]. Both glucanase and chitinase activities are induced in the roots and stems of chickpea (*Cicer arietinum* L.) plants in response to wounding [34].

In tobacco crown gall turmor tissues a 16-kDa glycine-rich hydrophobic polypeptide has been characterized, which is a cell wall protein and is induced by mechanical wounding [162]. This polypeptide is involved in the wound-healing process in tobacco plants by modifying the cell wall composition [162]. In tomato plants, several systemic wound-response proteins (swarps) have been described [35,160]. Mehta et al. [160] noticed the appearance of several novel proteins of 80.0, 63.0, 33.0, 28.5, 25.5, and 29.0 kDa and a decrease in the level of a 15-kDa protein as a result of wounding in tomato fruit tissues. These investigators noticed a marked difference in the mRNA populations after wounding. A full-length cDNA encoding an aspartic protease (LeAspP) was cloned from a tomato leaf cDNA library, the mRNA of which was shown to be systemically induced by wounding [35]. These observations suggest that wounding stress leads to differential protein accumulation and altered gene expression in tissues.

Metal Toxicity

Industrialization has led to the increased introduction of several heavy metals like Cd, Pb, Zn, Cu, and Hg in the soil environment. High levels of heavy metals in the soil adversely affect plant growth, cause the induction or inhibition of enzymes, and induce the synthesis of metal-binding cysteine-rich polypeptides called phytochelatins. Phytochelatins have a primary structure of $(\gamma\text{-Glu-Cys})_n$-

Gly or $(\gamma\text{-Glu-Cys})_n$-β-Ala, when n = 2–11, and have apparent function in the sequestration of metal ions within the plant.

Cadmium, which is a major environmental pollutant, inhibits the activities of many enzymes owing to its interaction with —SH groups of enzymes [36,37]. In rice seedlings raised under 500 μM Cd, an inhibition in the activities and a decrease in the synthesis of ribounclease and acid phosphatase isoforms have been observed [37,163].

When grown in the presence of Cd or Cu, many plants synthesize phytochelatins. However, several proteins with higher molecular weights than phytochelatins have also been reported in plants, which are induced by heavy metals [55]. A 18-kDa Cd-binding protein complex has been isolated by Shah and Dubey [55] from root tissues of rice plants grown in the presence of cadmium. This protein has four —SH groups per molecule and helps in the sequestration of Cd ions in rice tissues. Lupin roots exposed to lead, copper, or nitrite ions show an increased accumulation of a 16-kDa polypeptide, which appears to be a cytosolic Cu:Zn-superoxide dismutase [164]. From mercuric chloride–treated maize leaves transcriptionally activated cDNA clones have been isolated which represent various known proteins, such as glycine-rich proteins, PR proteins, chaperons, and membrane proteins [165]. A novel metallothionein like protein, the expression of which is regulated by metal ions, osmoticum or ABA, has been isolated from Douglas fir trees during embryogenesis [166]. These observations suggest that some of the heavy metal–induced proteins also are induced by other abiotic stresses.

Gaseous Pollutants

Ozone (O_3), sulfur dioxide (SO_2), and nitric oxide (NO_2) are considered as the major air pollutants. These molecules generate activated oxygen species, inhibit the synthesis of many proteins, and induce the activities of some antioxidant enzymes [40,167–170].

Ozone fumigation causes a decrease in the steady-state mRNA levels of genes encoding the small subunit of Rubisco, chlorophyll *a*/*b*–binding protein, and a 10-kDa protein of the water-evolving complex of PSII [169]. Similarly, in potato plants, ozone accelerates senescence with a decline in Rubisco small-subunit mRNA as well as a decline in transcripts of glyceraldehyde-3-phosphate dehydrogenase [167]. Plants grown in sites with high industrial pollution levels exhibit significantly low concentrations of soluble proteins [170].

Many antioxidant enzymes show an increased level when plants are exposed to ozone. Cytosolic Cu:Zn–superoxide dismutase is the best characterized enzyme, which shows increased activity with the simultaneous synthesis of new isoforms, in plants subjected to O_3 exposure [40,169]. In *Arabidopsis thaliana*, O_3 exposure enhances the activities of superoxide dismutase, peroxidase, glutathione reductase, and ascorbate peroxidase and modifies the substrate affinity of both glutathione reductase and ascorbate peroxidase [40,169]. However, in the chloroplasts of ozone-exposed plants, a decline in the levels of Fe–superoxide dismutase and glutathione reductase has been observed [169]. An ozone-induced transcript has been characterized in *A. thaliana* that encodes a 8.6-kDa basic protein which represents a novel stress-related protein [168]. It is suggested that major classes of ozone-induced proteins include antioxidant enzymes and a number of stress-related proteins associated with other biotic and abiotic stresses, and that ozone-induced responses are caused in part by the activation of a salicylic acid–dependent signaling pathway [168].

UV Radiation

Owing to the depletion of stratospheric ozone, in the future, the influx of solar UV-B radiation (280–320 mm) will tend to increase. UV-B radiation inhibits the growth of plants, causes inhibition in protein synthesis [171], and induces the activities of peroxidase-related enzymes [40] and the enzymes of flavonoid biosynthetic pathway [172]. Leaf protein biosynthesis is rapidly inhibited by UV-B radiation [172].

The chloroplast appears to the main target of UV-B radiation damage. Very early events of

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

UV-B damage include the decrease of mRNA transcripts for the photosynthetic complexes and other chloroplast proteins [171]. In pea leaves, exposure to UV-B radiation for 7 days causes a rapid inhibition in protein synthesis and a reduction in mRNA transcripts for the chlorophyll *a*/*b*–binding protein [173]. Genes encoding defense-related enzymes, for example, of the flavonoid biosynthetic pathway, are rapidly upregulated on UV-B exposure. The activity of flavonoid-synthesizing enzymes, especially phenylalanine ammonia-lyase, 4-coumarate:CoA ligase, chalcone synthase, and UDP-apiose synthase, are induced in a coordinate way with UV-B treatment [172]. Peroxidase-related antioxidant enzymes are induced under UV-B exposure [40]. In *Arabidopsis thaliana*, UV-B exposure preferentially enhanced guaicol-peroxidases, ascorbate peroxidase, and peroxidases specific to coniferyl alcohol and modified the substract affinity of ascorbate peroxidase [40]. In certain plants, the synthesis of some novel proteins has been reported under UV-B irradiation [38,165,174]. UV-B exposure in sunflower leaf disks causes the induction of PR3 and PR5 proteins [38], whereas expression of a membrane channel protein and PR proteins is induced in maize [165]. The accumulation of an atypical transcript encoding a 42.3-kDa polypeptide, and showing sequence similarity to O-methyltransferases (OMTs) from different plant species has been observed in barley leaves after UV-B treatment [174]. It is suggested that the response to increased levels of UV-B radiation is dependent on the developmental stage of the tissue and involves complex changes in gene expression [173].

CONCLUSIONS

In general, environmental stresses, including salinity, drought, heat, chilling, anaerobiosis, heavy metals, gaseous pollutants, and UV radiations cause an alteration in gene expression in plants leading to the induction of specific genes and an increased abundance of their translatable mRNAs and proteins. As a result, the increased synthesis of certain novel proteins occurs in stressed plants with a concomitant decrease in the level of certain preexisting proteins. These stress-specific proteins appear to endow plants with the capacity to adapt to a stressful environment by physiological and biochemical adjustments. Most of these stresses induce the synthesis of proteins specific for the particular stress. However, certain proteins are common and can be synthesized under more than one type of stress. For example, cold, drought, and salinity stresses cause the expression of some common proteins that can also be induced by treatment of normal tissues with abscisic acid. Many of the genes which are activated under stressed conditions have been isolated and sequenced. Most of the stress-induced proteins have been isolated and well characterized for their physicochemical properties and their amino acid sequences have been determined.

Although stress-specific proteins are thought to lend a protective role to the tissues against the deleterious effects of stress, the exact physiological functions of many of these proteins are not very clear. Further, experiments are necessary to determine the functions of these proteins. Proteins induced under salinity or water stress are believed to act as osmoprotectants, as regulatory proteins, or as enzymes of biosynthetic pathways for osmolytes. However, the functions of many proteins are still unknown. The HSPs are believed to perform many essential functions in normal as well as stressed cells. The molecular mechanisms underlying these processes and the role of HSPs in protecting heat-stressed tissues remain to be elucidated. Specific proteins are synthesized during cold treatment that improve freezing tolerance in crops, but the functions of these proteins in the acquisition of cold tolerance remain to be established.

Further studies are required to define the detailed functional roles of many of these proteins, to specify the signal transduction pathways, and the mechanisms by which expression of stress-specific genes are controlled. Such studies will enlighten the mechanisms of stress tolerance in crops at the genetic level, and based on the gene-technological tools, it will be possible to introduce single or multiple genes associated with stress tolerance from a tolerant to a sensitive plant in order to produce plants with enhanced stress tolerance. Nucleotide probes specific for these genes can similarly be utilized for the selection of stress-tolerant varieties of crops.

Heat-Shock Proteins and Temperature Stress

HITOSHI NAKAMOTO AND TETSUO HIYAMA
Saitama University
Urawa, Japan

INTRODUCTION

Plants growing in natural environments may encounter various stresses, such as high radiation stress, water stress, and high and low temperature stresses, during all or part of their growth and development. As plants cannot move to evade stresses and therefore have to endure any given environmental changes, they must have evolved mechanisms to adapt to these stresses.

In this chapter, we summarize the recent progress made toward understanding of the role of heat-shock proteins (HSPs) in terms of thermotolerance of plants and crops. A number of excellent reviews have been published, and the reader should consult for more detailed information and discussions concerning individual plant HSPs and for molecular ''chaperone'' functions [1–4] and for the regulations of plant HSP genes [5,6].

HEAT STRESS AND HEAT-SHOCK PROTEINS

Cellular Changes Induced by Heat Stress

Heat induces a wide variety of changes in cellular structures and metabolic processes. When the magnitude and duration of the heat stress exceeds a threshold, cells are irreversibly damaged and die.

In higher eukaryotes, heat shock perturbs many aspects of normal cellular physiology. Parcell and Lindquist (see Ref. 7 and references therein) described a number of changes and damages that heat produces. These are disruption of the cytoskeleton and microtubules, fragmentation of the Golgi apparatus, an increase in the number of lysosomes, swelling of mitochondria, a decrease in respiration and oxidative phosphorylation, disruption of normal protein synthesis, disappearance of polysomes, disruption of the splicing of mRNA precursors, cessation of pre-rRNA processing and a decline in transcription by RNA polymerase I, perturbation in DNA synthesis, inhibition in chromatin assembly, and a number of changes in cell membranes. Higher plants are no exception in terms

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

of all these heat-induced perturbations. Some observations to support this view are rapid degradation of polysomes into monoribosomes and subunits when an excised soybean hypocotyl was incubated at 40°C [8], repression of most normal protein synthesis and initiation of transcription/translation of a set of proteins [8–10], disruption of pre-rRNA processing and ribosome assembly in tomato cell cultures [11], uncoupling of respiration from oxidative phosphorylation in soybean mitochondria [12], and disruption of the splicing of *Arabidopsis* HSP81-1, 81-2 mRNA precursors [13], and other structural changes [14,15].

Among these changes, the synthesis of a set of proteins known as HSPs which is a ubiquitous phenomenon in all prokaryotes and eukaryotes appears to be particularly important for the protection of cells from thermal damage, as will be described in the following sections.

Correlation Between the Level of HSP Accumulation and Thermotolerance

The importance of the HSP induction in cellular thermotolerance comes from the apparent correlation between the level of HSP accumulation and thermotolerance.

When whole organisms or cultured cells are given short treatments at moderately elevated temperature, their resistance to be killed by extreme heat increases dramatically [7]. For example, when yeast cells grown at 25°C are pretreated at 37°C, they can survive at 50°C 1000-fold better than nonpretreated cells [7]. This increase in thermotolerance is observed in virtually every organism studied [7].

Such tolerance-inducing treatments generally also induce the synthesis of HSPs [7]. This induction is rapid and intense, suggesting that it should be an important emergency response. The extent of the HSP induction appears to be correlated with the dose of heat stress subjected to an organism. As shown in Figure 1, the expression of HSP (GroEL, an HSP60 homologue) increases proportionally to the temperature increase within a certain range of temperatures (H. Nakamoto, unpublished results). The temperature of maximum HSP synthesis varies among species and is positively correlated with the optimal growth temperature of each species [1].

Besides a short and rapid increase in temperature, a treatment that has often been used for an experiment in a laboratory but may not have relevance to plants in the field, a gradual increase in temperature also confers thermotolerance in plants [10]. When the temperature was gradually increased at the rate of 3°C/h, soybean seedlings responded differently to the temperature shift from those given a sudden heat shock [10]. There was an upward shift of several degrees in the temperature at which maximum protein synthesis occurred. A gradual increase in temperature into the heat-shock range (40–43°C) enabled cells to survive (as measured by staining with Evans blue) when they were subsequently exposed to a lethal temperature (52°C). This gradual increase in temperature effectively elicited the synthesis of HSPs as well. Similar observations have also been made in other plant species [16].

A treatment at a nonpermissive temperature for a permissive period followed by a treatment under unstressed conditions also induces HSPs and results in thermotolerance. Lin et al. [17] showed that a brief (10-min) pulse treatment at a nonpermissive temperature (45°C) followed by a 28°C incubation for 2–4 h made dark-grown soybean seedlings tolerant to a subsequent exposure at 45°C for 2 h at the same degree of effectiveness with a preconditioning at 40°C for more than 1 h. They measured the thermoprotection by monitoring both seedling growth and protein synthesis ($[^3H]$leucine incorporation). This brief heat treatment was not long enough to kill the seedlings, although prolonged incubation (1–2 h) at 45°C resulted in death. During the preincubation either at 40 or at 28°C after a shift from a brief ''pulse'' treatment at 45°C, a set of HSPs were produced as the major newly synthesized proteins [17]. HSPs, whose genes are activated by heat shock and accumulate during exposure to a high yet permissive temperature or normal temperatures, seem to be involved in protecting vital cellular functions and structures at these otherwise nonpermissive temperatures.

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

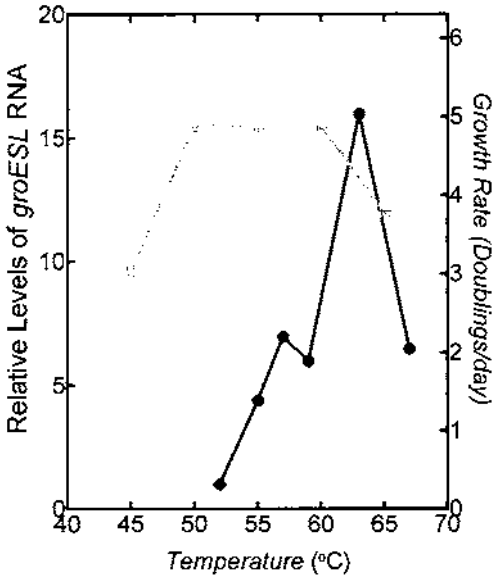

FIGURE 1 The influence of temperature on growth rate and accumulation of *groESL* mRNA in the thermophilic cyanobacterium *Synechococcus vulcanus* (H. Nakamoto, unpublished results). The growth rate is expressed as the reciprocal of days required for optical density at 730 nm of a liquid culture to double. The level of mRNA accumulation was determined by northern blot analysis of total RNA obtained from cells after shifting a culture (grown at 50°C) from 50°C to a different temperature and incubating for 30 min at that temperature. A specific radiolabeled probe for *Synechococcus vulcanus groEL* was used for the northern blot analysis [88], and the hybridization signals were quantified with a BAS1000 Mac bioimaging analyzer (Fuji Film, Tokyo).

A heat treatment for acclimation as shown above could also have some other effects than the induction of HSPs that might contribute to the induced thermotolerance as well. Several pieces of evidence, however, have indicated otherwise and further support the HSPs' major role in thermotolerance; a treatment of soybean seedlings with arsenite (50 μM for 3 h) at a regular temperature induced HSPs and the seedlings acquired thermotolerance [17]; and transgenic *Arabidopsis*, whose heat-shock transcription factor was genetically engineered to synthesize HSPs constitutively acquired thermotolerance without previous heat treatment [18]. These are just a few of many examples in prokaryotic and eukaryotic organisms to suggest that the acquisition of thermotolerance is correlated with de novo synthesis and accumulation of HSPs.

Plant species adapted to temperate environments, including crop plants such as soybean, pea, maize, and wheat, begin to synthesize HSPs when the tissue temperatures exceed 32–33°C [1] Therefore, it is likely that many crop plants reach heat-shock temperatures in the field, especially during summer and/or under nonirrigated conditions. Foliage temperatures increase as a consequence of the decline in water available for transpirational cooling. Under full sunlight, the leaf temperatures typically go up to 10–15°C above the surrounding air temperatures and often exceed 40°C (see Ref. 10 and references therein). Thus, the above-stated heat-shock response, that is, increased HSP synthesis, appears to have quite a relevance to plants in the field in coping with heat stress.

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

HSP Families

Several classes of HSPs have been described in eukaryotes, including plants. They are designated by their approximate molecular masses in kilodaltons as HSP100, HSP90, HSP70, HSP60, 15- to 30-kDa low molecular mass HSPs (also called low molecular weight HSPs or small HSPs; the term *small HSP* will be used hereafter), and others [1–3]. A unique feature of the heat-shock response in higher plants is that small HSPs, ranging in size from 15 to 30 kDa, dominate the protein-synthesis profile of many plants during heat stress and accumulate in abundance [1–3]. Notably, plants typically produce up to 30 distinct small HSPs in response to heat stress, with each HSP belonging to one of six nuclear gene families [1,2]. Other eukaryotes have far fewer genes for small HSPs; for example, only one single gene in mammals.

A comparison of the major HSPs in different organisms has shown that they are in general highly homologous among eukaryotes. In most cases, homologous proteins have been identified in prokaryotes as well. For example, HSP60 homologues are found in all extant species, including eubacteria, archaebacteria, and eukaryotes. The global alignment of HSP60 sequences indicates that a large number of positions in the sequences are highly conserved among all species [19]. The pairwise amino acid identity matrix of HSP60 sequences indicates that the minimum identity that is observed between any two HSP60 sequences is 42% over their entire length [19]. Surprisingly, the *Escherichia coli* homologue shows 50.5% amino acid identity and 68.4% similarity with that of humans. The HSP70s are also a highly conserved protein family ~50% amino acid identity among all species characterized [7]. Therefore, at least some HSPs are highly conserved across a wide variety of organisms not only in the way they are induced by heat but also in their primary structures. This suggests that HSPs play extremely important and common roles in the whole biological world.

HSPs Are General ''Stress Proteins''

Heat is not the only treatment that leads to elevated expression of HSPs. The expression of some HSPs in different organisms has been shown to be affected by a number of chemicals: arsenite [17,20,21]; sodium fluoride [20]; amino acid analogues, such as azetidine-2-carboxylic acid [22]; 2,4-dinitrophenol [20]; canavanine [20]; malonic acid [23]; methomyl, an insecticide-nematicide [24]; plant hormones such as abscisic acid, 2,4-dichlorophenoxyacetic acid, and kinetin [20,25]; and heavy metals such as cadmium, cobalt, copper, nickel, and silver [20,21]. It is also induced by some physical treatment: anaerobiosis [20], high concentrations of salts such as KCl [20,26], low water potential and dehydration [20,26,27], a shift from dark to light [28], and even low-temperature stress [26,29,30].

It should be noted that those stresses listed above do not necessarily induce all the HSPs alike; each HSP species may respond differently to different types of stress. This suggests that the same induction mechanisms may not be involved for different HSPs. For example, small HSP genes in sunflower are regulated differentially and mRNAs from one of the two small HSP genes of sunflower accumulated equally in response to heat shock, abscisic acid treatment, and mild water stress [31]. In contrast, mRNAs from another gene accumulated only in response to heat shock but not to other treatments. The expression of the ERD1 gene which encodes a ClpA,B–like protein in *Arabidopsis* was strongly induced by dehydration of plants but was affected neither by heat or cold stress, treatment with heavy metals, nor plant hormones [27]. This indicates that ERD1 is regulated differently from other usual heat-induced HSPs. These results suggest that each HSP species may have evolved differently to acquire specialized function(s) in response to specific type(s) of stresses in order to cope with various hostile environments.

Pre–heat treatments elicit resistance not just to high temperatures but also to other stresses [7]. In addition, exposure to other stresses elicits protection not just against higher doses of those particular stresses but also against high temperatures as well [7]. This remarkable phenomena can

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

be easily understood if we assume the involvement of HSPs in many forms of stress and the heat-shock response to be representative of more general stress responses.

Importance of HSPs Extends Beyond Their Potential Role in Protection from High-Temperature and Other Stresses

Not all, but some, HSPs are expressed under unstressed conditions. All major HSPs, at least in eukaryotes, are multigene families having more than one member in the families. Each member may not respond to a heat shock the same way. For example, one of the members of *Arabidopsis* HSP90 family is constitutively expressed and its expression is slightly enhanced by elevated temperatures, whereas another one is strongly induced by heat but stays in a very low level at normal temperatures [13]. Some HSPs are produced at particular stages of the cell cycle or during development in the absence of stress [1,3].

In fact, some HSPs appear to have an essential cellular function. Genetic analysis revealed that *E. coli* mutants that lacked the heat-shock sigma factor σ^{32} were extremely temperature sensitive and poorly grew even at temperatures lower than or equal to 20°C [32]. It has been known that σ^{32} is required for the heat-induced transcription of most of the heat-shock genes in *E. coli* [33,34]. Individual HSPs such as *E. coli* HSP60 (GroEL) [35] and yeast HSP90 [36] have been shown to be essential for viability at all temperatures.

A body of evidence has accumulated that at least some HSPs, such as HSP60 and HSP70, are involved in general and essential cellular functions; for example, protein folding and subunit assembly, protein translocation across membranes, and intracellular protein breakdown [37,38]. Given the ubiquitous need for the protein folding which is performed by a set of HSPs as molecular chaperones, as will be discussed later in this chapter, HSPs are being increasingly implicated as important players in virtually all aspects of cellular activities. In his review, Yahara [39] stated the importance of HSPs as, ''it is evident that cellular proteins are taken care of by stress proteins *from the cradle to the grave*''.

Genetic Evidence for Involvement of an Individual HSP in Thermotolerance

In addition to the above-stated results that correlate HSP accumulation with thermotolerance, genetic evidence also supports that HSPs can confer heat tolerance to an organism in vivo. One of the genetic approaches to prove a specific contribution of HSPs in thermotolerance is the selection, construction, and phenotype analysis of mutants and transgenic organisms in which expression(s) of a specific HSP(s) is either completely inactivated, partially repressed, or overinduced. If it is not easy or impossible to select or construct such a mutant, a mutant lacking a specific HSP, which has been successfully constructed with a certain species, is used to examine whether a homologous gene from a particular organism of interest can complement the mutant's phenotype.

Mutants of *E. coli*, yeast, and *Drosophila*, which produce no or a reduced amount of HSP70, showed defects in either growth, survival, or development at high temperatures (see Ref. 7 and references therein). Genetic analyses of heat-inducible family members of HSP100 from yeast (HSP104) and *E. coli* (ClpB) also showed that they are required for thermotolerance [40,41]. In addition to these studies with mutants and transgenic organisms expressing no or reduced levels of a specific HSP, studies on cells overexpressing a specific HSP also indicated that the acquisition of thermotolerance is attributed to HSPs. Overexpression of HSPs such as HSP90 [42], HSP70 [43], and small HSPs [44,45] rendered cells heat tolerant.

In higher plants, studies with mutants or transgenic plant to test critically the in vivo role of plant HSPs have still been limited. At present, there have been only two published papers which studied the role of HSPs with transgenic plants [47,48].

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

There are two types (cpn60α and cpn60β) of cpn60 (HSP60 homologue) present in chloroplasts [46]. They are also known as ribulose bisphosphate carboxylase-oxygenase (Rubisco)–binding proteins which are thought to be required for the assembly of the active Rubisco enzyme complex in vivo. Antisense cpn60β, transgenic tobacco plants with reduced levels of cpn60β showed drastic phenotype alterations, including slow growth, delayed flowering, stunting, and leaf chlorosis [47]. Several antisense plants failed to survive to maturity and, in another case, segregate in a 2:1 ratio and do not produce homozygous viable progeny. These results indicate that cpn60β is essential for viability. Unexpectedly, however, these transgenic plants accumulated Rubisco with specific activities equal to or even higher than that of controls. Thus, the result has challenged the prevailing function of cpn60 in the assembly of Rubisco. Details for the function of cpn60 will be discussed in a following section.

One of the main difficulties in characterizing the function of a plant small HSP is the genomic complexity of the small HSP gene family, which, in plants, encompasses a large number of well-conserved members, as described above. Osteryoung et al. [48], chose a small HSP of chloroplasts, HSP21, to generate transgenic *Arabidopsis* plants that either underexpress or constitutively overexpress that particular small HSP, because this chloroplast small HSP is known to be encoded by a single or a few genes in higher plants [49]. The overexpressing plants accumulated considerably more HSP21 in the absence of heat stress than the heat-stressed wild-type plants did. The HSP21 could be detected in leaves, stems, roots, and flowers. Since the overexpressed protein comigrated with mature, authentic HSP21, it is likely that the transit peptide had been cleaved and the protein was properly targeted to the chloroplasts. However, no obvious differences in any readily observable parameter of growth and development were noted between the wild-type sibling and the overexpressing plants.

These papers by Zabaleta et al. [47] and Osteryoung et al. [48] did not describe the thermotolerance of the resulted transgenic plants. Thus, to date, there is no direct evidence to confirm the in vivo role of an individual plant HSP in thermotolerance. However, complementation tests and overexpressions of a specific plant HSP in a hybrid system have shown there is an important role in thermotolerance in higher plants as follows: A gene encoding a HSP100 homologue was isolated from *Arabidopsis* [50]. The *Arabidopsis* homologue is 43% identical to the yeast HSP104. The expression of the gene was heat inducible, which is similar to that of the yeast homologue. When the plant homologue was expressed in yeast, it complemented the thermotolerance defect caused by a deletion of the HSP104 gene [50]. Similar results with a soybean HSP100 homologue were also obtained by Lee et al. [51]. The ability to protect yeast from severe heat stress strongly suggests that the plant HSP100 homologues have important roles in thermotolerance in higher plants as well.

In another case, a gene encoding the rice 16.9-kDa small HSP (class I small HSP), Oshsp 16.9, was introduced into *E. coli* using the pGEX-2T expression vector [52]. *E coli* cells transformed with a recombinant plasmid containing a glutathione S-transferase Oshsp16.9 fusion protein (after isopropyl β-D-thiogalactopyranoside induction) demonstrated thermotolerance at 47.5°C, a treatment lethal to the cells transformed with the pGEX-2T vector (the control). The result suggests that a plant class I small HSP provides thermotolerance to plants as well as to prokaryotic cells.

So far, there has been no report on the production of null mutations of HSPs in higher plants. Usually, in higher plants, it is not easy to inactivate a specific gene by a genetic method such as gene targeting. Another difficulty in characterizing the function of a plant HSP is that plant HSPs have multiple members within one HSP family. It would be difficult to define a specific phenotype for a certain gene product with its null mutants if there are other genes present which are homologous with that particular gene and some of their functions are interchangeable.

Cyanobacteria, like other organisms, synthesize a diverse range of HSPs on exposure to high temperatures [53]. Chloroplasts are thought to originate from a cyanobacterium that became associated with an originally nonphotosynthetic host cell. Cyanobacteria have proven to be valuable model organisms for studying photosynthesis, since they have a photosynthetic apparatus functionally and structurally similar to those of higher plants. Hence, information on the functions of HSPs obtained with cyanobacteria will be useful for understanding the functions of HSPs in chloroplasts. Importantly, cyanobacteria can readily be manipulated genetically [54].

Disruption of a single copy gene, *clpB* from *Synechococcus* sp. PCC 7942, which encodes a HSP100 homologue in the mesophilic cyanobacterium, reduces the cell's ability to develop thermotolerance in the cell's survival and photosynthetic activity by at least fourfold, but it has no effect on the survival of cells during sudden, severe heat shocks [55]. These results clearly show that induction of ClpB at high temperatures is vital for sustained thermotolerance.

The *htpG* gene that encodes HtpG, a homologue of HSP90, have been isolated from *Synechococcus* sp. PCC 7942 (N. Tanaka and H. Nakamoto, manuscript in preparation). Transcripts of *Synechococcus htpG*, which does not have any other homologous gene in the genomic DNA, increased 20-fold within 15 min on heat shock. Stable mutant strains in which the gene was interrupted by gene targeting were generated. Even under unstressed conditions (30°C), the photoautotrophic growth of the mutant was significantly inhibited. At higher temperatures (i.e., 45°C), the mutant could not grow at all, whereas the wild type could still grow. Our results with the photosynthetic prokaryote have shown a striking dissimilarity with the *E. coli* homologue. Deletion of the *E. coli htpG* has a slight growth disadvantage at normal temperatures and produces a subtle reduction in growth at high temperatures [56]. As described above, yeast HSP90 is essential for viability at normal temperatures, and increasing concentrations of HSP90 are required for survival at higher temperatures [36]. Thus, *Synechococcus htpG* appears to be functionally more similar to eukaryotic homologues, although it has a prokaryotic origin.

As described above, the antisense *Arabidopsis* which expressed a reduced amount of a chloroplast small HSP did not show a notable phenotype. Recently, a single copy gene, *hsp16.6*, encoding a small HSP homologue in the mesophilic cyanobacterium *Synechocystis* sp. PCC 6803 has been inactivated (H. Fukuzawa, H. Kosaka, and K. Ohyama, unpublished results). The mutant was sensitive to high temperatures and could not develop ''acquired thermotolerance.'' Characterization of the photosynthetic activities of the mutant at high temperatures may provide an important insight for the function of the small HSPs of chloroplasts in higher plants.

Plant HSPs Can Confer Thermotolerance to Organelle Functions and Proteins

Recently, direct evidence has been presented to show that the chloroplast small HSP protects photosystem II (PSII) electron transport during heat stress [57]. PSII is known to be a highly thermolabile step in the photosynthetic electron transport system [58]. However, isolated thylakoid membranes from preheated (at 43°C for 6 h) tomato plants showed an approximately twofold increase in PSII electron transport activities at a high temperature (47°C) as compared with those from nonheated control plants. This acclimation effect by the heat treatment was completely abolished by treatment with antibodies against the chloroplast small HSP. Furthermore, a purified chloroplast HSP preparation added to thylakoid membranes prepared from unstressed plants that did not contain small HSP protected PSII at the high temperature. Previously, 22- and 25-kDa chloroplast HSPs were shown to be bound to the thylakoid membranes on heat shock [59]. These results indicate that the chloroplast small HSP protects thermolabile PSII. The location(s) to which the small HSP is associated as well as the mechanism for the protection is not known. In contrast to HSP60 and HSP70, which are expressed even at normal temperatures, chloroplast small HSPs are specifically induced at elevated temperatures. This suggests that the small HSP is particularly important for the thermoprotection of photosynthetic activities.

The 70–100% ammonium sulfate fraction of the postribosomal supernatant of heat-shocked soybean seedlings enriched with all of the HSPs showed a significant ability to tolerate heat denaturation of the control postribosomal supernatant of non–heat-shocked seedlings [60]. Heated at 55°C, some 50% of the control proteins, which were normally denatured and precipitated out after heat treatment, were protected and kept in a soluble form for at least 1 h when the fraction was added. A similar assay to examine the thermoprotection of rice soluble proteins from heat denaturation was performed by using a purified recombinant rice 16.9-kDa heat-shock protein, a class I small

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

HSP, instead of using the ammonium sulfate fraction [61]. The recombinant protein protected soluble proteins from heat denaturation more highly than the HSP-enriched ammonium sulfate fraction did [61]. Thus, one possible function of HSPs, especially plant small HSPs, may be to stabilize cellular proteins in their soluble form. This is one of the functions of molecular chaperones, as described below.

Localization of HSPs

In eukaryotes, HSPs are found in essentially every cellular compartment [3]. This may not be surprising if we consider that major HSPs are molecular chaperones, as will be discussed below. For example, HSP70 and HSP60 (Cpn60) are localized in chloroplasts and mitochondria; some members of HSP100 (Clp proteins), HSP90, and HSP70 are in cytoplasm; and small HSPs are in cytoplasm, mitochondria, chloroplast, and endoplasmic reticulum.

Remarkably, several HSPs, originally localized (most likely) in the cytoplasm, become selectively localized and associated with organelle fractions such as nuclei, mitochondria, and ribosomes on heat shock, as shown in soybean seedlings [17]. In contrast to heat treatment, proteins induced by arsenite treatment are not selectively localized with organelle fractions at 28°C [17]. HSPs associated with the ribosomal and nuclei fractions were primarily HSPs with the molecular mass of 15–18 kDa. Also, 69- to 70-kDa HSPs are associated with the fraction though much less in amount. Additional HSPs with sizes ranging from 22 to 24 kDa were found associated with the mitochondrial fraction [17]. It has been shown that the association of small HSPs (15–18 kDa) with mitochondria is particularly important for the thermotolerance of the oxidative phosphorylation [12].

THE MOLECULAR MECHANISMS: HOW DO HSPs FUNCTION?

Accumulating evidence indicates that through stabilization of proteins in a particular state of folding, HSP90, HSP70, and HSP60 facilitate a wide diversity of important processes, including protein folding, transport of proteins across membranes, assembly of oligomeric proteins, and modulation of receptor activities [1]. All of these functions require the alteration or maintenance of specific polypeptide conformations. Based on these activities, HSP90, HSP70, and HSP60 have been termed ''molecular chaperones'' [1]. Furthermore, HSP100 and small HSPs have recently been shown to act as a type of molecular chaperone.

What are the mechanisms to protect cells from stresses? So far, at least two general roles of HSPs have been suggested for helping cells to cope with stress-induced damage to proteins [37]. Some HSPs, for example, some members of HSP100 (Clp) family, can promote degradation of abnormal proteins, whereas others can reactivate stress-damaged proteins and functions as molecular chaperones to prevent the aggregation or promote the proper refolding of denatured proteins. Some of the recent progress on these matters, especially HSP60 and HSP70, including the structural information, will be summarized below together with some historical background.

HSP60 Is the First Molecular Chaperone to Be Found

This family of HSP60 proteins include the GroEL of prokaryotes and cpn60 of chloroplasts and mitochondria. The first HSP60 to be reported was GroEL of *E. coli*, which was identified together with GroES as a gene product of an operon on the *E. coli* genome. Mutants that lacked the gene *groEL* could not form mature phages [62]. A purified preparation was first reported as an oversized ATPase complex, and was later identified as the GroEL itself from its amino acid sequence [63]. In a meantime, the so-called Rubisco-binding protein (RBP), known to be necessary for the assembly of the functional Rubisco complex, was found [64]. In 1988, when an amino acid sequence of RBP was determined, it became obvious that RBP was highly homologous with GroEL. At this point,

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

the name *chaperonin* was coined to describe ''one family of highly sequence-related proteins acting as molecular chaperones'' [65]. The term *molecular chaperone* was originally used by Laskey et al. [66] to describe the properties of nucleoplasmin, an acidic nuclear protein necessary to assemble correctly nucleosome cores out of DNA (acidic) and histone (basic). Nucleoplasmin looked quite unusual in its role. It binds to the histones only transiently and is not incorporated into the final assembly. As it does not change itself throughout this operation, the activity seems ''catalytic.'' Yet it should not be called an enzyme, because there is no chemical reaction involved.

The term *chaperonin* is presently used for HSP60 and its homologues, whereas other proteins of this nature are called molecular chaperones. The chaperones are molecular analogues of the human chaperone—an assistant accompanying a debutante. The traditional role of the human chaperone is to prevent improper interactions among people at a party, ''without either providing the steric information necessary for their correct interaction or being present during their subsequent married life—but often appearing at divorce and remarriage'' [67]. Soon after, a homologue was found in mitochondria as a stress-induced protein, HSP60 [68]. The basis of the currently popular mechanism of chaperonin action was founded when Lorimer and coworkers reassembled the Rubisco complex in vitro by using chaperonin and ATP [69].

HSP60 Forms Two Heptamer Rings

Presently, there is a consensus that two heptamer rings stack each other and form a tetradecamer from the GroEL monomer (~60 kDa) subunit. GroES, sometimes called co-chaperonin, is in the form of a single heptamer ring, and plays an important role in the chaperone action. ATP is necessary for successful refolding of once denatured proteins. X-ray analyses have revealed 3-dimensional structures of these complexes [70,71].

Chaperonin Works with HSP10 and Needs ATP

One of the recent proposals as to the action of a chaperonin is summarized in Figure 2 (based on Ref. 72). A denatured or half-denatured polypeptide (so-called ''molten globule'') enters in a hole of one of the GroEL rings (steps A and B). A small ring of the GroES heptamer binds to this side like a lid (step C, lower). The peptide is now folded to become a native form inside the central cavity (step D). The release of a matured protein by removing the GroES lid requires energy input from ATP hydrolysis (step E). Alternatively, the polypeptide leaves the GroEL ring unproductively without being repaired and seeks another chaperonin to repeat the cycle (step C, upper).

The mechanism depicted here is an oversimplified version. The reader should refer to more details that have been discussed particularly in terms of the binding sites of ATP/ADP and a substrate polypeptide [73]. The structures of the rings are quite flexible and overall behaviors of those components should be very dynamic. It should be noted, however, that this scheme is by no means definitive. The reader may refer to an excellent summary on this matter by Ellis [67].

Chloroplast cpn60

As stated in the previous section, chloroplast chaperonin (ch-cpn60) was first discovered as the Rubisco-binding protein (RBP). There are two isomers of ch-cpn60, α and β, in almost stoichiometrical amounts, whose nuclear encoded precursors are synthesized outside the chloroplast and imported into it. The proteins are constitutively expressed and the levels increase only slightly during heat shock. The two isoforms are only 50% identical in terms of amino acid sequence. Although these subunits form two heptamer rings, as in the case of GroEL of *E. coli*, little is known about whether the ring is a hetero-oligomer or homo-oligomer.

An antisense study has shown that the ch-cpn60β may not be essential for the assembly of the Rubisco complex, as described in the preceding section, although ch-cpn60α may substitute for the function of ch-cpn60β. It is now considered that the ch-cpn60 facilitates the folding, not assem-

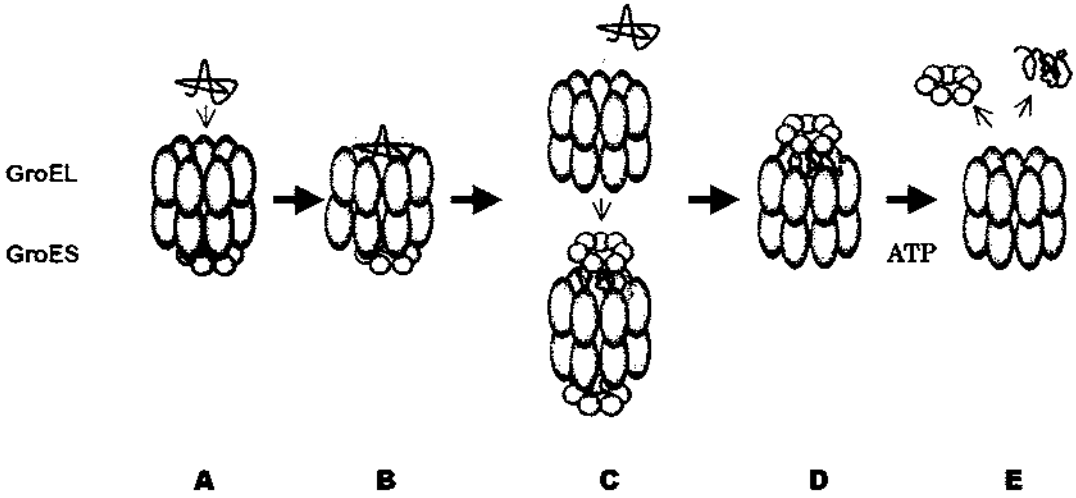

FIGURE 2 A simplified scheme to show how a GroEL/GroES chaperonin system works. For details, see text.

bly, of Rubisco large subunits [69]. A possibility remains that they might also take part in the folding of the small subunits [74,75]. On the other hand, there is no evidence at present that ch-cpn60 directly mediates the formation of the quaternary structure of the Rubisco complex.

Chloroplast cpn10 Is Rather ''cpn21''

Chloroplast cpn10 was originally isolated as a protein that formed a stable complex with GroEL [76]. Remarkably, the molecular weight was almost twice as that of GroES, and it had an amino acid sequence with two complete GroES-like sequences fused head-to-tail to form a single protein. Despite these unusual characteristics, these subunits form toroidal structures reminiscent of GroES under the electron microscope [77].

This unique 21-kDa cpn is widely found throughout the plant kingdom and in photosynthetic eukaryotes [77,78]. One should not confuse this chloroplast ''GroES'' with HSP21 described in the previous section, because the latter is a member of the small HSPs, which are a completely different type of HSP.

Folding Mechanisms by GroEL and chl-cpn60 Are Similar

Studies with purified proteins revealed a similar mechanism of protein folding in the case of chl-cpn60 and chl-cpn10 with that of GroEL and GroES [46,76–78]. Recent experiments showed that the chl-cpn60 functions equally well with bacterial, mitochondrial, or chloroplast cpn10 [78]. This means that the unique binary chloroplast protein is not obligatory for the chl-cpn60–mediated folding. In contrast to GroEL and mammalian and yeast mitochondrial cpn60s, the folding reaction mediated by chl-cpn60 does not require K^+ ions [78].

As in the case of GroEL, chl-cpn60 has a rather broad substrate specificity and forms a stable complex with a variety of proteins besides Rubisco, notably with those imported into chloroplasts

[75,79–81]. These are the Rieske FeS protein [80], ferredoxin $NADP^+$ reductase [81], and the multisubunit coupling factor CF_1 core complex [82].

Cyanobacterial HSP60

Cyanobacteria are of interest, as plant chloroplasts are thought to have evolved from endosymbiotic cyanobacteria, as described above. A few cases of GroELs have been reported so far from cyanobacteria [83–88]. These reports are all about genes encoding GroELs (*groEL*) except for [85], and little is known about the activity of expressed proteins. Recent investigations in our laboratory have revealed that GroELs from a thermophilic cyanobacterium, *Synechococcus vulcanus*, may exist in vivo at least partially in the form of monomer rather than in the tetradecameric form that is ubiquitous among other prokaryotes and organelles (T. Hiyama et al., manuscript in preparation). There is some indication that a monomeric form is also present in mesophilic cyanobacteria (H. Hayashi, personal communication). We found that this monomer had chaperone activities similar to those of the small HSPs described in the previous section; that is, ATP-independent protein folding, protection against heat denaturation, and prevention from aggregation (H. Nikaido and T. Hiyama, manuscript in preparation). A preliminary survey indicated some possibility that this monomeric form may be present in vivo in other prokaryotes. Although there is little doubt about the proposed mechanism of protein folding mediated by the HSP60 tetradecamer, the heptameric ring of HSP10 and ATP, and the majority of the case should be explained by the scheme outlined in Figure 2, it may not be an excessively wild speculation that this type of non–energy-consuming chaperone's actions are also important, particularly in a more hostile environment at temperatures higher than usual where much more vigorous chaperoning is needed.

TCP-1/CCT/TriC and Archaebacterial cpn60

Distantly related chaperonin-like proteins are present in the eukaryotic cytosol, and they are variously called TCP-1, CCT, or TriC [89]. In plants, however, very little is known about this type of cytosolic chaperonin and protein folding in plants, although several DNA sequences encoding proteins with some homology to the TCP-1 of the mammalian cytosol have been reported [90,91]. In terms of sequence homology, these cytosolic chaperonins are more related to archaebacterial HSP60s, which are highly heat inducible, whereas TCP-1 is not. They are now categorized as group II cpn60, as opposed to group I, to which other eubacterial and organellar types belong [92]. Judging from electron microscopic observations, a recent report proposed that the archaebacterial chaperonin forms the cytoskeleton [93].

HSP70 (DnaK)

HSP70, sometimes called HSC70 (for heat-shock cognate), or better known as DnaK, is present in abundance in the cytosol of virtually all eukaryotic cells. Some members of the HSP70 family are strongly induced by heat [94,95]. This HSP constitutes a family of highly conserved proteins [96]. According to a tertiary structure solved for bovine brain HSP70 [97], HSP70 consists of an N-terminal ATPase domain (~45 kDa) and a C-terminal peptide-binding domain (~25 kDa). Although there may be certain preferences in the sequence pattern like sequences with seven to eight amino acid residues of hydrophobic and/or basic rather than acidic nature [98–102], the overall substrate specificity is low, although not as low as that of HSP60 families.

DnaJ (HSP40) and GrpE Are Necessary for DnaK (HSP70) Actions

The chaperone machinery involving DnaK has been proposed to be progressive and structured models with other proteins like DnaJ and GrpE, which are also heat-shock proteins. One example is

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

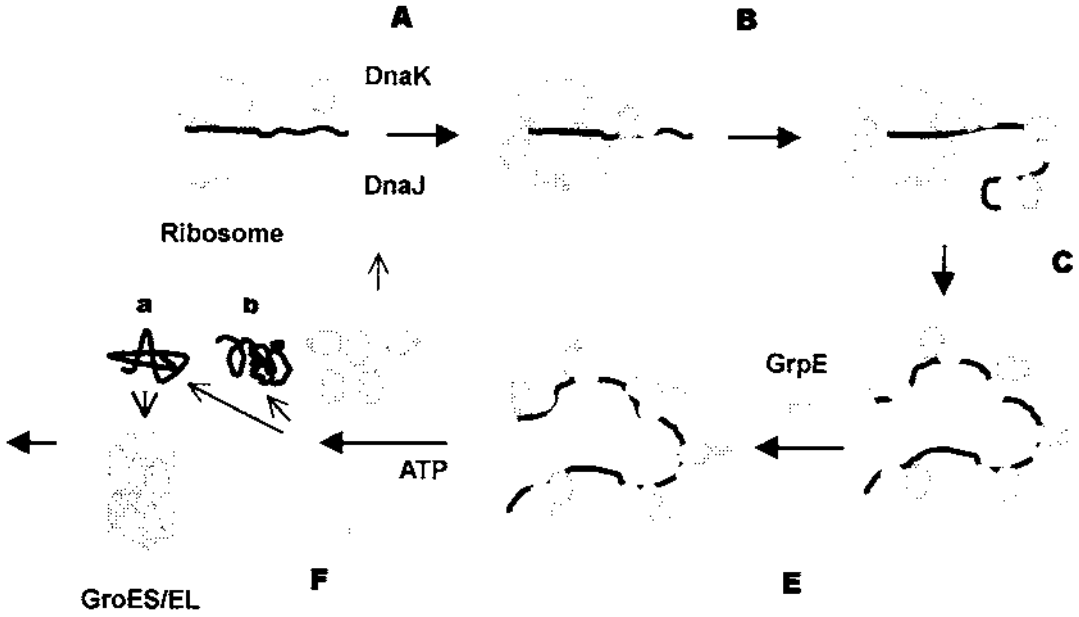

FIGURE 3 A simplified scheme of a DnaK/DnaJ/GrpE protein-folding system. For details, see text.

shown in Figure 3 (based on Ref. 103). To a nascent polypeptide just synthesized on a ribosome or to a denatured protein, DnaK and/or DnaJ bind (step A–B). As the polypeptide chain grows, more DnaK and DnaJ attach to the chain, protecting it from incorrect folding and/or aggregation (step C). Free from the ribosome, another factor, GrpE, comes on to the scene assisting the release of DnaK and DnaJ (step E). By this time, the peptide has either been correctly folded (*b*) or become an intermediary form (*a*, so-called ''molten globule''). The latter enters the next step where the GroEL and GroES machinery takes care of the final maturation stage (step F).

Plant Cytosolic HSP70s Are Encoded by Multiple Genes

A number of genes encoding plant cytosolic HSP70s have been reported (see a review in Ref. 3). A single plant species often has multiple genes, all of which encode proteins with more than 90% homology. Chloroplast counterparts are more of the bacterial type in terms of sequence [81]. It should be mentioned it as been implied that HSP70 has a role in importing proteins synthesized in the cytosol into organelles like chloroplasts. The relevance of this activity to thermotolerance remains to be elucidated.

Other Molecular Chaperones

Recent biochemical analysis of both HSP90 and small HPSs has revealed that they may act as molecular chaperones involved in protein folding and unfolding events [104]. Although small HSPs are one of the least conserved HSPs, they can be identified based on their similar hydropathy profiles and homology to the α-crystalline, an abundant protein in eye lenses [105]. The small HSPs from many different organisms are found in high molecular weight complexes in vivo, ranging from 200 to 800 kDa, that appear to be homo-oligomers [2,3]. Recently, it has been shown that α-crystalline, mammalian, and plant small HSPs possess molecular chaperone activity in vitro [106–108]. Small

HSPs are able to promote refolding of chemically denatured proteins in an ATP-independent manner in contrast to the ATP-dependent molecular chaperones of HSP60 and HSP70. Furthermore, they can prevent heat-induced protein aggregation and facilitate reactivation of heat-inactivated model substrates. HSP90 also act as an ATP-independent molecular chaperone [104]. Recent work on members of the HSP100 (Clp) family, which are ATP-dependent proteases, suggests that they may act as chaperones [105]. Detailed descriptions of these HSPs are found elsewhere [2,3].

CONCLUSIONS

Molecular chaperones are a diverse group of proteins that share the property for the binding of substrate proteins that are in unstable, nonnative structural states. Recent research indicates that many, if not all, cellular proteins interact with chaperones during their lifetime. Different chaperone systems are required for synthesis, targeting, maturation, and degradation of proteins in all cellular compartments. Thus, these diverse sets of proteins affect an exceptionally broad array of cellular processes required for both normal cell function and survival under stress conditions.

An overwhelming volume of evidence supports the assumption that HSPs are some of the most important entities to provide heat tolerance to plants. Most of the HSPs function as molecular chaperones, most of which have been shown to be essential for cellular functions at normal temperatures. They must become even more indispensable at higher temperatures where probabilities of denaturation, incorrect folding, and aggregation of cellular proteins are much higher.

The life on the Earth may have started originally under extremely hostile conditions, particularly very high temperatures. Thus, all primitive cells could have been thermotolerant in the beginning. In the course of the evolutionary development, cellular functions had to become more and more elaborate. As the temperature was gradually cooling down, cells might have undergone structural changes needed for functional sophistication in proteins and other molecules at the cost of losing heat tolerance. Thus, most of the present-day organisms are rather heat sensitive, because some, if not all, of the proteins and other macromolecular structures have become heat labile. In order to protect themselves from an occasional rise in temperature, the HSP, which is one of the most ancient proteins, judging from their ubiquitous presence, might have been preserved to the present, and evolved into one of the essential families of cellular proteins as molecular chaperones.

It is rather obvious that heat tolerance is by no means solely due to the activities of heat-shock proteins and molecular chaperones. Genetic manipulation to introduce a heat-tolerant HSP system alone may not suffice in an attempt to provide in a crop plant such traits as heat tolerance and resistance to dehydration, salt, and other stresses. Nevertheless, an understanding of heat shock proteins and molecular chaperones are essential for future development of such a crop plant strain.

ACKNOWLEDGMENT

The authors thank the following people, among many others, who helped us at various stages of the preparation of this chapter. Prof. Yoshibumi Komeda (Hokkaido University), Dr. Ichiro Yahara (The Tokyo Metropolitan Institute of Medical Science), Prof. Toshiya Endo (Nagoya University), Prof. Chu-Yung Lin (National Taiwan University), and Prof. Elizabeth Vierling (University of Arizona) for providing reprints of their papers, Dr. Hideya Fukuzawa (Kyoto University) for providing prepublication data; Dr. Garret J. Lee, Prof. Hidenori Hayashi, and Dr. Naoki Tanaka for comments and discussions.

CLIMATIC TEMPERATURE

Seasonal and Diurnal Temperature Changes

Temperature on Earth changes along latitudinal and altitudinal clines and in most localities also with season. Diurnal and seasonal changes are larger for continental and high-altitude climates and areas with low relative humidity than for areas near large bodies of water, in lowland tropics, or with high humidity. Plant life exists across the whole range of atmospheric temperatures (−89–+58°C). However, most plants are especifically adapted to, and grow over, a limited range of temperatures [1]. Factors such as toxins, water, and mineral availability may also interact with temperature to determine growth. For instance, if annual precipitation occurs mainly as snow in the winter, plants may grow at cooler temperatures than in regions with abundant spring and summer moisture.

Many species have a growth season of only a few weeks during the year. Others grow whenever conditions are suitable. For some, growth may occur in the spring and others in summer or fall. Some plants may have more than one growth period during the year. Although other factors are important, climatic temperature is often dominant in determining conditions for the growth of a particular species and thus its distribution worldwide [2,3].

Temperature Effects on Growth

Growth is an irreversible increase in volume and structural biomass involving cell division, cell enlargement, maturation, and specialization to form tissues and organs. The rate of growth is propor-

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

tional to the product of the rate of catabolic activity and the efficiency for conversion of photosynthate to structural biomass. Growth is influenced by several environmental factors, none more important than temperature.

The pattern of daily and seasonal temperatures and the effects on growth rates are complex. Plots of mean daily temperature and mean kinetic temperature over a year for a particular locality produce curves as in Figure 1. Because the relation between the growth rate and temperature is logarithmic, the growth rate is proportional to the mean kinetic temperature and not to the average temperature. Superimposed daily temperature extremes illustrate the range of temperatures and the constantly changing thermal environment encountered by plants.

Climatic temperature affects plants in three ways. First, seasonal temperature changes require that the timing of plant life-cycle events be appropriate for survival and reproduction. For example, in temperate climates, germinating too early can be fatal because of too cold spring temperatures, whereas germinating too late can be fatal if high temperatures occur before the plant is well established. Temperature can also affect flowering and seed set in similar ways. The growth and elongation of perennials, such as conifers, is often limited to those short periods of time when conditions are appropriate. These effects of seasonal temperature changes have been discussed elsewhere (1) and are not treated further here.

Second, extreme temperatures can limit plant survival and reproduction, and because this effect can be modeled in a simple yes/no way, it has been the most widely described in the literature. In this extreme temperature model, the growth range and season are set by the periods when the temperature extremes do not exceed the stability limits of the species. These temperature limits, both high and low, are commonly known approximately for many species, particularly crop plants.

Third, short-term temperature fluctuations within the extreme limits, typically diurnal, also affect plant growth, and thus the ability of a plant to compete or to produce well agronomically. Figure 1 shows that even when mean daily temperatures are within the range for active plant growth, diurnal changes may cause the growth rate to be very small during much of the day. Diurnal temperature variations thus have large effects on plant growth [4].

Because temperature is one of the strongest determinants of the plant growth rate, nearly all texts on plant physiology devote a section to the responses of plants to temperature. Typically, plant growth has been described as ''slow at low temperatures, then accelerated until a certain temperature is attained, above which growth becomes slower, and when a certain temperature is exceeded, growth ceases. The temperature at which growth rate is most rapid varies greatly with species'' [5]. Details

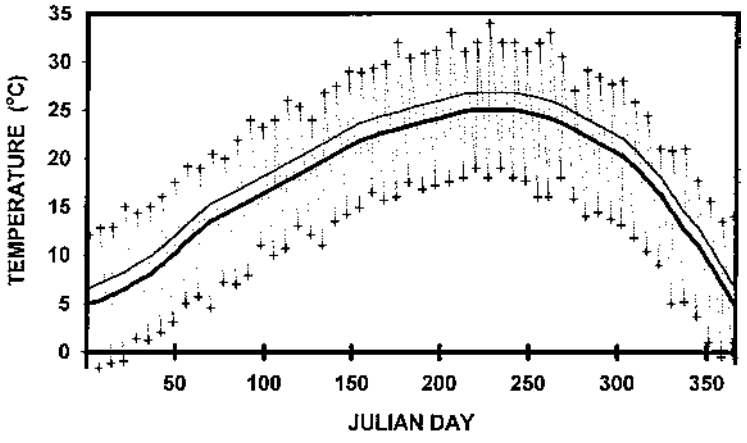

FIGURE 1 Mean daily (−), mean kinetic (−), and mean daily high and low temperatures (+, plotted weekly) at Davis, California.

of temperature effects on growth rates beyond such generalized descriptions have been difficult to obtain. Curves of the plant response to temperature [4,5] are commonly constructed by interpolation among a limited number of data points (typically less than 10). Consequently, the differences in temperature responses between and within plant species are often not well defined [6]. A quantitative understanding of the plant growth dependence on temperature is essential for the rapid selection of cultivars to optimize growth in different climates, to understand the physiological responses to climate change, and to identify and quantify the effects of climate.

Consideration of growth as the result of a concerted set of chemical reactions with known temperature dependences makes it readily apparent how small differences in enzyme activity among plants can give rise to large overall growth rate differences. Assume, for example differences arising between two plants because of a small mutational change in an enzyme that determines the growth rate. Mutation can give one of three outcomes: (1) either the enzyme activity (and consequently plant growth) is unchanged by the mutation, or (2) enzyme activity is destroyed, in which case the plant will likely fail to grow, or (3) the activity is altered but the enzyme is still functional. The last of these possibilities is the only one of interest here. A change in the catalytic rate indicates a change in the activation energy of the enzyme-catalyzed reaction; that is, a change in the temperature coefficient. Thus, the temperature dependences of the relative growth rates of mutant and nonmutant plants must differ. Because reaction rates change exponentially with temperature, the growth rate difference between the native and mutant plants is related to the difference between two exponentials, and small changes in temperature will have large effects on the relative growth rates. Although a small change in the rate of an enzyme-catalyzed reaction in a homeotherm may have little effect on growth, plants that encounter a wide range of constantly changing growth temperatures may show a large diversity of responses from small differences in enzyme activity.

Besides depending on the magnitude of the temperature, the effects of temperature on growth and metabolism are often also time dependent. A well-known example of this phenomenon is the response of chilling-sensitive plants to temperatures above freezing but below about 15°C. Temperatures near the upper end of this range damage tissues, but very slowly, whereas temperatures near freezing damage tissues very rapidly [7]. Figure 2 illustrates this with time-temperature surfaces for the metabolic heat rate for tomato tissue at high and low temperatures [8]. These surfaces describe the immediate metabolic response to temperature change; growth responses follow similar curves. The intermediate time response of plants to changing environmental conditions is by acclimation; that is, phenotypic plasticity. The process of acclimation to a stress is known as hardening [5]. In an even longer time frame, natural selection among populations may lead to adaptation. Both acclimation and adaptation are means for achieving tolerance to a particular stress.

Responses of plants to environmental stress, particularly temperature stress, have been the object of much study [9]. Since plants generally grow best under minimal stress, an easily and rapidly measured quantitative physiological predictor of plant growth (and response to stress) is highly desirable.

A quantitative mechanistic model [10] has recently made it possible to connect the temperature effects on growth to the better-known effects of temperature on metabolism. Previously, many of the effects of diurnal temperature variation on growth were ascribed to the differential effects of soil and air temperatures on different organs of the plant; for example, keeping the roots cool [11] and thus conserving carbon.

MECHANISM OF ACTION OF TEMPERATURE

Temperature and Reaction Rates

It is helpful to recall that temperature is not a measure of the amount or concentration of a substance or of total energy but is a measure of molecular motion; that is, the molecular kinetic energy within the system. Thus, the rates of all elementary reactions increase exponentially with increasing temperature. Metabolism is a combination of many elementary reactions, most of which have rates con-

Marcel Dekker, Inc.

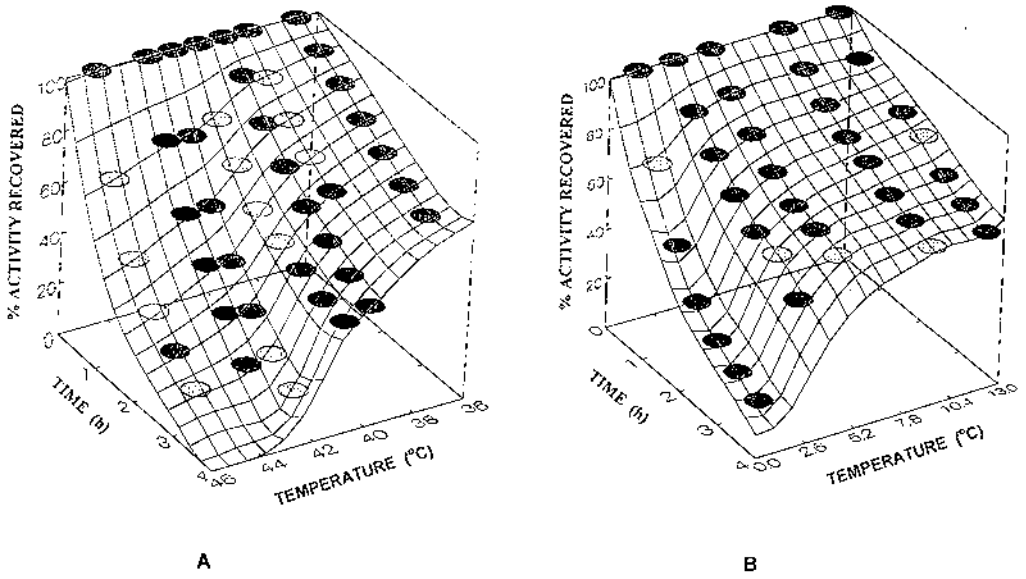

FIGURE 2 Response-surface plot for tomato cells. Activity recovered at 24°C is presented as a function of both exposure time and stress temperature. (a) Cells exposed to high temperatures. (b) Cells exposed to low temperatures. (From Ref. 8.)

trolled by enzyme activity. The rate of an enzyme-catalyzed reaction is typically regulated either by the number of active copies of the enzyme or by a temperature-dependent chemical equilibrium; for example, substrate, activator, or inhibitory binding. Therefore, the overall rate of reactions along a metabolic path may either increase or decrease with increasing temperature. Whether a reaction rate is controlled by kinetics (number of copies) or by a chemical equilibrium is not distinguishable from the functional form of the temperature dependence, however, because the Arrhenius equation for the temperature dependence of rate constants and the van't Hoff equation for temperature dependence of equilibrium constants are identical exponential functions of the reciprocal absolute temperature. In both cases, the rates of biological processes change exponentially with temperature. This has been experimentally verified for a wide variety of biological processes [12].

The most general means for describing the temperature dependence of a rate is thus the Arrhenius temperature coefficient, μ, as defined in Equation (1).

$$R = A \exp(-\mu/T) \tag{1}$$

where R is the rate, A and μ are empirical constants, and T is the Kelvin temperature. In linear form, Equation (1) becomes

$$\ln R = \ln A - \frac{\mu}{T} \tag{2}$$

and μ is readily obtained as the slope of a plot of $\ln R$ versus $1/T$. The use of Q_{10} values to describe temperature dependence should be discouraged, because these have no fundamental connection to the molecular description of matter, are not comparable unless measured at the same temperatures, cannot be used directly for extrapolation, and can be misleading. Note also that μ is constant (i.e.,

Equation [2] is linear) only over limited temperature ranges, and that the value of μ may be influenced by conditions other than temperature.

Relation Between Growth and Metabolism

Using direct measurements of plant growth rates to monitor and characterize plant responses to temperature change has many difficulties. Experiments conducted in the field are slow, expensive, difficult to reproduce, and often lack precise control over temperature and other conditions. Experiments to test multiple temperature conditions in chambers are limited by time and the number of chambers available. Thus, measurements over broad temperature ranges with multivariate, controlled environmental conditions are rare. In addition, growth rate measurements provide little information on the fundamental physiological responses that limit growth and therefore contribute little toward understanding the physiological basis of temperature responses. As a consequence, many efforts have turned toward defining the rates of various physiological processes other than growth as functions of temperature. If such are to be of value, they must ultimately be related to the growth and development rates at various temperatures.

Because metabolism is required for growth, it is clear that some relation must exist between the metabolic rates of plants and their growth rates. A major problem has been the identification of which metabolic reactions to examine; that is, which reaction is growth-rate determining under a given set of growth conditions. Moreover, simply measuring reaction rates that may correlate with the growth rate does not yield adequate information for understanding the effects of temperature on growth. A model must be developed that explains the widely differing growth and metabolic responses to temperature change among species and among ecotypes within a single species. The model must explain, by direct cause and effect functions, relations among changing physiological activities, growth rate changes, and temperature.

Most attempts at using physiological measurements to characterize plant growth rates and responses to temperature have centered on photosynthesis, but some have looked at respiration, because it is the source of energy for incorporating stored carbon into the structural biomass. Others have looked at the rates of nutrient uptake or incorporation. All of these processes are essential for growth at all temperatures, but which is appropriate for the study of growth rate responses to temperature? Certainly, photosynthesis is growth-rate determining for plants growing in extremely low light, just as any nutrient may become growth-rate limiting when present in low concentrations. Under conditions at which all required nutrients and photosynthate are available in ample quantities, the rate of incorporation of these materials into the biomass (i.e., respiration-driven biosynthesis) becomes growth-rate limiting. As growth conditions change, the identity of the rate-limiting process can also change.

One approach to define the rate-limiting process is to examine the variation in each of the putative growth rate–limiting reactions (or subset of reactions) with changing temperature. A parallel response should exist between temperature effects on the rate-determining process and the growth rate. However, although a parallel response to stress between the growth rate and a physiological reaction is necessary to prove cause and effect, it is not sufficient to prove causation. In contrast, a lack of a direct relationship between the stress response of a physiological reaction and growth is sufficient to eliminate that physiological reaction as the rate-limiting process for growth. Thus, if the temperature dependence of a process, such as photosynthesis, is not the same as the temperature dependence of growth, then that process can be ruled out as growth-rate determining under the conditions studied.

Photosynthesis-Based Descriptions of Plant Growth Rates

Photosynthesis supports nearly all life on Earth and has long been considered by many workers to be the growth-rate determining process for plants. Certainly, growth can proceed no faster than

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

carbon can be assimilated through photosynthesis. However, other factors such as mineral deficiency or lack of water can limit growth even when the rate of photosynthate supply is adequate. Thus, it is not surprising that although many studies have tried, none has established a general relation between rates of photosynthesis and growth [13,14]. (Note: the relation sought is not the tautological relation between integrated net photosynthesis and integrated growth [15,16].)

Observations of direct correlations between the plant growth rate and the photosynthetic rates are rare except in limiting light conditions. More commonly, no correlation is found and sometimes even a negative correlation is found between the growth rate and the photosynthesis rate. In some cases when photosynthesis has been stressed to lower rates by as much as 50%, there is no corresponding change in the plant growth rate [17]. Finally, the temperature dependences of photosynthetic rates have not been shown to be directly correlated with the temperature dependences of growth rates. As noted above, the lack of such a correlation between a physiological parameter and the plant growth rate response to temperature eliminates the possibility of a direct cause and effect relationship.

Variations in light-harvesting systems and the carbon fixation path generally result in differences in growth rates among C_3, C_4, and Crassulacean Acid Metabolism (CAM) plants. Many investigators have tried to establish correlations between the rates of photosynthesis and the growth rates among these photosynthetic types [14]. Generally, these studies sought to establish a relation between the rates of CO_2 uptake in the light and plant growth rates [18]. None has been successful in establishing a relation.

Using another approach, Farquhar et al. [19] demonstrated that as C_3 plants close their stomates in response to drought stress, transpiration water loss decreases more rapidly than CO_2 uptake. Because some plants are more effective at this than others, water-use efficiency is related to carbon isotopic fractionation [20]. Relative growth can then be predicted because of the inverse relation between growth and water-use efficiency. The method uses leaves that are collected in the field, dried, combusted, and the CO_2 analyzed in an isotope ratio mass spectrometer. Although cumbersome and expensive, the technique is now widely used to predict relative plant growth rates. Its use is limited to field-grown C_3 plants under water stress.

Another photosynthetic property that has been examined for its relation to growth is photosystem II fluorescence. Fluorescence competes in the deactivation of excited chlorophyll [21], and the variable to maximal photosystem II fluorescence ratio (F_v/F_m) has been used as a measure of damage caused by free radicals formed in response to temperature and other stresses. Fluorescence has not proved to be useful as a predictor of plant growth rates [22].

Respiration-Based Descriptions of Growth Rates

Burke and Upchurch [23] have shown a relation between the temperature dependence of K_m for several plant enzymes and the temperature dependence of growth rates. The kinetic parameters are altered by plant-growth temperature in patterns consistent with these enzymes having a determining role in growth. Correlative responses are thus established for these enzymes, but cause and effect relations between the growth rate and the kinetics of the reactions catalyzed by these enzymes are not clear.

Several lines of evidence imply that the respiratory activity should be proportional to the growth rate, because rates of catabolism are controlled by anabolic demand. The sites of control are phosphofructokinase for glycolysis and isocitric dehydrogenase for the Krebs cycle [24]. Pasteur observed that yeast cells produced as much or more CO_2 in the absence of oxygen as in air; however, more yeast cells per mole of CO_2 were produced in air. More substrate had to be converted to CO_2 to obtain sufficient energy for growth. Similarly, in the presence of uncouplers that destroy the proton gradient across the inner mitochondrial membrane, CO_2 production and O_2 consumption rates increase. Furthermore, mitochondria isolated from rapidly growing tissues exhibit respiratory control, responding with an increased O_2 consumption to the addition of ADP.

Respiration rates have been correlated with growth rates in many experiments [25], but the

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

question remains: Can measurements of respiration as a function of temperature provide quantitative growth rate information? The respiration rates of plants are readily measured in three ways: the rate of CO_2 production, the rate of oxygen consumption, and the respiratory heat rate. These three measures do not provide the same information and their temperature dependences are not necessarily the same. R_{CO_2} and R_{O_2} are measures of the mass flow through respiratory catabolism, whereas the heat rate (q) is a measure of the rate of energy loss. Because heat production in plants is primarily from oxidative reactions in the respiratory processes, heat-rate measurements are predominantly a measure of the rate of oxidative reactions of the respiratory pathway [26]. Contrary to common belief, the metabolic heat loss has little direct relation to the amounts of alternative pathway activity [27].

In plants, the dark-respiration rate has been shown to be both negatively correlated and positively correlated with growth [5,25]. Thornley [28] proposed a model based on partitioning respiration between growth and maintenance to describe the relation between plant growth and respiration, but the parameters in this model are impossible to measure or define in a meaningful way. These compartment models assume that the energy produced by respiration can be subdivided into two or more compartments which are amenable to calculation from measurements of R_{CO_2} or R_{O_2}. However, the calculation of both the growth respiration and the maintenance respiration requires assumptions that cannot be tested or measurements that cannot be made. The fundamental problem with this approach is that R_{CO_2} and R_{O_2} measure only the rate of mass flow, whereas the energy relation shown to be necessary by Pasteur's experiments must be guessed. A more recent approach uses simultaneous measurements of mass flow (as R_{CO_2}) and energy flow (as q) to predict the relative values of the specific growth rate [10], thus avoiding the assumptions inherent in compartment models.

Respiratory Heat Rate as a Function of Temperature

The rate of metabolic heat production can be measured directly on small whole plants or plant tissue sections by isothermal or temperature-scanning calorimetry [29,30]. The measurement of the metabolic heat rate as a function of temperature allows detailed examination of respiration rate differences among species or genotypes within species.

Isothermal heat-rate measurements at successive temperatures allow development of curves defining the plant metabolic heat-rate response to temperature (Fig. 3) [26,31,32]. Moreover, the

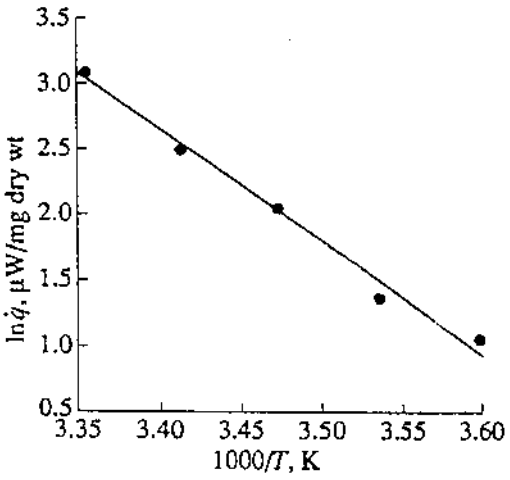

FIGURE 3 Representative Arrhenius plot for metabolic heat rate for maize shoot tissue. (From Ref. 31.)

decrease in metabolic heat rate with time at a series of temperatures can be combined to yield a time-temperature response, as shown in Figure 2 [8]. In comparison with scanning calorimetry, thermograms from isothermal calorimetry are less well defined along the temperature axis, because they are not continuous, but they are more accurate on the heat-rate axis, because the uncertainty is smaller. Isothermal calorimetry can also be used to measure R_{CO_2} [33].

In experiments lasting only a few hours [34] differential temperature-scanning calorimetry makes it possible to measure metabolic heat rates as a continuous function of temperature over the entire temperature range encountered by growing plants. The data obtained describe general patterns of respiration responses to temperature. The shapes of thermograms and key temperatures indicating metabolic activity changes are species dependent and define the response of plant tissue to a temperature increase. Figure 4 shows key features of thermograms collected over about 5 h with continuous temperature scanning. The major features of these curves that are useful for species or intraspecies comparisons are indicated by labels ''A'' through ''D.'' The segment of the curve from (A–B) is an exponential increase in the metabolic rate as temperature increases, in accord with the Arrhenius equation. At temperatures above B, metabolic rates no longer increase exponentially; instead the slope decreases with temperature. Thus, B is an inflection point and is termed the low shoulder temperature (T_{ls}). A second point with significance is T_{max}, the temperature at which the maximum heat rate is achieved (indicated by C in Fig. 4). The shape of the curve around the maximum is characterized by ΔT_w, the distance on the temperature axis from 80% T_{max} on the ascending curve to T_{max}. The decrease, in the metabolic activity with increasing temperature above T_{max} is irreversible on the time scale of these studies. Most plant tissues exhibit an exothermic reaction (probably oxidation of unsaturated lipids) at high temperature (D).

Figure 5 shows thermograms for several plant species, indicating the range of interspecies

responses observed. Although the thermograms in Figure 5 have several similarities, the large differences in temperatures of key events and in the detailed shapes of the curves show that there is no ''typical'' curve describing the effects of temperature on plant metabolism. All the samples tested have in common a nearly exponential rate of increase through the temperature range commonly encountered during growth, although the slope can vary a great deal between species and accessions [35]. The exponential rise is followed by a temperature range in which a species-specific array of responses to a further temperature increase is noted. Beyond these generalizations, the exact shapes of the curves, values of T_{ls}, T_{max}, and ΔT_w, temperatures of rapid inactivation of metabolism above T_{max}, and the temperature of the exothermic peak at high temperature all vary with species. In addition, metabolic heat rates can vary with developmental stage, growth location, and/or season.

Thermograms are highly reproducible for repeat measurements on individual plants when the scanning conditions and the tissue sample size, location, and age are all carefully controlled. Scanning rates must be carefully controlled among experiments, which is also for good reproducibility [34]. Both the peak temperatures observed in the thermograms and curve shapes can vary with the temperature-scan rate. Increasing scan rates generally result in higher values of T_{max}, because inactivation of metabolism at high temperature is a function of both time and temperature [8]. Intraspecies differences also exist among the thermograms of accessions of a single species that are adapted for growth in different climates (Fig. 6). The temperature coefficient, μ, and T_{max}, T_{ls}, and T_{hs} all differ systematically for plants collected from across such a growth range [35]. The correlation between temperature parameters obtained from the curves (i.e., T_{ls}, T_{max}, and ΔT_w) for different accessions and climatic temperature at the native growth site demonstrate that metabolism adapts to the climate to optimize growth, survival, and reproduction of the species.

In summary, scanning calorimetry allows rapid and continuous assessment of the respiratory rate as a function of temperature, which in turn offers important insights into climates suitable for successful growth of a particular genotype. Thermograms of metabolic heat rate versus temperature

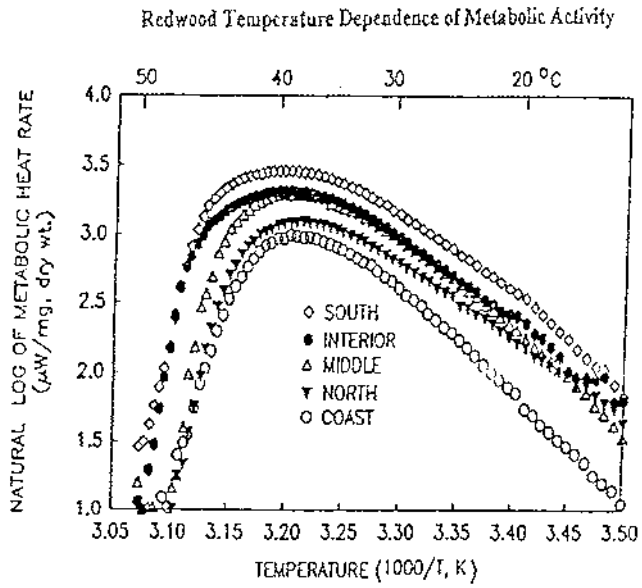

FIGURE 6 Continuous temperature-scanning thermograms for meristem tissue from *Sequoia sempervirens* accessions. (After Ref. 35.)

can clearly define (a) temperature limits to robust respiratory metabolism and therefore to growth, (b) differences in temperature responses within and among species, and (c) temperatures at which changes in metabolic pathways occur. The differences observed among the thermograms of species reflect a wide range of responses to a temperature change and provide information that should ultimately be related to the growth climates.

Acclimation of plant respiratory metabolism to a climatic or seasonal temperature change occurs over much longer time periods than the experimental times typically employed in calorimetric experiments. Thus, measurements of metabolic heat rates across a range of temperatures indicate short-term responses to temperature and reflect plant responses to short-term, continuously changing temperatures like those experienced daily during growth (e.g., see Fig. 1). Evidence for acclimation of metabolic heat rates to growth at different temperatures must be obtained from examination of tissues collected throughout the season or across a temperature cline.

A Respiration-Based Model Describing the Temperature Dependence of Growth

The temperature dependence of the rate and efficiency of respiratory and biosynthetic metabolism provides insight into the processes controlling temperature effects on growth. Plant growth may be limited by the rate of acquisition of carbon or of other resources, or by the rate of processing of those resources into the structural biomass. (Note that photosynthate which is used for energy production and anabolic processes is not part of the *structural* biomass). As previously stated, the photosynthesis rate will be proportional to the growth rate only if carbon is the limiting resource. In general, the rate of growth will be equal to the rate of acquisition of any resource only when the resource is growth-rate limiting. In contrast, it is always true that the rate of growth is proportional to the rate of processing of substrate into a new biomass multiplied by the efficiency of the process.

The general relation between the respiration and growth rates is easily derived by inspection of the chemical reaction describing aerobic growth (Equation [3]).

$$C_{\text{substrate}} + (xO_2 + \text{N, P, K, etc.}) \rightarrow \varepsilon C_{\text{biomass}} + (1 - \varepsilon)CO_2 \quad (3)$$

where ε is the substrate carbon conversion efficiency. (The symbol ε is used here to avoid confusion with various earlier symbols and definitions of efficiency.) The quantitative relation between the specific growth rate (R_{SG} in moles of carbon per time per mass), specific respiration rate (R_{CO_2} in moles/time per mass), and substrate carbon conversion efficiency of a plant or tissue is given by Equation (4).

$$R_{SG} = R_{CO_2}\left[\frac{\varepsilon}{1 - \varepsilon}\right] \quad (4)$$

where $[\varepsilon/(1 - \varepsilon)]$ derives from the ratio of coefficients in Equation (3). Equation 4 accurately describes the plant growth rate no matter what the nature of the growth-limiting factor; that is, whether the growth is limited by photosynthate, nitrogen, some other nutrient, the metabolic rate, or other factors, but it is only useful if ε can be readily determined.

Beginning at low temperatures, R_{CO_2}increases with increasing temperature until some physical change occurs or a limitation on the rate of transport or nutrient acquisition occurs. Above this temperature, R_{CO_2} usually decreases rapidly with further temperature increases. The substrate carbon conversion efficiency, ε, may go through a maximum or continuously decrease with increasing temperature across the range of growth temperatures; that is, from 0 to 50°C. Increasing temperature through this range in a period of a few hours or less thus causes the growth rate to increase, go through a maximum, and then decrease; the exact function depending on how various metabolic pathways respond to temperature. Because other environmental stresses also affect metabolic pathways, the temperature response is affected by other stresses. Whether this interaction leads to cotolerance or synergism of the stresses depends on how the metabolism is affected.

The dependence of ε on time-temperature can be measured by relating ε to the metabolic heat rate (q) and the respiratory CO_2 rate (R_{CO_2}), as shown in Equation (5) [10].

$$\frac{q}{R_{CO_2}} = 455\left(\frac{1 - \gamma_p}{4}\right) - \left[\frac{\varepsilon}{1 - \varepsilon}\right]\Delta H_B \quad (5)$$

where γ_p is the average oxidation state of the substrate carbon for respiration and biosynthesis, ΔH_B is the enthalpy change for conversion of substrate carbon to biomass carbon, but including all other elements, and the constant 455 kJ/mol of O_2 is from Thornton's rule [10]. Thus, if γ_p and ΔH_B do not change, changes in the ratio q/R_{CO_2} measure the changes in ε with temperature or time-temperature.

The temperature dependence of growth rates is thus a function of the temperature dependences of the metabolic rate and the metabolic efficiency, both of which change continuously with temperature. The ultimate cause of high-and low-temperature growth limits is not primarily membrane phase transitions or enzyme denaturation, as has been commonly supposed, but loss of substrate carbon conversion efficiency; that is plant cells lose the ability to produce energy at a rate sufficient to maintain the cellular structure. Structural changes may then occur as a consequence of the lack of energy, not as a cause.

As described earlier, variation of the plant metabolic rate and pathways with temperature determines how plant growth rates vary with temperature, since, aside from morphological differences, the ability of a plant to grow and survive in a given environment is defined by metabolism. If the growth rate is expressed as the rate of storage of chemical energy in the structural biomass with the substrate as the reference energy state, then the growth rate can be expressed as the difference between the rate of energy produced by respiration and the rate of energy lost to the surroundings. Equation (6) is a form of Equation (4), obtained by combining Equations (4) and (5), and assuming the substrate carbon compound is carbohydrate with γ_p equal to zero.

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

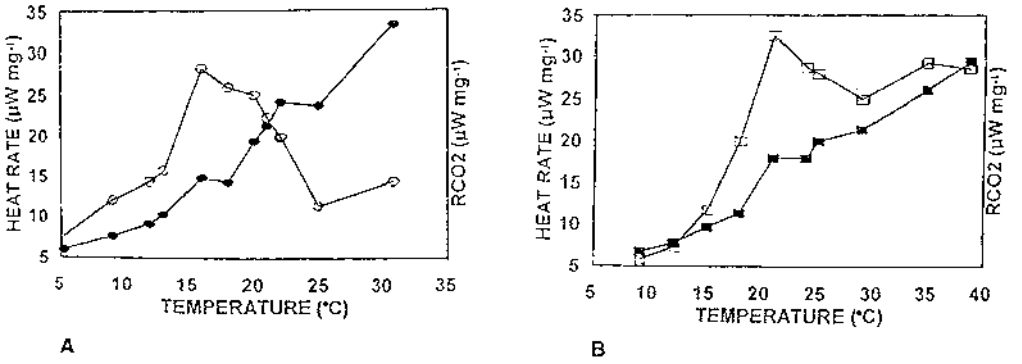

FIGURE 7 Values of isothermal heat rates (●) and 455 R_{CO_2} (○) at various test temperatures. (a) Cabbage leaf tissue. (b) Tomato leaf tissue. (From Ref. 32.)

$$R_{SG}\Delta H_B = 455R_{CO_2} - q \tag{6}$$

Equation (6) states that the growth rate is proportional to the difference between the rate of energy loss, that is, the heat rate (q), and the rate of energy generation, that is, a constant times the CO_2 rate. Measured temperature dependences of R_{CO_2} and q and Equation (6) can be used to predict the growth rate as a function of temperature. Further, the ratio q/R_{CO_2} provides easily measured, relative values of the substrate carbon conversion efficiency, ε, as indicated by Equation (5). The absolute value of q/R_{CO_2} also provides information on the oxidation state of the substrate carbon; that is, γ_p.

Relating Growth to Environmental Temperature with a Respiratory Model

Tomato and cabbage are representative warm- and cool-climate species that are used here to illustrate broad differences in the growth and respiration responses among Temperate Zone plants. Similar differences are expected both within and among other species, because their respiration characteristics reflect adaptation strategies for fitting into available thermal niches. Methods outlined here can provide temperature response profiles identifying appropriate growth temperature ranges for other cultivars of tomato and cabbage or for other species [32]. Figures 7 and 8 show the metabolic heat

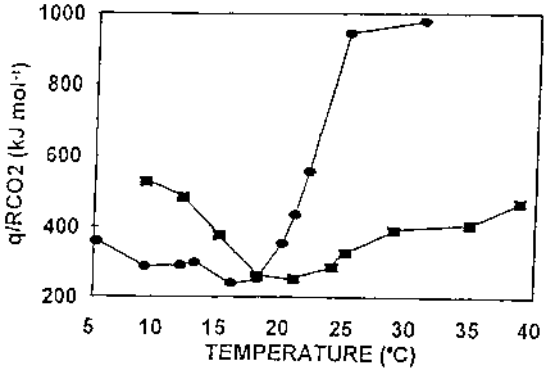

FIGURE 8 Values of q/R_{CO_2} for tomato (■) and cabbage (●) at various temperatures calculated from the data of Figure 7. (After Ref. 32.)

rates, the CO_2 production rates, and the ratio q/R_{CO_2} measured at different temperatures for tomato and cabbage leaf tissue [32]. For each species, q and R_{CO_2} have distinctly different temperature responses. The values of q increase approximately exponentially over the temperature range measured, but the CO_2 rates show a marked discontinuity in the rate of increase with temperature. The responses also differ between the species. For cabbage, a maximum in R_{CO_2} is observed between 15 and 16°C. Tomato has a maximum R_{CO_2} between 21 and 22°C.

For cabbage, plots of q and $455R_{CO_2}$ intersect below 0°C and again at 21°C (see Fig. 7). At temperatures where $q > 455R_{CO_2}$, q/R_{CO_2} becomes large, indicating a negative substrate carbon conversion efficiency or a change in substrate. From 7 to 20°C, q/R_{CO_2} is small, has a minimum near 16°C (large ε), and then increases rapidly (decreasing ε and/or change in γ_p from 0 to negative values) as the temperature is increased above 16°C (see Fig. 8). $R_{SG}\Delta H_B$ is positive but small near 0°C, reaches a maximum near 16°C, and then decreases and becomes negative above 21°C, where $455R_{CO_2} > q$ (see Equations [5] and [6]) (Fig. 9). Thus, these data predict that cabbage will grow slowly at temperatures near freezing, grow at increasing rates up to 16°C, and then at decreasing rates up to a temperature near 21°C, where growth stops, energy gradients are lost, and tissue damage begins.

The curves for tomato differ greatly from those of cabbage. For tomato, the q and $455R_{CO_2}$ versus temperature curves intersect near 12°C and again near 38°C (see Fig. 7). Below 12°C and above 38°C, q is greater than $455R_{CO_2}$ and no growth is expected. Values of q/R_{CO_2} for tomato are high (small or negative ε) at temperatures below 12°C. As the temperature increases in the range 12–20°C, $455R_{CO_2}$ becomes increasingly greater than q so that q/R_{CO_2} decreases, indicating an increasing substrate carbon conversion efficiency (see Fig. 8). From 20 to 35°C, q/R_{CO_2} increases and calculated values of $R_{SG}\Delta H_B$ indicate that growth becomes less efficient as 35°C is approached. Growth stops, that is, $R_{SG}\Delta H_B$ becomes negative, above 35°C (see Fig. 9).

Observed growth rate measurements on tomato as a function of temperature are consistent with the calculated values of $R_{SG}\Delta H_B$. The classic studies of Went [4] established 10°C as a critical low temperature for the growth of common tomato cultivars and defined conditions of decreased growth rates above 30°C. Many subsequent studies have confirmed the temperature range from 10 to 12°C as a region below which precipitous decreases in growth rates are noted for tomato and other chilling-sensitive plants [7]. Also, our studies with tomato cell cultures show diminishing

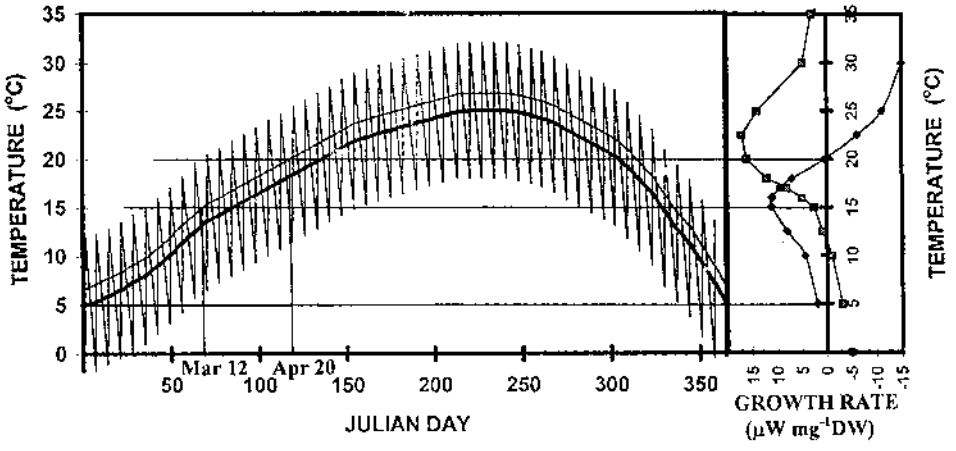

FIGURE 9 Growth rates ($R_{SG}\Delta H_B$, see Equation [6]) calculated from measured q and R_{CO_2} values (see Figs. 7 and 8) for cabbage (◆) and tomato (■) keyed to climatic temperatures at Davis, California. (From Ref. 32.)

metabolic rates above about 30°C and a rapid decrease above 35°C (see Fig. 2) [8]. Growth rate versus temperature data on cabbage is less abundant, but again the known general pattern of the cabbage growth rate response to temperature is described by the respiration parameters. Cabbage and other cold-climate crops such as wheat have significant growth rates near zero, grow well at temperatures below about 20°C, and grow slowly or experience tissue damage when temperature is high. Recent studies on wheat elongation show a maximum rate around 20°C with a sharp downturn by 25°C [36].

The data on tomato and cabbage [32] presented here leads to a novel rationale for growth rate maxima and growth rate changes observed at temperature extremes. The growth rate increases with temperature only so long as the product $R_{CO_2}[\varepsilon/(1-\varepsilon)]$ increases with temperature (see Equation [4]. The growth rate decreases with increasing temperature when efficiency decreases faster than R_{CO_2} increases. Because the temperature responses of q and R_{CO_2} are different, the substrate carbon conversion efficiency (ε, see Equation [5]) must change continuously with temperature and can exhibit either an increase or decrease with increasing temperature.

The temperature responses of q and R_{CO_2} observed for cabbage and tomato cause their specific growth rates to increase, go through a maximum, and decrease with increasing temperature. Their growth behavior as a function of temperature thus can be explained without postulating a reversible or irreversible inactivation of the enzyme activities or the membrane phase changes. Thermal damage may occur but is a consequence of the energy imbalance rather than direct thermal inactivation of enzymes or membranes. Many efforts have been made to identify a thermally induced event such as a lipid membrane phase transition as the ultimate cause of observed high- and low-temperature tissue damage [37]. However, the crossing of the curves for $455R_{CO_2}$ and q at about 12°C for tomato (see Fig. 7) show that chilling sensitivity does not require a physical event but can be accounted for by an inability of respiration to supply sufficient energy to maintain structures in the tissue.

Figure 9 shows that tomato achieves nearly double the specific growth rate of cabbage (assuming equal ΔH_B), but tomato grows rapidly in a narrower temperature range than does cabbage. Plants adapted to cool climates usually show a growth pattern similar to cabbage; that is, they grow slowly at a fairly constant rate over a wide range of low temperatures. We hypothesize such an adaptation is an advantage in temperate, arctic, and alpine climates with large diurnal temperature fluctuations. To achieve a relatively constant growth rate across a wide range of temperatures requires minimizing the difference in the temperature dependences of q and R_{CO_2}. Plants from climates with small diurnal temperature fluctuations are expected to have higher temperature dependences of q and R_{CO_2} and greater differences in the temperature dependences of these parameters. Thus, the temperature dependence of the respiratory metabolism is related to the ability of a plant to survive and reproduce within a given temperature environment.

The vertical lines in Figure 9 relate the growth-rate responses calculated from respiration-rate measurements to calendar dates through climatic temperatures; that is, seasonal, diurnal fluctuations, and mean kinetic temperature. The line at 20°C connects the high-temperature growth limit of a particular cabbage cultivar to seasonal times when it will not grow well at this location (Davis, California). Figure 9 shows that by day 115 (April 25), the mean kinetic temperature exceeds the high-temperature limit and does not decrease below this limit until after day 310 (November 6). At this location, this cabbage cultivar is predicted to grow well during the period from mid November to mid April, with maximum growth rates at about March 12 and November 27. The optimum growth period for this tomato cultivar is predicted to be from about day 150 (May 30) to about day 300 (October 27) when the mean kinetic temperature is near optimum and daily minimums do not exceed the low limit. Figure 9 thus demonstrates how measurements of q and R_{CO_2} over a range of temperatures can be used to predict the growth of a plant in a particular climate.

Terminology and Mechanism of Action of Temperature Stress

Terminology previously used to describe the effects of the temperature on plant growth was derived as a parallel to the effects of nutrient concentrations on plant growth; that is, a low-temperature

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

threshold comparable to a low-concentration threshold below which growth is limited, a range of temperatures or concentration sufficient to support maximum growth, and a high-temperature threshold or a threshold concentration beyond which stress was exhibited. But temperature is not an extensive property related to the amount or concentration of a material, but it is an intensive property related to molecular kinetic energy. Concepts of threshold ''stress temperatures'' or ''unstressed growth temperature ranges'' are invalidated by the data in Figures 7–9. Because there is no temperature range in which the changing temperature does not affect the growth rate, there is no such thing as an ''unstressed temperature range.'' The term *temperature stress* should be limited to qualitative comparisons only at temperature extremes, and a more proper term would be *time-temperature stress*.

Lipid phase changes and protein denaturation have been invoked to explain the tissue damage from both chilling and high temperature [37]. However, evidence that such phase changes occur in intact tissues at temperatures and conditions relevant to plant inactivation is circumstantial; no phase change has been directly observed in intact plant tissue [34,38,39]. Phase transitions (which in this context includes ''melting'' of protein tertiary structures and phase separations as well as lipid phase transitions) can occur at a discrete temperature in pure substances or can occur across a broad range of temperatures in both pure substances and in mixtures. First-order phase transitions occurring at a discrete temperature must have $\Delta H > 0$ for melting and are detectable by temperature-scanning calorimetry, but higher-order transitions occur across a range of temperatures, have $\Delta H = 0$, and are not readily detected by temperature-scanning calorimetry [38,39].

It is clear that changes in unsaturation do correlate with changes in cold tolerance. For example, Nishida and Murata [40] prepared mutants with altered lipids and demonstrated changes in cold tolerance. What is not clear is the implication that the changes are due to effects on, for example, structure and phase transitions. Such changes in the lipid composition must have very important effects on the metabolic rates, μ values, and/or efficiencies.

Another proposed explanation for observed temperature responses is a change in a rate-limiting metabolic process [12,38,39]. Such a change in kinetics produces a change in the slope of an Arrhenius plot of ($\ln R$) versus $1/T$ if the activation energies of the rate-limiting processes are different. Changes in the slope of Arrhenius plots are frequently observed but difficult to interpret. It is difficult unambiguously to ascribe the kinetic data to phase transitions or structural changes.

Although structural changes may be associated with plant responses to a temperature change, a change in the structure need not be the ultimate cause of the response or the damage eventually observed as a consequence of the temperature change. Cells are compartmentalized and concentration gradients of ions and molecules exist across the membranes of the compartments. These gradients, both of concentration and of electrical potential, are the immediate energy source used to drive biosynthesis in the cell. Biosynthesis creates not just new molecules from substrate but also new structures as well. Thus, energy gradients are necessary both to create and to maintain structures. Respiration is the source of these energy gradients. In any circumstance in which respiration is unable to replenish the gradient as rapidly as it decays, the gradients will be lost and loss of structure will follow. Thus, we conclude energy gradients cannot exist without structure and structure cannot exist without energy gradients. At any temperature where respiration is either too slow or too inefficient to provide energy at a rate sufficient to maintain the energy gradients in at least a steady state, the gradients will diminish until the structure can no longer be maintained and the system will then begin to lose structures within the cell. If the process continues too long, the cell will be unable to repair itself and death ensues.

TEMPERATURE AND ECOLOGY

Respiration and Plant Distribution

Respiratory rates and efficiencies for plants from the same species but from different climatic regions in the growth range have quantitatively different temperature dependences [31,35,41,42]. Evolutionary adaptations to permit growth and reproduction in different regions are necessary for species

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

survival [1–3]. For example, some plants are adapted to warm and other to cold climates, some to a narrow range, and others to a broad range of temperatures. Different responses to temperature are seen within as well as among species. Plant metabolic activities in tropical areas must be optimized for warm, comparatively invariant climates, whereas metabolism in arctic plants must be matched to a cooler and broader range of rapidly changing ambient temperatures.

Consequences of Differences in Temperature Dependences of Heat Rates and CO_2 Rates

Biosynthesis (anabolism) is closely coupled to and dependent on respiratory catabolism. R_{CO_2} is thus proportional to the rate at which energy is made available to drive growth. q Measures the rate of energy loss from the plant or tissue. The difference between the rates of energy production and loss is the rate of addition of chemical energy to the photosynthate to produce the structural biomass by biosynthetic reactions; that is, a measure of the growth rate. When the rate of energy production during respiration is greater than q, the growth rate is positive; that is $[455(1 - \gamma_P/4)](R_{CO_2})$ is greater than q, or when $455R_{CO_2} > q$ if $\gamma_P = 1$ (see Ref. 10). When the difference between 455 R_{CO_2} and q becomes zero, growth stops, and under these conditions, the plant must use energy reserves to survive. If the difference becomes negative, the tissues are breaking down through spontaneous, exothermic reactions. The difference between q and $455(1 - \gamma_P/4)R_{CO_2}$ changes with temperature, because the temperature dependence of q (μ_q) and the temperature dependence of R_{CO_2} (μ_{CO2}) are not the same (see Equations [1] and [2] for a definition of μ). Therefore, plots of $455R_{CO_2}$ and q plotted against temperature on the same axes must cross. These curves cross in temperature ranges commonly encountered by plants growing in their native climatic temperature ranges [31,32,42]. For plants adapted to growth in a warm, stable climate, $455R_{CO_2}$ is greater than q between a low temperature of about 10°C and a high temperature of about 35°C; that is, growth only occurs between these temperatures (e.g., see data for tomato in Fig. 9). For plants adapted to cold, highly variable climates, $(455R_{CO_2} - q)$ is positive at low temperature and goes to zero above a temperature in the range 20–30°C (see data for cabbage in Fig. 9). Such plants grow well below, but not above, the crossover temperature.

Because $(455R_{CO_2} - q)$ is small near the crossover temperature, plants will have slow growth rates in this temperature range. Farther from the crossover temperature, growth rates will be greater. The change in the growth rate with temperature thus depends on the relative and absolute values of μ_q and μ_{CO_2}. When μ_q and μ_{CO_2} are greatly different, growth rates will change rapidly with temperature. When they are similar, growth rates will change only slowly with temperature. These patterns of the growth-rate response to temperature are linked to survival within a given climate and therefore to plant distribution.

Perennial plants grown in their native location and in common gardens have μ_q values related to their climate of origin [35]. Plants from low-elevation and low-latitude sites have lower μ_q values than plants from high elevation and high latitude. μ_q Appears to vary linearly with an additive function of latitude and elevation. Consideration of elevation and latitude as a surrogate for climatic temperature suggests that plants from cool and highly variable temperature sites have low μ_q, whereas those from warmer, more constant temperature regions have higher μ_q. μ_{CO_2} Appears to be lower for plants from cooler climates with more extreme temperature fluctuations than for plants from warmer, more thermally constant environments.

Plant Distribution and μ Values

Jeffree and Jeffree [2,3] have performed a data analysis that clearly illustrates the importance of extreme temperatures in determining plant distributions. They prepared plots with the mean temperature of the coldest month as the x axis and the mean temperature of the warmest month as the y axis for locations including the entire known distribution of a species. The occurrence of the species at each combination of mean high and mean low temperatures was indicated on the graph and an

ellipse drawn to include 77% of the total samples. Maximum and minimum high temperatures and maximum and minimum low temperatures for species survival at the 77% level were obtained from inspection of ellipses which enclose the ''temperate space'' allowing growth, survival, and reproduction of the species. In this analysis, annual temperature variation was assumed to be the key determinant of plant distributions.

As an aid in visualizing the effects of temperature on plant distributions, Jeffree and Jeffree [3] also produced a figure showing the possible vector directions of changes in seasonal temperature and the relation of these changes to climatic temperature patterns (presented in modified form as Fig. 10). The temperature patterns at various locations were described using the terms *oceanic* to indicate regions with little annual temperature fluctuation and *continental* for regions with large temperature fluctuations. Regions at higher elevations and high latitudes generally have the large temperature fluctuations implied by continental. Regions of low elevation and low latitude are more oceanic. Vector directions presented in the Jeffree and Jeffree plot indicate the consequences of various patterns of climatic temperature.

Figure 10 is a modified form of the Jeffree and Jeffree drawing showing the relation between the vector direction plot and the physiological parameters μ_q and μ_{CO_2}. Although the plots of Jeffree and Jeffree are based only on yearly temperature fluctuations, diurnal fluctuations in temperature, particularly during the growing season, are also extremely important to plant growth, survival, and reproduction. There is a generally positive correlation, but not a one-to-one relation, between sea-

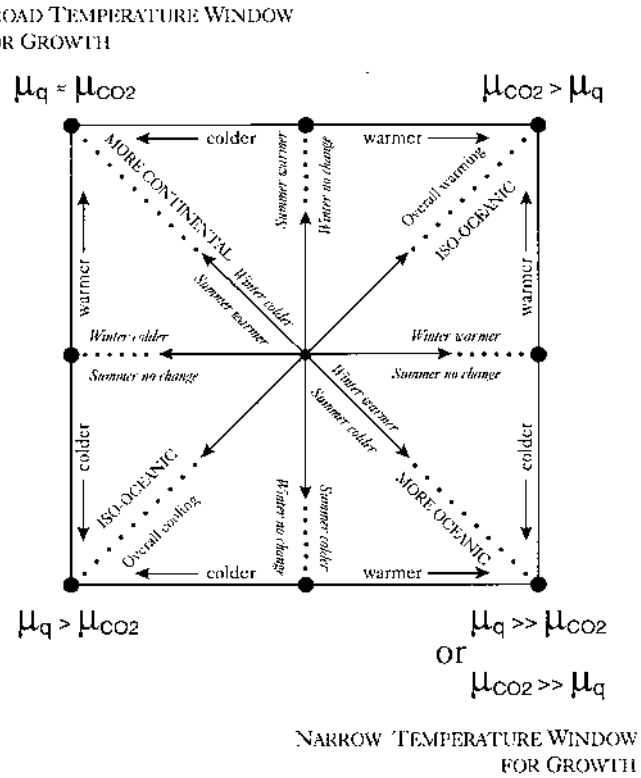

FIGURE 10 The influence of climatic thermal dependences on metabolism. Modified from Jeffree and Jeffree [3] to include the relation between growth climate and temperature coefficients for q and R_{CO_2}.

sonal fluctuations and diurnal fluctuations. Thus, conclusions based on seasonal differences must be carefully considered in finer terms of day-to-day and day-to-night fluctuations during the growing season. This is important when considering responses to a climatic temperature change at both the species and the individual plant level or when considering moving plants from one location to another. Physiological parameters provide a better reflection of the temperature responses of growth during specific periods when growth is occurring and emphasize potential growth and competition in the realm of the ''potential niche'' size rather than the ''realized niche'' size determined by ecological and historical limitations and observed in studies of natural distribution [43].

Although Figure 10 shows the relations among μ_q, μ_{CO_2}, and oceanic or continental, it does not uniquely identify μ values best suited for each temperature zone. Note, for example, that where the figure indicates constant temperature, more oceanic regions may be suitable for plants with either $\mu_{CO_2} \gg \mu_q$ or with $\mu_q \gg \mu_{CO_2}$ but does not identify which of these options is better for warmer or cooler oceanic climates. A more complete representation is needed to be able to define the growth conditions for which plants with μ_{CO_2} greater or less than μ_q are favored [30].

Figure 11 shows changes in the growth rate with temperature as a function of the ratio of μ_q/μ_{CO_2}. When $\mu_q > \mu_{CO_2}$, specific growth rates are significant near 0°C, increase slowly with increasing temperature, and then decrease rather abruptly as the temperature is increased further. The larger the ratio of μ_q/μ_{CO_2}, the better the plants are adapted for growth at low temperature, the narrower the range of temperature allowing growth, and the lower the high-temperature limit for growth. Growth rates for such plants are positive below temperatures where the ratio $\mu_q/\mu_{CO_2} = 1$. These plants are best suited to the nearly constant temperatures of cool, oceanic-type climates. When $\mu_q < \mu_{CO_2}$, the plant growth rate is zero or very slow at low temperatures and increases rapidly as the temperature is increased. Smaller ratios of μ_q/μ_{CO_2} indicate adaptation to higher temperatures, narrower ranges of temperature allowing growth, and a higher low-temperature limit for growth. Growth rates for such plants are positive above temperatures where the ratio $\mu_q/\mu_{CO_2} = 1$. These plants are best suited to the nearly constant temperatures of warm, oceanic-type climates. When values of μ_q and μ_{CO_2} are nearly equal, plants are adapted to a broad range of temperatures and grow relatively slowly over the entire range of temperatures. Such plants are best suited for survival

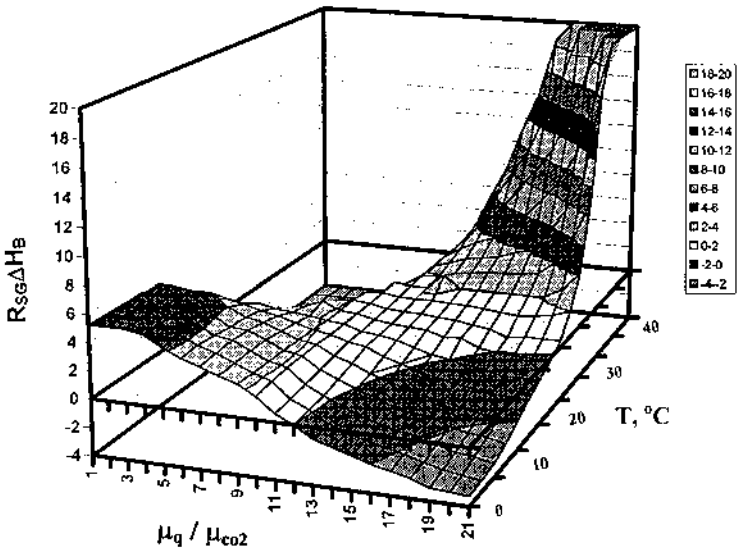

FIGURE 11 Plot showing the relation of growth rate (vertical axis) to temperature and the ratio of the temperature dependences of q and R_{CO_2} (i.e., μ_q/μ_{CO_2}).

in continental-type climates with large and rapid temperature fluctuations. They also can potentially grow in narrow temperature zones but will commonly be out-competed in such niches, because narrowly adapted species will grow more rapidly.

Figure 11 illustrates the relation between the temperature limits of growth described by Jeffree and Jeffree [2,3], seasonal and annual temperature fluctuations, and plant physiological parameters. With Figures 10 and 11 and the established physiological relationship, it is possible to understand the relations among the metabolic rates, efficiency, plant growth rate, and plant growth range. Plants adapted to narrow temperature windows, either cold or warm, can have very high metabolic efficiencies (large values of $[455R_{CO_2} - q]$) and, therefore, rapid growth over a narrow temperature range. This is done at the risk of severe damage in the form of the loss of energy to maintain potential gradients if the temperature moves outside the allowed narrow limits.

Plants that are adapted to broad temperature ranges can maintain relatively small positive values for $(455R_{CO_2} - q)$ over the entire range. They do so at the expense of being able to have large values in any given narrow temperature range. Thus, such plants are at a competitive disadvantage within niches having oceanic climate character.

The experimental observations of differences in μ values for the energy-producing and energy-using metabolic pathways of plant metabolism force the conclusions that energy-use efficiency must change with temperature and that the pattern of change describes the ability of a plant to grow in a given climate. Plant distribution is uniquely explained in terms of the temperature dependence of metabolic efficiencies. Figure 11 focuses only on the ratio of μ values. In addition, the absolute values of the rates, not just their ratios, impacts growth rates. Individual plants with identical ratios of μ values can have different growth rates while having the same responses to temperature change.

Certainly, additional factors enter into the determination of plant distribution. For example, the morphological features of plants allow buffering of the plant responses to temperature, water fluxes, salt, and other stresses. Dormancy considerations also define when a plant will grow and therefore what temperatures it must face during its growing season. Still, even with all of the known plant adaptations developed to aid plant survival, the plant growth and metabolism must respond to an ambient temperature and its daily and seasonal fluctuations with the general pattern illustrated in Figure 11. The metabolic and energy-based considerations illustrated here will contribute strongly to all plants (as well as other poikilotherms) in any environment.

The above conclusions about the relation between temperature coefficients of respiration and plant distribution are readily extended to consider growth seasons for plants. Figure 9 shows the relation of temperature throughout a growing season, among growth rate, and species or cultivar. This figure extends the discussion of seasonal temperature associated with Figure 1 to show how the mean, temperature, mean kinetic temperature, and daily high and low temperatures are related to the growth-temperature–response curves for specific cultivars of two annuals, tomato and cabbage.

Cabbage, a cool-climate species, has relatively low μ values and $\mu_q > \mu_{CO_2}$. As discussed earlier and illustrated in Figure 9, cabbage grows slowly at 5°C, increases the growth rate up to about 15°C, and stops, growing above about 21°C. In January at Davis, California, 5°C is near the mean temperature. The mean kinetic temperature on this date is 6–7°C, and the mean daily high is near 12°C. Thus, cabbage will grow for a significant portion of the time in here, even during early January. By March 12, the mean kinetic temperature is about 15°C and growth of cabbage is optimum. Daily temperature fluctuations do not go below a range allowable for growth and rarely exceed the high-temperature limits for active growth of cabbage. However, by April 20, the mean kinetic temperature limits the active growth of cabbage. By April 20, the mean kinetic temperature begins to exceed 21°C and cabbage encounters a temperature condition at which there is no growth. Survival during these periods depends on the use of stored energy reserves. This pattern quite accurately reflects the seasonal growth of cabbage at this location.

Tomato, a warm-climate plant, also has $\mu_q > \mu_{CO_2}$, but Figure 9 shows that growth for the cultivar examined does not proceed rapidly below about 12–15°C. The values of the mean kinetic temperature in Davis do not reach this level until the first or second week in March. From this time on, tomato can grow for a fraction of the day, but much better growth rates are achieved when the

The dashed vertical line emphasizes the separation of subgenera on the basis of respiratory traits. (After Ref. 44.)

mean kinetic temperature is near 20–25°C. This does not occur until early to mid May. Daily high-temperature fluctuations during mid to late summer in Davis extended into ranges that exceed the optimal values for the growth rate but seldom reach values that exceed the zero growth limit. The growth of this tomato cultivar is well suited to the Davis climate over the season from mid May until the end of August, because the mean kinetic temperature is in a near-optimum temperature range and the temperature extremes generally fall within the allowable range for tomato growth.

Other cultivars of cabbage and tomato may have different patterns of growth-rate responses to temperature. The examples used in this discussion to illustrate detailed patterns of the growth-rate response to temperature have focused largely on a single cultivar or genotype. However, intra- as well as interspecies heterogeneity exist with respect to temperature. An envelope drawn to include $R_{SG}\Delta H_B$ versus temperature curves for the entire population of tomato genotypes would be much broader than the tomato curves of Figure 9, as each plant would have its unique pattern of response to temperature. The broad envelope is indicative of the temperature range for growth and survival of the species.

Patterns of the growth-rate response to temperature and the respiratory parameters defining the growth rate are heritable, and values of respiratory properties are related to plant origin (or climate). Canonical analysis of the respiratory and growth parameters show distinct separations of

species for the two major *Eucalyptus* subgenera based on this respiration rates and their temperature dependence [44] (Fig. 12). A relation between respiration and the limiting temperature has been observed for growth among ecotypes within coast redwood (see Fig. 5). Examination of the respiration rate versus temperature for redwoods collected from locations across the species range, but grown in a common garden, shows high-temperature limits of respiration for each population reflect the climatic temperature at the site of origin [35]. Respiration in plants from northern sites with cooler summer temperatures were inactivated at lower temperatures than those from warmer southern and interior sites. Direct evidence of heritability also comes from recent studies (G.F. Moran, personal communication,) showing defined loci for q, R_{CO_2}, μ_q, μ_{CO_2}, and R_{SG} on quantitative trait loci gene maps of *Eucalyptus nitens*.

Plant distribution studies have been used to develop equations to define seed and plant transfer rules for vigor and survivability [45–48]. Rehfeldt [49] and Sorensen and Webber [50] indicate that ''300 m of elevation is generally proposed as the critical limit of safe transfer of western conifers.'' Although this appears to be a good general estimate, some individuals within a species at a given area may survive a 400- to 500-m increase in elevation quite well but only a 100-m decrease, whereas others may tolerate a larger elevation decrease than an increase. The distribution of individual plant tolerances within a population also determines the consequences of a climatic change on the species. The ability to recognize and quantify the variability in individual tolerances by rapid measurements of q and R_{CO_2} will be valuable for the selection of plants capable of undergoing desired growth responses to meet patterns of climatic change or for transport into new environments.

CONCLUSIONS

Plant growth and distribution are a function of temperature; temperature being one of the key environmental variables that limits survival, growth, and reproduction of plants. The life cycle, morphology, and metabolism of a plant must be matched to the seasonal and diurnal cycles of temperature, and the plant must be able to withstand or avoid unseasonal extremes of temperature in the growth environment. Just as plants have adapted their morphology, they have adapted their metabolism to optimize growth, survival, and reproduction at the average, seasonal, and diurnal temperatures of their environment.

Plant growth is determined by metabolism. Metabolic rates and pathways change with temperature. The plant-growth rate may be limited by a limiting nutrient such as carbon or nitrogen or by the rate at which the plant can process substrates into the structural biomass. The growth rate under any condition must be proportional to the rate of catabolic respiration times the efficiency of substrate carbon conversion. Growth-rate responses to temperature can thus be predicted from measurements of the metabolic heat rate and the respiratory CO_2 rate as functions of temperature.

Temperature limits to growth, both high and low, can be predicted from measurements of the metabolic heat rate and the respiratory CO_2 rate as functions of temperature. Thus, damage from chilling and too high temperatures is initiated by the loss of energy gradients across membranes within the cell. Loss of structure then follows the loss of energy gradients generated by respiration.

The metabolic heat rate and the respiratory CO_2 rate have different temperature dependences in the same sample of tissue. The metabolic heat rate typically increases exponentially with temperature until high-temperature tissue damage occurs. The CO_2 rate typically increases exponentially at low temperature, goes through a maximum, and then begins to decrease before temperatures high enough to cause tissue damage occur. Thus, both the metabolic (i.e., respiration-driven biosynthesis) rate and the substrate carbon conversion efficiency (which is related to the ratio of the metabolic heat rate to the CO_2 rate) change with temperature and the growth rate is closely related to the temperature dependences of the heat and CO_2 rates.

The relation of the growth rate to the temperature dependences of the heat and CO_2 rates can be used to understand how plants adapt their metabolism to optimize their chances for survival, growth, and reproduction at the climatic temperature conditions where they grow. Describing the

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

temperature dependences of the metabolic heat rate and CO_2 rates by their Arrhenius temperature coefficients, that is, μ_q and μ_{CO_2}, respectively, allows definitive statements of the correlation between the metabolism and climate.

Effect of Low Temperatures on the Structure of Plant Cells

INTRODUCTION

Cell ontogeny is considered to be a chain of structural and functional processes that represent changes in cell development from structurally simple to the highly specialized cell types. Plant cell development encompasses three types of processes: (a) new cells are produced by division in meristems, (b) cell growth and enlargement, and (c) cell differentiation into its specialized state.

Cell development is continuous process that is governed by internal and external factors carried out in a certain environment. The pathway of cell ontogeny is changed when the natural environment is distinctly modified. Many processes are interrupted and others only occur in response to particular circumstances. Structural and morphological changes of the cells are the result of the expression of the cell genome under the influence of external factors.

Among the external factors that greatly affect cell development is temperature. A favorable temperature has a positive effect on structural and physiological processes of plant cells. When the temperature is increased or decreased, a harmful effect on the plant cells can be observed.

Different plants distinctly react to temperature fluctuations. Plant sensitivity to the temperature depends on the plant's origin and phylogeny. The effect of temperature on cell ontogeny has been extensively studied and there are reviews elsewhere concerning this topic [1,2].

In this chapter, we have tried to submit the results regarding the effect of low temperatures on the structure of the plant cell. Mutual comparison of existing results and their generalization is not easy, because variable plant species in different ontogenetic phases have been used in the observations. In spite of these difficulties, the plants sensitively react to the low temperatures by changes of their metabolism by adaptive reactions, and therefore its quite tempting to find out how the cell architecture is changed under these conditions.

The temperatures on the Earth's surface are very different, changing during the seasons as well

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

as during the day and night. Despite these differences, plants grow almost everywhere. However, to be able to survive the unfavorable temperatures, plants have to adapt to this oscillation in temperature. Plants are divided into three groups on the basis of their sensibility to the temperature [1]:

1. *Chilling-sensitive plants*: These are seriously injured by the temperatures above zero (usually below 15°C).
2. *Chilling-resistant plants*: These are able to tolerate low temperatures but are seriously injured when ice starts to form in their tissues.
3. *Frost-resistant plants*: These are able to tolerate exposure to very low temperatures (−50–−100°C even when immersed in liquid nitrogen).

Most perennial plants growing in the temperate regions undergo a ''hardening'' process in the autumn of each year to prepare for overwintering. In most agricultural areas, unseasonal frost can occur throughout much of the growing season. During periods of active growth, most crop species do not tolerate freezing. Depending on the minimum temperature and the duration of the frost, plants may be partially damaged or killed, resulting in lower yield and quality at harvest or even complete crop failure. Most winter crops, however, have the ability to develop freezing tolerance when exposed to hardening conditions.

Each plant is characterized by a certain genetically fixed level of resistance to low temperatures, which reduces its metabolic activity. This level of resistance (or survival capacity) can vary among individual plants and species. Low temperatures act as a stress factor that has a strong impact on the growth, reproduction, and distribution of plants. The ability of plants to survive and grow depends on different ecological and physiological mechanisms [1–6].

Since plant metabolism is, in fact, a set of chemical reactions, the effect of cold stress (both chilling and freezing) strongly influences metabolic processes in the cells. These metabolic changes are accompanied by structural alterations of the cells.

CHILLING

Chilling injury can be observed on many plants of tropical and subtropical origin when they are exposed to low, but nonfreezing temperatures, in their chilling range, which is usually from 25 to 10°C [7]. For plants of temperate origin, the chilling temperatures usually range from 15 to 0°C. The chilling effect is manifested by physiological and cytological changes. Depending on the time and temperatures, the cytological changes can be either reversible or irreversible. However, the chilling-sensitive plants are also able to adapt to the chilling if they are hardened a certain amount of time at temperatures slightly above their critical temperatures.

Many light and electron microscopic studies have shown different structural changes of the cells in chilling-sensitive plants after their exposure to a long period of chilling stress [8–11].

Cell Membranes

The cellular membranes are those cell compartments, where the primary events of chilling stress occur [12]. An increase in the permeability of the plasmalemma and leakage of organic and inorganic substances is considered to be the first symptom of cell injury [13]. Light- and electron microscopic observations of tomato cotyledons growing at 5°C for 3 days have revealed the loss of cell turgor, vacuolization of the cytoplasm, swelling, and desintegration of cell organelles [14]. More detailed ultrastructural time-course studies have shown injury of the plasmalemma after 20–24 h. Desintegration of the plasmalemma can be observed after prolonged cold treatment or at lower temperatures [15,16].

During plasmolysis of hardened and nonhardened cells of rape and alfalfa plants, the plasmalemma is pressed against the tonoplast and deleted into the vacuole as sac-like intrusions [17].

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

The similar sac-like invaginations of the tonoplast into the vacuole during the hardening of potato leaves at 5°C can be seen [18].

Chilling of the roots of the tropical plant *Episcia reptans* results in tonoplast discontinuity within 1 h at 5°C and 3 h at 10°C [19]. Two types of crystalline deposits (cytoplasmic and tonoplast-associated) are seen in root cells after chilling stress. Since similar deposits also have been observed in the epidermal, mesophyl, and vascular cells of *Episcia reptans* leaves [20] and on the tonoplasts of potato cotyledons [16], and these deposits closely follow tonoplast disruption, it can be supposed that these deposits probably serve as an indication of cell injury in the plants with increased time of exposure. Although the injury of a majority of the membranes after a short period of chilling is usually reversible, injury of the tonoplast is irreversible [21]. Irreversible injury of the tonoplast may govern the ability of plants to survive rewarming [22].

Frequently, as a result of chilling stress or hardening at low, above-zero temperatures, lipid bodies accumulate in the cytoplasm or in close association with the plasmalemma [23–26].

Plastids and Mitochondria

Swelling of plastid membranes and mitochondria is very a common symptom of chilling temperatures. The harmful effect of these temperatures is mostly time dependent. Chloroplasts from the leaves of *Episcia reptans* chilled for 6 h at 5°C have an irregular and less organized membrane system and fewer plastoglobules. An increase in the exposure time results in both swelling of the chloroplast thylakoids and in a decrease in the size and number of starch grains [20]. After 4 h of exposure at 5°C, injured chloroplasts desintegrated thylakoids can be seen [14]. Full grana desintegration and increasing of the number and size of the plastoglobules can be observed in hardened cucumber leaves after 11 days of chilling. Hardening of potato leaves for 10 days at 5°C causes dilation of the thylakoids and the disappearanse of starch grains [18]. The chilling stress induces the reduction of starch grains and thylakoids in winter wheat and in maize [24,27]. When *Ephedra* cells are cultivated after 15 days at 2°C, the plastids together with the mitochondria are organized into groups. Plastid grana are innumerous and plastids very often contain membrane-free stroma [28].

During transition of poplar xylem ray cells from summer to winter conditions (chilling at 0°C), the amyloplasts are without starch and thylakoid dilation has been observed [29]. Contrary to this result, the long-term hardening of young seedlings of Norway spruce at 3°C increases the content of the starch grains in plastids and the thylakoids are not distinctly dilated. Such plastids possess numerous plastoglobules [23]. The similar accumulation of starch after 8 days of hardening at (5/2°C day/night) has been recorded in chloroplasts of hardy *Solanum acaule* but not in the chloroplasts of less hardy *S. tuberosum* [30].

After the 1-day exposure of *Ephedra* cells to 2°C, the mitochondria have less dilated cristae and their matrix is transparent [28]. Swollen mitochondria with reduced cristae have been observed in chilled onion cells [31], in maize root cortex (Fig. 1) [11], and in both the root and leaves cells of *Episcia reptans* [19,20]. Owing to the mitochondrial swelling in chilled tissues, their volume is doubled in comparison with the mitochondria from the plants grown at a favorable temperature [20]. The first visible symptoms of injury of the mitochondria have been recognized after exposure of tomato cotyledons at temperature 5°C for 4 h [16]. These mitochondria possess a reduced number of cristae and discontinuities in their envelope. Structural alterations of the mitochondria have been seen in the microsporocytes and tapetum of *Rhoeo discolor* exposed to temperatures of 4–5°C for 4 days [32].

No visible changes in the mitochondria have been detected in xylem ray cells of poplar trees at a temperature of 0°C for 14 days [29].

Endoplasmic Reticulum and Dictyosomes

The endoplasmic reticulum of plant cells seems to be very sensitive to cold. After exposure of plants to cold, an extensive dilation and vesiculation of the smooth endoplasmic reticulum cisternae can

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

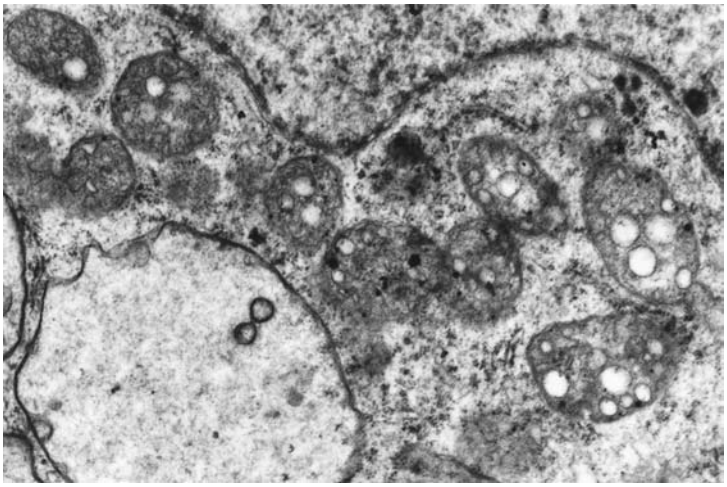

Figure 1 Mitochondria with dilated cristae from maize root cortex cells at 5°C (× 24 000) (From Ref. 11.)

be observed quite clearly, and the profiles of the rough endoplasmic reticulum almost completely disappear. These dilated vesicular endoplasmic reticulum cisternae probably serve as accumulation sites of cryoprotective substances [29].

Prolonged exposure of *Cornus stolonifera* callus cells to 0°C for 12 h results in partial dilation followed by microvesiculation of the rough endoplasmic reticulum and releasing of the ribosomes from the membranes. Vacuolization of the smooth endoplasmic reticulum is visible after 24 h of chilling [21]. Dilation of the rough endoplasmic reticulum without ribosomes has been observed in cooled microsporocytes [32]. The vesicles originating from the dilated rough endoplasmic reticulum without ribosomes have autolytic functions in chilled cells [14,15]. It might be suggested that the transformation of the rough endoplasmic reticulum into vacuolated smooth endoplasmic reticulum represents an early stage of chilling [21].

A strict correlation has been found between the temperature (between 30–5°C) and the volume of the endoplasmic reticulum labyrinths irrespective of the sampling at different hours of the day in five different plant species. The endoplasmic reticulum labyrinth that was extended at 20°C had disappeared completely with the drop in temperature to 5°C [33]. In fact, since the volume and form of the endoplasmic reticulum system in mature leaves fluctuates diurnally in response to environmental factors such as temperature and light, we could suggest a full reversibility of the ultrastructural changes. This shows that the endoplasmic reticulum system is very dynamic; it is probably the most dynamic structure in plant cells [34].

Dictyosemes are cell organelles that also respond to chilling stress by swelling. The swollen dictyosome cisternae occur in tomato cotyledons after 4 h of chilling at 5°C [16] or after 24 h at 0°C in *Cornus stolonifera* cells [21]. Longer exposure to a chilling temperature causes desintegration of the dictyosomes [21,35].

Nucleus

The nucleus of plant cells also sensitively reacts to unfavorable temperatures. Numerous studies of the effect of chilling temperatures from 0 to 4°C on the functional and structural behavior of nuclei in pollen mother and tapetal cells of *Rhoeo discolor* have been done. A short treatment of nuclei with cold does not cause any important changes in the morphology of the nuclei or in DNA synthesis [36]. However, a longer cold treatment considerably reduces both DNA and RNA synthesis [37].

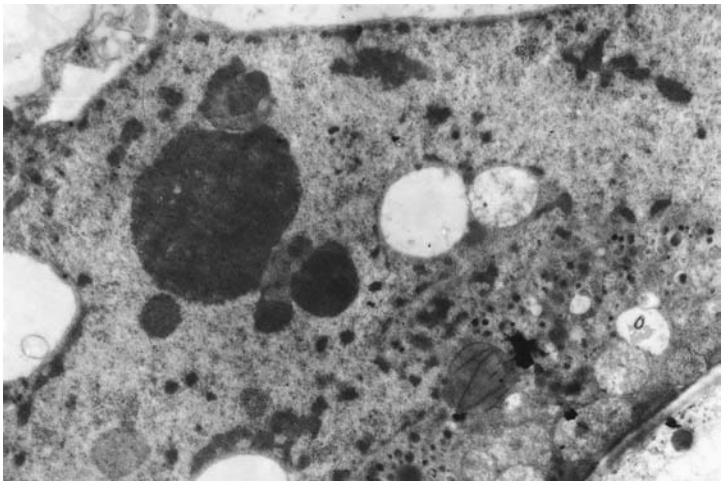

FIGURE 2 Nucleus with a nucleolus, pronounced nucleolus organizer region and nuclear bodies in the nucleoplasm from maize root cortex cells at 5°C (× 18 000). (From Ref. 42.)

Modification of the nuclear structure of plant cells has been observed by both light microscopy and electron microscopy. Lobed nuclei in *Ephedra* cells have been observed after long-time (15 days) exposure to 2°C [28]. The nuclei of other plants respond to a longer exposure to low temperatures by swelling and modification of the nuclear envelope [16,32] and chromatin coagulation [38–40]. Following cold stress at 5°C for 3 days, the nuclei in the root cells of maize contain rather dispersed chromatin and nuclear bodies often occur in the nucleoplasm, and the nucleolar organizer regions are pronounced (Fig. 2) [41,42].

Full nuclear disruption is observed in *Cornus stolonifera* cells and in very sensitive *Episcia reptans* cells after 2 days at 5°C [19,21]. In tomato cotyledons, irreversible injury of nuclei is seen after 20–24 h of chilling [16]. After exposure of wheat cells to the chilling temperatures, the fibrillar zone of the nucleolus is more abundant and the granular zone becomes diffused [39,43]. A high amount fibrillar components can result in the formation of nucleolus-like bodies in the cytoplasm [44] or in the nucleoplasm [11,27,42].

Besides the nuclear structure, the mitotic activity in plant cells also is strongly influenced by low temperatures. A decrease in the temperature from the optimum value to the minimum value (about 1°C) is accompanied by a progressive slowdown of the mitotic cycle as well as of the duration of mitosis. At the temperature of 3°C, for instance, the mitotic cycle in *Vicia faba* root cells may be 22 times longer than at 25°C [45].

Cytoskeleton

According to some investigators, the alterations that occur in the cellular membranes of plants at low temperature can be only a secondary response to the chilling stress. The primary response may be a breakdown of the cytoskeleton. It has been suggested that chilling stress has a direct effect on the microtubules [46], which form a major component of the cytoskeleton, because they have been found to depolymerase during cold treatment [47,48]. Depolymerization of the cortical microtubules at chilling temperatures (0–4°C) has been repeatedly observed in several chilling-sensitive species of higher plants [47] and in various cell types, including the root cells of maize [49], the guard cells of onion [50], the suspension culture cells of maize [51], and protoplasts isolated from tobacco [52].

In experiments with cucumber cotyledons, it has been found that treatment with antimicrotu-

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

bular drugs makes the chilling worse, whereas treatment with abscisic acid protects cotyledons from drug effect and chilling injury [53].

There is a connection between chilling of the cytoskeleton and the inhibition of cytoplasmic streaming. The chilling temperatures can influence the equilibrium of Ca^{2+} and ATP, which is connected with F-actin activity [8,9,54]. Actin filaments have also been found to be involved in cold-induced conformational changes and the reorganization of the endoplasmic reticulum [33,35]. These results indicate that low temperatures (4–0°C) most likely influence either the interaction of the force-generating system, probably myosin, with actin filaments or the force-generating mechanism of the actomyosin-driven intracellular movement, but they do not affect actin-filament integrity [55].

The effect of low, nonfreezing temperatures on the plants also is visible at anatomical and morphological levels. These aspects are connected mainly with the adaptation reactions of less chilling-sensitive and cold-resistant plants (like winter cereals) to growth at low temperatures. Such anatomical and morphological changes like altered stomatal frequency [56], decreased epidermal cell size [57], increased mesophyll cell size, and suberinization [56,58] are associated with acclimation of plants to nonfreezing temperatures.

From the above-mentioned results, it is obvious that the extensive and variable structural reactions of cell compartments are the response to chilling temperatures. According to Wang's scheme of the responses of sensitive plants to the chilling-stress alteration of cellular structures are only one of many secondary responses [18]. The primary response is an alteration in the cell membranes—a physical phase transition of membranes from the liquid-crystalline to the solid gel state [12].

FREEZING

Generally, freezing in plants consists of the conversion of liquids in cells to a solid state, which is accompanied by loss of heat. Two types of freezing occur in plant cells and tissues: (a) vitrification—solidification of the cellular content into a noncrystalline (amorphous) state and (b) crystallization—arrangement of liquid molecules into orderly structures [59]. Vitrification of liquids in cells is a result of rapid freezing (more than 3°C/min) of plant tissues to a very low temperature. It is enhanced by hardening of plants at low temperatures. Although vitrification does not occur in nature, it is of great interest to researchers, because it enables plants to survive temperatures close to absolute zero [3].

On the other hand, crystallization (or ice formation) is a very common phenomenon in nature. The crystallization of ice may occur either within or outside the cells, but the process depends on the speed of cooling. The formation of ice inside the cells may occur by both internal nucleation or by penetration of external ice crystals into the cells [60]. In both cases, this type of freezing, also called intracellular, is lethal because of the immediate disruption of the cells. Only in the case of cells that exhibit deep supercooling may there be an exception to this rule [61,62]. Plant cells can also survive intracellular ice formation when the ice crystals that form by freezing are very fine, cooling is extremely rapid, and these crystals melt before they reach a harmful size [63].

There are three types of intracellular ice formation in the epidermal cells of onion plants at high-speed of cooling [64]: (a) Ice formation spreads from cell to cell through the plasmodesmata Freezing from cell to cell is observable on the *Tradescantia* staminal hair cells [65] and in mesophyll cells of Norway spruce during the winter frosts [66]. (b) Less frequently, ice can be formed in the cell walls adjacent to the intercellular spaces. Ice arises first in the plasmolyte between the cell wall and cytoplasm and then rapidly in the cytoplasm. (c) Intracellular ice originates spontaneously from centers of nucleation within the cytoplasm and later in the surrounding plasmolyte.

If the speed of cooling is slow enough (in nature, the cooling rate seldom exceeds 1°C/h), the liquids in the cells freeze extracellularly, causing cell dehydratation of cytoplasmic solutes and a reduction in cell volume and surface area, all factors which can potentially damage the cells irreversibly [5]. Ice formation for most plant tissues begins on the surface of the cell walls, in water

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

transport elements, or on external surfaces [62,67]. Although the cooling is slow and the plasmalemma remains intact, ice formation will be confined outside of cells [68].

There are two major strategies allowing plants to survive freezing stress: freezing tolerance and freezing avoidance [2]. Tissues displaying freezing tolerance respond to freezing stress by the loss of cellular water to extracellular ice, resulting in collapse of the cell. As a consequence, an increased concentration of the cell sap and a lowered freezing point will occur. In plants displaying second-strategy–freezing avoidance, tissues exhibit deep supercooling, in which cellular water is isolated from the dehydrative and nucleating effects of extracellular ice [69].

The formation of ice in tissues and the appearance of frozen plant cells is well documented, mainly in studies employing light microscopy [3,65]. Descriptions of frozen cells at the electron microscopic level also have been done [70,71].

Cell Membranes

As already mentioned [68], functionally intact cell membranes are an effective barrier to the propagation of ice; however, this barrier may vary depending on the temperature or cold hardening [72,73]. Although the mechanisms involved in plant cold acclimation and frost injury are extraordinarily complicated, the freezing and thawing of cellular water have been found to be basic elements of freezing injury in plant tissues [60]. It has been established that the cellular membranes are more susceptible to freezing damage than soluble enzymes. The plasma membrane seems to be the most susceptible and, therefore, it has been identified as the major site of lethal injury [74].

Leakage of ions from thawed tissues is a common phenomenon of freezing injury. The leakage is usually considered the consequence of the loss of membrane semipermeability or membrane rupture by freezing injury. However, observations on onion epidermal cells have shown that freezing injury does not result in membrane rupture or complete loss of semipermeability. These results indicate that freezing injury is due to a specific alteration in the membrane semipermeability to K^+, and secondary effect is protoplasmic swelling [75].

There are numerous studies dealing with the physiological and biochemical changes occurring in membranes during the freezing and cold hardening processes, respectively [6,74–80] but observations regarding alterations in the cellular membranes are rather insufficient [63,70,81–83].

Isolated plant protoplasts make an excellent model system to study destabilization of the plasma membrane after freezing stress. The using of protoplasts has shown that destabilization manifests in various ways: by intracellular ice formation, by loss of osmotic responsiveness, or by expansion-induced lysis [73]. If cellular membranes are the site of freezing injury, then cellular alterations during cold acclimation that allow the cells to survive freezing also will appear in membranes [77].

Cold acclimation involves chemical and structural alterations of the plasma membrane to resist freeze dehydration, mechanical stress, molecular packing, and other events caused by extracellular freezing. Cytological changes associated with an abrupt increase in hardiness occur at 0 or $-3°C$ within 7–10 days. However, these cytological changes may be indirect.

From studying the reaction of the plasmalemma to freezing, it is obvious that this cell membrane is very sensitive to this type of stress. Observations on *Robinia pseudoacacia* have revealed a seasonal transition in the plasmalemma from a physical state of relative smoothness and regularity in summer to a highly folded state in winter. It is considered that a highly folded membrane state would facilitate water flow and alleviate the stresses of contraction and expansion during freeze-thaw cycles [84]. However, the plasma membrane of the cortical cells of mulberry twigs in winter is relatively smooth, and highly folded states have not been observed. Only after cold acclimation in October at 0 for 20 days or $-3°C$ for 7 days, when hardiness increased from $-15°C$ to $-70°C$, was the plasma membrane highly folded and microvesicles with a double lipid layer membrane appeared in the peripheral cytoplasm. These microvesicles originate from the endoplasmic reticulum. A very similar ultrastructure has been observed in the cold-acclimated cells collected at the end of autumn. In April, at a decreased hardiness of $-15°C$, the plasma membrane is already smooth and regular. When these dehardened cells are rehardened at 0°C for 10–15 days, the hardiness increases,

the plasma membrane becomes folded, and microvesicles reappear near the periphery of the cytoplasm. From these results, it appears that a highly folded state of the plasma membrane and the formation of numerous microvesicles represent a transition associated with higher freezing tolerance rather representing a special membrane structure characteristic for extremely hardy cells in the winter state [85].

Formation of osmiophilic regions associated with the plasmalemma has also been observed. Substantial regions of the plasmalemma bilayer are transformed into either amorphous, osmiophilic or densely packed regions or into multilayered structures with high surface curvatures [86,87]. Deep invaginations of the plasmalemma and formation of electron-dense deposits outside the plasmalemma in the xylem parenchymal cells occur in peach and oak trees in a frozen state at −10°C [69]. We have observed similar changes of plasmalemma in the mesophyll cells of silver fir [88] and numerous electron-dense lipid bodies associated with the plasmalemma in the mesophyll cells of Norway spruce during winter when the frost resistance of these species is very high [66]. Augmentation of lipidic globules and their localization in the cytoplasm along the plasmalemma apparently results from the changes in the lipidic part of membranes during the freezing treatment [89].

It has been found [72,90] that osmotic shrinkage of protoplasts isolated from *Secale cereale* results in an irreversible decrease of the surface area of the plasmalemma concurrent with the formation of endocytotic vesicles. The present observations of in-turning of the plasmalemma together with vesicles in the cytoplasm may lend support to the idea the reduction of the plasmalemma surface area and the reduction of the volume of the protoplast through dehydration occur as initial responses to slow freezing [91].

Most microscopic investigations report changes in the plasmalemma, and sometimes the tonoplast, which can be correlated with the deletion of the membrane into vesicles as the cell volume is reduced by dehydration [17,72,90,91].

An increase in the intramembranous particles and plasmalemma invaginations has occurred in the more frost-resistant *Chloromonas* cells, whereas in the frost-sensitive *Chlamydomonas cells*, they are absent [92]. A higher frequency of osmiophilic globules in acclimated (−25−−30°C) isolated protoplasts of *S. cereale* have been found than in nonacclimated (−3−−5°C) protoplasts. Osmiophilic regions observed under transmission electron microscopy corresponded to the extrusions of the surface of acclimated protoplasts observed under scanning electron microscopy (EM) [73].

Scanning EM observations on apple parenchyma cells have revealed similar copula-shaped protrusions on the surface membranes. The protrusions are associated with the fibrillar formations of exoplasm. It is clear that mechanical breaks of the membrane may arise on the plasmalemma near protrusions under stress conditions of freezing. It can be supposed that plasmalemma instability zones are formed under freezing stress connected with protoplast compression under dehydratation, whereas protrusions themselves consist of structural lipids of higher unsaturation. Intracellular processes leading to the membrane stabilization are evidently related to condensation of polyphenols, which makes cell resistance under stress conditions at super-low temperatures essentially higher [93].

If plants are nonacclimated or the freezing stress is very severe, disruption of the plasmalemma and cell organelles and the collapse of the cell wall with the protoplast can occur [26,91,94]. On the basis of present results, the plasmalemma is the most injured membrane during the freezing-thawing process [95,96]. If the plasmalemma is considerably damaged, its protective function against quick dehydratation of cells or penetration of ice into cells can be replaced by parallel layering of the endoplasmic reticulum [95].

Endoplasmic Reticulum

The endoplasmic reticulum is a structurally and functionally highly dynamic part of the endomembrane system of plant cells. The response of the endoplasmic reticulum is immediate at the low temperatures, which is accompanied by shift of its structure and space organization in the cells.

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

One of the specific features of wintering plants is the absence of rough endoplasmic reticulum (ER) in the cells. This type of endoplasmic reticulum, observed in the cortical cells of apple during the growing season, at freezing temperatures in winter becomes sparse and replaced by vesicular endoplasmic reticulum [97]. The cells enriched with numerous tubular and vesicular smooth endoplasmic reticulum cisternae have also been observed in ray parenchyma cells of poplar. These smooth endoplasmic reticulum cisternae are the most characteristic components of cells in the winter stage, and they are suspected to be the site of sugar accumulation [98]. In the cells that survive freezing temperatures by a deep supercooling mechanism, the presence of tubular endoplasmic reticulum is a feature of dehydratation tolerance [99].

The ultrastructural study of such extremely cold hardy cells as cortical parenchyma cells of mulberry collected in winter has shown that initiation of freezing at 5°C results in the formation of multiplex lamellae that completely cover the area in the vicinity of the plasmalemma. The multiplex lamellae are produced by fusion of preexisting vesicular ER via a reticular network. The complete multiplex lamellae are composed of a parallel array of sheet-like ER cisternae. The formation of multiplex lamellae on the initiation of freezing is largely dependent on seasonality in close association with the development of freezing tolerance [100].

Parallel layering of endoplasmic reticulum sheets has been found in various plant tissues. The phenomenon has sometimes been associated with different types of stress, for example, water deficiency [101], freezing [95], and anaerobic conditions [102,103].

Examples of stacked endoplasmic reticulum were also found in the dormant buds in potato and in several other species, mainly trees, species, such as *Betula* [104], *Sorbus, Querous, Fraxinus* [104,105], *Rhododendron* [106], and *Salix* [107]. The stacking of endoplasmic reticulum disappears in spring in association with the breaking of dormancy. In a study of dormant *Tilia* buds, using freeze-fractured material, no concentric layering of the endoplasmic reticulum was observed, but an extensive network of endoplasmic reticulum close to the plasmalemma was found [108].

The groups of stacked endoplasmic reticulum cisternae have been observed in cells of wheat seedlings at −10°C, whereas at −30°C, endoplasmic reticulum has been present in the form of numerous vesicles and sacs [109]. The presence of numerous vesicles and cisternae of smooth endoplasmic reticulum close to the cell wall is considered to be a characteristic feature of frost-resistant cells [70,84,95,110]. The occurrence of the concentric type of rough endoplasmic reticulum in frozen cells is an adaptive mechanism protecting ribosomes against injury by low temperature [35].

In most cases, the stacking of the endoplasmic reticulum is reversible. The stacking observed in dormant buds is possibly a consequence of water stress in buds during winter conditions, although an effect of low temperature [35,83,111] or anaerobic conditions [102,103] cannot be excluded.

A striking increasing of the number of cisterna-like cytoplasmic membranes has been observed after ice encasement of winter wheat seedlings. The imposition of an ice cover results in the proliferation of the endoplasmic reticulum membrane system in the cells and in the formation of concentric whorls of membranes that often enclose cytoplasmic organelles. It has been suggested that these membranes are the consequence of the reorganization of preexisting membrane components, possibly vesicular endoplasmic reticulum [112,113].

Many studies on numerous plant species have shown that the formation of parallel and concentric layering of endoplasmic reticulum cisternae can by induced by different types of stress, and therefore it might be suggested that these configurations are a manifestation of an adaptive mechanism protecting the cells and of repairing processes within stress-damaged cells [112].

The endoplasmic reticulum is considered to be the locus of membrane biosynthesis and is intimately involved the turnover of plasma membrane components. Thus, the endoplasmic reticulum plays an important role in membrane transformation during cold acclimation.

Vacuole

The vacuolization of the cytoplasm is a very important phenomenon, and it is often described as a structural reaction of cells to freezing. Reversible splitting of the large central vacuole into many

smaller ones has been observed in many plants; namely, woody species. At the beginning of cold acclimation of peach stem tissue, the cells have their typical architecture—a large central vacuole and a thin band of peripheral cytoplasm—but with continuing cold acclimation, distribution of the cytoplasm gradually becomes more homogeneous—the nucleus is located centrally and many small vacuoles appear in the case [69]. Splitting of the central vacuole has been recorded in the mesophyll cells of *Pinus cembra* and *Picea excelsa* after the first autumn frosts [114], and in the phloem cells of *Metasequoia glyptostroboides* [115], and in the mesophyll cells of Norway spruce and silver fir during winter [66,88].

A dense and extensive cytoplasm containing numerous small vacuoles is characteristic for winter-hardy cells. Cell vacuoles contain a variety of lytic enzymes, such as protease, acid phosphatase, ribonuclease, carboxypeptidase, aminopeptidase, invertase, hydrolase, and ATPase. Autophagic activity of the vacuoles after severe cold injury has been observed in many plant cells, which results in the digestion of cytoplasmic structures and the reorganization of distinct cytoplasmic organelles. The release of protein-toxic vacuolar substances results in frost injury of spruce needles due to loss of cell compartmentation and concomitant flooding of the cell interior [115]. The functional stability of the tonoplast, therefore, can play an important role in the frost resistance of spruce needles.

Seasonal changes in the vacuole from winter to spring in mulberry cortical cells consist of an engulfment of the tonoplast, fusion and inflation of small vacuoles, and coalescence into larger vacuoles [84]. Similar findings have been seen in the mesophyll cells of both Norway spruce and silver fir [66,88] and in the leaves of the evergreen species *Aucuba japonica* and *Prunus laurocerasus* [26]. With the fall in temperature the central vacuole splits into smaller ones forming small vacuoles in the cytoplasm. This phenomenon occurs, at temperatures below zero. Decay of the central vacuole to small vacuoles is an adapting mechanism of the plants to low temperatures in autumn and in winter. It is a feature of hardening of the plants against low temperatures and is accompanied by the loss of water from the cells. This process of adaptation is reversible. With increasing temperatures in spring, the central vacuole is differentiated again by the fusion of small vacuoles. It appears that such intracellular digestion from winter to spring plays an important role in the adaptation of plants to changing environmental conditions [116].

On the other hand, although the splitting of the central vacuole is also observed in other woody trees (e.g., *Sambucus* and *Betula*), at temperatures of −30–−50°C, this phenomenon can be considered the consequence of a decrease in frost resistance [95,110]. A decrease of frost resistance in the cells of *Robinia pseudoacacia* also results in the degradation of cell membranes, including the tonoplast [117].

Vesiculation of the tonoplast into the vacuole may represent a similar mechanism (like vesiculation of the plasmalemma) for the reduction of the surface area of the tonoplast and the volume of the vacuole. Observations using osmotically manipulated isolated cells of *Brassica napus* and *Secale cereale* support this assumption [17].

Chloroplasts

The response of chloroplasts to low-temperature stress depends on the temperature and hardening capacity of a particular species. Numerous data from some extremely hardy conifers and from a few moderately frost-resistant herbaceous plants indicate variable changes in the chloroplast membranes in different species [118]. For instance, coniferous species tolerate temperatures at around −40°C (and lower), whereas moderately frost-resistant plants such as winter annual herbs and grasses are killed at −10–−15°C.

It is often assumed that the chloroplasts are the cell organelles most sensitive to low temperatures [35]. Observations of three grass species have been shown that the transition from 25°C to low-temperature conditions (10°C, 0°C, −5°C) causes swelling of chloroplasts in mesophyll cells at 0°C. Dilatation of thylakoids has occurred at −5°C. Similar structural changes of chloroplasts and the disappearance of starch grains were observed in the mesophyll cells of *Sorghum* and *Paspalum* [119].

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

During the growing season, the chloroplasts in the mesophyll cells are of oval shape and are placed in the cytoplasm along the cell wall. In the winter when the temperature goes down, the chloroplast architecture is altered, but to what extent depends on the plant species and its physiological state. The onset of the hardening process of winter rape leaves grown under field conditions in autumn (above-zero temperatures) causes some modifications in the cell membranes; however, the chloroplasts still have their typical oval shape, the stroma is filled with ribosomes, starch grains, and tiny osmiophilic globules, and a well-developed membrane system can be observed. In winter (temperatures −5–−10°C), the chloroplasts are clumped into groups, the thylakoids and grana are swollen, and the chloroplast envelope also is damaged. There are no starch grains in the stroma, but many osmiophilic globules are present. After rewarming during the spring, the structural recovery of the chloroplasts can be observed [96].

The comparison of three varieties of winter wheat with different levels of frost resistance has shown that, after the first stage of hardening, all investigated varieties have chloroplasts with well-developed membranes. During the second stage of hardening at −16°C, loss of starch and swelling of the thylakoid membranes are seen. At the same time, in the case of plants with lower frost resistance, the chloroplast membranes and also other organelles are injured lethally [116]. The chloroplasts of resistant wheat varieties change their shape during the hardening and retain their individuality, but during winter, they are clumped together [120]. On the other hand, cold acclimation of rye does not induce any substantial changes in the structure of chloroplasts.

A 1-day exposure of nonacclimated hybrid wheat plants to a temperature of −4°C does not induce morphological changes in chloroplasts, whereas a 1-day exposure to a temperature of −8°C results in the degradation of the chloroplasts and their gathering into groups [81].

According to the position of chloroplasts in the cells during freezing stress, plants can be divided into two groups: (a) the chloroplasts retain their integrity but migrate from a summer position near the cell wall to a crowded position in the cell center and (b) the chloroplasts agglutinate, lose their integrity, and merge with each other to become a continuous mass from which the chloroplasts separate again when spring approaches [3].

Hardening of winter wheat causes the preservation of the chloroplast structure and membranes during the freezing period and recovery of their functional activity after thawing [121]. These adaptative alterations in the chloroplast membranes during hardening are probably the result of changes in their lipid composition [122].

The correlation of the chloroplast ultrastructure and membrane lipid composition to the different degrees of frost resistance in leaves of ''moderately hardy'' spinach, ''very hardy'' ivy, and ''extremely hardy'' spruce have shown characteristic differences with respect to changes in the lipid composition and chloroplast structure during adaptation to subzero temperatures [123]. In spinach leaves, there is no increase in the total lipids, whereas the membrane lipid content in ivy leaves and spruce needles increases considerably. A striking shift from saturated to unsaturated fatty acids can be detected in ivy and spruce chloroplasts. This increase in the lipid content is related to the increase in the chloroplast envelope surface resulting from the formation of many protrusions and invaginations that occur during cold hardening [123,124].

Much attention has been focused on the seasonal changes of the chloroplasts in woody plants, especially in evergreen species. The studies have been on evergreen broadleaf woody plants, of which frost resistance is considered to be that of between the above-mentioned moderately hardy plants and the extremely frost-resistant conifers [118]. Unlike later studies, in earlier observations, the substantial changes in the chloroplast structure in the leaves of broadleaf evergreen woody species that occurred during the year were found [125,126].

Contrary to these results, the observations on broadleaf evergreen woody species such as *Aucuba japonica* [127], *Prunus laurocerasus* [128], *Skimmia japonica* [129], and *Mahonia aquifolium* (unpublished observations) have revealed remarkable changes in the chloroplast structure occur during the year. In summer, the chloroplasts are oval shaped, they are placed along the cell walls, and their inner architecture is the same as in other higher plants [130]. At this season of the year, this position of the chloroplasts and the presence of starch granules in them are typical.

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

In autumn, the originally lens-shaped chloroplasts of *Aucuba* and *Skimmia* become globular and move gradually from the cell wall to the center of the cell. The chloroplasts of *Prunus* and *Mahonia*, which are more frost resistant than *Aucuba* and *Skimmia*, are still positioned at the cell wall. At this season of year, no starch grains have been observed in the chloroplasts of the plants studied [131].

In winter, the chloroplasts of *Prunus* are still distributed along the cell wall, whereas the chloroplasts of *Skimmia* and *Aucuba* create irregular formations in a different part of the cell. The well-developed membrane system with the signs of slight dilatation can be observed. The membrane system of the chloroplasts is often located in one part of chloroplast, leaving only membrane-free stroma in the other part (Fig. 3). In the chloroplast stroma, a small group of plastoglobules are present and no starch grains are visible.

A characteristic feature of the mesophyll cells of all these species in the spring is the presence of a large number of starch grains in the chloroplasts. Because of this, the plastid shape becomes irregular. These irregularly shaped plastids represent an atypical stage within the plastid ontogenesis chloroamyloplasts [130]. The increased presence of starch in the plastids during the spring is not only typical of broadleaf species. The same large content of starch also is observed in the cells of *Abies alba* and *Picea abies* [23,88]. Reports have confirmed that the plasticity of the chloroplast membrane system enables the cell to overcome unfavorable conditions during the winter.

Mistletoe is well-known semiparasitic plant in which its leaves exhibit a high level of frost resistance. We have not found any striking differences in the ultrastructure of *Viscum* chloroplasts in the winter and summer. In the winter, green leaves possess chloroplasts of oval to elongated shape. The plastid envelope is smooth with no signs of plastid protrusions. The thylakoid system of the chloroplasts is composed of numerous grana and stroma lamellae. Both the stroma lamellae and marginal thylakoids of grana show signs of slight dilation. The membrane system remains well differentiated even at a temperature as low as 7°C. The chloroplasts are regularly sheathed by membranes of the endoplasmic reticulum during the summer, but in the winter, these membranes are fragmented into vesicles of variable shape and size (Fig. 4) [132].

Extensive studies of seasonally and experimentally induced changes in the chloroplast ultrastructure have been done on conifers; for example, on Norway spruce needles [133] and pine needles [134]. The chloroplasts of conifers respond to cold acclimation and freezing by extensive changes in their architecture and localization in the cells. Generally, the chloroplasts of conifers respond to

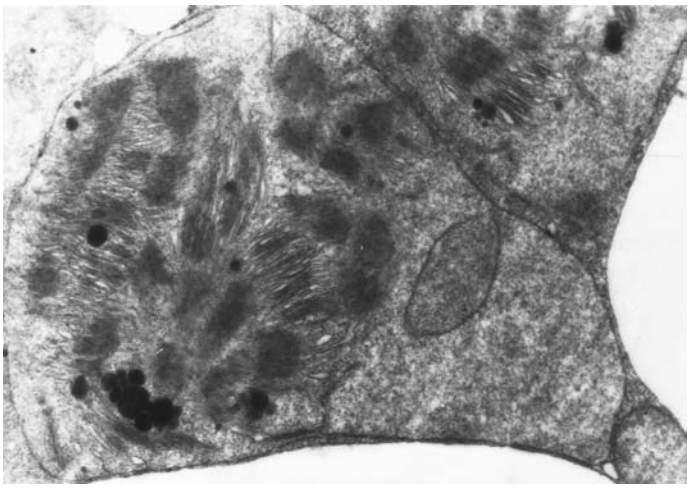

FIGURE 3 Chloroplast of *Aucuba japonica* in winter with membrane free stroma and slight thylakoid dilation. (×22 000). (From Ref. 127.)

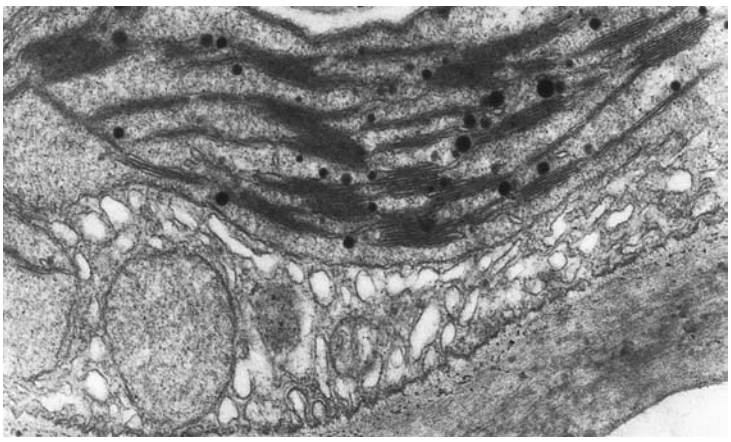

FIGURE 4 Mistletoe chloroplast with an extensive fragmentation of endoplasmic reticulum into vesicles at −7°C (×19 000). (From Ref. 132.)

low temperatures mainly by a reduction of the starch content, with an increase in the number of osmiophilic globules and of membrane-free-stroma, and by swelling of the chloroplasts and their aggregation in one part of the cell [134].

When the needles of Norway spruce are both artificially and seasonally frozen, the thylakoids are dilated and the starch disappears. The chloroplasts are tightly pressed together at one side of the cell or they move toward the cell center around the nucleus [23,66,133,135]. Similar studies have been done on white spruce [126], balsam fir [136], and Scotch pine [135].

The significant presence of numerous starch grains, the thylakoid system has been recorded in the chloroplasts of all investigated evergreen species in the spring when the chloroplasts are again less frost resistant. This, so-called ''spring starch'' serves as a source of energy for the growth processes in this period [127,128,133]. On the other hand, the disappearance of the starch from the chloroplasts during cold acclimation is a typical reaction of both broadleaf and coniferous evergreen species [126,133], as well as of the cells cultivated in vitro on a decrease in temperature [23,137]. The hydrolysis of starch is one of the basic physiological mechanisms for the increase in the frost resistance of plants [138].

Nucleus

Although the nucleus, because of its regulation of cell metabolism is considered to be the cell organelle most resistant to the nonlethal effect of low temperature [139], there are not many studies concerning its structural response to freezing stress and to the process of developing frost resistance. The nuclei in the cells of black locust bark become more dense during cold acclimation in the autumn [140]. The nuclei of the acclimated cells in the shoot apex of rhododendron plants are ovoid and contain relatively large nucleoli and little heterochromatin, or they are irregularly shaped with small protruding lobes or nucleoplasmic extensions [106]. In the cortical cells of apple [97] at the stage of cold acclimation, each nucleus contains relatively lower amounts of heterochromatin and is located in the central part of the cell.

The cooling of tobacco cells to −10°C induces the formation of numerous small vacuoles in the nucleus [141]. Similar vacuolization of nuclei also have been observed in the cells of wheat leaves at −4°C after 8 days of freezing, whereas in the nuclei exposed to −12°C, vacuoles already occur after 1 day [81].

The second step of wheat hardening at −16°C results in folding of the nuclear membrane

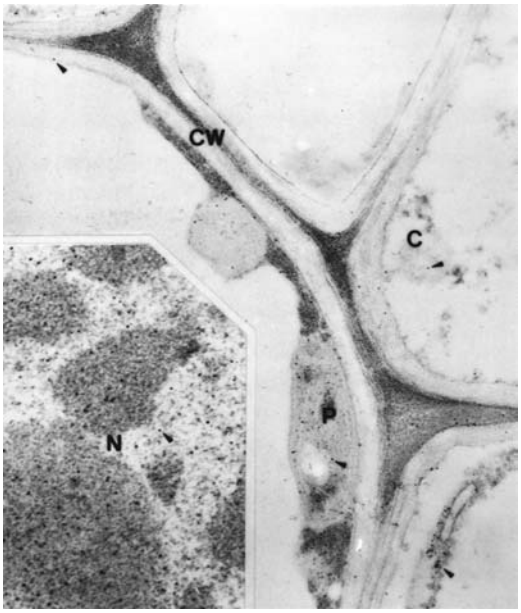

FIGURE 5 Epitops of abscisic acid in the nucleus (inset) in the pea epicotyl tissue from the seedlings grown for 2 days at 25°C and then 7 days at 2°C. (×34 000) (From ref. 144.)

and condensation of the chromatin [116]. Heterochromatin condensation seems to be a common reaction of the nuclei to a freezing temperature both in perennial grasses [81,82,142] and in woody plants [66,143]. In the mesophyll cells of spruce, in addition to nuclei with condensed heterochromatin, large nucleoli and a changed nuclear membrane also occur during winter at −10°C–−15°C [66]. During the winter, the nuclei move to the central portion of the cells and are surrounded by aggregations of the swollen chloroplasts. The movement of nuclei toward a central position in the cortical cells of apple during cold acclimation also has been observed. The gathering of plastids around the nucleus begins in late November when the temperature drops to −20°C [97]. The aggregation of the chloroplasts around the nucleus is a phenomenon associated with the winter metabolism of the cell and is a characteristic feature of the most frost-resistant species [125].

Owing to its regulatory role in plant metabolism the nucleus also is involved in the process of hardening, and it is known that abscisic acid considerably affects frost hardening. Using an electron microscopic immunohistochemistry method in which gold-conjugated antibodies recognized abscisic acid (ABA) has proved the presence of ABA epitopes in the nuclei in pea tissues during cold acclimation (Fig. 5) [144]. This finding supports the idea that hardening is governed by nucleus through abscisic acid activation. However, there is no comparison between the accumulation of abscisic acid and the structural changes (i.e., the occurrence of heterochromatin) in the nucleus of pea tissues [97].

Mitochondria

The mitochondria are the primary sites of intermediary metabolism in the cell, and therefore they are an excellent means to study of the plant response to the changes in the environment [145]. The alterations of the mitochondrial membranes directly influence the process of cell respiration.

Decreasing the temperature in the environment is accompanied by a decrease in the number of mitochondrial cristae. The mitochondria in the cortical cells of woody species have well-devel-

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

oped cristae and an electron-dense matrix at favorable temperature conditions. The fall in temperature in winter results in the reduction of the cristae and the matrix becomes electron transparent [85,95,110]. Swollen mitochondria and a reduction in the number of the cristae or their atypical orientation in the cell have been found in the dormant buds of *Salix* in early winter [107] and in the shoot apex cells of *Rhododendron* [106].

The reaction of herbaceous plants to freezing stress is similar to that seen in woody species. The mesophyll cells of winter rape in October at a temperature −6°C possess mitochondria with a reduced number of cristae and low electron density of the matrix. In December, when the cells are highly injured (about 80%), the mitochondria are hardly visible because of their changed structure in the strongly vacuolated cytoplasm. However, after 48 h recovery of the conditions the swollen mitochondria are able to rebuild their membrane system [96].

Well-developed mitochondria are present in rye mesophyll cells at 5°C, but in the cells of both cold-acclimated and cold-nonacclimated rye plants slowly frozen to −12°C, the mitochondrial cristae are strongly disorganized [91,146]. No significant differences in the respiration of the mitochondria in the extracellularly frozen cells of both acclimated and nonacclimated rye seedlings have been detected [147]. It can be concluded that the mitochondria in situ retain normal function even after the cells have been killed by extracellular freezing. However, reports have shown that the mitochondria of rye leaf cells frozen in situ are much more susceptible to frost injury than the chloroplasts [91,146].

Dictyosomes

The dictyosomes are the cell organelles which are metabolically very active in such cell functions as protein sorting and membrane formation. Abundant dictyosomes, usually composed of four to seven cisternae with numerous vesicles originated from their ends, are a common feature in the cells of different species not only during growth season but also during cold acclimation [97,106,148].

The presence of dictyosomes in poplar cortical cells in September is common. The number of dictyosomes decreases with the fall in temperature in October, and their level continues to the decreased on until the next spring [149]. Since some vesicles generated from dictyosomes are confined to the surface of protein-lipid bodies, dictyosomes might be involved in their formation as well as other organelles. During cold hardening, the cells of *Arabidopsis thaliana* contain more microvesicles that are either associated with the dictyosome cisternae or located in their vicinity. The dictyosomes probably take part in the structural and conformational modification of the plasmalemma [150]. In mulberry parenchyma cells, the dictyosomes secrete numerous vesicles and some of them are located beneath the plasmalemma during slow freezing at −5°C [100]. It may be possible that these secretory vesicles might participate in the formation of the multiplex lamellae that are very often found during slow freezing in mulberry cells.

In spite of the frozen state of tissues, the dictyosomes in the cells of woody plants can be occasionally identified in their original form. There is evidence [97] that in mid November, when the cortical cells of apple survive freezing at a temperature −20°C, the dictyosomes are still active and they produce vesicles. In late January, when the cells are hardy to a temperature of −30°C, dictyosomes can be observed, but they are not active. Similar alterations in the dictyosome ultrastructure and their localization in the cell have been observed in the cortical parenchyma cells of mulberry twigs [85], in the xylem ray parenchyma cells of *Prunus persica* [69], and in bark tissue of *Robinia pseudoacacia* [84].

Cytoskeleton

The cytoskeletal components take part in many structural and functional processes in the plant cell; for example, cytoplasmic streaming, secretory and transport processes, cell division, cell polarity, and stability of the cell size. For this reason, cytoskeletal elements may play an important role in the cell response to different stresses, including low-temperature stress. The altered stability of the

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

cytoskeletal elements at low temperatures has been recognized in different plant species. Cold-induced depolymerization of microtubules at temperatures below 0°C has been observed; for example, in the cells of onion [48], cotton [151], spinach [152], garlic and winter wheat [153], and rye [154,155].

The existence of both cold-labile and cold-stable microtubules in the root cells of onion has been reported [48]. It is suggested that the cold stability of microtubules is related to the cold hardiness of the plant [153]. However, although the plant cells respond to cold hardening by altered stability of the microtubules, the lack of consensus regarding a positive correlation between cold acclimation and the cold stability of microtubules still prevails [152–154].

The effect of cold acclimation on cortical microtubule stability during freezing has been studied in cold-acclimated and cold-nonacclimated rye leaves [155]. The experiments have shown that unchanged microtubule arrays are still present in cold-acclimated leaf cells after a −4°C temperature treatment, whereas microtubules are shorter and less abundant in the leaf cells of nonacclimated plants and in the root cells of both cold-acclimated and cold-nonacclimated plants. After a −10°C temperature treatment, the cortical microtubules are almost totally depolymerized in both types of root cells and in the leaf cells of nonacclimated plants, whereas cold-acclimated leaf cells constantly have abundant cortical microtubule arrays. Semiquantitative analyses of the cortical microtubules of protoplasts have confirmed the findings with intact leaf cells. These experiments have shown that the cortical microtubules of nonacclimated leaf cells are cold labile and that cold acclimation induces cold-stable microtubules in leaf cells as well as in protoplasts (Fig. 6) isolated from cold-acclimated leaves [155].

A similar cold stability of microtubules has been found in cold-acclimated garlic and winter wheat cells [153]. The above results suggest that the cells need to have enough long cortical microtubules to keep their plasmalemma intact and responsive to the osmotic changes caused by subzero temperatures. Under these stressful conditions, the microtubules may serve as a necessary support for the plasmalemma [155].

It has been found that, besides the microtubules, the actin filaments play a role in the cell response to cold treatment. The crucial role of microtubules and/or microfilaments in the movement

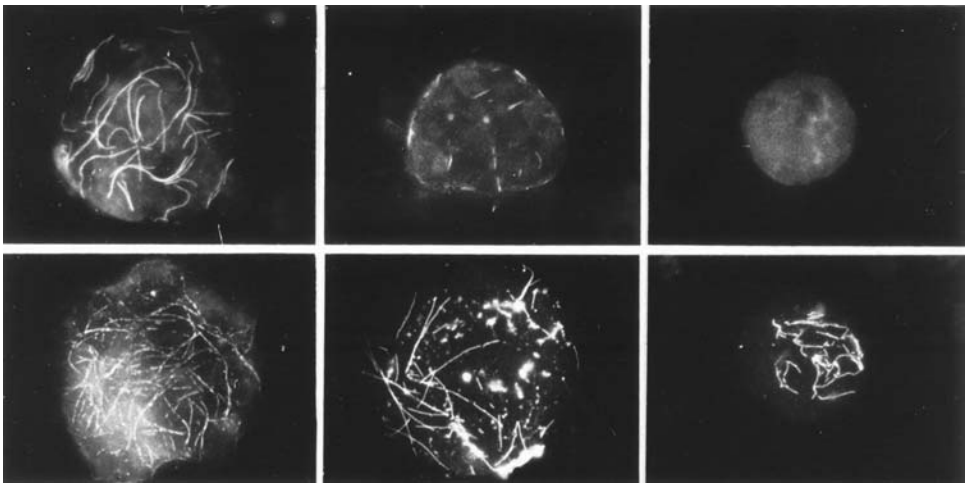

FIGURE 6 Responses of microtubules of isolated leaf protoplasts to freezing visualized by indirect immunofluorescence with anti-α-tubulin (1:100). MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

and reconstruction of the endoplasmic reticulum on the freezing has been reported in the cortical parenchyma cells of mulberry [100]. A contraction of the endoplasmic reticulum tubule (functional state) to a central rod (nonfunctional state) in the plasmodesmata during cold treatment is caused by changes in the actin-myosin filaments [33]. The partial disruption of actin filaments can accompany or promote freezing tolerance of carrot cell suspensions during preservation at extremely low temperatures [156].

CONCLUSIONS

From the presented results, it is obvious that low-temperature stress considerably affects the structure of plant cells. The structural response of the cells is variable and is determined by external (strength and duration of stress) and internal (plant species, ontogenetic phase of the plant, type of the tissue, and genetically determined level of resistance) factors. Therefore, it is difficult to decide which cell compartment plays the primary or the most important role in the cell responses to both chilling and freezing stresses.

INTRODUCTION

Alterations in the light environment, ambient temperature, and mineral and water supply to plants and algae may affect their viability. The rapidity and efficiency of the metabolic responses of plants differ among plant species or even among cultivars and their aptitude to adapt to unfavorable conditions is a major factor for their survival. The photosynthetic apparatus is one of the most important targets of stress in chlorophyllous organisms. Indeed, most of the metabolic responses induced by stress conditions (e.g., stomata closure) have consequences on the aptitude of the plant to maintain an efficient light energy conversion. The photosynthetic pigments, especially carotenoids which exhibit both light-harvesting and photoprotective functions, are affected by a large variety of stresses. In this chapter, we present a short discussion about the diversity of carotenoid responses to stress and focus on their photoprotective participation in the stress response through the so-called xanthophyll cycle and on the production of economically important secondary carotenoids by microalgae as a consequence of stress.

PROPERTIES OF CAROTENOIDS IN PHOTOSYNTHETIC ORGANISMS

Carotenoids are C40-polyisoprenic compounds characterized by a large number of conjugated double bonds ($n > 7$). Over 600 carotenoids have been identified to date and several new ones are reported annually. Conjugated double bonds allow carotenoids to absorb light in the near ultraviolet

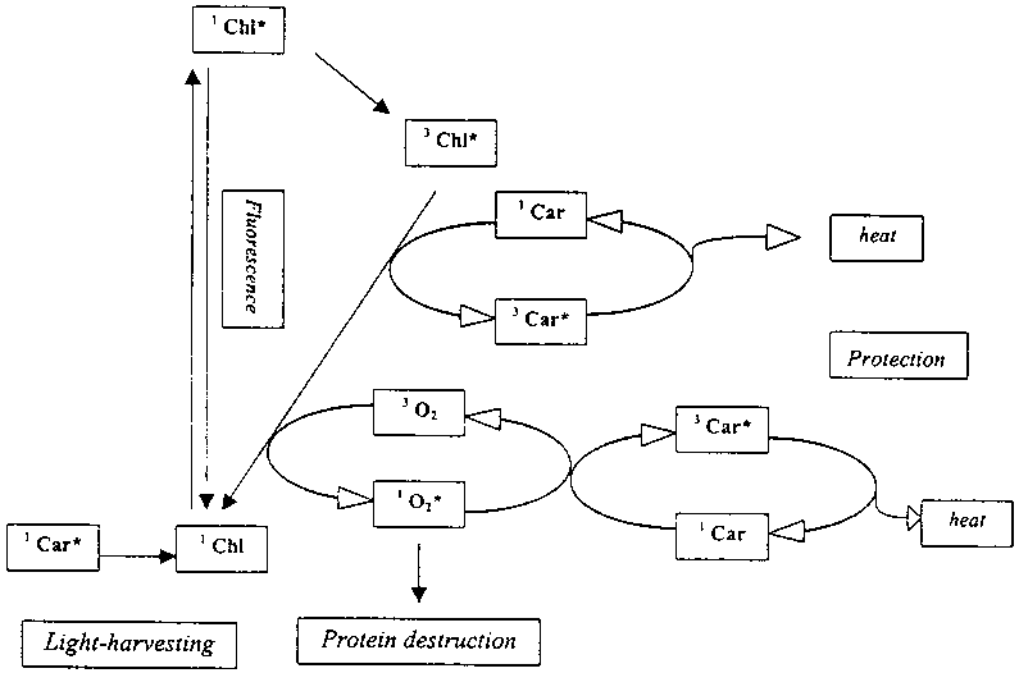

FIGURE 1 Schematic representations of light-harvesting and photoprotection roles of carotenoids in the photosynthetic apparatus. An efficient singlet-singlet energy transfer occurs in antenna complexes from the carotenoid excited state to chlorophyll. Singlet excited chlorophyll can give rise to the longer-lived triplet species. Carotenoids can protect either by quenching ^{3}Chl* before it can interact with oxygen or by quenching $^1O_2^*$ that can be formed.

(UV) as well as in the visible region. In photosynthetic organisms, carotenoids are bound, together with chlorophylls, to proteins and participate to light harvesting (Fig. 1). This very efficient singlet-singlet energy transfer from carotenoids (Car) to chlorophyll (Chl) needs a precise arrangement of pigment molecules in the light-harvesting complexes. Carotenoids are also recognized to be essential for the survival of illuminated plants, since their numerous conjugated double bonds are able to quench the Chl triplet state and also scavenge singlet oxygen and the other reactive oxygen species which are abundantly produced during photoinhibition (Fig. 1). This photoprotective function is generally achieved via triplet-triplet energy transfer.

DIVERSITY OF STRESS EFFECTS ON CAROTENOIDS

Various environmental stress factors (e.g., nutrient deficiency, excess light, drought, chilling) are known to have consequences on the photosynthetic apparatus and photoinhibition may be often observed. This happens when the rates of transfer of energy from the antennae to the photochemical reaction centers are in excess of the rates of transfer of excitation energy to the transducers [1]. This means that even low light levels may become excessive if present in combination with chilling and then may result in photoinhibition in crops or in algae. The consequences at the carotenoid level of any stress may be multiple, and they have been reviewed previously [2]. Among these stresses, the *photoisomerization* of carotenoids may be noted. Besides large amounts of all-*trans*-β-carotene, a low proportion of Z-isomers, essentially 9-13′-*cis*-, 13-*cis*-, and 15-*cis*-β-carotene, have been detected in reaction centers of spinach [3]. On illumination, a decrease of 13-*cis*- and

15-*cis*-β-carotene in photosystem I (PSI) reaction centers of the cyanobacteria *Synechococcus vulcanus* has been noted [4]. *High-light plants* also differ from low-light plants in their pigment composition [5]: smaller physiological photosynthetic unit, lower xanthophyll:β-carotene ratio and higher photosynthetic rates at high quantum flux densities. Similar differences may be observed between the leaves on the south- and north-facing sides of a tree [6]. Exposure to photoinhibitory conditions may lead to *photobleaching* of carotenoids and chlorophylls, the extent of carotenoid photooxidation, with β-carotene being the highest among them [7]. β-Carotene 5,6-epoxide may be produced at the expense of β-carotene destruction when photooxidative damage occurs [2,8].

Acclimatization to *cold stress* has been largely studied in conifers of the boreal zone which encounter a considerable combined stress of low temperature and high light during winter when photosynthetic dissipation of energy is blocked. The winter-stressed Scots pine (*Pinus silvestris*) has been shown to accumulate substantial amounts of xanthophylls, essentially zeaxanthin, in a large complex maintained in a highly quenched state that dissipates excitation energy nonradiatively [9]. Despite a greater β-carotene content in the PSI reaction center which may act as a sink for excess excitation energy, photoinhibition of photosynthesis remains a significant component of the winter-stress effects that Scots pine encounters during the winter. Since pine enters a dormant state during the fall, photoinhibition may be of significant importance as a mechanism for controlled dissipation of energy. In winter rye (*Secale cereale*), on the contrary, cold acclimation induces increased resistance to photoinhibition which appears to be beneficial for the maintenance of active growth and development at low temperatures in this species [10].

Drought is a harmful phenomenon for plants which may induce irreversible damage or death in case of severe stress. Little attention has been paid to the drought effect on pigments. In their analysis of drought effects in bean plants (*Phaseolus vulgaris*), D'Arcy-Lameta et al. [11] revealed a decrease of both chlorophylls and of α- and β-carotenes together with xanthophylls. A different pattern in the distribution and relative enrichment in the xanthophylls was due to the appearance of antheraxanthin and zeaxanthin as observed in drought-stressed *Nerium oleander* [12] and *Gossypium hirsutum* [13]. In contrast to the observations of Barry et al. [14] in barley, no xanthophyll esters could be detected.

Atmospheric pollutants, including several photooxidants such as O_3, SO_2, NO_x, have caused severe destruction of northern European forests (see Ref. 2) with degradation of photosynthetic pigments. A *mineral supply deficiency* also may have important consequences on the pigment composition of higher plants. The best-documented deficiency concerns the iron supply to plants [15]. In response to iron deficiency, pea plants have the peculiarity to exhibit increasing stages of chlorosis from bottom leaves to the apical leaves and thus to offer the possibility to follow, by comparison of the leaves, the effects of increasing iron depletion. The most chlorotic leaves showed a reduction of 97% of their pigment content [16]. The Chla/Chlb ratio reached six times that of the control and the carotenoids/chlorophylls ratio was nine times higher. The main carotenoids were violaxanthin, antheraxanthin, and zeaxanthin, which represented up to 36% of the total pigment content of the yellow leaves. Iron deficiency favored a dramatic decrease of light harvesting chlorophyll protein (LHCP) complexes and a relative enrichment in PSII reaction center complexes (Cpa).

Some xanthophylls have been shown to be concerned in most of the various stress conditions we have surveyed. They are implicated in the nonphotochemical quenching of chlorophyll fluorescence in plants and algae and thus participate in an important photoprotective process known as the xanthophyll cycle. On the other hand, under environmental stress conditions, some algae accumulate economically important carotenoid species such as β-carotene and astaxanthin. We will particularly focus on these two aspects of carotenoids and stress.

XANTHOPHYLL CYCLE

Discovery and Description

In their natural environment, plants are confronted with reconciling an excessive energy supply with the demands of the photosynthetic carbon reduction cycle for the products of electron transport,

Marcel Dekker, Inc.

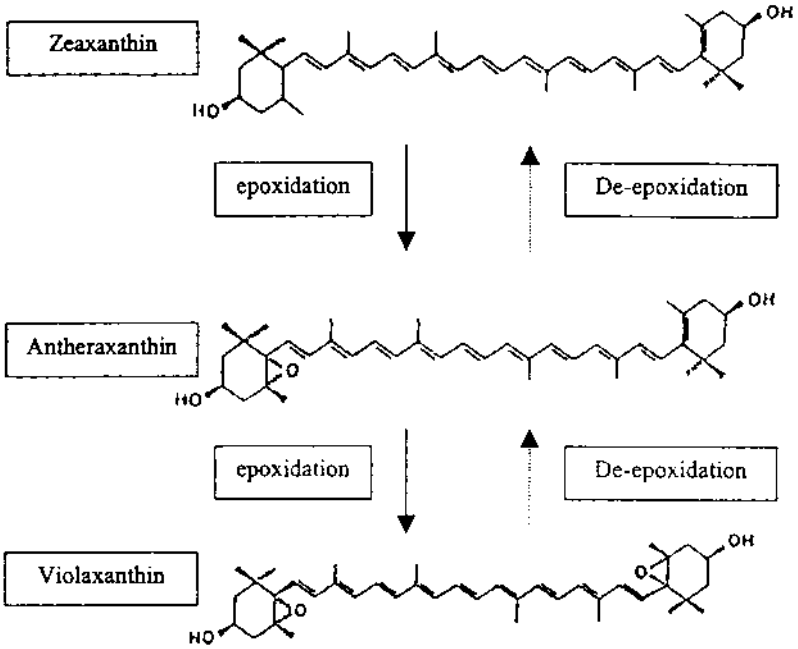

FIGURE 2 The violaxanthin cycle. Under stress conditions, violaxanthin is deepoxidized into antheraxanthin and zeaxanthin and after suppression of the stress its amount is slowly restored by the addition of 5,6- and 5′, 6′-epoxy groups.

ATP and NADPH. When light absorption by photosynthetic pigments exceeds both the capacity to use the photosynthetic NADPH and ATP for carbohydrate synthesis and the capacity of energy-dissipation mechanisms, photosynthesis is progressively inhibited (i.e., photoinhibition phenomenon) and pigment composition starts to change mainly through the xanthophyll cycle [17–20].

Sapozhnikov et al. [21] were the first to report a dramatic decrease of the amount of violaxanthin in various leaves under high-light intensities. Yamamoto et al. [22] related this violaxanthin decrease to an increase of both antheraxanthin and zeaxanthin. Later on, Hager [23] and Yamamoto et al. [24] demonstrated that the violaxanthin pool is reconstituted from zeaxanthin in darkness or under low-light conditions, confirming the pigment interconversions in a cycle called the xanthophyll cycle (Fig. 2).

The xanthophyll cycle has not only been evidenced in higher plants, ferns, mosses, and lichens (see Ref. 25 for a review) but also in algae [26] in which various effects are observed owing to their pigment composition. Both Chlorophyta (green algae) and Phaeophyta (brown algae) present a cycle similar to that found in higher plants. In some Rhodophyta (red algae) which are devoid of violaxanthin, a partial cycle limited to the conversion of antheraxanthin-zeaxanthin often may be observed [27]. Sometimes zeaxanthin is the only pigment of the cycle to be present and no pigment interconversion happens: Cyanobacteria such as *Spirulina* are very rich in zeaxanthin, up to 40% of their carotenoid content, but they are totally devoid of any xanthophyll cycle. In other algae, as for instance *Cryptomonas rufescens* (Cryptophycea), all the pigments of the xanthophyll cycle are absent.

Besides the extremely frequent presence of the violaxanthin cycle, another xanthophyll cycle has been discovered in algal classes such as the diatoms (Bacillariophyceae) by Hager and Stransky [26]. In this cycle diadinoxanthin, a monoepoxide compound with an alkaline bond in the 7,8 position is deepoxidized into diatoxanthin (Fig. 3). Thus, it appears that the xanthophyll cycles developed

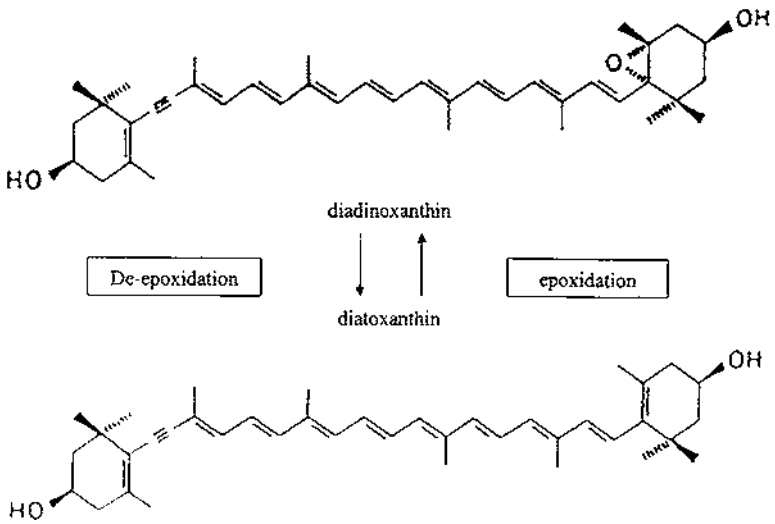

FIGURE 3 The diadinoxanthin cycle. Under stress conditions, diadinoxanthin may be de-epoxidized into diatoxanthin and after suppression of the stress epoxidation restores its amount.

and exhibited some diversity among algae and that the violaxanthin cycle has been maintained during evolution to higher plants.

Operation of Xanthophyll Cycle and Photoprotection

In greening tobacco leaves, where photoprotection needs are important, higher levels of xanthophyll cycle pigments than those of mature leaves could be detected [28]. Similarly, an increased resistance to photoinhibition could be correlated to higher contents in the xanthophyll cycle pool of pigments in *Chlorella* [29]. In two Pheophyceae, *Pelvetia canaliculata* and *Laminaria saccharina*, the amounts of zeaxanthin accumulated, via the xanthophyll cycle operation, after a light stress are very different on a chlorophyll *a* basis (respectively, 11.0:100 and 2.9:100). Such a difference has been shown to be one of the main factors responsible for the specific distributions of these two species at opposite levels on the seashore [30]. Thus, as well in higher plants as in algae, a better phototolerance appears to be frequently associated with an increase of the xanthophyll cycle pool of pigments.

Molecular Location of Xanthophyll Cycle

In order to investigate the role that the xanthophyll cycle might play in photosynthesis, it is important to be precise about its location and its site of action. It is likely that, in vivo, more than 80% of the carotenoids involved in the xanthophyll cycle are bound to proteins, but these have not been yet identified precisely in higher plants. This is mainly due to the fact that pigments are loosely bound to proteins and are easily detached during sample preparations. Since no violaxanthin was found associated with the core antenna proteins, it was suggested that the xanthophyll cycle takes place on the light-harvesting complex (LHC) proteins. This was confirmed by violaxanthin extraction from pigment-protein complexes obtained from grana and stroma membranes [31–34].

The first attempts to localize the precise site of pigment photoconversion in PSII submembrane fractions were realized by Bassi et al. [35]. These authors suggested that the xanthophyll interconversions were restricted to the minor LHCII complexes (CP24, CP26, CP29). Each minor complex binds one violaxanthin per monomer. On the contrary, Horton's group [36] showed that, owing to

the much higher amount of pigments associated with the main LHCII complexes, more than 50% of zeaxanthin may be part of LHCIIb, and then the xanthophyll cycle appears to be operative in all LHCII complexes. This is confirmed by the observation of equivalent deepoxidation states (Z + 0.5 A)/(V + A + Z) in LHCIIb, c, and d. Nevertheless, the ratio of xanthophyll cycle carotenoids/Chl is much higher in the minor complexes, which support an important role for these xanthophylls in the control of energy dissipation through the ''high-energy state quenching QE'' in these complexes. Nevertheless, a pool of violaxanthin was demonstrated to be transformed into zeaxanthin in the total absence of LHCII proteins in the *chlorina f2* mutant of barley [37]. These authors, as well as Adamska [38], have suggested a possible association of these xanthophylls to ELIPs (early light–induced proteins). On the contrary, Yahns and Krause (see Ref. 39) proposed that, when the antennae are reduced (intermittent light–grown plants), a part of the xanthophylls could be free in the thylakoid membranes.

Brown algae present a higher violaxanthin to the chlorophyll *a* ratio than higher plants. In these algae, a pure LHC fraction may be prepared [40] which accounts for more than 50% of the total pigment content and contains, besides chlorophyll *a*, high amounts of chlorophyll *c*, fucoxanthin, and violaxanthin. In *Pelvetia canaliculata*, this main LHC has been separated into two fractions by isoelectric focusing [41]. The first fraction was enriched in chlorophyll *c* and fucoxanthin and was totally devoid of violaxanthin. Since it exhibited efficient energy transfer to chlorophyll *a*, it was concluded that it could be specialized in light harvesting. The second fraction was highly enriched in violaxanthin, and the xanthophyll cycle was found to be operative in this fraction on light stress

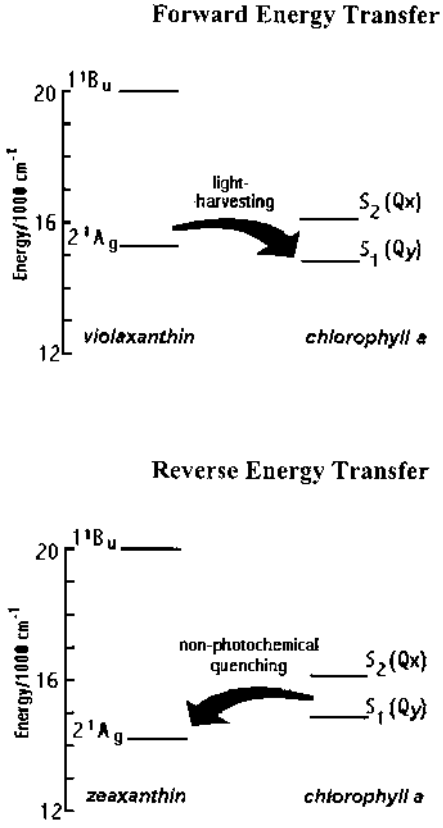

FIGURE 4 The molecular gear shift model showing S1 energy levels of violaxanthin and zeaxanthin relative to Chla. (Redrawn from Refs. 59 and 61.)

suggesting an efficient photoprotective function. Such a specialization of the chlorophyll-protein complexes in photoprotection or in energy supply is an original feature which has not yet been observed in other organisms.

In any stress condition, part of the violaxanthin is not deepoxidized. It may reach 20–30% of the total violaxanthin content [42–44]. This fraction could have a structural role as revealed by LHCII reconstitution experiences in vitro (see Ref. 39 for a review).

Enzymes Involved in the Xanthophyll Cycle

Two different enzymes have been identified as being involved in the xanthophyll cycle: violaxanthin deepoxidase and zeaxanthine epoxidase. Both are associated with photosynthetic membranes, with violaxanthin deepoxidase and zeaxanthine epoxidase being localized at the lumen and stromal side of the photosynthetic membranes, respectively [45,46]

Violaxanthin Deepoxidase

The enzyme violaxanthin deepoxidase is free in the lumen at neutral pH. During a strong illumination, the lumen pH decreases, since proton import into the lumen is very active in these conditions. This pH shift triggers conformational modifications allowing the enzyme to bind the membrane [43]. The optimum pH for enzyme activity is around 5.2 [47].

Violaxanthin deepoxidase enzyme has been isolated and even purified in an active state [48–50]. The isolated enzyme has an apparent molecular weight of 43 kDa [50–52] and is very specific for all-*trans*-3-hydroxy-5,6-epoxy-carotenoids presenting a 3S,5R,6S conformation [49]. Full enzyme activity does not require cofactors other than ascorbate [42,50] and lipids, such as monogactosyldiacylglycerol (MGDG), which is the main lipid found in chloroplast membranes [51,52]. The enzymatic activity is strongly inhibited at low temperature [53,54] and also by the addition of DTT (dithiotreitol), which strongly suggests that disulfur bridges are required for full activity [55].

Zeaxanthine Epoxidase

The enzyme zeaxanthine epoxidase was isolated but never purified [46]. Recent results suggest that this enzyme could be a flavoprotein [56,57]. Its optimun pH is around 7.5. Full activity requires oxygen and NADPH [58]. The NADPH requirement explains why the back transformation of zeaxanthin to violaxanthin is quicker under a weak illumination than in complete darkness.

Hypothesis for Xanthophyll Cycle–Induced Photoprotection

When light absorption by photosynthetic pigments exceeds both the possibility for its utilization by the transducers and the capacity of energy dissipation mechanisms, violaxanthin is progressively converted to antheraxanthin and zeaxanthin. A linear relationship has been found between the amount of zeaxanthin produced and the capacity for energy dissipation. Several mechanisms have been proposed to explain the photoprotective properties of the zeaxanthin molecules formed through the xanthophyll cycle operation.

- Zeaxanthin has a higher number of conjugated double bonds than violaxanthin (11 instead of 9). These two additional conjugated double bonds lower the energy of its lowest singlet state (2^1Ag) which in turn can directly accept energy from the first chlorophyll excited state (^{1}chl) via a singlet-singlet energy-transfer process [59–61]. The excess of energy on the carotenoid is then dissipated as heat (Fig. 4).
- Zeaxanthin could also indirectly participate in the deviation of excess light energy as heat [52,62,63]. The acidification of the thylakoid lumen (associated with the electron transfer at the plastoquinone level) brings about protonation of the LHC apoprotein and LHCII aggregates [64]. Ruban et al. [65,66] have shown in vitro that aggregation of LHCII by acidification is accompanied by a quenching of chlorophyll fluorescence. Such an aggrega-

tion may be stimulated by the addition of zeaxanthin and inhibited by violaxanthin [66]. Zeaxanthin, which is much more hydrophobic than violaxanthin, was shown to induce LHCII aggregation even in a hydrophobic medium [67]. Zeaxanthin accumulation via the xanthophyll cycle operation could participate in the induction of LHCII aggregation and to the resulting chlorophyll fluorescence quenching and to the increase of energy dissipation as heat (Fig. 5). The main features of these carotenoid-mediated alterations to the LHCII organization have been discussed recently [61].

It was also proposed that zeaxanthin epoxidation is a way to remove active oxygen species formed during a stress [68,69]. The violaxanthin formed could be again deepoxidated. In such a case, the epoxidation could be nonenzymatic [69].

A light-induced decrease in membrane fluidity occurs in thylakoid membranes when violaxanthin is allowed to convert to zeaxanthin under stress, and thus the thermostability of the thylakoid membranes increases. The LHCII prepared from illuminated leaves was shown to be poorer in xanthophyll cycle pigments than the LHCII prepared from dark-adapted leaves [70]. A diffusive displacement of zeaxanthin from the pigment protein complexes to the surrounding lipid domain [18,71] has been suggested to increase membrane rigidification. On the other hand, the thylakoid membranes which contain a very high proportion of unsaturated fatty acids are a good target for lipid peroxidations. Recently, it was demonstrated that photoinduced peroxidative damage in leaves is highly increased if the violaxanthin cycle operation is inhibited by the addition of DTT [72]. Thus, besides its direct photo-

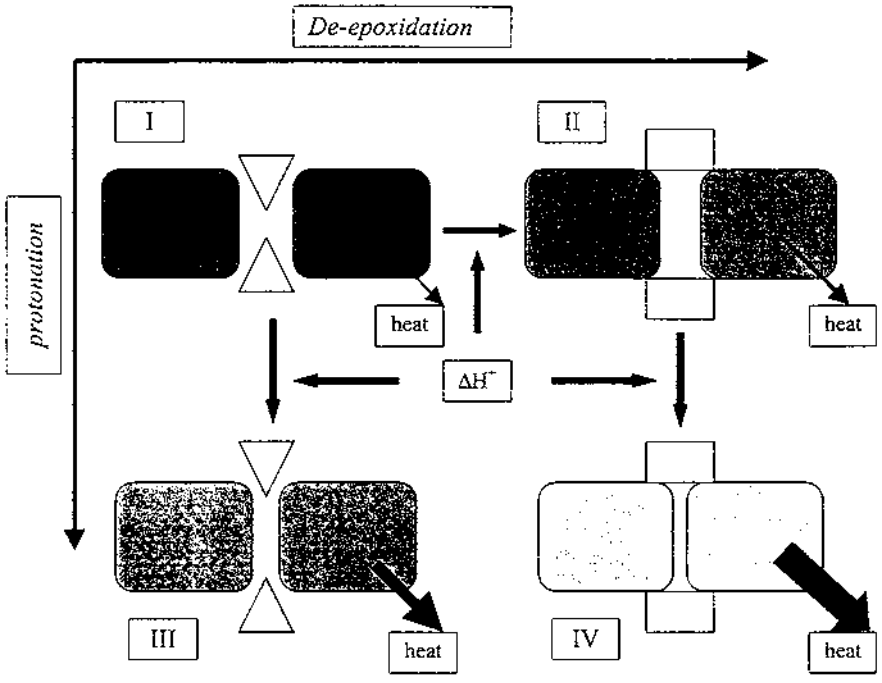

FIGURE 5 LHCII model for the control of energy dissipation as heat by structural changes brought about by deepoxidation and protonation. Four states are shown: I unprotonated, binds violaxanthin (△) and unquenched; II unprotonated, binds zeaxanthin (□), slightly quenched; III protonated, binds violaxanthin, quenched; IV protonated, binds zeaxanthin, highly quenched. (Redrawn from Refs. 63 and 61.)

protective effect through excess energy dissipation improvement, the xanthophyll cycle could also increase the resistance of the photosynthetic membranes toward stress-induced peroxidations.

SECONDARY CAROTENOID PRODUCTION BY MICROALGAE UNDER STRESS

Under unfavorable conditions (e.g., nitrogen depletion, high photon flux densities, extreme temperatures), algae synthesize and accumulate several secondary carotenoid species. Secondary carotenoids accumulate out of the thylakoid membranes and their biosynthesis regulation is not similar to that of photosynthetic carotenoids. The most frequent carotenoids which accumulate are β-carotene and/or its derivatives echinenone, 4′-hydroxyechinenone, canthaxanthin, and astaxanthin. These carotenoids sometimes accumulate inside of the chloroplast in the interthylakoidal space. Volvocales of the genus *Dunaliella* (e.g., *D. salina* var. *bardawil*) are the only photosynthetic organisms which accumulate β-carotene in intraplastidial lipid globules. These globules are essentially constituted of polar lipids and of a small amount of nonpolar membrane lipids [73]. Some other organisms such as the Ulvophyceae sp. *Trentepohlia aurea* [74] or the halotolerant cyanobacterium *Aphanothece* sp. [75] may also accumulate high amounts of β-carotene. Generally, secondary carotenoids accumulate out of the plastids. The extraplastidic pigments which are found under adverse nutritional conditions in the green alga *Protosiphon botryoides* are located in lipid globules which contain a high proportion of proteins. These carotenoproteins appear to originate from chloroplast-degenerating structures and to accumulate into the cytoplasmic globules during encystment of the alga. They contain mainly lutein and canthaxanthin [76].

Several other algae produce extraplastidic ketocarotenoids when exposed to stress conditions (see Ref. 77 for a review). Among them we may quote *Haematococcus pluvialis* and *Chlamydomonas nivalis*, the aplanospores of which cause the color of ''blood rain'' and ''blood snow'' [78]. Several strains of *Scenedesmus* and *Chlorella* accumulate echinenone and astaxanthin at the expense of chloroplasts carotenoids. High amounts of echinenone and canthaxanthin accumulate in colonies of the hydrocarbon fuel–producing palmellaceae *Botryococcus Braunii* under the effect of nitrogen deficiency [79]. These secondary carotenoids synthesized by algae under the effect of stress have economical importance: β-carotene as provitamin A in human food or as antioxidant and astaxanthin as an additive to fish feed that is responsible for the pink color of the flesh in Salmonideae [80]. For now, *Dunaliella salina* var. *bardawil* and *Haematococcus pluvialis* are the most frequently studied microalgae, and we will discuss the studies which have been devoted to them.

Response of *Dunaliella salina* to Stress

The biochemical and physiological response of the halotolerant green alga *D. salina* var. *bardawil* to conditions of stress has been reviewed by Cowan et al. [81]. This alga responds to hypersalinity stress by increased glycerol concentration in the cytoplasm as a product of photosynthesis rather than a synthesis of starch in the chloroplast [82]. Glycerol functions as a solute to adjust the cellular water potential to the osmotic concentration of the surrounding medium. Glycerol synthesis appears to be regulated by the intracellular concentration in orthophosphate (Pi) which plays a key role in the regulation of carbon metabolism. According to these investigators [82], cell shrinkage in hypersaline conditions results in an increased (Pi) in the cytoplasm which drives the Pi/triose phosphate translocator located in the inner chloroplast membrane to transport Pi into the chloroplast and triose phosphate out to the cytoplasm where it finally gives glycerol. The high glycerol 3P amounts needed for this antiport system are obtained in the plastids through starch degradation (phosphofructokinase) and via the photosynthetic Calvin cycle operation. Part of this carbon flux also triggers isoprenoid biosynthesis and especially the resulting β-carotene accumulation that is commonly observed [73,83]. Levels of β-carotene approaching 14% of cell dry weight have been reported [73,84].

All *Dunaliella* species are not able to accumulate β-carotene in stress conditions (e.g., *D. prava*). Massyuk and Radchenko [85] have reported canthaxanthin accumulation in a *Dunaliella* species under stress. *D. salina* var. *bardawil*, which may accumulate very high levels of β-carotene, is grown for a commercial purpose. When synthetic β-carotene has a >99% all-*trans* configuration, β-carotene accumulated by *Dunaliella* is a mixture of 9-*cis*-β-carotene and of all-*trans* molecules, the relative proportions of which depend on light intensity: when the ratio of 9-*cis* to all-*trans* was 0.2:1 in *D. salina* grown in low light, it could reach 1.5:1.0 under high light [86,87].

Carotenoids that accumulate and function in the chloroplast are biosynthesized within that organelle [88]. Xanthophylls such as zeaxanthin, antheraxanthin, and violaxanthin are elaborated from β-carotene through the introduction of hydroxy groups at C3 and C3′ and epoxy groups at C5-C6 and C5′-C6′. When the cells experience osmotic and light stresses, the xanthophyll cycle operates in the opposite way and thus violaxanthin and antheraxanthin are deepoxidized to zeaxanthin. Such a high level of zeaxanthin could retard the conversion of β-carotene to zeaxanthin and contribute to the accumulation of β-carotene [81].

A modification of abscisic acid (ABA) balance seems to participate in the regulation of the cellular responses to stress conditions in *Dunaliella*. The levels of this hormone are known to rise and fall dramatically in several tissues and organisms in response to environmental changes. Increased levels of ABA have thus been noticed in *Dunaliella* when the organism is exposed to a salinity stress [89] before the accumulation of β-carotene. The ABA is synthesized from all-*trans*-violaxanthin via 9′-*cis* neoxanthin which is cleaved to form xanthoxin and then converted in ABA via ABA aldehyde [90,91]. Thus, the operation of the xanthophyll cycle, which suppresses a large proportion of violaxanthin, could contribute to limit ABA biosynthesis: Low amounts of ABA have been measured in β-carotene–accumulating and zeaxanthin-enriched salt-stressed *Dunaliella* [81]. Cellular volume changes in response to osmotic stress alter the cytoplasmic pH and would be responsible for a redistribution of intracellular ABA which results in an inhibition of the plasma membrane H^+-ATPase and in an activation of the Na^+/H^+ antiporter [92]. The ABA activation of phospholipase C results in the hydrolysis of inositol-containing phospholipids such as phosphatidylinositol 4,5-bisphosphate (PIP2), which is present in plasma membranes, to inositol triphosphate (IP3) and diacylglycerol (DG). The IP3 acts as a second messenger in the cytoplasm in mobilizing intracellular calcium and the DG, in concert with the elevated concentration of calcium, activates a protein kinase [93]. The effect of ABA on Ca^{2+} channels could also contribute to increase cytoplasmic Ca^{2+} concentration by a Ca^{2+} influx, and the metabolic response seems to be promoted through Ca^{2+}-calmodulin regulation and protein kinase activity.

The accumulation of β-carotene appears to be an economically important feature of the response of *Dunaliella* to stress. This happens when it is grown under high light intensity, high salt concentration, extreme temperatures, or nitrate deficiency [73]. β-Carotene accumulates in lipid droplets essentially composed of neutral lipids together with small amounts of nonpolar membrane lipids, proteins, or carbohydrates [73]. These lipids enhance the stability of the secondary carotenoids which accumulate [94]. β-Carotene accumulation has been considered by Borowitzka et al. [95] to be a carbon sink for *Dunaliella*. Increased ATP and triose phosphate levels in the chloroplasts would induce isoprenoid biosynthesis at the expense of photosynthetically fixed carbon rather than carbohydrate synthesis.

When exposed to stress, the production of ABA precedes β-carotene accumulation. The new production of enzymes for β-carotene synthesis could depend on ABA control as shown by the suppression of both accumulations in the presence of inhibitors of chloroplast protein synthesis [96,97]. On the other hand, the operation of the xanthophyll cycle (zeaxanthin accumulation) seems to be associated with the transduction and translocation of a nuclear gene, *cbr* [98], coding for a thylakoidal peptide (19 kDa). These investigators suggest that this pigment-protein complex (Cbr-zeaxanthin) could be a modification of LHCIIb which could participate in the protection of the photosynthetic system against excess light, as was suggested for ELIPs in higher plants [38]. The accumulation of β-carotene has also been considered by Ben-Amotz et al. [87] to act to protect *Dunaliella* against high irradiations in the blue region of the spectrum. This hypothesis is explained

by the decrease of photoinhibition resistance induced by the addition of the phytoene desaturase inhibitor norflurazon [99] in *Dunaliella salina* var. *bardawil* which is then depleted in β-carotene.

Astaxanthin Production by *Haematococcus pluvialis*

A few microorganisms have the capacity to accumulate astaxanthin: *Chlamydomonas nivalis* [100], *Euglena rubida* [101], *Acetabularia mediterranea* [101], *Protosiphon botryoides* [76], and the fungi *Phaffia rhodozyma* [102] for instance.

Most studies on astaxanthin accumulation were conducted in *Haematococcus pluvialis*, a freshwater monocellular green alga (Volvocale) very common in ponds and puddles, which may sometimes be tinted red by its astaxanthin-rich akinetes [103]. It may also cause the red color of so-called blood rain. The various conditions inducing the accumulation of astaxanthin and its mono- and bi-esters are nitrogen deficiency, excess light, drought, or extreme temperatures [104]. *Haematococcus* may grow within a wide range of temperatures [105], and when environmental conditions are suitable, it appears as a biflagellated chlorophyllous cell with an eyespot in the chloroplast which is responsible of phototactic movements [106,107]. Under stress conditions, the motile cells lose their flagellae and give rise to motionless spherical cells (akinetes). Astaxanthin accumulates in the cytoplasm; up to 8% total fresh weight [108,109] after growth stops [110]. Kakizono et al. [111] have shown that an increase of the C:N ratio causes encystment, the associated astaxanthin accumulation, and important metabolic changes which give rise to resting spores with a thick cell wall. On return to suitable environmental conditions, the red akinetes give rise to oval chlorophyllous cells which become sensitive to stress [112].

Astaxanthin synthesized by *Haematococcus* constitutes more than 99% by the 3S,3′S optical isomer. The cytoplasmic droplets containing astaxanthin and its esters are located at the periphery of the cell or around the nucleus. These red droplets could constitute a screen absorbing excess light radiations, mostly in the blue and UV region, and reduce light absorption by the pigment-protein complexes. Such a limitation of photoinhibition and photodamage has been proposed for astaxanthin accumulated by Antarctic red snow algae (*Chlamydomonas* spp.) by Bidigare et al. [103]. The esterification of astaxanthin with fatty acids is postulated by these investigators to represent a mechanism by which the chromophore can be concentrated within lipid globules to maximize its photoprotective efficiency. Astaxanthin could then play a similar photoprotective role as proposed for β-carotene in *Dunaliella* [109,113] even if these two pigments have different accumulation sites [112], respectively, in the cytoplasm and in the chloroplast.

The different steps of carotenoid biosynthesis to β-carotene are well known in higher plants and algae. Nevertheless, the precise biosynthetic pathway from β-carotene to astaxanthin has not been definitely established. Harker and Young [94] suggested the existence of two synthetic pathways via, respectively, echinenone, canthaxanthin, and adonirubin for the first one and via β-cryptoxanthin, zeaxanthin, and adonixanthin for the second. Chumpolkulwong et al. [114] have confirmed both possibilities and Harker and Hirschberg [115] have suggested in addition the possible participation of two other intermediates (3′-hydroxyechinenone and 3-hydroxyechinenone).

Lotan and Hirschberg (see Ref. 114) have recently cloned a *CrtO* gene from *Haematococcus* coding for the enzyme C-4-oxygenase. This enzyme allows the conversion of β-carotene to canthaxanthin. Nevertheless, it is not definitely established in which order in vivo the keto groups in C4 and C′4 and the hydroxy groups in C3 and C′3 are introduced by the products of *CrtO* and *CrtW* genes.

The synthesis of astaxanthin by green *Haematococcus* cells under the effect of a high light stress was followed by Rmiki et al. [116]. During a first period corresponding to the four earliest hours of stress, the amount of astaxanthin accumulated appeared to be exactly equivalent to the linear decrease of the β-carotene content of the cells suggesting pigment conversions. Low-temperature fluorescence emission spectra revealed a large decrease in the PSI emission band traducing the alteration of the PSI antennae which are known to be enriched in β-carotene [117]. An association of astaxanthin with PSI chlorophyll-protein complexes was previously proposed [118]. Free astaxan-

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

thin may be detected during the first hour of stress, with its mono-esters appearing only during the second hour and its bi-esters after more than 2 h of light stress. A second reddening period which began 4 h after the onset of the light-stress was characterized by a net carotenoid biosynthesis corresponding to a small rise in the β-carotene content and especially a huge accumulation of astaxanthin and its esters. A depletion of the photosynthetic capacity of the cells happened corresponding to the bleaching of the cells described during encystment by Kobayashi et al. [119–121] Astaxanthin mono-esters represent the preponderant form at the begining of encystment and later on astaxanthin di-esters are more abundant in thick cell walled cysts [104].

CONCLUSIONS

Carotenoids are commonly concerned in environmental stress and participate efficiently to the plant response which is necessary to its survival strategy. In this regard, their photoprotective function appears to be of great importance. An essential function of carotenoids in photosynthesis is to prevent harmful photooxidative reactions related to the presence of oxygen. This is particularly important at the level of the reaction centers: One to two β-carotene molecules are known to be associated with each P680 in the PSII reaction center. Besides their contribution to improve light harvesting in the pigment-protein complexes, the xanthophylls may also participate efficiently in the regulation of nonphotochemical energy dissipation via the operation of the xanthophyll cycle which may be observed in most of stress conditions. In some algal species, the metabolic response to stress leads to the accumulation of economically important secondary carotenoids.

Light Stress: Photoinhibition of Photosynthesis in Plants Under Natural Conditions

DA-QUAN XU AND YUN-KANG SHEN
Shanghai Institute of Plant Physiology
The Chinese Academy of Sciences
Shanghai, People's Republic of China

INTRODUCTION

Since sunlight is the energy source for photosynthesis, its deficit inevitably limits photosynthesis. However, too much sunlight can induce photoinhibition of photosynthesis and even photodamage of the photosynthetic apparatus in plants, and thus it may become a stress factor (i.e., light stress).

Photoinhibition is a phenomenon of a light-induced decrease in photosynthetic activity when light energy received by the photosynthetic apparatus is in excess of what can be used by photosynthesis. It is mainly characterized by a decline in the photosynthetic efficiency, which is often expressed as the ratio of variable to maximal fluorescence, Fv/Fm, or the photosynthetic quantum yield of carbon fixation or oxygen evolution. According to the recovery time, photoinhibition can be distinguished into two main classes: dynamic and chronic. Dynamic photoinhibition is more rapidly recovered, and it is associated principally with some energy-dissipation processes, whereas chronic photoinhibition is more slowly recovered, and it is largely related to photodamage of the photosynthetic apparatus [1]. It is different from photooxidation or photobleaching characterized by a bulk loss of pigment [2]. It has been estimated that one-tenth of the potential carbon gain in willow shoots is lost owing to photoinhibition under conditions of optimal temperature [3].

Before 1950, there were only a few ecophysiological studies on this phenomenon, although reports on photoinhibition-like phenomena could be found as long ago as the middle of the 19th century [4]. Kok [5] first used the term *photoinhibition* in 1956. Since the 1980s studies on the mechanism of photoinhibition increased in number. In the past decade, it became an important topic in several international conferences on photosynthesis. Moreover, at least two books on photoinhibition have been published [6,7]. Nevertheless, its exact mechanism is not clear because of its complexity.

In the past, many studies on the mechanism of photoinhibition were carried out in laboratories

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

with isolated material such as chloroplasts of plants grown in growth chambers. Such in vitro studies are absolutely necessary for revealing the molecular mechanism of photoinhibition. However, these studies are inadequate for understanding the essence of photoinhibition in vivo under natural conditions. Therefore, studies in vivo on photoinhibition in nature are more important. The amount of such studies has increased in recent years owing to the development of portable equipment suitable for photosynthetic measurement and chlorophyll fluorescence analysis in the field. In this chapter, the recent progress of photoinhibition research concerning photodamage, thermal energy dissipation, and protective systems of the photosynthetic apparatus is discussed with emphasis on those field studies where other stress factors were absent.

PHOTODAMAGE TO THE PHOTOSYNTHETIC APPARATUS

Most of the studies on the mechanism of photoinhibition, especially the earlier ones, were conducted with algal cells or isolated chloroplasts, thylakoids, or particles of photosystem II (PSII) reaction centers from higher plants grown in growth chambers under low light conditions and by using some extreme treatments, for example, very intense light of more than 3000 μmol photons $m^{-2}s^{-1}$ that never have been encountered in nature, to induce photoinhibition. Such photoinhibition is often a result of damage of the photosynthetic apparatus, mainly D1 protein loss [8–11].

It is well known that the primary site of damage during photoinhibition is mainly PSII. In such photodamage, there are two possible mechanisms: acceptor-side and donor-side mechanisms [12–15]. The acceptor-side mechanism occurs when the plastoquinone pool is fully reduced owing to the inhibition of photosynthetic carbon assimilation. In this case, the doubly reduced QA accumulates and then is protonated, forming QAH_2. Owing to the blocking of electron transport to QA, the radical pair $P680^+Pheo^-$ recombines, generating the triplet state of P680, $^3P680$. In the presence of oxygen, the $^3P680$ can readily react with oxygen to produce singlet oxygen, $^1O_2$, a strongly oxidizing species. $^1O_2$ can damage the proteins or pigments in its vicinity. Several histidines in the D1 protein, His190, His195, and His198, are speculated to be potential targets for $^1O_2$ formed around P680. Obviously, the mechanism is oxygen dependent. The donor-side mechanism occurs when water oxidation is inhibited. The lifetime of $P680^+$ increases, because the oxygen-evolution complex cannot rapidly provide electron to the reaction center. $P680^+$ is a strong oxidant that is able to extract electrons from substances surrounding it leading to the damage of both protein and pigment such as D1 protein, chlorophyll, and carotenoids. In contrast to the acceptor-side mechanism, this mechanism is not oxygen dependent; it also occurs in the absence of oxygen.

There has been work indicating that the acceptor-side mechanism may be the more common route of photodamage. The studies on donor-side photodamage are few, and most of them have been made with isolated thylakoid membranes or the particles of the PSII reaction center and have used various ways to inhibit the donor-side activity of PSII, for example, Tris-washing, hydroxylamine treatment or Cl^- depletion. Because the thylakoid luminal pH is expected to be around 5.0–5.5 during continuous illumination in vivo, based on their results that donor-side–induced photoinhibition became dominant below pH 4.5, Spetea et al. [16] have proposed that intact plants can probably avoid extensive donor-side–induced photodamage.

Although for nearly a decade photoinhibition has been almost synonymous with D1 protein loss, there has been no direct evidence of the photoinhibitory loss of the D1 protein of leaves in natural environments [17–19]. Perhaps the paradox originates from a lack of the link between laboratory and field studies. In other words, the conception about the mechanism of photoinhibition based on the laboratory studies in vitro may not fit the actual case of photoinhibition in nature.

LIGHT ENERGY DISSIPATION AS HEAT IN THE PHOTOSYNTHETIC APPARATUS

In field studies on the photosynthetic efficiency in plant leaves, we found that the apparent quantum yield of photosynthetic carbon fixation often displayed a significant midday decline in many C_3

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

plants such as soybean and wheat on clear days. However, the midday decline did not occur on cloudy days. And shading could prevent it; namely, the photosynthetic efficiency in shaded leaves was higher than that in control leaves exposed to full sunlight. Considering these facts, it was deduced that photoinhibition may be a likely cause of the midday decline in the efficiency [20–22]. The deduction was supported by the experimental results from chlorophyll fluorescence analysis [23–25]. Similar to our finding, Ögren [26] reported that photoinhibition often occurred in willow leaves even if water and nutrients were sufficient and temperature was optimal. Through further study, we found that at noon on clear days, photoinhibition in sweet viburnum leaves was not accompanied by a significant loss of D1 protein [27]. A similar case was observed in wheat leaves [28]. Nevertheless, DTT (dithiothreitol), an inhibitor of deepoxidase involved in the xanthophyll cycle, introduced via the transpiratory stream resulted in a substantial loss of D1 protein in wheat leaves exposed to strong sunlight around noon [28]. It appears that under natural conditions with strong sunlight as the sole stress factor, photoinhibition is a result of the enhancement of some protective processes such as xanthophyll cycle–dependent energy dissipation rather than the damage to the photosynthetic apparatus.

Xanthophyll Cycle–Dependent Energy Dissipation

The light-dependent interconversions of the leaf xanthophylls were found about 40 years ago [29,30], but the xanthophyll cycle did not attract much attention until Demmig and coworkers [31] proposed a possible role for it in the protection of the photosynthetic apparatus against photodamage. There have been several papers reviewing the regulation and function of this cycle [18,32–38].

The xanthophyll cycle consists of the interconversions of three carotenoids. Under conditions of excessive light, a deepoxidation process operates from the diepoxide violaxanthin (V) via the monoepoxide antheraxanthin (A) to the epoxide-free zeaxanthin (Z), whereas under light-limited conditions, an epoxidation process occurs in the reverse direction. The two processes are catalyzed by two enzymes, deepoxidase and epoxidase, respectively. Zeaxanthin has two possible action patterns in the energy dissipation as heat. It interacts directly with the singlet excited state of chlorophyll [32] or it facilitates aggregation of light-harvesting complex II (LHCII) and, as a consequence, increases energy dissipation [39]. The key site of energy dissipation is thought to be the antenna systems within the photochemical apparatus under physiological conditions [35].

The remarkable characteristics of the xanthophyll cycle–dependent heat dissipation are the declines in photosynthetic quantum yield, PSII photochemical efficiency (Fv/Fm), and the initial fluorescence level (Fo), because light energy transfer to PSII reaction centers is reduced due to heat dissipation.

There have been many reports showing the diurnal variations in both the contents of xanthophyll cycle pigments and heat dissipation, the difference in both the pool size of the pigments and heat dissipation between sun and shade leaves, and the increase in the pool size and capacity of heat dissipation caused by environmental stresses such as low temperature, drought, and nutrient deficit [35,40].

Besides V, A, and Z derived from β-carotene, other xanthophylls such as lutein (Lut) and loroxanthin (Lor), both derived from α-carotene, may also be involved in thermal dissipation. Through genetic experiments using *Chlamydomonas*, a single-celled green alga, Niyogi et al. [41] have provided the first evidence that xanthophylls derived from both β-carotene and α-carotene play critical roles in the thermal dissipation of light energy. The generality of their results in the vascular plants remains to be demonstrated.

More recently, Demmig-Adams and Adams [42] reported that all increases in thermal energy dissipation were associated with increases in the zeaxanthin level in the leaves of the 24 plant species examined. It seems that these responses to excessive sunlight are not species specific, and the xanthophyll cycle–dependent energy dissipation acts as the predominant protective mechanism against photodamage to the photosynthetic apparatus in all plant species. However, the following results from our laboratory indicate that among several types of energy dissipation as heat, the

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

xanthophyll cycle–dependent one is unlikely to be a predominant protective mechanism in soybean leaves. First, the initial fluorescence level, Fo, in soybean leaves always increased significantly after exposure to strong light. Second, in soybean leaves, DTT had little effect on the changes in Fv/Fm induced by strong light. Third, the number of inactive PSII reaction centers in soybean leaves increased under strong light and decreased in subsequent darkness. These results indicate that the changes in Fo and Fv/Fm in soybean leaves during strong light illumination and subsequent dark recovery are mainly due to the inactivation and reactivation of some PSII centers [43].

Energy Dissipation Dependent on PSII Reaction Center Inactivation

Since the concept of PSII heterogeneity was suggested in the 1970s [44], a hypothesis that the reversibly inactivated PSII reaction centers can protect the photosynthetic apparatus from photodamage has been put forward by some investigators [19,45–47].

There are two types of PSII reaction centers: the active and inactive. They are different from each other in both structure and function. The active centers are linked with a larger antenna, localized in the granal partitions, and can transport electrons to plastoquinone, whereas the inactive centers are linked with a smaller antenna, localized in the stromal lamellae, and cannot transport electrons to plastoquinone [44,48–51]. The inactive centers, the formation of which is a phase in the repair cycle for those damaged PSII centers, can transform into the activated form [52].

There are several different methods for the measurement of inactive centers. One is based on the amplitude of the electrochromic band shift at 518 nm (ΔA518) and is due to photochemical charge separation in the reaction centers under both in vitro and in vivo conditions [53]. The other method uses the amplitude of the initial fluorescence yield (Fo) increase in the induction dynamic curve as a measure of the relative concentration of the inactive centers based on the inability of them to transfer electrons from QA to QB [54]. In addition, the amount of inactive centers can be calculated from a change in the content of active centers caused by some treatments. Functional PSII reaction centers are conveniently assayed by repetitive flashes in leaf disks [55,56].

There have been several lines of evidence demonstrating the presence of physiologically inactive centers in leaves [51]. The reversible inactivation of PSII reaction centers is likely an effective mechanism protecting PSII from photodamage [57]. Anderson and Aro [46] proposed a hypothesis that under strong light an increase in the photoinhibited PSII reaction centers can act as a pathway of light energy dissipation protecting the functional centers against damage. Moreover, they have demonstrated that photoinactivation of PSII is a light-dosage effect depending on the number of photons absorbed rather than the rate of photon absorption. Hence, it will occur at all light levels from limiting to supersaturating light [58]. Recently, the hypothesis has been supported by our experimental results from soybean leaves grown in the field. Based on these results, it has been deduced that photoinhibition in soybean leaves may result from enhanced thermal dissipation by the inactivated PSII reaction centers rather than D1 protein loss or xanthophyll cycle–dependent heat dissipation [24]. The main reasons for this deduction are as follows.

First, the initial fluorescence level, Fo, always increased significantly, while Fv/Fm decreased in soybean leaves even under unsaturating light conditions without environmental stress. There are several explanations for the mechanism of Fo change. On the basis of the model, suggested by Kitajima and Butler [59], Demmig et al. [31] proposed that the damage to PSII reaction centers can lead to an increase in Fo, and an increase in heat dissipation can result in a decline in Fo. In some studies, therefore, an increase in Fo was taken to indicate photodamage [60,61]. Moreover, a good correlation between the rise in the Fo level and the loss of the D1 protein was observed from the moss samples grown under low light (60 μmol photons $m^{-2}s^{-1}$) and subsequently exposed to high light (1000 or 2000 μmol photons $m^{-2}s^{-1}$) for 1.0–4.5 h [62]. However, such explanations of the Fo rise to be due to PSII center damage are not always valid in every case. In some cases, the photosynthetic function in leaves could recover within a short time after photoinhibition had occurred and Fo increased significantly. Therefore, an increase in Fo can also be explained by the

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

inactivation of PSII reaction centers [14,48,57,63–65]. Recently, it has been suggested that as well as the separation of the light-harvesting chlorophyll protein complex of PSII from the PSII core complexes, partially reversible inactivation of the PSII reaction centers at high temperature is the cause of the increase in the Fo level [66]. The reversible part of the Fo increase can also be ascribed to the formation of the reduced QA [67].

Second, after the removal of photoinhibitory conditions, the PSII photochemical efficiency, Fv/Fm, could recover in the dark at the same rate as under weak light of 30–100 μmol photons $m^{-2}s^{-1}$. This indicates that the photoinhibition observed by us in soybean leaves is not involved in net loss and resynthesis of D1 protein, because D1 protein synthesis is strictly light dependent [14,68].

Recently, new evidence supporting the above deduction has been obtained. Photoinhibition caused by strong light in leaves of soybean grown in a phytotron was accompanied by an increased Fo and an accumulation of inactive PSII reaction centers manifested by chlorophyll fluorescence analysis but no net loss of D1 protein (S.-S. Hong and D.-Q. Xu, unpublished data).

Unfortunately, the nature of the inactive centers and the mechanism whereby excessive light energy is dissipated as heat remain unclear, although there have been some studies related to the mechanism of PSII center inactivation. Some examples are as follows.

The light-induced inactivation of the PSII reaction centers can be resolved into a reversible conformational change (characterized by a rise in Fo and a decrease in Fm) followed by an irreversible modification of D1 protein [69] or three processes with different kinetics: the fast process ($t_{1/2}$ = 1–3 min), the slow process ($t_{1/2}$ = 15–40 min), and the very slow process ($t_{1/2}$ more than 100 min) [70]; or four intermediates: fast ($t_{1/2}$ = 30s), semistable ($t_{1/2}$ = 2 min.), stable ($t_{1/2}$ = 30 min), and nondecaying on the basis of their Fo fluorescence decay times [67].

PSII complexes can exist in dimeric and monomeric states. The more stable dimers are monomerized during photoinhibition, and phosphorylated D1, D2, and CP43 retard the photoinduced monomerization [71]. The less stable PSII monomers are located in the nonappressed granal margins, whereas the more stable PSII dimers are located in the appressed granal cores [72]. The cyanobacterium *Synechococcus* sp. pcc 7942 possesses two functionally distinct forms of the D1 protein: D1:1 and D1:2, and PSII centers containing D1:1 are less efficient and more susceptible to photoinhibition than those centers containing D1:2 [73]. Once D1 protein is phosphorylated, it is neither dephosphorylated nor degraded in the light [74].

These data are very useful but not sufficient for understanding the mechanisms of the PSII center inactivation and reactivation. In addition, dissociation of P680 from the light-harvesting antenna of PSII also can explain the apparent inactivation of PSII reaction centers [75]. Moreover, there have been some reports in which an increase in Fo caused by heat treatment is linked to the supposed disconnection of PSII reaction centers from the antenna complexes [76]. It appears that the relationship between the disconnection and the reversible inactivation of PSII reaction centers is worth studying.

Energy Dissipation Associated with Cyclic Electron Flow Around PSII

Cytochrome b_{559} is always present in isolated PSII reaction centers, but its function remains unclear. It has been proposed that PSII cyclic electron transport involving Cytochrome b_{559} may act as a mechanism to protect the reaction center from photodamage [77–80]. This is an attractive hypothesis, but it is yet to be demonstrated experimentally. The report that pyocyanine stimulated light-dependent Cytochrome b_{559} reduction and alleviated photoinhibition in spinach thylakoids [81] is in favor of the hypothesis. Critchley and Russel [57] have suggested that the inactive centers could dissipate excessive light energy as heat through a cyclic electron flow around PSII.

More recently, Prasil et al. [82] proposed a model about the relationship between PSII function and cyclic electron flow around PSII. According to this model, the redox state of the plastoquinone (PQ) pool is a determinant of the extent of the coupling between the noncyclic electron flow from

PSII via quinone acceptors to PSI and water oxidation. Under weak light, the PQ pool is mostly oxidized and the noncyclic electron flow is fully coupled to the oxygen evolution; under strong light, low-oxygen concentration, or low-temperature conditions, the PQ pool becomes mostly reduced and a cyclic electron flow via Cytochrome b_{559} in the high-potential form around PSII operates in parallel to the noncyclic one.

ΔpH-Dependent Energy Dissipation

As electrons are transferred directionally on the membrane, a proton gradient across the thylakoid membrane, namely, ΔpH or high-energy state, is developed during illumination. This ΔpH is not only necessary for ATP formation but also an important regulatory factor in the energetic metabolism of chloroplasts. Fork et al. [83] proposed that such a high-energy state is a protective mechanism of the photosynthetic apparatus. It was demonstrated that the removal of the high-energy state by an uncoupler could exacerbate the photodamage in chloroplasts [84] and leaves [85]. More recently, using the experiments of the cumulative exposure to strong light for a short time, Shen et al. [86] showed that such a proton gradient across the thylakoid membrane played a protective role for PSII when other protective mechanisms did not operate effectively during the induction of leaf photosynthesis.

An increase in the proton gradient across the thylakoid membrane is a fast response to excessive light energy. It is not only an effective protective mechanism itself but also an essential prerequisite for the operation of other thermal dissipation processes mentioned above. At least the activity of violaxanthin deepoxidase is controlled by the luminal pH [38].

The thermal dissipation processes mentioned above play important protective roles against photodamage to the photosynthetic apparatus when light is in excess of photosynthetic demand. It was estimated that in leaves of irrigated cotton exposed to full sunlight, about 25% of the excitation energy was used for CO_2 fixation, an additional 19% was consumed in photorespiration and the remainder, 56%, was dissipated via thermal dissipation [87].

PROTECTIVE STRATEGIES OF THE PHOTOSYNTHETIC APPARATUS AGAINST PHOTODAMAGE

Higher plants always live in an environment where light intensity often changes substantially. Unlike animals, they cannot escape from unfavorable environments. Therefore, plants have developed some strategies for both increasing light absorption under light-limited conditions and avoiding photodamage to the photosynthetic apparatus under excessive light. Besides those thermal dissipation processes mentioned above, there are several protective strategies against photodamage to the photosynthetic apparatus, which are as follows.

Decreasing Light Absorption

When the received light energy is in excess of the photosynthetic requirement, plants may reduce light absorption by light-avoiding movements of leaves and/or chloroplasts or by an increase in leaf reflectance through hair cover or an accumulation of salt crystals on the leaf surface [88].

Reducing Light Energy Distribution to PSII

When a transition to state 2 occurs, light energy received by PSII decreases, thus alleviating the pressure of excessive light energy on PSII. It was considered that state transition might make a significant contribution to the total nonphotochemical dissipation of light energy in leaves even under conditions of saturating light [89]. However, different opinions exist regarding the role of state transition under high light [90]. Our study showed that the transition to state 2 induced by a stream of weak red light could alleviate photoinhibition caused by strong light in wheat leaves [91],

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

but in leaves of wheat, sweet viburnum, and soybean grown in the field, of the three components (fast, middle, and slow) of the nonphotochemical quenching of chlorophyll fluorescence, the middle one related to the state transition had the smallest quenching coefficient under strong midday sunlight [T. Hong and D.-Q. Xu, unpublished data] indicating that state transition is not likely an important protective mechanism.

Increasing Photosynthetic Utilization of Light Energy

After plants are transferred from a low-light environment to a high-light one for several days, the contents of both the components of the photosynthetic electron transport chain and Rubisco in leaves increase resulting in an increased photosynthetic capacity [92].

Enhancing Energy Consumption by Metabolic Processes

Since photorespiration was discovered, its physiological function has been an open question. Osmond [93] suggested that photorespiration in C_3 plants can be effective in preventing photoinhibition under strong light with no CO_2, because it can dissipate excessive light energy. Since this suggestion is based on experiments performed under strong light and in the absence of CO_2, naturally the question appears whether photorespiration can also play a role in preventing photoinhibition in normal air. We observed that after exposure of a cotton leaf to strong light for 3 h, photoinhibition was enhanced on suppression of photorespiration by low O_2 (2%), indicating that photorespiration can indeed alleviate photoinhibition under strong light with normal CO_2 [94]. However, these results can not be fully explained by the suggestion of Osmond, because under low O_2, increased photosynthesis can use the excessive light energy induced by inhibition of photorespiration. Namely, only from the point of view of energy utilization, one would not expect that a low O_2 treatment may lead to an enhanced photoinhibition. Considering the suggestion by Sharkey et al. [95] that a deficient Pi supply may limit photosynthesis, and the suggestion by Gao et al. [96] that photorespiration has a function of maintaining the internal level of Pi in the chloroplast, it is reasonable to speculate that photorespiration can alleviate photoinhibition by enhancing the recycling of Pi in the photosynthetic process of chloroplasts. This speculation is supported by our experimental results of Pi content determination and Pi feeding. Under strong light and low O_2 conditions, the net photosynthetic rate gradually declined. As is consistent with this, the Pi content decreased more in the leaf segment in low-O_2 air than that in normal air. However, the difference in the decline of the net photosynthetic rate between the low-O_2 treatment and control (normal air) disappeared after Pi feeding [94].

From the carbon metabolic pathways of photosynthesis and photorespiration, it is clear that with respect to Pi release photorespiration is a faster way than starch or sucrose synthesis. This is because Pi release in photorespiration is performed only through a reaction from phosphoglycolate to glycolate, whereas that in starch or sucrose synthesis needs to pass through many reactions from phosphoglycerate to starch or sucrose. Therefore, photorespiration can considerably accelerate the Pi turnover during photosynthesis.

More recently, Park et al. [97] presented evidence that the electron transport to oxygen via the twin processes of photorespiration and the Mehler reaction mitigates the photoinactivation of PSII in vivo, and photorespiration is as effective as the Mehler reaction in protecting PSII against light stress. Interestingly, dark respiration also plays a role in the protection of the photosynthetic apparatus, as shown by a report that inhibition of dark respiration by azide increases the susceptibility of the cynobacterium *Anacystis nidulans* to photoinhibition and slows down the recovery from photoinhibition [98].

Raising Capacity of the Scavenging of Active Oxygen

Even under optimal conditions, some metabolic processes (e.g., the Mehler reaction) in plants can produce active oxygen species which have severe destructive effects on the photosynthetic apparatus.

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

However, the active oxygen–induced damage to the photosynthetic apparatus does not occur under normal conditions owing to the effective operation of an antioxidative defense system, which can scavenge active oxygen species at an adequate rate in chloroplasts. Recently, Foyer et al. [99] have reviewed in detail the mechanisms of generating and scavenging of active oxygen in photooxidative stress.

The antioxidative defense system in plants is composed of both nonenzymatic and enzymatic constituents. The enzymatic antioxidative components include superoxide dismutase (SOD), catalase (CAT), and ascorbate peroxidase (AsPOD) as well as those enzymes involved in the synthesis and regeneration of the small-molecule antioxidants, such as dehydroascorbate reductase and glutathione reductase (GR). O_2^- forms H_2O_2 and O_2 by catalysis of SOD. H_2O_2 can interact with ascorbate in a reaction catalyzed by AsPOD to produce H_2O or be destroyed by CAT. Xu et al. [100] found that in soybean leaves the activities of these enzymes displayed significant diurnal variations with increases around noon on clear days. The nonenzymatic antioxidants are some small molecules such as ascorbate, glutathione, tocopherol, and flavonoids as well as carotenoids. They can interact with active oxygen species to scavenge them. For instance, the carotenoids may change $^1O_2$ into normal oxygen.

Accelerating Reparation of Damaged Parts

The D1 protein of the PSII reaction center has the highest turnover rate among thylakoid membrane proteins encoded by chloroplast genomes. For the damage and repair of PSII reaction center, Aro et al. [52] have proposed a complex cycle involving several key stages: (a) the reversible inactivation of PSII center, (b) the formation of nonfunctional center with a damaged D1, (c) the migration of the nonfunctional center from the granal region to stromal lamellae, (d) the removal of damaged D1 from the nonfunctional center followed by its degradation, (e) the insertion of a newly synthesized D1 into the nonfunctional center, and (f) the migration of the complex with a new D1 back to the granal region and the recovery of photochemical competence.

The fact that photoinhibition in leaves of wheat grown in the field was not accompanied by a net loss of D1 protein [28] does not imply the nonoccurrence of D1 degradation during photoinhibition. It is likely that under strong light D1 protein is constantly degraded and synthesized forming a dynamic equilibrium with no net loss of the D1 protein. Just owing to the effective operation of the protective system mentioned above, no net loss of the D1 protein was observed during photoinhibition under natural conditions [28]. During photoinhibition caused by some extreme conditions, the loss of the D1 protein is often unavoidable, because those experimental plants grown under low light have such low capacities for photosynthesis and protection of the photosynthetic apparatus from photodamage that they cannot adapt to a sudden strong light, or because the isolated thylakoids [101] or PSII reaction centers [11,102] used in experiments have lost most components of their protective systems.

In addition, specific light-stress proteins can be considered to be part of these protective strategies. These proteins are stable under light-stress conditions but are rapidly degraded during recovery at low light. Their function may be related to transient binding of chlorophylls, which may subsequently be reused for insertion into newly synthesized proteins [103].

RELATIONSHIP BETWEEN PHOTOINHIBITION AND PHOTODAMAGE

It is often thought that photoinhibition is a result of net loss of the D1 protein, so it occurs only when the rate of damage to the D1 protein exceeds the rate of its repair [9,71,104–106]. However, some experimental results from plants grown in cabinets [107–111] and grown in the field [27,28] have clearly indicated that photoinhibition is not necessarily accompanied by a net loss of the D1 protein. Furthermore, under anaerobic conditions, the restoration from light-induced PSII electron

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

transport inhibition of isolated spinach thylakoids without de novo protein synthesis has been reported [112]. Obviously, one should not simply equate photoinhibition with photodamage. The cause of photoinhibition is not always photodamage. Nevertheless, there are some different viewpoints about the relationship. For instance, Tyystjarvi and Aro [113] have defined photoinhibition as the light-dependent irreversible inactivation of PSII reaction center activity, which can be restored only via the degradation and synthesis of the D1 protein. Moreover, they consider that photoinhibition is as common as light, not restricted to stress conditions and high light, but occurs in vivo under all light intensities, and that the repair mechanism is normally rapid enough to prevent the symptoms of photoinhibition from appearing under optimal growth conditions.

Since the photosynthetic function could rapidly recover within minutes or hours after photoinhibitory conditions were removed, Krause [63] and Öquist [114] proposed that photoinhibition can be viewed as a controlled protective mechanism that serves to dissipate excessive energy and to minimize damage to the photosynthetic apparatus. Furthermore, Björkman et al. [115] reported that the observed responses of mangrove leaves to excessive light may reflect a regulatory and protective response rather than a damage to the reaction center complex of PSII. Therefore, photoinhibition in vivo should be viewed as the capacity of plants to adjust photosynthetically to the prevailing environmental conditions rather than a process which inevitably results in damage or injury to plants [116]. Critchley and Russell [57] proposed that what has been considered previously as photodamage may in fact be the mechanisms of reversible downregulation, and actual damage to the photosynthetic apparatus by light may be an event restricted to extreme environmental conditions, including those used in laboratories. Meanwhile, Björkman and Demmig-Adams [88] guessed that photoinhibitory damage is uncommon in natural plant stands, and responses that in the past were thought to be indicative of photoinhibitory damage in many cases now appear to be reflections of the operation of protective processes. Our studies also indicate that under natural conditions without other environmental stress, photoinhibition is mainly a reflection of the enhancement of the thermal energy-dissipation processes [24,28]. Similarly, photoinhibition also occurs in rain forest understory plants when they are exposed to saturating sunflecks, and it may most likely be the result of rapid heat dissipation, as no indication of photodamage has been seen [117]. In a word, photoinhibition of PSII in vivo is often a protective strategy rather than a damaging process [58].

Under natural conditions, photodamage to the photosynthetic apparatus is often a result of the combined effects of light and other severe environmental stress such as low temperature, drought, or nutrient deficit. For instance, under low temperature, especially frost conditions, low temperature not only inhibits photosynthesis leading to an excess of light energy but also hinders both the protective systems and repair process from operating effectively inducing photodamage to the photosynthetic apparatus, because the rate of damage exceeds the rate of repair. Therefore, a pronounced photooxidative bleaching of chloroplast pigments was often observed in winter [118].

CONCLUSIONS

Light stress often causes photoinhibition of photosynthesis in the upper layer leaves of plant canopies. In the last two decades, photoinhibition has been an important subject in photosynthesis research. However, the studies carried out under natural conditions have been few until now. From the available data, it appears that under natural conditions without any environmental stress other than light, photoinhibition is only a reflection of enhanced operation of thermal energy dissipation rather than a result of photodamage to the photosynthetic apparatus. In plants, there are many protective strategies against photodamage to the photosynthetic apparatus under light stress. The irreversible photodamage is unavoidable only under extreme conditions, including natural and artificial conditions, which hinder seriously the operations of both photosynthesis and protective systems. For understanding the molecular mechanism(s) of photoinhibition in nature, there are some topics to be studied such as the mechanism of reversible inactivation of PSII reaction centers, the relative contribution of each type of thermal energy dissipations in protecting the photosynthetic apparatus

against photodamage, and the physiological and biochemical bases of interspecific and intraspecific differences in resistance to photodamage.

ACKNOWLEDGMENTS

Some of our studies cited here were supported by the National Natural Science Foundation of China (Grant No. 39570068). We thank Professor T.-D. Wang and Dr. W.S. Chow for their critical reading of the first version of this manuscript.

Photooxidative Stress in Higher Plants

IVAN N. MINKOV, GALINA T. JAHOUBJAN, ILIA D. DENEV, AND VALENTINA T. TONEVA
University of Plovdiv
Tzar Assen, Bulgaria

INTRODUCTION

Plants have a high capacity to convert light energy to chemical energy under optimal conditions. Several conditions, like low concentration of carbon dioxide, low or high temperatures, and water deficit can cause a decrease of the energy-transfer efficiency from light to carbon dioxide, resulting in an excess of light energy. Plants have mechanisms to dissipate the energy excess as heat, but high-light excess and/or failure of these mechanisms allows the generation of reactive molecules: triplet excited chlorophyll and active oxygen species (AOS) [1].

The generation of active oxygen species occurs even under optimal conditions, because they are normal metabolic products of many processes [2]. Plants have several mechanisms to suppress the production of active molecules [1]. The failure of the scavenging systems or even high excess of photons leads to an excess production of active oxygen species [1]. Such a light-dependent AOS generation is referred to as a photooxidative stress [3].

PHOTOSYNTHETIC APPARATUS UNDER LIGHT STRESS

Light-Induced Production of Active Oxygen Species

The biologically important oxygen species are the singlet oxygen ($^1O_2$), the superoxide radical anion ($O_2^{\bullet -}$), the hydrogen peroxide (H_2O_2), and the hydroxyl radical ($OH^{\bullet}$).

The generation of singlet oxygen will be described later. Active oxygen species are produced by the reduction of molecular oxygen in a series of one-electron transfers [1]. The superoxide radical anion is formed by one-electron reduction of a ground-state oxygen. Mehler [4] originally proposed that the stromal side of photosystem I (PSI) is the major site of superoxide production. Later it was shown that there are two sites of oxygen reduction on the reducing side of PSI [1,5,6].

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

The reduced ferredoxin (Fd) is a major $O_2^{\bullet -}$–generating component [7]. The apparent K_m value in physiological conditions is about 60 μM [1].

$$2\ O_2 + 2\ Fd_{red} \rightarrow 2\ O_2^{\bullet -} + 2\ Fd_{ox}$$

The $O_2^{\bullet -}$ reduction can occur in the aprotic interior of thylakoid membranes, where the solubility of oxygen is much higher than in water. The sites of reduction are the Fe-S centers X and A/B. The K_m for oxygen reduction in this centers is 10 μM, but it increases severalfold with an increase in light intensity or in damaged membranes [1,3]. However, there is evidence that under physiological conditions, superoxide may donate electrons to the electron donors of PSI, so there might be a superoxide-mediated cyclic electron flow around PSI [1].

Oxygen can be reduced by PSII during photooxidation [8]. Superoxide radicals can receive an additional electron, undergo protonation, and produce hydrogene peroxide. Most of the hydrogen peroxide in chloroplasts arises in the disproportioning of superoxide. This reaction occurs spontaneously, but its rate is greatly increased by the thylakoid-bound and stromal superoxide dismutases [1].

$$O_2^{\bullet -} + O_2^{\bullet -} + 2H^+ \rightarrow H_2O_2 + O_2$$

or from the reduction of superoxide by ascorbate, manganese ions, or ferredoxin [1].

$$O_2^{\bullet -} + AH_2 + H^+ \rightarrow H_2O_2 + AH$$

The last reaction has a minor contribution as compared with the enzyme-catalyzed reaction [9]. Additionally, H_2O_2 may be generated in glyoxysomes as well as peroxisomes by glycolate oxidase during photorespiration or by acyl-CoA oxidase via β-oxidation and the glyoxylate cycle [10,11].

Hydrogen peroxide can be converted into a strongly oxidizing hydroxyl radical ($OH^{\bullet}$) by one-electron transfer. The main source of ($OH^{\bullet}$) is the decomposition of hydrogen peroxide in the Fe-catalyzed Haber-Waiss reaction; that is, a superoxide-assisted Fenton reaction [12]. In this reaction, trace amounts of Fe^{3+} are reduced by $O_2^{\bullet -}$ to produce Fe^{2+} which subsequently reacts with H_2O_2 to form $OH^{\bullet}$.

$$Fe^{3+} + O_2^{\bullet -} \rightarrow Fe^{2+} + O_2$$
$$Fe^{2+} + H_2O_2 \rightarrow OH^{\bullet} + OH + Fe^{3+} \text{ (Fenton reaction)}$$

Although superoxide and hydrogen peroxide are able to migrate a considerable distance in membranes before reacting with other molecules, hydroxyl radicals are extremely reactive, so they can only diffuse a few molecular diameters before reacting [9,13].

Photoinhibition of Photosynthesis

Photoinhibition of photosynthesis is generally used to denote a decrease in the photosynthetic activity when plants are exposed to a high-light intensity that exceeds the capacity of the dark reactions (electron transport and carbon metabolism) or the ability of the light-harvesting system to dissipate light energy not used for photosynthetic functions. Powles [14] considers the photoinhibition as a first stage of high light–induced damages related to the reduction of photosynthetic capacity. The second stage, which he refers to as a pigment photooxidation, occurs after a long-term exposure of plants to strong light and concerns the bleaching of the antenna pigments. The latter process requires light and oxygen [15]. Since the photoinhibition represents the other side of the Blackman light-response curve, and simply equates with photosynthesis under conditions of photon excess (at excessive photosynthetically active photon flux density [PPFD]), the catena of processes which participate in photoinhibition is the same as in photosynthesis [16]. On basis of the relaxation times of biophysical, biochemical, physiological, and ecological processes included in the catena, two main classes

of photoinhibition are distinguished—dynamic photoinhibition, usually predominant in sun plants, and more slowly relaxing chronic photoinhibition, predominant in shade plants [16].

PSII is primarily affected by photoinhibition [14]. Two mechanisms of photoinactivation are involved which affect the acceptor side and donor side, respectively [17,18]. They are distinguished on the basis of differences in the primary site of electron transport malfunctioning, the subsequent D1 protein degradation, the light intensity, and the oxygen requirement of the process (Fig. 1).

Acceptor side–induced photoinhibition of PSII occurs under high-intensity irradiation that exceeds the saturation level of the photosynthetic electron transport [17]. Excess photon exposure causes nonphysiological overreduction of the first quinone electron acceptor in PSII. Sequential modifications happen at the level of the QA and/or QB acceptors [19]. These conditions lead to the recombination of the radical pair, $P680^{+}Pheo^{-}$ [20] and the production of the triplet state of P680-^{3}P680 [21]. Under aerobic conditions, these chlorophyll triplets may be quenched by oxygen and singlet oxygen $^{1}O_2$ thus produced [22,23]. Alternatively, oxygen may receive electrons and thus produce oxygen radicals [24]. It has been shown that the addition of singlet oxygen scavengers such as histidine [25–28], diazobicyclooctane [26,29], azid [23], or rutin [27] as well as free radical scavengers such as uric acid or propylgallate [30] provide partial photoprotection against the acceptor side–induced photoinhibition of PSII. All steps in this mechanism, prior to singlet oxygen formation, are reversible if plastoquinone is reoxiding.

There is still no consensus on the role of active oxygen in photoinhibitory damage. The singlet

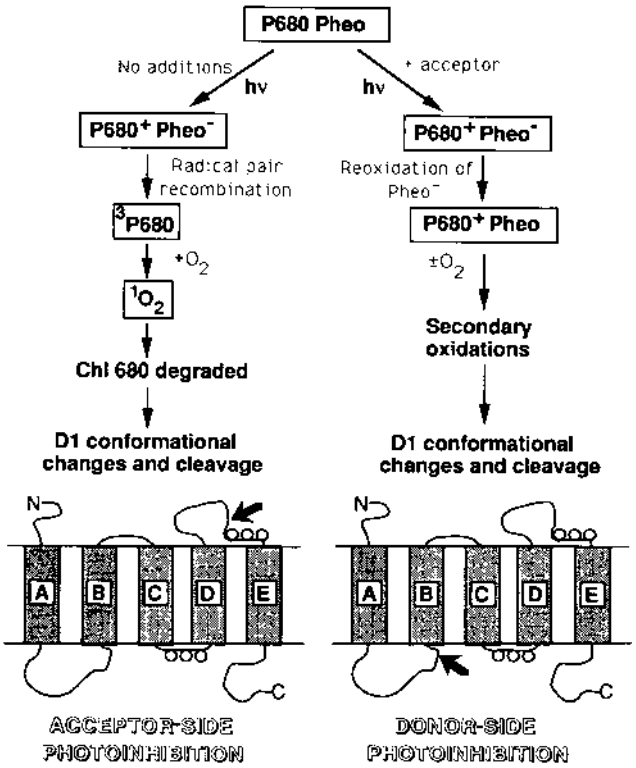

FIGURE 1 Scheme showing the two routes of damage due to acceptor- and donor-side photoinhibition, as identified from experiments conducted with isolated reaction centers of PSII. Putative cleavage regions are indicated with arrows on the folding diagrams for the D1 protein. (From Ref. 18.)

oxygen participates in the initiation of the following degradation of the reaction center protein D1 [31,32]. It is able to trigger D1 protein damage, probably by promoting a special conformational change, which makes the protein susceptible to proteolytic cleavage [33]. One possibility is that in complex in vivo systems, such as leaves and photosynthetic algae, the D1 protein may be cleaved by the direct action of active oxygen [26]. The major cleavage site on D1 is on the stromal side of the thylakoid membrane [33–37], and the characteristic degradation products of the D1 protein are 23-kDa N-terminal [33,36] and 10-kDa C-terminal fragments [36]. The D1 protein is the protein in PSII with the highest turnover rate [38,39]. This phenomenon might be linked to the requirement to repair PSII after it has been damaged by photoinhibitory light [40].

Donor side–induced photoinhibition of PSII occurs under both high- and low-light intensities when the capacity of the water-oxidizing complex to donate electrons to P680 is inactivated before irradiation by other stress factors such as low temperature [41,42]. The water-oxidizing complex is unable to keep up with the rate at which electrons are transferred from P680 toward acceptor-side components. This may lead to an increase in the lifetime of $P680^+$ with a high oxidizing potential [43]. This process would occur both in the presence and absence of oxygen. The $P680^+$ is able to extract an electron from its surrounding environment and subsequently destroy the proteins D1, chlorophylls, and β-carotenes associated with reaction center II or within the vicinity [44,45]. Cleavage sites on D1 are on the luminal side of the membrane [35,36,46], and hence the characteristic degradation products of the D1 protein are 9-kDa N-terminal and 24-kDa C-terminal fragments [46].

PSI is also affected, and recent studies indicate that the mechanism of oxygen-dependent light inactivation is similar to the acceptor side–induced photoinhibition in PSII. The recombination of the primary charge separation products in PSI leads to the formation of P700 in the triplet state and thus to the production of singlet oxygen [47]. Alternatively, in this photosystem, oxygen can be reduced by reduced ferredoxin to the superoxide radicals through the so-called Mehler reaction [4,7,47]. PSI has stability which is explained in terms of an effective control process associated with this system [48].

Under favorable natural conditions, mild photoinhibition frequently occurs even at light levels below the light saturation. There is an efficient recovery process operating which ensures that mild photoinhibition is restricted to clear and changeable days; photosynthetic efficiency is regained not later than the next morning in the absence of climatic stress [49].

The damage resulting from excess light absorption may also be induced by changes in other environmental factors other than light. Many types of stress causing a decrease in the rate of photosynthesis will lead to an increase in excess photon flux [50]. Plants which are exposed to severe stress have an increased susceptibility to photoinhibition with subsequent photooxidative damage. This is because stresses such as chilling temperature [51,52], mineral deficiencies [53], or gaseous pollutants [54] disturb plant metabolism and often cause a decrease in the capacity for photosynthetic carbon assimilation. Although there are a number of recovery mechanisms for avoidance of photoinhibition, environmental stress may cause a decrease of the photosynthetic activity when the rate of damage exceeds the capacity of these mechanisms and exhausts the adaptation systems. Taken alone, photoinhibition, may serve as a drastic but very efficient strategy to cope with the photooxidative processes in an early stage by reducing the light-driven formation of highly active oxygen species [55].

Photooxidation Processes in Plants

During photosynthesis, in conditions of intensive illumination of the plant cell, the continuous production of oxygen is observed, which creates a potential hazard from the development of a variety of photooxidation processes, including photodestruction of the photosynthetic apparatus. Experimental data propose clear evidence of the oxygen-dependent oxidation character of a whole chain of photodestructive processes taking place in the chloroplasts [56–59].

The double nature of oxygen which on one hand is absolutely necessary for most living organ-

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

isms on Earth, but on the other hand is a toxic element for all life forms is due to the structure of its molecule, chemical interactions, and biological functions. Oxygen in its basic or triplet state, $^3O_2$ (or O_2), possesses two single electrons with parallel spins at different orbitals. On excitation, the molecule of oxygen can be transferred into one of two possible singlet states. The first one, ($^1\Delta$), is found 22.5 kcal\mol higher than the basic one; and the second one, ($^1\Sigma$), 37.5 kcal\mol higher. In its first singlet state, oxygen is exclusively reactive owing to its excess of energy and its very long lifetime. In its second singlet state, its lifetime is very short. Chlorophyll is the main generator of the triplet state in the chloroplasts. Its photoexcitation results in the production of triplet molecules of the pigment ^{3}Chl [60–63], which can generate $^1O_2$ under normal conditions and especially well in the absence of carotenoids. Oxidation can also be due to other plant pigments: porphyriens and phlavins [64,65]. Accumulated in plant tissues, the active oxygen forms show a complex influence on the total plant metabolism by inhibition of photosynthesis, inactivation of key enzymes of the oxidation path of specific amino acids, damage of the cell membranes due to the oxidation of the membrane proteins and nonsaturated fatty acids, and finally all reactions lead to the disintegration of the plant tissues [66–69]. Regardless of the damaging role of highly reactive forms of oxygen, under ''ordinary'' circumstances, they are ''normal'' cell metabolites. Probably there is a critical balance between the generation and detoxification of reactive oxygen in the plant cell. During the course of evolution, the chloroplasts have elaborated their own endogenous defense systems which perform either detoxification of active oxygen or stringent control over its production [15,70,71].

ANTIOXIDATIVE SYSTEM

Nonenzymatic Defense

Photoprotective Role of Carotenoids

The essential function of carotenoids is photoprotection. The β-carotene protects the PSII reaction center against photooxidative damage via quenching of singlet oxygen or of the chlorophyll triplet state that sensitizes singlet oxygen formation [72]. It has been shown that β-carotene limits the destructive reactions by scavenging singlet oxygen rather than by trapping the chlorophyll triplet [25]. Chlorophyll triplets are unable to give their spin to β-carotene [22], because they are not situated sufficiently close to each other in the PSII reaction center. If carotenoids were close enough to quench ^{3}P680 efficiently, they would be competing with water as an electron donor to $P680^+$ and thus be efficiently oxidized and rapidly degraded. A likely explanation is that the oxidizing photochemistry in PSII prevents evolution of an efficient quenching system for chlorophyll triplets in the PSII reaction center [73].

Quenching of chlorophyll triplet	Quenching of singlet oxygen

The β-carotene in the PSII reaction centers, together with Chl670, play a protective role and acts as a secondary electron donor to prevent donor-side photoinhibition [74]. Under conditions where their oxidation may be relatively infrequent, both of them could serve to protect against accumulation of $P680^+$. The reaction centers are only photoinactivated after the secondary donors are exhausted, presumably because $P680^+$ can now oxidize the protein matrix.

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

Krieger and Weis [75] show that the reaction center quenching is caused by Ca^{2+} release from PSII, when the lumen pH falls below 6. The water-splitting complex is inhibited by Ca^{2+} and electron donation to the oxidized primary donor, $P680^+$, is decreased. The $P680^+$, per se, may be responsible for quenching. This type of quenching is redox sensitive and does not lead to a significant decrease in the F_0 level of chlorophyll *a* (chla) fluorescence.

Xanthophylls are involved in a second type of photoprotective process: regulation of absorbed light energy utilization in the PSII antenna of higher plants and some algae [76]. In this process, generally referred to as an energy- or ΔpH-dependent nonphotochemical chlorophyll quenching (q_E or NPQ), the excess of absorbed light energy in the PSII antenna is dissipated as heat [76]. Therefore, NPQ decreases the efficiency of PSII when the rates of electron transport and carbon metabolism reach saturation at high photon fluxes and favor antenna-based photon protection [16].

Two general types of molecular mechanisms have been proposed to account for NPQ. The first is based on a strong correlation between NPQ and the extent of violaxantin conversion to zeaxantin via the xantophyll cycle [76,77]. The mechanism for the role of zeaxanthin in NPQ has been studied in detail by Owens and coworkers [78]. The participation of the different carotenoids in a definite type of energy transfer depends on their excited state singlet (S_1 and S_2) and triplet energy levels. That a singlet-singlet energy transfer from carotenoids (violaxanthin) to chla originates from the carotenoid S_1 state has been concluded from studies of the light-harvesting function [72].

The NPQ is associated with the conversion of violaxanthin to zeaxanthin that consists of deepoxidation of the epoxide groups forming cyclohexenyl rings, and this results in an increase in the number of conjugated carbon-carbon double bonds from 9 to 11. The key process in this mechanism of NPQ is the conversion of violaxanthin to zeaxanthin that lowers the energy of the carotenoid S_1 state to approximately the same level as the chla S_1 state and introduces a potential new pathway for reversible singlet-singlet energy transfer from chla to zeaxanthin [79] (Fig. 2). Because the total rate of radiative and nonradiative transitions from S_1 to the ground state is more than 2 orders of magnitude larger for carotenoids than for chla-typically 10–40 ps for carotenoids and 5 ns for chla [78], weak quenching centers in the antenna are produced.

$${}^1\mathrm{Chl}^* + \mathrm{Car} \rightarrow \mathrm{Chl} + {}^1\mathrm{Car}^*$$

Singlet-singlet energy transfer from chlorophyll to carotenoids—NPQ via xantophyll cycle

An alternative mechanism associates the increase in NPQ with changes in the aggregation of the light-harvesting complex II (LHCII) in vivo [80]. In the light-harvesting chla/b–binding proteins, chlorophyll molecules, although at close distance, are separated from each other by xanthophyll molecules. These strong antiquenchers prevent close chl-chl interaction and quenching [81,82] and do not interfere with optimal energy transfer. The key process in this way of NPQ is protonation-promoted changes in the protein structure leading to a xanthophyll/chl aggregation and allowing the direct quenching of singlet chl by carotenoids and energy dissipation (Fig. 3). The studies of the dependence of xanthophyll's aggregation on the increasing polarity of ethanol/H_2O mixture show that zeaxanthin has the strongest tendency to aggregate [83].

State transitions can adjust the excitation ratio of PSI and PSII by changing the cross section of antenna chlorophyll for the respective reaction centers depending on the environmental light spectrum [84].

The yield of NPQ is regulated by the size of the pH gradient across the thylakoid membrane [76]. When the lumen pH falls, protonation of specific amino acids on the luminal side of LHCII in the vicinity of zeaxanthin increases the energy transfer between chla and zeaxanthin by modulating

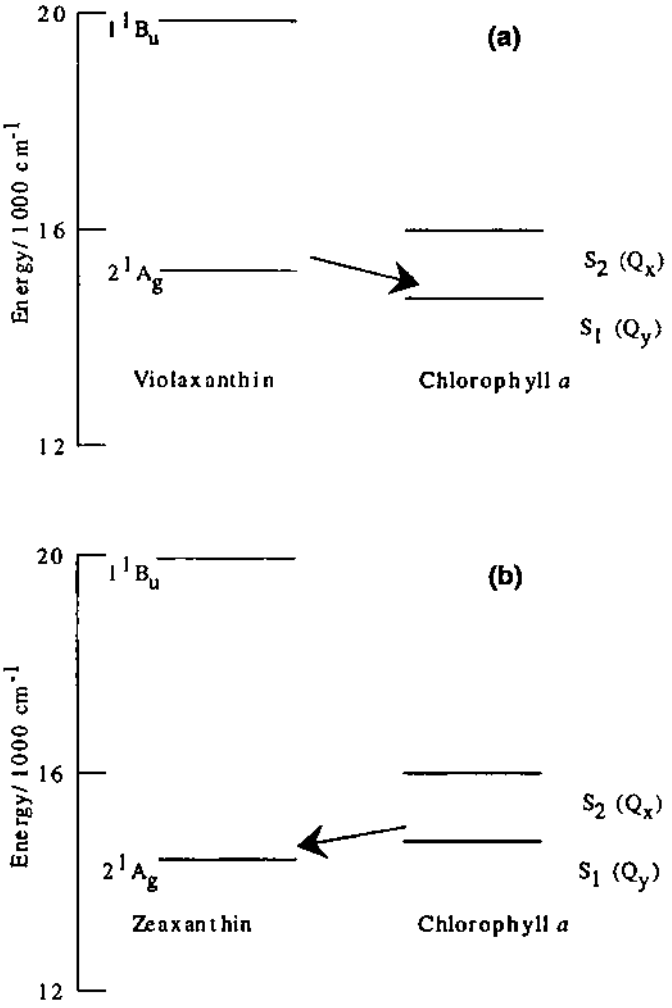

FIGURE 2 Process of (a) light-harvesting by violaxanthin (i.e., forward energy transfer from carotenoid to chlorophyll) and (b) nonphotochemical quenching by zeaxanthin (i.e., reverse energy transfer from chlorophyll to carotenoid). (From Ref. 79.)

the chla-zeaxanthin spectral overlap or the dipol strength of the zeaxanthin $S_1 \rightarrow S_0$ transition [78,85,86]. The low pH could also increase the activity of the violaxanthin deepoxidase located on the luminal face of the thylakoid membrane [87]. At the same time, the differences in ΔpH may also determine the capacity for NPQ by the level of chl/xanthophyll aggregation [88].

Thus, the relationship between the NPQ, xantophyll cycle, LHCII aggregation state, and ΔpH could be highly dependent on the experimental conditions and on the physiology of the sample. Under conditions where NPQ becomes saturated, photoinhibition develops [89].

Photooxidative stress can be also produced by the irradiation of plants in which the biosynthesis of colored carotenoids has been blocked by treatment with bleaching herbicides such as Norflurazon (SAN-9789) [90]. In green plants or dark-grown plants irradiated with high-intensity light, the effect of Norflurazon could be connected to the photoprotective role of carotenoids [91,92] for chlorophyllide-sensitized photodestruction or to their structural role [93,94].

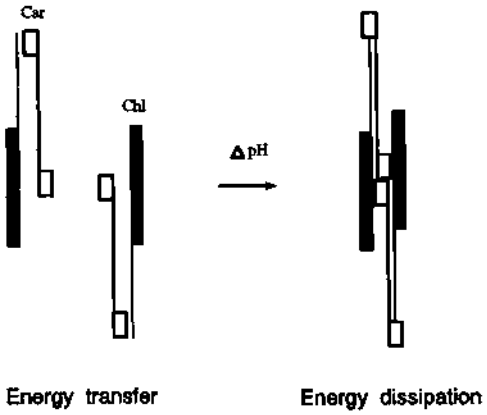

FIGURE 3 A model to explain how quenching may arise from specific interactions between xanthophylls and chlorophylls in LHCII. In the relaxed state, pigment-pigment distances are extended and prevent quenching, but on protonation of amino acid residues, pigment aggregates are formed giving rise to energy dissipation and accounting for absorption changes associated with nonphotochemical quenching. (From Ref. 88.)

On the other hand, our findings show that the total Chl content is higher during the first hours of irradiation (weak red or moderate white light) of Norflurazon-treated dark-grown wheat plants compared with the nontreated plants which is followed by a decrease in chlorophyll due to progressive photodamage (Fig. 4) [95]. The flash irradiation or a brief irradiation with weak light of carotenoid-deficient dark-grown plants causes phototransformation of a greater number of originally accumulated prolochlorophyllide (Pchlide) molecules to chlorophyllide (Chlide), and in that way the chl

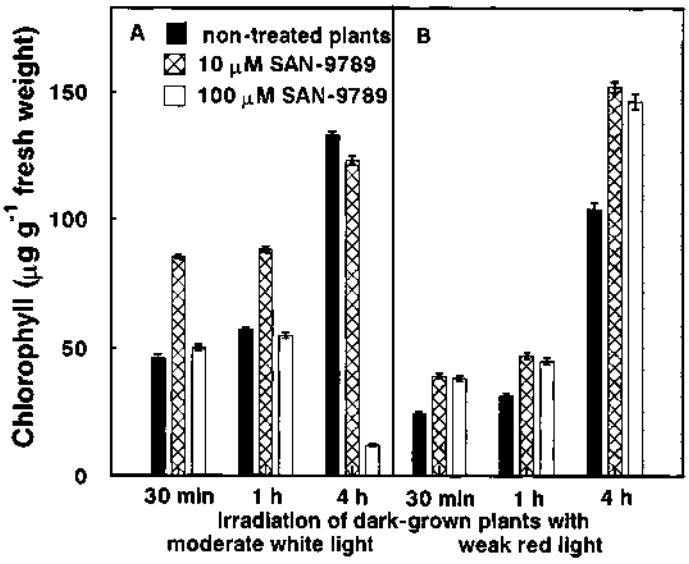

FIGURE 4 Chlorophyll accumulation after irradiation of young dark-grown Norflurazon-treated wheat plants with moderate white (A) or weak red (B) light.

synthesis that stops in darkness can continue more efficiently [96]. These results confirm the statements of Koski and coworkers [97] that carotenoids depress the phototransformation of protochlorophyll to chl in normal etiolated leaves, because they absorb blue light very strongly, and that the lower efficiency of the photochemical action in normal seedlings compared with albino ones can be attributed to the competitive absorption of blue light by carotenoid pigments.

According to the hypothesis of Reinbothe and coworkers [98], an oxygen-insensitive Pchlide oxidoreductase protein (POR) is formed that tightly bounds the protochlorophyllide and used light and NADPH for the reduction of protochlorophyllide to chlorin. In both gymnosperms and angiosperms, POR is active during the transition from dark to light [99] when protochlorophyllide and chlorin must be shielded from interacting with O_2 in the atmosphere. During the early stages of the dark-light transition of etiolated plants, while the newly formed chlorophyllide is still bound to POR, the photoprotection of the Chlide against the O_2 occurs even at a carotenoid deficiency.

High Light–Dependent Protein Synthesis

The early light–inducible proteins (ELIPs) are found in etiolated plants exposed to light, and being expressed in the first hours of the greening process [100,101]. In the greening of dark-grown plants, ELIP transcription is induced by red light, so it is controlled by the phytochrom receptors [102]. Recently, ELIPs were detected in mature green pea plants with strong light-promoted photoinhibition [103,104]. In mature light-grown plants, ELIP transcription is under the control of a criptochrom receptor [103,105], which is induced specifically by strong blue or ultraviolet A (UVA) light.

Sequencing of ELIP cDNA clones of pea [106,107] and barley [101,108] shows that ELIPs are related to the light-harvesting chla/b (cab) gene family. They are synthesized in the cytosol as precursors, imported into the chloroplast, and inserted into the thylakoid membranes after processing [100,101], predominantly in the fraction enriched in PSII complexes [109].

Because ELIPs are induced and stable under light-stress conditions but disappear during the recovery process, it may be inferred that they take part in one of the protective mechanisms against the light damage. There are many experimental results concerning the physiological role of ELIPs, but to a certain extent they are contradictory. Nevertheless, it is possible that ELIPs may act as a carrier or a transient structural component of the LHCII responsible for carotenoid location and/or their protective activity in the reaction center-antenna complexes during light stress [76,110,111]. The other possibility for ELIPs is that they bind the free Chl, generated by the degradation of Chl-protein complexes, such as the PSII reaction center or LHCII during light stress [104,108,112].

Under high-light conditions, there can be overexpression of genes for the synthesis of the D1 protein replacing the photodamaged protein [113] and for scavenging enzymes against photoinhibition [3]. At the same time, high-light stress could limit the expression of the light-harvesting proteins [104] in order to reduce the antenna size for minimum absorption of light quanta.

Other Protective Mechanisms for Avoidance of Photoinhibition

The PSII cyclic electron transport involving cytochrome b_{559} can also serve as a mechanism to protect the reaction centers from damage caused by light with high intensity [43,114,115]. According to the model of Barber and De Las Rivas [116], the cytochrome b_{559}, which exists in two forms, may also be involved in a regulation of photoinhibition. The high-potential form protects against donor-side photoinhibition by acting as an electron donor to the oxidizing side of PSII. The low-potential form protects against acceptor-side photoinhibition by acting as an electron receptor from reduced pheophytin.

The cyclic electron flow around PSI can adjust the ratio of NADPH to ATP production depending on the requirement of the stromal biosynthetic reactions, which also promotes the photon-utilizing capacity as a whole [117–119]. Photorespiration supplies carbon dioxide and other indirect photon energy acceptors (ADP, NADP) for leaf cells by consuming photosynthetic products resulting in an increase in the photon-utilizing capacity [120].

Enzymatic Defense

Plants generate active oxygen species even under nonstressful conditions [2]. They have developed protective systems to suppress the production of active molecules and for removal of AOS [1]. These protective systems can be grouped into two categories: enzymatic and nonenzymatic defenses [121]. The enzymatic defense system involves a series of enzymes for detoxification of AOS. The plants usually respond to stress conditions by an increase in the activity of certain protective enzymes, as is the case with Norflurazon-treated plants (Fig. 5).

The investigations of this area start with the discovery by McCord and Fridovich [122] that a copper-containing protein from bovine serum can dismutate two superoxide anion radicals to hydrogen reoxide and molecular oxygen. McCord and Fridovich called the enzyme superoxide dismutase (SOD). The SOD localized in chloroplasts, together with the ascorbate-specific peroxidase (APX), monodehydroascorbate reductase (MDAR), dehydroascorbat reductase (DHAR), and glutathion reductase (GR), can fully reduce the toxic superoxide radicals to water [121]. According to this scheme, SOD catalyzes the dismutation of superoxide into hydrogen peroxide and oxygen at diffusion controlled rates. The ascorbate peroxidase, both stromal and thylakoid-bound forms, reduces H_2O_2 to water via monovalent oxidation of ascorbate to monodehydroascorbate (MDA) [123]. The ascorbate is regenerated by the ascorbate-glutathione cycle using electrons from PSI and including several parallel reactions:

The MDA produced by the thylakoid-bound APX is reduced by ferredoxin [123].

The stromal MDAR catalyzes the reduction of MDA by NADPH. The MDA can dissociate into ascorbate and dehydroascorbate and stromal DAR, using glutathione as an electron donor, reduces dehydroascorbate to ascorbate. Glutathione is regenerated by GR with NADPH as an electron donor [9].

Superoxide Dismutases

Superoxide dismutases (EC 1.15.1.1) are metal-containing enzymes that catalyze the dismutation reaction of two superoxide anions to oxygen and hydrogen peroxide [122,124]. On the basis of their metal cofactors, three different isoforms can be distinguished: the copper and zinc (Cu/Zn) form, manganese (Mn) form, and iron (Fe) form.

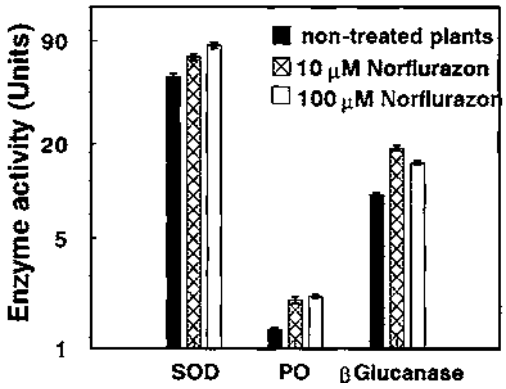

FIGURE 5 Enhanced activity of certain protective enzymes, superoxide dismutase (SOD), peroxidase (PO), and β-(1,3) glucanase in young light-grown wheat plants treated with Norflurazon (unpublished data).

Mn- and Fe-SOD are structurally related: In some bacteria, the metal cofactors can be exchanged without loss of activity. The Cu/Zn-SOD is structurally unrelated to other SODs [125].

Plants usually contain all three SOD forms [126]. The Mn-SOD is typical for mitochondria and the cytosol contains Cu/Zn-SOD [126]. Chloroplasts contain generally Cu/Zn-SOD. A chloroplastic Fe-SOD has been recently found in many plant families [55,126,127]. Plastidic Cu/Zn-SOD and Fe-SOD are expressed differentially in *Nicotiana plumbaginifolia* and they probably complement each other in action [128]. The preferential expression of Cu/Zn-SOD or Fe-SOD can depend on the plant species, tissue, stage of development, or environmental conditions [55].

The subcellular localization of SOD and superoxide radical production often coincides. Since superoxide radicals are mainly produced at the electron transport chains of chloroplast, of mitochondria, and in the endoplasmatic reticulum, most of SOD activity is localized in these compartments [2].

Mn-SOD and Cu/Zn-SOD have also been found in peroxisomes of pea leaves and watermelon (*Citrullus vulgaris* Schard). It is suggested that Cu/Zn-SOD occurs in the matrix, whereas Mn-SOD is bound at the external side of peroxisomal membrane [129]. There is also evidence of the existence of SOD in the extracellular space [130].

The expression analysis in several plants show that *Sod* genes are differentially regulated throughout development and respond in a different way to environmental stress [131]:

- In *N. plumbaginifolia*, expression of cytosolic Cu/Zn-SOD (*SodCc*) mRNA is enhanced most by heat shock, chilling, or paraquat treatment in the dark in contrast to Fe-SOD (SodB), in which expression is induced mostly by chilling and paraquat treatment in the light [132].
- The expression in tomato of both the choroplastic and cytosolic Cu/Zn-SOD genes (*SodCp* and *SodCc*) is stimulated by paraquat treatment and light, but only the cytosolic isoform shows induction of expression after exposure to drought [133].
- Different members of the maize Mn-SOD gene family (*SodA*) are differentially expressed during the development and pattern of Mn-SOD mRNA accumulation. Accumulation generally depends on mitochondrial activity during plant growth [134].

The large increase of SOD transcription on stress treatment generally correlates with a much more moderate increase in SOD activity. Possibly stress causes a more rapid turnover of SOD proteins, thereby necessitating activation of gene expression to maintain SOD levels [131].

Different stress conditions might lead to a different extent of oxidative stress in the various subcellular compartments, necessitating the expression of those *Sod* genes encoding the SOD isoform(s) needed to protect a particular compartment. The nature of the expression signals is still unclear [131,132]. However, the opportunity to increase the stress tolerance of crops via overexpression of superoxide dismutase and other antioxidant enzymes is a rather tempting issue and recently a large number of laboratories are working in that direction.

A chimeric gene, containing a full length cDNA of chloroplast Cu/Zn-SOD under the control of the Rubisco ssu promotor from *Petunia*, is overexpressed in tobacco and tomato. Fifteen independent transformants of tobacco have been obtained, which according to the data express from total leaf extracts 30- to 50-fold more SOD [135]. Some experiments show 30-fold increase of chloroplastic SOD activity, but this percentage decreases with leaf age [136]. However, such a massive overexpression does not protect CO_2 assimilation, the PSII reaction center or the light-harvesting pigments against methyl viologen [135] or against ozone [137], and chilling-induced photoinhibition [135]. In contrast, overproduction of Mn-SOD in tobacco chloroplasts increases the resistance against paraquat [138].

A chimeric gene consisting of the coding sequence for chloroplast Fe-SOD from *Arabidopsis thaliana* coupled to the chloroplast-targeting sequence from pea Rubisco ssu is expressed in tobacco [139]. Expression of the transgenic Fe-SOD protects both the plasmalemma and PSII against superoxide generated during illumination of leaf disks impregnated with methyl viologen [139]. In contrast, the overproduction of mitochondrial Mn-SOD form *Nicotiana plumbaginifolia* in the tobacco

cv SK1 chloroplasts protects only plasmalemma but not PSII against methyl viologen [136]. The possible reason might be the different membrane affinities of the transgenic Fe-SOD and Mn-SOD [139].

Ascorbate Peroxidase

The ascorbate peroxidase (APX, EC 1.11.1.7) belongs to the group of heme peroxidases. The enzyme catalyzes the oxidation of ascorbate by hydrogen peroxide. Similar to other heme peroxidases, APX is oxidized by hydrogen peroxide to the intermediate compound I. Reduction to the oxyferryl heme and the occurrence of tryptophan radicals near the heme show an analogy to the cytochrome *c* peroxidases [1,140]. Compound I then univalently oxidizes ascorbate forming compound II and the monodehydroascorbate radical (MDA). The interaction of compound II with another ascorbate molecule produces a second MDA [1].

$$2 \text{ Ascorbate} + H_2O_2 \rightarrow 2 \text{ MDA} + 2H_2O$$

Based on their subcellular localization, the four types of APX are the chloroplast stromal soluble form (sAPX), chloroplast thylakoid-bound form (tAPX), cytosolic form (cAPX), and glyoxisome membrane form (gmAPX) [1,141–143]. APX is inactivated in the absence of an electron donor, especially in the case for sAPX and tAPX, whose half-inactivation time is only 15 s [123]. The inactivation is caused by a rapid degradation of the intermediate compound I. Since the stroma thylakoids are enriched in PSI complexes, the tAPX is bound close to the sites of superoxide production [1]. This means that the generated H_2O_2 is scavenged primarily by tAPX at the thylakoid level, whereas the sAPX represents a second level of defense against hydrogen peroxide which escaped the tAPX [144].

The comparison of the molecular properties shows a high degree of homology in the amino acid sequence of the N-terminal of tAPX and sAPX but not with the same region of cAPX [144]. The molecular mass of tAPX is 10 kDa higher than that of cAPX and sAPX. The additional size of tAPX might contribute to its binding to the thylakoid membranes [1,144]. The gmAPX is recognized as 31-kDa polypeptide with a single, membrane-spanning region near the C-terminal [142].

Genes encoding the four types of APX have already been cloned [131,142]. Apx gene expression is rapidly induced by various stress conditions, such as paraquat, ethylene, drought, and heat shock. It would suggest an important role for APX in stress tolerance [145]. A marked discrepancy is found between the increase in Apx steady-state transcript abundance, which is relatively large, and the increase in APX protein activities, which is relatively small. It appears that the high level of Apx transcript observed in response to stress is restricted from interaction with polysomes [146,147]. It has been shown that a three-fold increase in cAPX activity and APX mRNA occurs in transgenic tobacco plants with overexpressed chloroplast Cu/Zn-SOD. Similar data have been reported about chloroplast APX activity in transgenic tobacco overexpressing Fe-SOD [136]. It has been concluded on the basis of these results that the increased level of the gene product in one part of the antioxidant pathway can affect other enzymes in the enzyme defense system [147].

Enzyme Systems Involved in Regeneration of Ascorbate

For the operation of hydrogen peroxide–scavenging system in chloroplasts, the regeneration of ascorbate from monodehydroascorbate (MDA) and/or dehydroascorbate (DHA) is indispensable [1]. As it is mentioned above, the MDA produced by the tAPX is reduced by ferredoxin [148].

The reduction of the stromal MDA is catalyzed by a FAD enzyme called MDA-reductase (MDAR, EC 1.6.5.4). The enzyme operates with NAD(P)H as a electron donor. The NAD(P)H reduces the enzyme FAD to $FADH_2$ and then the enzyme donates electrons to MDA through two one-electron transfers with FAD semiquinone as an intermediate [1].

When MDA is not reduced to ascorbate either by reduced ferredoxine or by MDAR, DHA will be produced by disproportion of two molecules of MDA to ascorbate and DHA. The regeneration of

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

DHA to ascorbate is catalyzed by the thiol enzyme DHA-reductase (DHAR). The DHAR is localized in the chloroplast stroma and operates with glutathione as an electron donor. Since the predominant amount of MDA is directly reduced to ascorbate, the contribution of DHAR and glutathione is a minor part of the regeneration of ascorbate [1].

Recently, a full-length cDNA clone encoding MDAR was isolated from cucumber and pea [149,150]. The DHAR is purified from spinach chloroplast. It has been found that the amino-terminal sequence of DHAR is similar to the Kunitz-type trypsine inhibitors [151]. The DHAR and soybean trypsine inhibitor are both capable of reducing dehydroascorbate when in reduced form and acquiring trypsine-inhibiting activity in the oxidized form [151].

Glutathione (γ-glutamyl-cysteinyl glycine, GSH) is the major low molecular weight thiol compound in most plants. Many of the important metabolic regulatory and antioxidative roles of glutathione result in its oxidation to glutathione disulfide. For most of its functions, glutathione must be in the reduced form [152]. The reduction of GSH is carried out by the flavoprotein oxidoreductase glutathione reductase (GR, EC 1.6.4.2). The GR operates with NADPH as an electron donor [9].

Glutathione reductase has been studied in a wide range of plants. Most of the GR activity in plants cells is present in the chloroplasts [152]. It has also been found that in pea leaves 77% of total GR activity is localized in the chloroplasts, only 3% in the mitohondria, and the rest is cytosolic [153]. In pea leaves, GR is a protein with a molecular weight of 55 kDa. However, eight different isoforms have been detected by two-dimensional isoelectric electrophoresis. It is not possible to conclude from the biochemical data whether GR isoforms represent different gene production or arise as a result of posttranscriptional or posttranslational modification [152].

The full-length cDNA encoding GR from pea and tobacco has been isolated and extensively studied. The pea and tobacco GR cDNA shares 78% homology at the nucleotide level. Both plant GR sequences contain an amino-terminal extension, which is probably a chloroplast transit peptide. In addition, they have similar C-terminal extensions rich in alanine, lisine, and serine, which suggests that this domain probably has a function as an additional signal sequence [152].

The GR activity is also influenced by various environmental factors known to increase oxy radical formations like gaseous pollutants, extreme temperatures, senescence, and pathogen attack [152]. The combination of high light with magnesium deficiency, which would be expected to cause photooxidative damage in the chloroplasts, increases the GR activity by seven times [154].

There have also been several experiments done with GR overexpression in transgenic plants. The GR from *Escherichia coli* is overexpressed in the cytosol of tobacco [155,156] and in the chloroplasts [157], with the level of GR activities of transgenic plants being between 1.4 and 4.0 times higher. It has been found that GR overexpression does not protect CO_2 assimilation after gaseous fumigation, but a decrease of sensitivity to methyl viologen has been found [155,157].

Catalase and Other Enzyme Systems Involved in Plant Oxidative Defense

The overexpression of GR could increase the reduction of the glutathione pool under stress conditions. The existing data suggest that glutathione may have a pivotal role in the defense against oxidative stress [158].

Glutathione can serve as a substrate for glutathione-S-transferase. This enzyme can detoxify the products of lipid peroxidation and xenobiotics. It also shows peroxidase activity [159,160].

One recently proposed mode of action is the role of GHA as a substrate of glutathione peroxidase (GPX, EC 1.11.1.9). The glutathione peroxidases are a family of multiple isoenzymes which catalyzes the reduction of H_2O_2, organic hyperoxides, and lipid hyperoxides by reduced glutathione and thus help to protect cells against oxidative damages [161,162]. They are known as an antioxidative defense enzymes in animals, but there are indications that they also exist in plants. Genes with significant sequence homology to one member of the animal GPX family, namely, phospholipid hyperoxide glutathione peroxidase, have been isolated from several plants. So far, only one protein,

Cit-SAP, a product of the citrus *csa* gene, which is induced by salt stress, has been isolated and characterized. This protein differs from the animal enzyme in its rate of enzymatic activity and in containing cysteine instead of selenocysteine. The physiological role of Cit-SAP and its homologues in other plants is not yet known [163].

The plants eliminate H_2O_2 by catalases and peroxidases. The metalloenzyme catalase is one of the most efficient proteins in the redox reaction:

$$2\ H_2O_2 \rightarrow 2\ H_2O + O_2$$

At present, three differentially regulated catalyses have been revealed. In *Nicotiana plumbaginifolia* the *Cat1* gene product plays a role in the removal of photorespiratory H_2O_2. The expression pattern of the *Cat3* gene suggests that the encoded protein has a role in scavenging of H_2O_2 generated by the β-oxidation of fatty acids in the glyoxisomes. The *Cat2* product most likely has a specific role in protecting the cell from H_2O_2 produced during the oxidative stress [131]. Exposure of plants to ozone, sulfur dioxide, and UVB radiation all lead to a rapid decline in *Cat1* steady-state transcript levels and a concomitant rapid increase in *Cat2* transcript levels [164]. The control mechanisms are still unclear, but a number of evidence supports the idea that the balance between catalyase expression and hydrogen peroxide production play a central role in the tolerance of plants to different types of stress [131].

PHOTODYNAMIC HERBICIDES

Long before Rebeiz [165] announced the discovery of a new class of herbicides, called photodynamic, or ''laser,'' herbicides, it was known that exogenous δ-aminolevulinic acid (ALA) causes accumulation of large amounts of chlorophyll precursors in the dark [166]. The action of the photodynamic herbicides is due to the accumulation of protoporphirin IX (Proto), Mg-protoporphyrin(ester) (Mg-Proto[E]), and protochlorophyllide (Pchlide) in exclusively large amounts in plants kept in darkness. Light is a specific factor which determines the rate of damage of the plants treated with photodynamic herbicides in darkness. After exposure to high-light intensities, such plants exhibit oxidation-destruction processes due to the photosensibilization caused by porphyrins, usually resulting in the death of the plant [165,167–175]. It is well known that porphyrins act as effective sensibilizors of the photooxidation processes leading to damage of living systems due to the action of light in the presence of oxygen [176–182]. First Granic [176] and later other researchers [183,184] have also shown that the irradiation of etiolated plants which have accumulated exclusively large amounts of chlorophyll precursors from exogenous ALA leads to the death of the plant cells.

Some diphenyl ethers can also act as photodynamic herbicides [185–189], since they cause an accumulation of exclusively high levels of Proto in plant tissues [168,187–191], which is most probably the mechanism of their photodestructive action. As a whole, the tetrapirol-dependent photodynamic herbicides are compounds which force green plants to accumulate unnecessary amounts of metabolite precursors of the biosynthetic pathways of heme and chlorophyll. In light, the accumulated tetrapirols photosensibilize the formation of singlet oxygen, and the latter kills the treated plants by the oxidation of their cell membranes.

The compounds which can induce the formation of porphyrins [192] in the treated plant tissues are usually called modulators of the chlorophyll biosynthesis [165]. Tetrapirol-dependent photodynamic herbicides are usually composed of ALA, the precursor of all tetrapirols in plant and animal tissues, and one of the modulators of the chlorophyll biosynthesis such as, for example, 2,2′-dipyridyl and 10-phenantroline. The ALA and the modulator act simultaneously. The amino acid is the precursor of damaging tetrapirols, whereas the modulator increases their effect [165,171]. If plants are treated with ALA in the beginning of the dark phase, in dark there is an accumulation of porphyrins, photodynamically active protochlorophyllide and other photoactive compounds. These precursors are not part of the light-collecting complex and are not able to transform the excitation to the

reactive centers of photosynthesis [171]. During the next light period, the formed tetrapirols act as effective photosensibilizators leading in their turn to the death of the sensitive plants [165,193]. Oxidation-destructive changes take place in the plant cell. Transformed into the excited triplet state, the accumulated porphyrins interact with oxygen and form oxygen-containing products with a destructive effect [185].

Our investigations in this respect show that the photodynamic light stress is caused by the tetrapyrrole precursors of Chl synthesis. One of the most important precursors in this respect may be Pchlide. There are data which suggest that the accumulation of superoptimal amounts of the monovinil- and divinil-Pchlide forms are the most important cause of cell destruction in certain plant types [165,194,195]. Other precursors, for example, Proto-IX, also could be accumulated under the influence of photodynamic combinations [182,190]. Our investigations show an accumulation of both those precursors (Figs. 6 and 7), although in different amounts in the monocotyledons and dicotyledons. The proposed mechanisms of action of the precursors [196] suggest that there might be no direct connection between the amount of the accumulated precursors and the photodynamic effect. The photodestructive effect of the precursors strongly depends on the plant type (monocotyledons or dicotyledons) and not entirely on the Pchlide and Proto levels (Figs. 6 and 7). At the same time, the species-dependent variations in the accumulation of Proto, as well as the differences between the plant tolerances, are the critical factors in defining the photodynamic effect in plants [179]. This applies particularly to the changes in the Proto content which may be in direct correlation with the photoherbicide effect in the sensitive plants.

In treatment with acifluoren, the photoherbicide action correlates with the Proto level in cucumber leaves [190]. However, it is known that the Proto is not photostable in vivo and it is photooxidized by singlet oxygen which it generates in the presence of molecular oxygen and light. Proto photodestruction is faster in vivo, because molecular oxygen is dissolved easily in the lipids of the membranes, than in water, and Proto is a lipophilic molecule [196]. In addition, the singlet oxygen initiates a rapid build-up of lipid peroxides, which leads to a sequence of peroxidase reactions which might play a role in the oxidative photodestruction of Proto in vivo [196]. This means that the

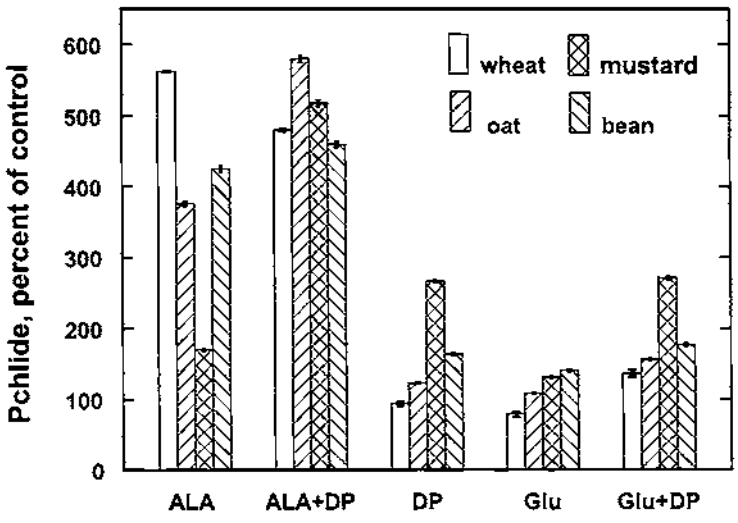

Figure 6 Effect of 2,2′-dipyridyl (2,2′-DP), glutamic acid (Glu), and δ-aminolevulinic acid (ALA) and their combinations on the protochlorophyllide (Pchlide) content in green plants darkened for 17 h after treatment.

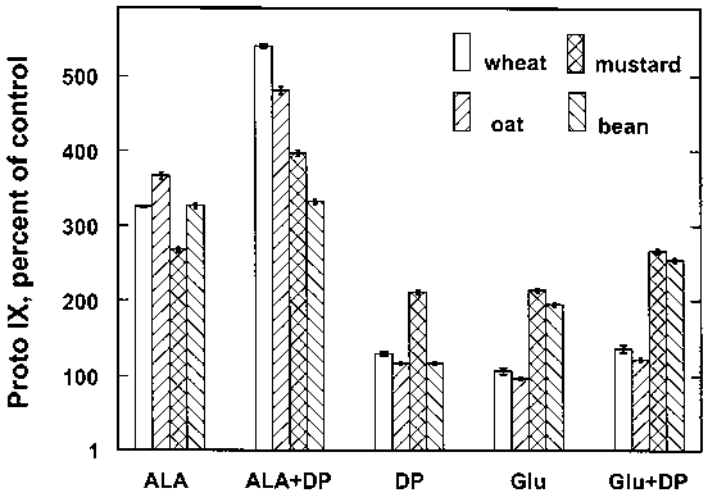

FIGURE 7 Influence of 2,2′-dipyridyl (2,2′-DP), glutamic acid (Glu), and δ-aminolevulinic acid (ALA) and their combinations on the protoporphyrine IX (Proto) content in green plants darkened for 17 h after treatment.

photodestruction is not necessarily always connected with the Proto level (Fig. 6 and Table 1). This might be the reason for the higher resistance of some monocotyledonous plants to the Chl precursors which have accumulated in darkness. However, there is no visual photodynamic damage in monocotyledonous plants (oat and wheat) and no visible destruction of the plants. Despite the differences in the precursor levels (see Figs. 6 and 7) in the treated plants, they do not differ from the controls neither in their appearance nor in their leaf color. This difference might be a consequence of the biochemical heterogeneity of the Chl biosynthetic pathway, as well as the different ways of greening of different plant groups. The experiments support the finding of Rebeiz et al. [197] that show despite the increased levels of Pchlide and Proto, there are no visible signs of destruction in monocotyledonous plants (wheat and oat). This is most probably due to the fact that these plants belong to the greening group D MV/L DV [171]. The accumulation of tetrapyrroles in the treated plants may be considered necessary, but not the only condition for the specific photodynamic sensitivity and

TABLE 1 Photodynamic Herbicidal Damage (%) of Various Plant Species to δ-Aminolevulinic Acid, glutamic Acid, and 2,2′-Dipyridyl

Early precursors and modulator of Chl synthesis	Photodynamic damage of the leaves (%)			
	wheat	oat	mustard	bean
Control	0	0	0	0
δ-Aminolevulinic acid	0	0	70	5
δ-Aminolevulinic acid and 2,2′-dipyridyl	0	0	100	30
2,2′-dipyridyl	0	0	70	10
Glutamic acid	0	0	100	15
Glutamic acid and 2,2′-dipyridyl	0	0	100	20

Destruction was determined visually according to Ref. 165.

photodynamic damages of the different plant species [171,198]. The level of this destruction depends most probably on the amount of accumulated tetrapyrroles, the greening group of the plants, as well as the chemical nature of the synthesized precursors. For example, it is known that mustard plants belong to the D DV/L DV greening group [197]. Under the treatment of such a plant with ALA and 2,2′-DP, the plants are forced to synthesize the wrong tetrapyrrole type (MV) in darkness [197], which makes them sensitive and leads to their destruction.

Concerning the phytolized pigments, all the investigated species mainly accumulate higher amounts of Chlb and less Chla (Fig. 8a–d). This result is rather surprising, since it is well known that Chlb is synthesized through a biosynthetic pathway from Chla [199]. There are also some contradictory data for greening plants showing a higher sensitivity of Chlb if compared with Chla [200]. A negative correlation between the level of the precursors, especially Proto IX, and the chlorophylls, is found in other plant species like *Amaranthus retroflexus* and *Abutilon theophrasti* Medic. that have been treated with acifluoren [190].

The protein content is relatively stable in all investigated plants. This could mean that the destruction of plants is a specific photodynamic effect and it is not a result of an inhibition of protein synthesis or a toxic effect on other processes connected with the protein synthesis. It might also influence the Chla\b–binding proteins (LHCP), presumably through the inhibited transport of the

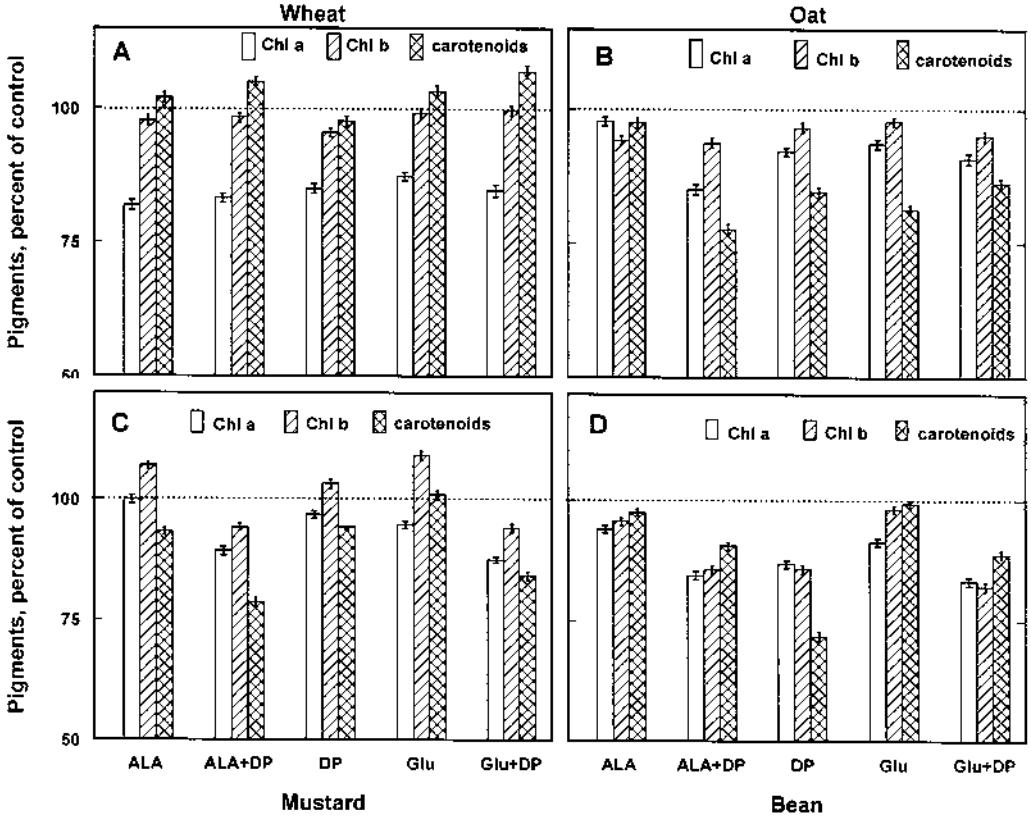

FIGURE 8 Changes in the content of the chlorophyll *a* (Chla), chlorophyll *b*(Chlb), and carotenoids (Car) in green plants of (a) wheat, (b) oat, (c) mustard, and (d) bean plants darkened for 17 h after treatment.

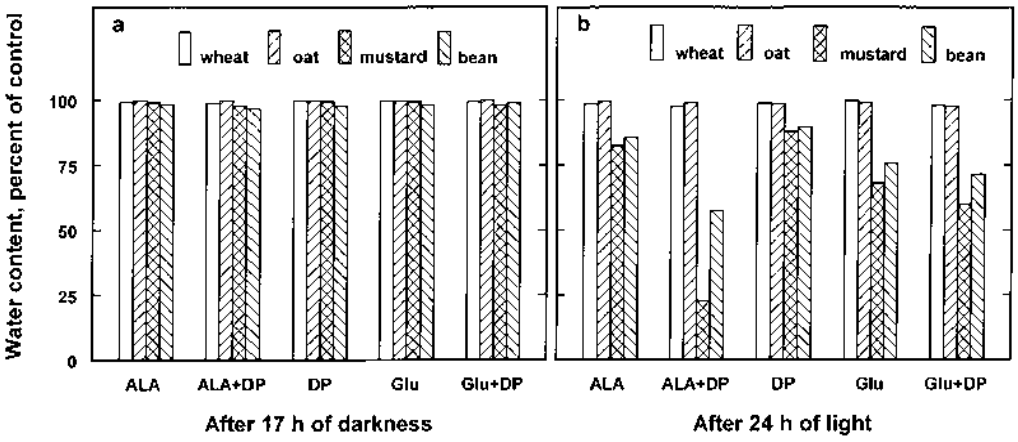

FIGURE 9 Changes in the water content of the leaves of the investigated plants immediately after the dark incubation (a) and after irradiation for 24 h (b).

protein in the plastids [201]. The Glu and 2,2′-DP does not influence the total protein amount which makes the combinations we used a nontoxic photoherbicide.

The changes in the water content in the treated plants (Fig. 9a,b) correlate very closely with the well-known effect of the combination ALA and 2,2′-DP, which is associated with the membrane's destruction and damaging of the selective permeability of the plant cell [165,194].

Our investigations characterize the dicotyledonous plants bean and mustard as being highly sensitive to the treatment with substances that cause the accumulation of Chl precursors, such ALA and Glu, in combination with 2,2′-DP [202]. In comparison, wheat and oat are more resistant, which might also be connected with the different permeabilities of the leaves owing to the differences in their morphological structures. The biochemical mechanism of the different sensitivity is mostly associated with the diverse rate of tetrapyrrole destruction in the cell, as well as with the specific acceleration of the synthesis of monovinyl and divinyl tetrapyrroles induced by different exogenous substances. Generally, concerning the photodamaging effect, the influence of a combination of Glu and 2,2′-DP was relatively close to the action of the better-known effect of ALA and 2,2′-DP but was a little less active when they were compared.

INTRODUCTION

When we started to write this chapter on photosynthetic pigment degradations and transformations under stress, we had to face up to an essential question: What is the definition of a stress? After consulting a dictionary and several textbooks on plant physiology, we decided to adopt the following definition: ''A stress is an adverse force or influence that tends to inhibit normal systems from functioning'' [1]. Complementary precisions have been brought by Lichtenthaler [2] on the stress concept in plants.

Hendry et al. [3] estimated that around 10^9 tons of chlorophyll (Chl) are broken down annually worldwide. This estimation took into account degradations occurring during autumn, those resulting from human activities, and those involved in daily pigment variations.

As the daily pigment turnover concerns a small proportion of molecules at a defined moment, investigations are especially difficult in green leaves. For this reason, experiments on pigment catabolism were principally conducted on senescent tissues (e.g., leaf and cotyledon during seed degreening and fruit ripening) where the totality of the pigments is transformed. Pigment transformations occurring in these tissues can be considered as part of the normal developmental sequence, but in respect to the stress definition adopted, they can also be regarded as the result of various simultaneous stresses (e.g., temperature, nutrient, light).

In the first part of this chapter, we present the main steps of the catabolism pathways of Chl and carotenoids as established with senescent tissues. In the second part, we describe pigment modifications occurring as a response to various stresses. Owing to the limitation of space, only an overview of these changes is given here.

CATABOLIC PATHWAYS

Chlorophylls

Since Hendry's review in 1987 [3], entitled ''The chlorophyll degradation: a biological enigma,'' significant progress has been reported (reviewed in Ref. 4). Although a general scenario for the Chl degradation pathway has been proposed [4], the existence of some intermediates remains only speculative. Moreover, it cannot be excluded that several pathways are involved in Chl degradation or (co)exist depending on the plant species and the stress conditions. It also remains to be determined whether Chl degradation intermediates occurring during leaf yellowing and seed degreening are similar to that involved during daily Chl turnover.

The first steps of Chl degradation pathway consist of dephytylation and demetallation to give their chlorophyllides (Chlide) and pheophorbides (Pheoide), respectively [8–9] (Fig. 1).* The order of the reactions was reported to vary from organ to organ and also from species to species [8]. Enzymes removing the phytol moiety and the central Mg atom from Chl have been described. The former is called chlorophyllase (EC 3.1.1.14; reviewed in Ref. 10) and the latter Mg-dechelatase [11].

In *C. protothecoides* and *Chenopodium album*, Pheoide is 13^2-demethylated prior to the tetrapyrrole ring cleavage [12–13], whereas in *Brassica napus*, the reaction occurs later [14] (Fig. 2). A pheophorbidase catalyzing this reaction has been recently isolated from *C. album* leaves [14]. The subsequent decarboxylation of the 13^2-carboxy-PPheoide to pyropheophorbide (PPheoide, 13^2-demethoxycarbonyl-PPheoide) is a nonenzymatic step which was observed under *C. protothecoides* culture acidification. PPheoide production can also result from a preparation artifact [12–13]. Then the 13^2-methylcarboxy- or 13^2-carboxy-PPheoide ring is oxidized between C4 and C5 by one oxygen molecule through the catalytic action of a monooxygenase without any carbon loss [15]. This contrasts with heme oxidation which requires three oxygen molecules with loss of one carbon [4]. In higher plants, the monooxygenase activity requires reduced ferredoxin as a reductant [16]. A putative mechanism for the reaction has been proposed by Gossauer and Engel [4]. The chlorophyllase and the monooxygenase were found associated with the chloroplast and gerontoplast envelopes [17,18]. To be comprehensive, we must add that several other enzymatic activities have been reported to be involved in the oxygen-dependent Chl breakdown (e.g., peroxidase [19] lipoxidase [20], Chl oxidase [21]). However, their products are not related to those obtained with monooxygenase, which have been identified as the common structural motif in the Chl-degradation product pathways.**

Thus, in the green unicellular alga *C. protothecoides* and under the monooxygenase activity, (13^2-carboxy)-PPheoide is transformed to (13^2-carboxy)-10,22-dihydro-4,5-dioxo-4,5-seco-PPheoide, which is excreted in the culture medium. There either it isomerizes to (13^2-carboxy)-*15(E)*-10,22-dihydro-4,5-dioxo-4,5-seco-PPheoide or it is transformed to a yellow pigment (13^2-carboxylate)-10,15,22,24-tetrahydro-4,5-dioxo-4,5-seco-PPheoide [12] (Fig. 3) which probably constitutes the endproduct of chlorophyll degradation in this organism. In *B. napus* cotyledons and in barley leaves, Pheoide is transformed by the mononooxygenase to 13^2-methylcarboxyl-10,20-dihydro-4,5-seco-4,5-dioxo-22H-PPheoide (also called *Bn*-FCC-2) [6]. The 13^2-methylcarboxyl-10,20-dihydro-4,5-dioxo-4,5-seco-22H-PPheoide isolated in *C. protothecoides* would be an intermediate

* Catabolites from Chla and Chlb have been found in *Chlorella protothecoides* [5]. The Chlb catabolite intermediates reported are similar to that of Chla except that the 7-methyl residue of Chla is replaced by a 7-formyl residue in Chlb. Consequently, here Chl means Chla and Chlb for *Chlorella* and only Chla in the other cases, since in higher plants, only catabolites derivating from Chla have been described [6]. Interestingly, it was recently reported that Chlb can be enzymatically transformed to Chla [7] in higher plants.

** Until recently, both Chlide *a* esterification by geranylgeraniol pyrophosphate and removal of the phytol moeity were ascribed to chlorophyllase. Although enzymes responsible for these two activities are not yet purified, it seems more likely that the two reactions are catalyzed by two different enzymes.

(not shown in Fig. 4). *Bn*-FCC-2 is a nongreen pigment [9] whose formation is light-dependent and inhibited by 3-(3,4-dichlorophenyl)-1,1-dimethylurea (DCMU), an inhibitor of photosynthetic electron transport. This finding strongly suggests that *Bn*-FCC-2 formation utilizes photosynthetic ATP inside chloroplasts [22]. The light-dependent *Bn*-FCC-2 formation can be mimicked if exogenous ATP is added to chloroplasts in darkness [22]. The 8-ethyl residue is then hydroxylated and subsequently becomes the tautomerization of the 13^2-methylcarboxyl-10,20-dihydro-4,5-seco-4,5-dioxo-8-hydroxyethyl-22H,24H-PPheoide to 13^2-methylcarboxylate-10,20-dihydro-4,5-seco-4,5-dioxo-8-hydroxyethyl-22H,24H-PPheoide (structure not shown on Fig. 4) [23,24]. These reactions are probably used to help the exportation of this compound to the mesophyll cell vacuoles [25] where it is accumulated. Then the intermediate undergoes an ultimate transformation consisting of the hydrolysis of the 13^2-methylcarboxyl group to a 13^2-carboxyl (Fig. 4, right). The final product is a pink pigment denoted *Bn*-NCC-3 [14]. A similar compound *Hv-NCC-1* (formerly called RP14) has been isolated from senescent barley leaves [26]. It differs by the presence of a 3-malonyl residue instead of the 3-vinyl residue found in *Bn*-NCC-3 [23,26]. It is interesting to note that both *Bn*-NCC-3 and *Hv*-NCC-1 are similar to the endproduct of the Chl catabolism found in *C. prothecoides*.

The reactions reported above have been established using senescent organisms. As we mentioned previously in the Introduction section, there are several reports indicating that the Chl content varies daily (Table 1). These data point out that in vivo, Chl stability greatly varies with the plant developmental stage. The older the leaf, the more stable the Chl. Sironval [28] measured daily Chl content oscillations in *Fragaria* (strawberry) plants. The amplitude of the oscillations appeared to be dependent of the leaf developmental stage and on the day length. We found that Chl degradation is much stronger in 2-day-old bean leaves than in 10-day-old leaves during the dark period (8 h) following the first illumination (16 h). In these conditions, Chlb is found more sensitive than Chl *a* [30]. Although the high-performance liquid chromatography (HPLC) method used was able to separate both pheophorbide and pheophytin [31–32], no evidence for their accumulation was observed suggesting that the degradation reactions are fast. Data reported by Shioi et al. [33–34] show that both Mg-dechelatase and chlorophyllase are present in the chloroplasts.

Carotenoids

During the autumnal senescence, carotenoids are less degradated than chlorophylls, thus giving yellow to red leaf coloration (however, some exceptions exist [35]). During senescence, the levels of most xanthophylls (i.e., lutein, neoxanthin, violaxanthin, and antheraxanthin) were found to decrease [36–37]. Those which remain were found to be acylated in many species [37]. Other derivatives, that is, xanthophyll epoxides and esters, have also been observed. The latter constitutes the major carotenoid pool when the leaves turn completely yellow [35]. They are progressively accumulated in plastoglobuli [38], which may serve to increase their relative stability with respect to oxidation. The pattern of carotenoid degradation varies from species to species [39]. During the senescence process, β-carotene and violaxanthin appear to be the least and the most sensitive carotenoids, respectively. Enzymes probably operate during some of the senescence events (e.g., a peroxidase

TABLE 1 Literature Data About the Chl Turnover Rate as Determined in Various Plants and Different Developmental Stages

Material	Pigment type	Half-life time (h)	Reference
Soya leaf	Chl *a* and Chl *b*	24	27
Young soybean leaf	Chl *a*	108	28
Young soybean leaf	Chl *b*	93.6	28
Barley leaf greened for 24 h	Chl *a* and Chl *b*	16.4	29
Barley leaf greened for 48 h	Chl *a* and Chl *b*	58.3	29

activity) [40]. Although the regulation of carotenoid degradation is not established, it is interesting to note that phytochrome could delay this process [41].

PIGMENT MODIFICATIONS UNDER STRESS CONDITIONS

Light-Intensity and Oxidative Damage

When light absorption by photosynthetic pigment exceeds both the capacity to use the photosynthetic NADPH and ATP for carbohydrate synthesis and the capacity of energy dissipation mechanisms, photosynthesis is progressively inhibited (i.e., photoinhibition phenomenon). As a consequence, the pigment composition starts to change mainly through the xanthophyll cycle. If these adverse conditions are prolonged, pigment destructions through photooxidation occur (i.e., energy transfer from the lowest excited triplet state of Chl to molecular oxygen in its triplet ground state resulting in the formation of singlet oxygen). The formation of a strong cation radical ($P680^+$) has an oxidizing potential high enough to oxidize Chl and β-carotene associated with the reaction center II (reviewed in Ref. 42). Since NADPH and ATP are used in enzymatic reactions whose rates are primarily a function of temperature, light-damage can happen even at low-light intensities [43]. Chla is more sensitive to photooxidation than Chlb, since the latter transfers excitation energy to the former. In contrast to what was observed with senescence, β-carotene is the most sensitive chloroplast pigment to photooxidation [44]. Several mechanisms helping plants to fight against adverse effects of light and implying pigment transformations have been shown. Most of them are involved in the modification of excessive energy dissipation, whereas others imply Chl binding to particular proteins (e.g., early light–inducible proteins: ELIPs).

Dissipation of Excessive Energy

Carotenoids are recognized to be essential for the survival of illuminated plants, since their numerous conjugated double bonds (>9) are able to quench the Chl triplet state and also scavenge singlet oxygen and the other reactive oxygen species which can photooxidize Chl (reviewed in Ref. 45). Plant mutants devoid of carotenoids cannot survive in light [46]. It was suggested that β-carotene-5,6-epoxide formation was the result of β-carotene oxidation by light [47], since its production is low in the dark and progressively rises during the day [48].

Another photoprotecting mechanism involving xanthophyll interconversions has been described in many species (reviewed in Ref. 49). In green plants (including green algae), the xanthophyll cycle is a light-induced deepoxidation pathway from zeaxanthin to violaxanthin via antheraxanthin triggered by overacidification of the inner thylakoid space during the light stress [50] (Fig. 5A). The reaction also requires O_2 and a reducing power [51]. Zeaxanthin seems to exert its photoprotective function by direct singlet-singlet energy transfer from the excited singlet Chl state to that of zeaxanthin, followed by loss of the excitation energy by heat. Another hypothesis proposes an indirect action of zeaxanthin via alteration of the properties of the thylakoid membrane [52]. In

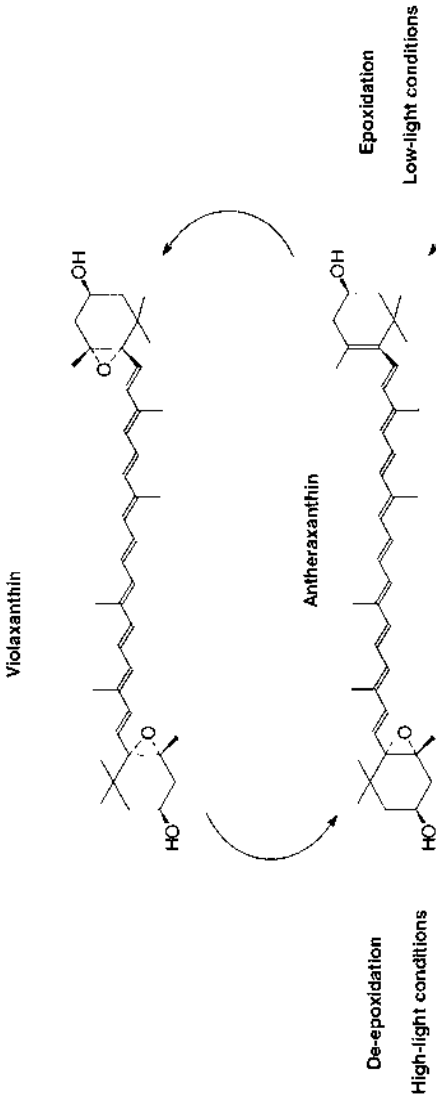

FIGURE 5 Xanthophyll cycle in (A) higher plants and in green algae and (B) in chromophytes.

MARCEL DEKKER, INC.

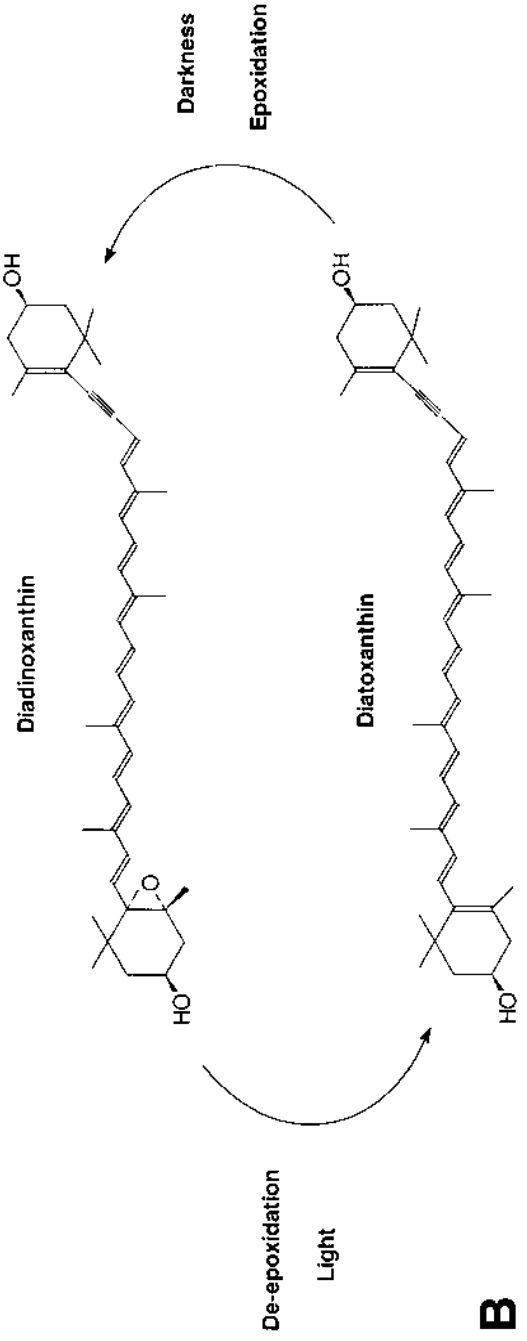

FIGURE 5 Continued.

Digitalis purpurea, the deepoxidation state of the cycle increases to a maximum at a growth-light intensity of 500 μmol m^{-2} s^{-1} and then slightly decreases with a further increase in growth-light intensity [53]. Other investigations showed that the xanthophyll cycle activity depends on light intensity and is strongly enhanced at fluence rates beyond those saturating photosynthetic CO_2 fixation [51].

Some rhodophytes (*Gracilaria gracilis* [Stackhouse] and *Gracilaria multipartita* [Clemente; Harvey]) have shown an atypical xanthophyll cycle [54], whereas others [*Gracilariopsis longissima* [S.G. Gmelin], *Ahnfeltiopsis concinna* [J. Ag.] Silva et DeCew, *Laurencia mcdermidiae* [J. Ag. Abbott], *Porphyridium cruentum*) are devoid of this pathway [54–56]. Chromophytes presented another xanthophyll cycle involving diadinoxanthin to diatoxanthin transformation [54,57] (see Fig. 5B). The xanthophyll cycle has not been demonstrated in cyanobacteria. However, in *Oscillatoria*, an increase of the photon flux density triggers a decrease of the Chla and phycocyanin levels and a relative increase of myxoxanthophyll and zeaxanthin corresponding to a decrease of β-carotene and echinenone [58].

Intertidal macroalgae are regularly stressed because of high-light intensity, desiccation, and temperature changes occurring during emersion. A morphological and pigmentary adaptation against too high photon flux densities was described for tropical intertidal rhodophytes [55]: *A. concinna* and *L. mcdermidiae* grow in dense turf allowing self-shading over small vertical distances and exhibit microscale pigmentary adjustments; the canopy of *A. concinna* appears yellow-orange, whereas the canopy of *L. mcdermidiae* appears green. Tissues from understory locations of both species appear red to purple-black. Actually, *A. concinna* reduces the levels of all phycobilins, whereas *L. mcdermidiae* maintains the phycocyanin and allophycocyanin levels while reducing phycoerythrin with exposure to high photosynthetic flux densities. Both turfs increase the levels of carotenoids and mycosporine-like amino acids [59], but only *L. mcdermidiae* increases absorbance of ultraviolet A (UVA) radiation.

During the first stages of chloroplast development, newly formed Chlide *a* is not protected by carotenoids and can be easily photooxidized [60]. Nevertheless, Chlide *a* shows a relative photoprotection against photodestruction when it is under the form of a Chlide-NADPH: protochlorophyllide oxidoreductase–NADPH complex [61] (reviewed in Ref. 62). It was shown that this complex can be transformed to a Chlide-NADPH : protochlorophyllide oxidoreductase–$NADP^+$ complex under illumination. This light reaction can be reversed in darkness [63]. A cycle between the two complexes thus exists (Fig. 6) and has been recently correlated to Chlide protection against photooxidation [64,65].

Early Light–Inducible Proteins

It was found that ELIPs accumulates under light stress condition correlates with the photoinactivation of photosystem II (PSII) degradation of reaction center protein D1 and changes in the level of pigments [66]. ELIP-related proteins, namely, cbr (for carotene biosynthesis–related), have been described in the green unicellular *Dunaliella bardawil* in response to light-stress proteins [67]. The mechanism of protection by ELIP is still unclear. Since Chl, which is not associated with protein-carotenoid complex, can be very harmful when sensitized by light absorption, it was proposed that ELIPs may be involved in the transient binding of pigments under light-stress conditions. Alternatively, ELIPs may have a function of free Chl scavengers and be involved in the binding of released Chl and thus ensure protection against free radical formation through Chl sensitization.

Accumulation of Specific Pigments

A limited number of algae (e.g., *Dunaliella, Haematococcus*) present the peculiar property of accumulating secondary carotenoid (mainly β-carotene, canthaxanthin, and astaxanthin) as a response to a light stress (e.g., see Refs. 68 and 69; reviewed in Ref. 70). Little is known about the regulation of these syntheses. We found that at the beginning of the stress, green *H. pluvialis* cells synthesize astaxanthin at the expense of β-carotene present in the PSI [69]. The bulk of astaxanthin requires

Marcel Dekker, Inc.

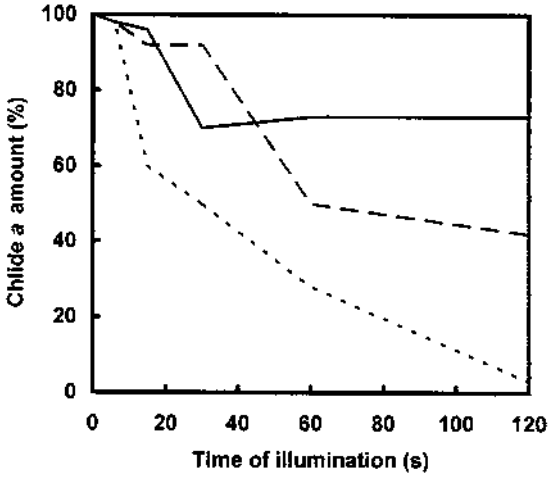

FIGURE 6 Time course of Chlide a degradation under different light-intensities. Chlide a amounts are expressed as the percentage of the absorbance measured at 678 nm in vivo before the illumination. Light intensities: 21 μE m^{-2} s^{-1} (—), 105 μE m^{-2} s^{-1} (––); 210 μE m^{-2} s^{-1} (----). (Adapted from Ref. 30.)

β-carotene resynthesis. Although the postulated role of secondary carotenoid accumulation is photoprotection, the molecules or cellular structure(s) which would benefit from this protection remain to be determined.

The peculiar property of carotenoid accumulation in higher plants is not common. When stressed by high irradiance and drought, *Aloe vera* accumulates the xanthophyll rhodoxanthin [71].

Chilling/Freezing Stress

As noted previously, photoinhibition can occur at low temperature even at low-light intensities. The result is that pigment degradation by photooxidation is more pronounced at higher temperature, especially in high-light conditions. This situation is worsened by the impairment of zeaxanthin formation at low temperature [72]. In contrast, it was reported that exposure of canola fields to sublethal freezing conditions (−5°C) during seed development inhibits seed degreening, possibly due to the inactivity of the peroxidase that degrades Chl [19]. Pigment degradation is more pronounced in chilling-sensitive *Cucumis sativa* and maize than in the chilling-tolerant *Pisum sativum* L. [72,73].

Salinity Changes

As a general rule, salt stress induces the modification of the carotenoid composition and Chl degradation in salt-sensitive plants, with the latter being partly due to a chlorophyllase activity enhancement [74]. Chl degradation mainly affects Chla. In contrast, an increase in the Chl content has been observed for tolerant species (reviewed in Ref. 75).

Variation of seawater salinity from 40‰ to 30 or 25‰ triggers bleaching of scleractinian corals [76]. This change in color is mainly due to a decrease in both the number of zooxanthella in each polyp and in the total amount of pigments in each zooxanthellae (i.e., Chla, $Chlc_2$, peridinin, diadinoxanthin, and dinoxanthin).

Herbicides

Herbicides which inhibit photosynthetic electron transport (e.g., DCMU) and redox-active herbicides (e.g., paraquat) are known to allow generation of active oxygen species (e.g., superoxide) which

are able to induce extensive leaf chlorosis and necrosis [77]. Moreover, DCMU and monuron both inhibit the deepoxidation of violaxanthin [70].

Photodynamic herbicides (e.g., diphenyl ether–type) inhibit the Chl biosynthetic pathways at the level of protoporphyrinogen oxidase (EC 1.3.3.4) [78]. Protoporphyrinogen IX is then accumulated and partly exported out of the chloroplast where it is autooxidized to protoporphyrin IX [79]. Protoporphyrinogen IX exportation is understood as a mechanism associated with the removal of a potential oxygen-sensitizer which can damage the membranes and their components [80]. In effect, singlet oxygen has a lifetime much longer in nonaqueous solution (20–25 μs) than in aqueous medium like the cytoplasm (3–4 μs) [81,82]. The exportation activity appeared to be very weak in dark-grown leaves [83]. The production of oxygen-sensitizer tetrapyrroles also occurs in plants fed with δ-aminolevulinic acid, the tetrapyrrole precursor, except that other Chl precursors are accumulated [84] (reviewed in Ref. 62). After a prolonged treatment with photodynamic herbicides, large amounts of xanthophyll acyl esters are produced. The production of these esters is not light dependent and could result from lipid peroxidation [70].

Other herbicides (e.g., diflufenican, aminotrizole) interfere with the carotenoid biosynthetic pathway. For instance, they inhibit the desaturase and the cyclization reactions resulting in the accumulation of carotenoid precursors (e.g., phytoene) lacking cyclic structures and extended conjugated double bonds [85]. These carotenoids are unable to bind photosynthetic protein and consequently to photoprotect Chl molecules.

Atmospheric Pollutants

O_3, NO_2, and SO_2 generally trigger the photooxidative destruction of both Chl and carotenoids [86]. However, the data remain puzzling and sometimes contradictory (reviewed in Ref. 70). Long-term exposure of spruce trees to low levels of SO_2 or $SO_2 + O_3$, but not of O_3 or acidic precipitation (pH 4), causes a decrease in the Chl content of the needles [87]. The phytol release from Chl increases with the ozone amounts applied to *Picea abies* [88]. Interestingly, low concentrations of O_3 may serve to promote the epoxidation of violaxanthin to zeaxanthin [89]. Plants actually have no defense system protecting their pigments against atmospheric pollutants.

Nutrients and Heavy Metals

As a general rule, nutrient deficiency induces plant senescence, the appearance of necrosis, and chlorosis (reviewed in Ref. 90). As a consequence of these phenomenons, pigment composition is altered. For example, a potassium deficiency lowers the carotenoid content in sunflower leaves [91]. In several cases, it was reported that nutrient deficiency triggers an increase of the xanthophyll cycle activity [91,92]. The Chla/b ratio is found to be higher in iron-deficient leaves than in the control [93].

Little is known about the influence of nutrient abundance on photosynthetic pigments. In contrast, the excess of a metal on photosynthesis is quite well documented. For instance, cadmium was found greatly to reduce the Chl content in *Chlamydomonas* cells, whereas manganese has only a slight effect [94] (B. Schoefs and M. Bertrand, unpublished results). Recently, a study was performed on maize in order to determine the copper toxicity sites. Copper was found to interfere with the primary photochemistry, principally at the PSII level, and with the light-adaptation processes allowing light-harvesting migration from PSII to PSI, decreasing the light-adaptation capacity [95]. In these conditions, pigment destruction would be favored. In vitro experiments carried out with submersed plants have even shown that the Chl magnesium could be substituted by mercury, copper, cadmium, nickel, zinc, or lead [96].

Photoinhibition of Photosystem II in Leaves: Stress, Acclimation, or Regulatory Response?

Christa Critchley, A. Wendy Russell, and Belinda C. Morrison
The University of Queensland
Brisbane, Australia

INTRODUCTION

Light Stress in Leaves

Stress is defined in *Chambers Science and Technology Dictionary* (W&R Chambers, Ltd. and Cambridge University Press, Cambridge, 1988) as follows: ''Excessive and aversive environmental factors that produce physiological responses in the individual.'' A maximum sunlight irradiance of approximately 2200 μmol m^{-2} s^{-1} is considered excessive for most plants [1]. This is because irradiance-driven photosynthesis in many C_3 species saturates at about half that photon flux. In such species, the quantum efficiency and often the maximum rate of photosynthesis are reduced when exposed to irradiances above the saturation level [2].

Interestingly, photosynthesis in C_4 plants, whose bundle sheath chloroplasts operate in higher than ambient CO_2, saturates at >2000 μmol m^{-2} s^{-1}. This suggests that the electron transport capacity can be very high indeed, and in C_3 species, it may exceed the rates required for carbon fixation [3]. It is also significant that these very high electron transport rates in some types of C_4 bundle sheath chloroplasts are achieved with little or no granal structure or photosystem II (PSII). In these chloroplasts, ATP is generated by rapid cyclic electron transport around photosystem I (PSI). More intriguing, leaves with chloroplasts that have very large granal stacks and lots of PSII have only very low rates of photosynthesis. High uncoupled rates of electron transport measured in vitro also suggest that the electron transport capacity can exceed the carbon fixation rate and capacity. All this points to the possibility that PSII actually controls the rate of electron transport.

Evolution of Energy Use and Dissipation

Oxygenic photosynthesis probably evolved in much lower light intensities and higher atmospheric CO_2 concentrations, so that originally the photosystems became optimized for light absorption.

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

When species moved onto the land, moderate light intensities were combined with high CO_2 levels, and further increases in absorption capacity may have been made to increase the photosynthetic rate. The means of dealing with ever-increasing light intensities and O_2 levels and decreasing CO_2 concentrations as the atmosphere changed seem to involve O_2 radical scavenging systems, reflective leaf surfaces, and multiple cell (chloroplast) layers in individual leaves and multiple leaf layers in canopies. Furthermore, although very efficient absorption properties were maintained, highly effective dissipation processes and the C_4 (CO_2-concentrating) mechanism were added to deal with exciton pressure in excess of the carbon-fixing capacity in leaves exposed to maximum light intensities [3].

Although carbon fixation and electron transport capacity colimit the photosynthetic rate [4], in reality, C_3 photosynthesis is often limited by carbon-fixation activity. This limitation must exert a feedback regulation on the operation of the electron transport chain reducing the electron flow rate during periods of low CO_2 availability and increasing the energy dissipation rate. Therefore, photosystems reflect in their protein architecture, pigment organization, and arrangement in the thylakoid membrane all the requirements for efficient light absorption and maximum electron flow as well as effective energy dissipation. The two apparently conflicting properties have to be built into the same type of photosystem, or the photosystem has to change with fluctuating circumstances (i.e., become heterogeneous). PSII fulfills these requirements. PSII certainly is heterogeneous, since it has active and inactive forms. Several questions about what PSII heterogeneity actually means and what role it plays have yet to be answered. The questions can be summarized as follows:

How is multiple functionality of PSII achieved?
Is photoinhibition a stress response or is it the dissipation (downregulated) state of chloroplasts that have reached their maximum rate of CO_2 fixation?
Is photoinhibition a manifestation of PSII photodamage?
Is PSII especially sensitive to stress or particularly adaptable?
Does PSII effectively regulate the rate of electron transport?

Photoinhibition

Photoinhibition (also referred to as high-light stress), which has received much attention and research over the past two decades, has focused on the effects of excess irradiance on photosynthetic organisms. In many instances, irradiance is an exacerbating factor concomitant with other abiotic or biotic stresses. Photoinhibition is manifest in chlorophyll fluorescence changes, which, when measured at ambient temperatures, are attributable almost entirely to PSII. Therefore, PSII functioning measured as a reduction in chlorophyll fluorescence has become synonymous with an estimate of the degree of stress experienced by the plant. In fact, PSII fluorescence changes are considered the earliest and most sensitive stress monitors available. Parameters such as the dark-adapted Fv/Fm ratio, the fluorescence yield in the light, $\Delta F/Fm'$, or a fluorescence-quenching parameter, qN, are all used increasingly to identify and diagnose a stress response [5]. Measurement of these parameters is sometimes accompanied by an analysis of the underlying biochemical/physiological processes in attempts to understand the mechanism of photoinhibition and the nature of the response causing the fluorescence change.

Photoinhibition has historically been conceptualized as injury or damage to PSII [6], since it causes a reduction in the quantum efficiency and often, but by no means always, a decrease in the maximum rate of photosynthesis. It was then, and still is, inconceivable to most scientists that a reduction in activity, especially photosynthetic activity, should be a good thing for the plant. Photoinhibition has, therefore, always been considered to be deleterious to plants. In some instances, it did indeed reduce productivity [7].

D1 Protein Turnover

When the D1 protein was identified as one of the two reaction center proteins of PSII [8], its high turnover rate was immediately explained: photon absorption and charge separation processes in

oxygenic organisms damage the D1 protein and its renewal is therefore required [9]. Rapid D1 protein turnover was neatly accounted for in this way and photoinhibition simply explained. The lack of even a correlation, let alone evidence for a causal relationship, between the degree or the severity of photoinhibition and the rate or the extent of D1 turnover has not stood in the way of this paradigm becoming widely accepted. The D1 damage/repair model of photoinhibition, the fatal flaw of PSII, although highly complex biochemically [10], is conceptually simple and therefore appealing.

In this chapter, a different view of photoinhibition and the role of D1 turnover is presented. Experimental evidence will be provided which shows that photoinhibition is not directly linked to D1 turnover, and that D1 turnover does not cause photoinhibition. It will be suggested instead that D1 turnover is a light-activated, largely constitutive activity that is switched on by reduction of QB and the generation of high assimilatory power rather than by damage-induced D1 degradation. It will be argued that photoinhibition is synonymous with a significant proportion of PSII being converted to a dissipative function so that quantum efficiency, and sometimes maximum light and CO_2 saturated rates of photosynthesis, are reduced. Some of the questions posed above will be answered. Photoinhibition clearly occurs independently of the rate of D1 turnover unless this turnover is artificially blocked. The maximum rates of D1 turnover are measured when no photoinhibition is apparent. Whether and how DI turnover influences photoinhibition and/or the photosynthesis rate remains to be elucidated.

RELATIONSHIP BETWEEN D1 TURNOVER AND PHOTOSYNTHESIS

In recent years, many studies have shown that D1 turnover proceeds at maximum rates when the photochemical efficiency and the light-saturated rate of photosynthesis are maximal and when there is no evidence of photoinhibition [11]. Indeed, the maximum rates of D1 turnover can be measured at light intensities below saturation [12,13]. Other factors appear to influence D1 turnover more than light intensity per se.

It was also demonstrated that photoinhibition does not cause a net loss of D1 protein in vivo [14] or in vitro [15] unless chloroplast protein synthesis inhibitors are employed [16]. The argument that damaged D1 protein becomes phosphorylated, arresting its susceptibility to degradation, is not very convincing. Even more importantly, only a proportion of PSII functions at times of maximum photosynthesis [17]. It follows that only a proportion of D1 protein has to be functional at any one time. The function the thylakoid membrane system has to perform is this: The photosystems, especially PSII, have to be built and arranged in such a way that excitation energy is maximally absorbed and optimally channeled to those that are functional when photons are rare. At low-light intensity, excitation energy must go to QB reducing active PSII to achieve maximum or near maximum quantum efficiency. When photons are in excess, dissipative centers are formed and excitation energy is channeled to them as well as the active centers. If large proportions of dissipative centers persist in low-light intensity, the quantum yield is reduced until the balance is restored. For both scenarios and both types of PSII, the D1 protein has to be in place and functional. Whether D1 is different in dissipative, inactive, and active centers that function differently remains to be established.

Centers in the process of reconstruction obviously do not normally absorb many photons or participate in electron transport or energy dissipation. Minimal absorption may be ascertained by their location in the thylakoid membrane, by light-harvesting complex II (LHCII) disconnection, CP43 displacement from the core [18], and monomerization [18,19].

Experimental Evidence: Varying Irradiance

In sun and shade leaves of *Schefflera arboricola*, D1 turnover was measured as degradation (disappearance) of radioactively prelabeled D1 protein [12]. The palisade parenchyma and spongy meso-

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

phyll tissues were separated because of a strong light gradient in these leaves. D1 turnover rates in the spongy mesophyll tissue of sun leaves when illuminated with limiting or saturating irradiance (90 or 300 μmol m^{-2} s^{-1}, respectively), which caused absolutely no change in Fv/Fm ratios, were virtually identical (Fig. 1A). Similarly, high D1 turnover rates were measured in the palisade tissue from sun and shade leaves exposed to 24 h of excess irradiance (1500 μmol m^{-2} s^{-1}), whereas PSII photochemical capacity, estimated from dark-adapted Fv/Fm ratios, decreased at very different rates (Fig. 1B). There was generally no correlation between D1 turnover rates and the degree of photoinhibition. Moreover, D1 turnover rates seemed remarkably similar under very different experimental illumination as well as previous growth conditions. Only in shade leaves was there a small difference between the treatment light intensities.

Similar results were obtained in studies of high- and low-light–grown pea leaves [20,21].

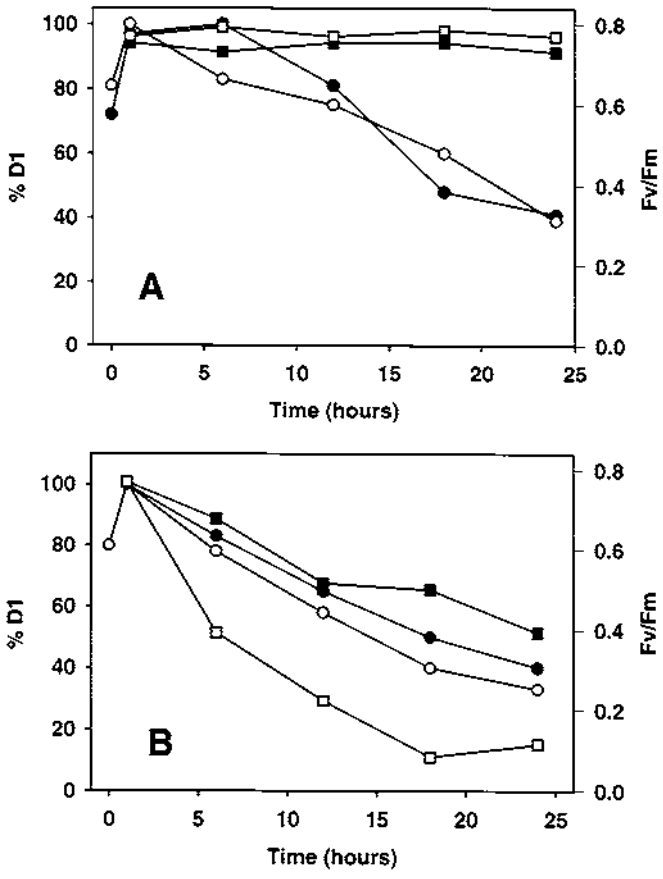

FIGURE 1 (A) Degradation of prelabeled D1 protein (○●) and the Fv/Fm ratio (□■) as a function of exposure time to excess irradiance. Thylakoids and D1 protein were isolated from palisade parenchyma cells of *Schefflera arboricola* leaves grown in the sun (●■) or the shade (○□). (B) Degradation of prelabeled D1 protein (○●) and the Fv/Fm ratio (□■) as a function of exposure time to saturating (●■ or limiting (○□) irradiance. Thylakoids and D1 protein were isolated from spongy mesophyll cells of *Schefflera arboricola* leaves grown in the sun.

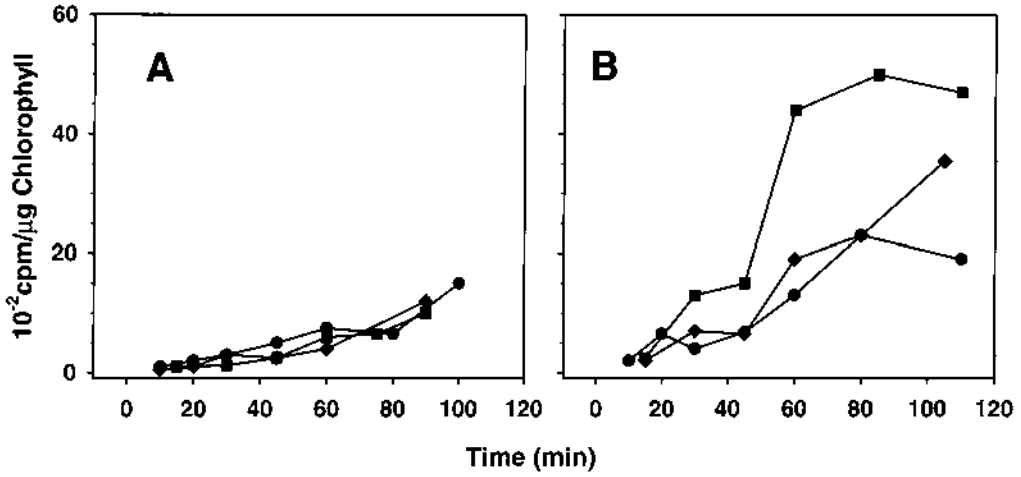

FIGURE 2 Accumulation of radioactive label in the D1 protein of *Pisum sativum* leaves grown in (A) high light (1200 μmol m^{-2} s^{-1}) or (B) low light (90 μmol m^{-2} s^{-1}) and exposed during labeling to limiting (90 μmol m^{-2} s^{-1}, ■), or saturating (350 μmol m^{-2} s^{-1}, ◆), or excess (1500 μmol m^{-2} s^{-1} ●) irradiance.

There was also no difference between treatments in high-light–grown leaves (Fig. 2A), but there was some variation in D1 turnover with irradiance in low-light plants (Fig. 2B). In the low-light–grown leaves, D1 turnover rates were maximal in limiting light conditions, a little lower in saturating light, and somewhat inhibited in excess irradiance (Fig. 2B), which are quite inconsistent with a causal relationship of photoinhibition and D1 turnover but confirms the correlation between high rates of photosynthesis and maximum D1 turnover activity.

These data clearly contradict the results obtained in other laboratories, although the different experiments are not strictly comparable: Aro and colleagues [22] suggest that the rate constant of photoinhibition is directly proportional to the light intensity and that there is a kinetic agreement between D1 protein degradation and the inactivation of PSII. However, this is only ever observed in leaves in which chloroplast protein synthesis, and hence D1 turnover, is prevented by treatment with lincomycin or chloramphenicol. Under such conditions, both D1 protein degradation and photoinhibition are light-intensity dependent and appear to be linked. What these experiments do show is that light-dependent D1 protein degradation can proceed without concomitant protein synthesis, and that photoinhibition is eventually more severe when D1 synthesis is blocked.

Degradation of D1 protein in extremely low light has also been shown to occur independent of protein synthesis activity [23]. This degradation was suggested to be due to recombination of QB^- and $S_{2,3}$ states creating damage to the protein, thereby causing its degradation. These experiments were also carried out in the presence of chloroplast protein synthesis inhibitors.

In both sets of experiments, D1 protein detection and quantification was performed by Western blotting. This method may not quantitate the D1 protein accurately (B. Morrison and C. Critchley, in preparation). In a comprehensive study on *Arabidopsis thaliana* leaves, Russell and collaborators [13] showed that there was no correlation between D1 turnover and any other activity or parameter measured. It was revealing that the two methods used to identify and quantitate the D1 protein following the exposure of leaves to different irradiances, that is, Western blotting and ^{14}C-DCMU binding, did not agree with each other. They also did not correspond with the number of functional PSII present (Fig. 3). Of the two quantitative measures, antibody-detectable D1 protein correlated somewhat better with amounts of functional (O_2 evolving) PSII than did ^{14}C-DCMU binding.

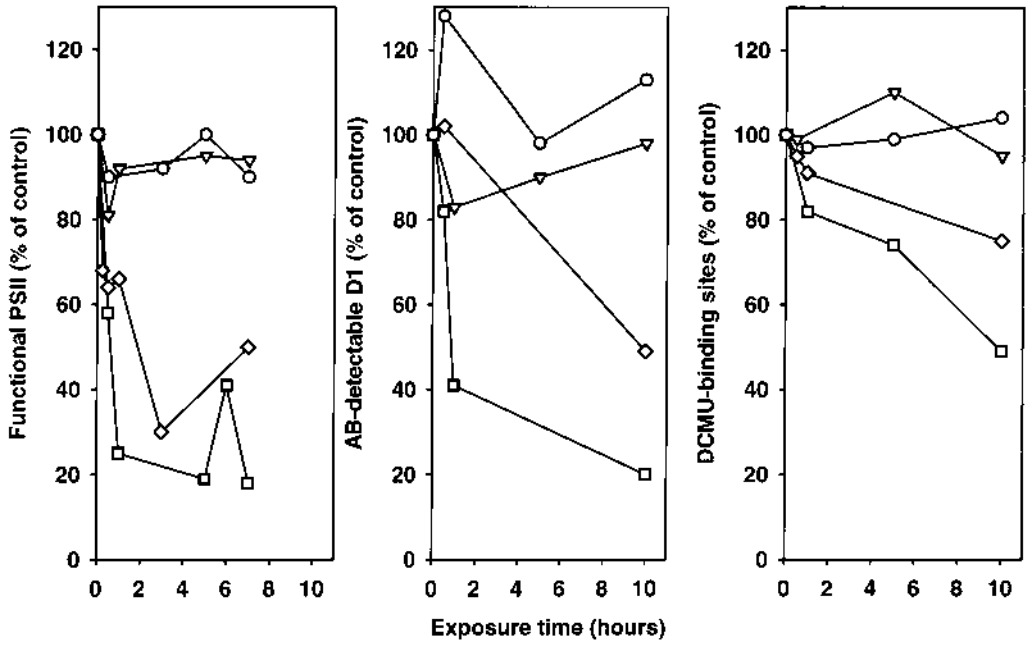

FIGURE 3 Changes in the amounts of (A) functional PSII, (B) antibody detectable D1 protein, and (C) DCMU binding sites in leaves of *Arabidopsis thaliana* grown in low light as a function of exposure to limiting (250 μmol m^{-2} s^{-1}, ○), saturating (420 μmol m^{-2} s^{-1}, ▽), mildly photoinhibitory (1350 μmol m^{-2} s^{-1}, ◇), or strongly photoinhibitory (2200 μmol m^{-2} s^{-1}, □) irradiance.

Experimental Evidence: Varying CO_2 Concentration

CO_2 availability is a major constraint on the photosynthetic rate and many plants respond positively to an increase in the CO_2 concentration during long-term growth or short-term change. Under controlled conditions and supplied with sufficient nutrients, *Schefflera arboricola* had increased saturated rates of CO_2 fixation in elevated CO_2 both in high and low irradiance (Table 1). When light and CO_2 concentrations were experimentally altered, the most significant change in the rate of D1 protein turnover was observed when the CO_2 concentration was changed. In fact, the rates of D1 protein turnover were linearly related to the photosynthetic rate, but not at all correlated with the

TABLE 1 Changes in the Rates of D1 Turnover in Leaves Grown in High-Light and Ambient or Elevated CO_2 Concentrations as a Consequence of Experimentally Changing the CO_2 Concentration for 9 h

	% of Prelabeled D1 protein degradation (turnover)	
	Ambient CO_2 grown	Elevated CO_2 grown
Ambient CO_2 treatment	6.8 (±1.6)	7.2 (±2.6)
Elevated CO_2 treatment	15.0 (±1.5)	19.9 (±4.8)

degree of photoinhibition (A.W. Russell et al., submitted for publication). These experiments clearly demonstrated that a temporary stimulation of photosynthesis by elevated atmospheric CO_2 caused an increase in D1 turnover despite a decrease in the electron pressure on PSII.

Experimental Evidence: Varying Maximum Rates of Photosynthesis

Altering the maximum rates of photosynthesis in identical irradiance and nonphotoinhibitory conditions should confirm the dependence of D1 turnover on the rate of photosynthesis. Experiments with wheat grown in small pots at elevated temperature or under N deficiency but in identical light conditions were performed. Although on a leaf area basis the photosynthetic rates were identical in all treatments and control leaves (maximum light and CO_2-saturated rate 20 μmol O_2 m^{-2} s^{-1}), they differed significantly between controls and treatments on the basis of the amount of chlorophyll. The rates of the N-deficient and elevated temperature leaves were higher, whereas those grown in small pots were much lower than control rates. The D1 turnover rates, measured as the rate of radioactive labeling of the protein (also on a chlorophyll basis) matched these rates very well (Fig. 4). There was no evidence of photoinhibition in any of the control or treated leaves.

ROLE OF PHOTOINHIBITION: EFFECTIVE DISSIPATION OF EXCESS ENERGY

Many plants recover fully from daily photoinhibition events but others seem to maintain a level of dissipative capacity that is partially retained overnight [24]. In both types of leaves, D1 turnover

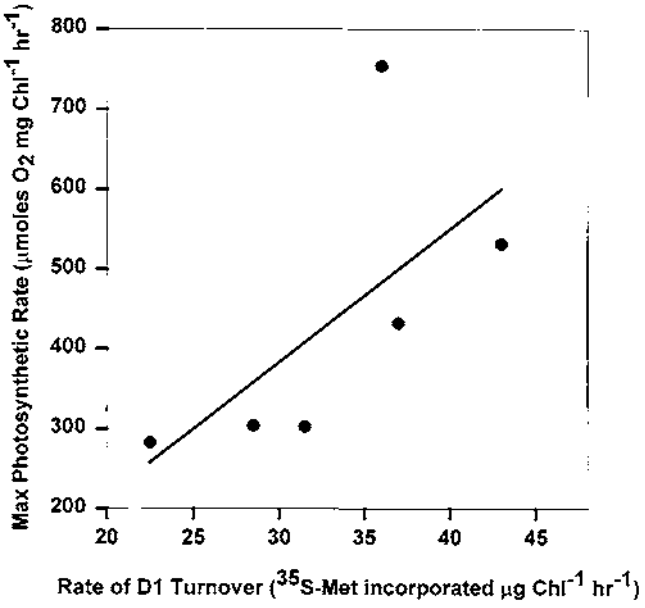

FIGURE 4 Relationship between the maximum photosynthetic rate (light and CO_2 saturated) and the rate of D1 protein turnover calculated from ^{35}S-methionine incorporation of various *Triticum aestivum* leaves grown under control, elevated temperature, small-pot, and N-deficient conditions. Growth irradiance was approximately 1500 μmol m^{-2} s^{-1}; irradiance during labeling was 800 μmol m^{-2} s^{-1}.

proceeds at high rates. This suggests two possibilities. Dissipative centers are prevented from turning over D1 protein (perhaps by phosphorylation) and remain associated with active centers, always sharing excitation energy and reducing quantum efficiency [25]. On the other hand, both dissipative and active centers undergo D1 turnover, becoming inactive during that time [26]. This question can only be resolved when inactive, active, and dissipative centers have been isolated and biochemically identified.

Although no inactive or active centers have been isolated and biochemically identified, they are known to be present in the chloroplasts [27,28]. The structural differences between them may be very subtle, because they may involve only small conformational changes in the D1 protein of the type suggested by Bracht and Trebst [29]. Attempts to isolate such centers from leaves and separate them biochemically may fail for two reasons: multiple cell layers in leaves causing a light gradient and heterogeneity among the chloroplasts and the inability to separate these cell layers.

The answer to the first and second questions posed above may be that: multiple functionality of PSII is achieved by changing populations of active, inactive, and dissipative centers present in leaves at any one time, providing for optimum quantum efficiency as well as effective dissipation, and depending on irradiance and other environmental conditions. This heterogeneity may be achieved by interconversion of the various forms. Photoinhibition is an adaptive response during which PSII is modified and downregulated. Modification and turnover of the D1 protein may play a role in this.

ROLE OF D1 TURNOVER: LIGHT ACTIVATION AND CONTROL OF PSII ELECTRON TRANSPORT RATE

Since there is no convincing or compelling evidence that D1 turnover is a response to PSII photodamage in vivo, the possibility of a positive role for this turnover in the chloroplast must be considered. In view of the light requirement for D1 turnover, this positive role may lie in activating the requisite number of PSIIs for the adequate rates of electron transport to be achieved. We know that electron transport rates initially have to be very high to satisfy the requirements for enzyme activation, nitrogen metabolism, and the generation of assimilatory power. This may be achieved by D1 turnover causing dimerization, thereby activating PSII. D1 turnover may also play a role in the formation of supercomplexes, enzymes catalyzing dark and light reactions associated with nonappressed membranes in the chloroplast [30]. Süss and Sainis [31] provide evidence for such supercomplexes and have termed them photosynthesomes. These supercomplexes may channel substrates and cofactors effectively by being associated with several active electron transport chains. They may also concentrate CO_2 to some extent.

PSII photodamage only occurs when photoinhibitory adaptation is no longer sufficient. PSII is especially adaptable because of its heterogeneity which is unlike any of the other electron transport complexes. PSII heterogeneity thereby controls the quantum efficiency and electron transport rate.

CONCLUSIONS

For many years, photoinhibition and D1 turnover have been studied in conjunction and have, therefore, become inextricably linked. This is very unfortunate because of the failure to approach the two processes separately. We have provided much evidence, some of it summarized in this chapter, demonstrating that the two are not necessarily linked and may occur quite independently of each other. That evidence has been largely ignored in the literature.

Both processes are highly complex and regulated. D1 turnover activates and regulates the electron transport rate and perhaps facilitates the formation of supercomplexes. Photoinhibition ensures the dissipation of excess energy. Whether D1 turnover influences the extent of the dissipative state or whether dissipative centers undergo D1 turnover remains to be established.

Oxidative Damage to Proteins in Plants

JULIAN P. WHITELEGGE
University of California, Los Angeles, California

INTRODUCTION

Although oxidative modification of protein and oxidative stress have been studied for many years, it is only recently that molecular analysis of protein damage has been generally considered. As complete genomes become sequenced, our experiments can expand to consider the whole variety of gene products that make up the proteome. For example, where previously a general assay of protein oxidation may have revealed some manifestation of protein damage, future definitive analysis will seek the identity of all of the modified proteins as well as their sites of modification. In this way, an overall picture of sensitivity will emerge highlighting potential targets for genetic manipulation. Maybe the structures of key enzymes can be altered to lower susceptibility or the expression of protective enzymes can be upregulated to boost antioxidant capacity. Furthermore, it will be necessary to tie our understanding of vulnerability to the mechanisms that recognize damage and initiate replacement. There are likely to be cases where susceptibility cannot be avoided, thereby requiring acceleration of turnover and reassembly processes for effective improvement of performance under conditions of oxidative stress.

OXIDATIVE MODIFICATION OF PEPTIDYL AMINO ACID RESIDUES

Specific Modifications Required for Function

Disulfide Formation

Disulfide cross links are formed via oxidation of a pair of peptidyl cysteine thiols. This occurs spontaneously in the presence of oxygen but may require the assistance of enzymes, such as protein-disulfide isomerase, for the formation of the correct disulfide [1,2]. Specific disulfides may be required for correct folding and consequent enzymatic activity. Free thiols are common and play a variety of roles in catalysis, metal binding, and regulation. Reversible disulfide formation is be-

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

ing found to be a common means of linking redox poise to enzymatic activity and gene expression [3–6] as well as modulating physiological responses such as phloem fiber cross linking in response to wounding [7]. In summary, the correct management of thiol/disulfide is essential to many aspects of plant health and may be upset if oxidative stress leads to irreversible oxidation of cysteine residues (see section on Nonspecific Modifications/Damage below).

Other Modifications

A novel oxidative modification is found at the active site of the enzyme arylsulfatase. The original cysteine residue is altered to a serine semialdehyde, 2-amino, 3-oxopropionic acid [8]. Humans unable to perform the modification lack arylsulfatase activity and suffer from multiple-sulfatase deficiencies. The observation of the same modification in arylsulfatase from *Volvox carteri* was used as an argument for its ubiquitous presence in eukaryotes [9]. Workers using the enzyme as a reporter [10] should be aware of the requirement for modification of the arylsulfatase precursor by other gene products.

Nonspecific Modifications/Damage

Reversible Modifications

Reversible oxidative modifications to proteins are of considerable importance. They raise the possibility of a scavenging role for proteins in the protection from oxidative damage [11,12] and introduce the potential for the presence of feedback mechanisms connected to appropriate pathways of metabolism and gene expression [13–15].

Methionine

A common oxidative modification to plant proteins is that of methionine to its sulfoxide (MetO) [16,17]. The amino-acyl thioester is an effective scavenger of active oxygen species (AOS) provided it is exposed to the aqueous environment. Buried methionyl side chains may be highly resistant to oxidation by virtue of inaccessibility.

The formation of sulfoxide on proteins can be highly inhibitory, especially if an active-site functionality is modified [18]. More subtle effects may arise owing to disturbance of tertiary structure [19]. The quaternary structure may also be perturbed on modification of methionyl residues, with implications for regulation; the T-state of hemoglobin, for example, is completely destabilized by oxidation of met55 of the β-subunit [20].

Peptidyl methionine sulfoxide can be readily converted back to the native thioether by the enzyme peptidyl methionine sulfoxide reductase (MSR) provided that the enzyme is expressed in the local tissue and can interact favorably with the sulfoxide. A modified buried sulfoxide might not be accessible to reduction unless the protein was unfolded or became degraded. Multiple turnovers of MSR require that it be regenerated via thioredoxin, thioredoxin reductase, and NADPH [21]. Deficiency in any of the components necessary for MSR turnover can be predicted to result in accumulation of MetO. The enzyme MSR is assumed to be ubiquitous [21] and has been detected in a number of plants. The enzyme has been cloned and its expression confirmed in *Brassica napus* [22]. Yeast cells, where expression of MSR has been knocked out, are sensitive to oxidative stress and peptidyl methionine sulfoxides accumulate confirming the essential role of this enzyme as an antioxidant in vivo [23]. Oxidation of methionine to the sulfone is less frequent but irreversible.

Cysteine

Proteins containing free thiols have the potential to be readily oxidized to mixed disulfides in the presence of oxygen (S-thiolation). Partners may include other proteins or more usually small free thiols such as glutathione, γ-glutamylcysteine, and cysteine. Thus, a decrease in free thiol [24,25] can be a useful measure of protein oxidation. Such a technique detects oxidation in vertebrate cell

lines as well as thiol regeneration after insult [26], and it was suggested this reversible modification might serve a protective function. Protein disulfide isomerase may play a role in reversal [27]. Free thiols can be modified in reactions with AOS to the progressively more oxidized sulfenic (RSOH), sulfinic (RSO_2H), and sulfonic acids (RSO_3H). Sulfenic acid can react with a free thiol to generate a disulfide providing a pathway for reversibility, but the latter higher oxidation states are effectively irreversible. Thus, it makes considerable sense for plants to tie up free thiols as disulfides during oxidative stress. The disulfide itself is not completely resistant and maybe cleaved oxidatively generating the more highly oxidized species above.

Irreversible Modifications

All of the amino acid residues of proteins are susceptible to oxidative modification, and the vast majority of these covalent changes are irreversible. Side chain modifications, backbone cleavage, and cross linking are all possible [28,29]. The protein becomes permanently modified raising the possibility for aberrant behavior. Thus, it is thought that oxidized proteins are generally targeted for proteolysis and degradation [29,30] leaving the deficit to be replenished by protein synthesis. Systems for recognition and removal of oxidized protein are ubiquitous owing to the unavoidable consequences of ionizing radiation. Damage may result from direct absorbance of radiation by protein or via attack by hydroxyl radical generated by radiolytic cleavage of water even in the absence of oxygen. The extreme reactivity of the latter species precludes complete protection via scavengers. Under normal conditions, oxidized protein is removed efficiently, however, overload of the system leads to accumulation of damaged molecules [31]. The different AOS have been described in detail elsewhere [32–34] and will be referred to in specific examples. Irreversible modification can also result from the reactivity of other products of oxidative damage. For example, malondialdehyde, which is a by-product of lipid peroxidation, can modify peptidyl amino acid residues contributing to protein damage.

EXPERIMENTAL APPROACHES FOR ANALYSIS OF OXIDATIVE DAMAGE

Analytical Biochemistry

Assays

Until recently, most studies of protein oxidation involved the use of assays to measure some general feature associated with protein oxidation. Assays of protein carbonyl [35], free thiol [25], or methionine sulfoxide [36] have all been used. Although these assays have provided important indications of cellular oxidative stress, their nonspecific nature provides no indication as to the identity of the damaged proteins.

Molecular Characterization Using Mass Spectrometry

Once the goal of the experiment progresses to the identification of the targets of oxidative damage, the criteria required of the methodology become much more rigorously defined. Proteins must be separated from the biological milieu and unambiguously identified prior to localization and mapping of the sites of sensitivity. Definitive studies of protein oxidation will rely increasingly on mass spectrometric analysis of potential targets.

The accuracy of mass measurements that may now be achieved, around 0.01% with a quadrupole machine, is sufficient to observe the first and subsequent oxidations (usually + 16 Da) on protein molecules up to 50 kDa and beyond. Electrospray-ionization (ESI) is the technique of choice because of the superior resolution that is usually observed. Thus, the first oxidation adduct (+16 Da) may be resolved next to the unmodified protein. Matrix-assisted laser desorption ionization combined with time of flight detection (MALDI-TOF) can achieve favorable accuracy but poorer

Table 1 Techniques for Analysis of Molecular Protein Damage

Method	Performance[a,b]	Limits of detection (with respect to oxidative modification)
SDS-PAGE	Accuracy 2–10%; poor resolution	Major molecular weight changes. Gross changes in polypeptide mobility, cross linking/polymerization, backbone cleavage.
MALDI-TOF	Accuracy to 0.01%; moderate resolution	Subtle molecular weight changes provided all species are similarly modified. Detects the alteration of mass of the most dominant species in a mixture.
Electrospray-ionization (ESI-MS)	Accuracy $< 0.01\%$; good resolution	Detects appearance of low-abundance (<10 %) adducts compared with major species. Resolves earliest site of oxidation.

[a] Accuracy: % error = (measured mass − actual mass) × 100%/actual mass.
[b] Resolution: ability to detect small amounts of a species of mass close to the most abundant species in a mixture.

resolution. Thus, information is lost, because less abundant adducts are obscured by the most abundant form. In the case of increasing oxidation, this will manifest itself as a measurable increase in mass concomitant with broadening of the peak. This situation is favorable compared with sodium dodecylsulfate–polyacrylamide electrophresis (SDS-PAGE), which only reveals more extensive changes in mass that alter electrophoretic mobility (Table 1).

In a sample of mixed proteins, it is usually necessary to separate the individual components prior to mass spectrometry (MS). MALDI-TOF has a reasonable capacity to deal with a protein mixture, but ESI requires highly purified material, particularly when low-abundance adducts must be observed. Two-dimensional polyacrylamide gel electrophoresis (2D-PAGE) is commonly used to separate a complex mixture of proteins in a biological sample and several groups have applied MS to identify and characterize individual polypeptides after 2D-PAGE [37,38]. However, there are severe drawbacks to using this approach for studies of protein oxidation. The exposure of proteins to SDS-PAGE and the extraction procedures required to recover protein for MS analysis routinely lead to oxidation of methionine and acrylamide adducts of cysteine as well as other modifications even in samples that have not experienced an oxidative insult. Furthermore, proteins are usually fragmented by in-gel digestion prior to extraction, since smaller peptides are more easily recovered. The peptide maps that are subsequently obtained by MS allow identification of the protein by comparison to fragments predicted from genome data, but they are frequently incomplete, especially in the case of membrane-bound proteins [38]. Thus, a potential for lost information arises when modified peptides are not recovered. Consequently, it is desirable to obtain mass spectra of the intact proteins from oxidized samples to compare with controls. In this way, the entire molecule can be screened for the earliest signs of oxidative modification. Protocols have been presented for the recovery of intact proteins from SDS gels [39], but routine problems of low yield, especially in the case of larger proteins, persist. Fortunately, attractive alternative methodologies are available to

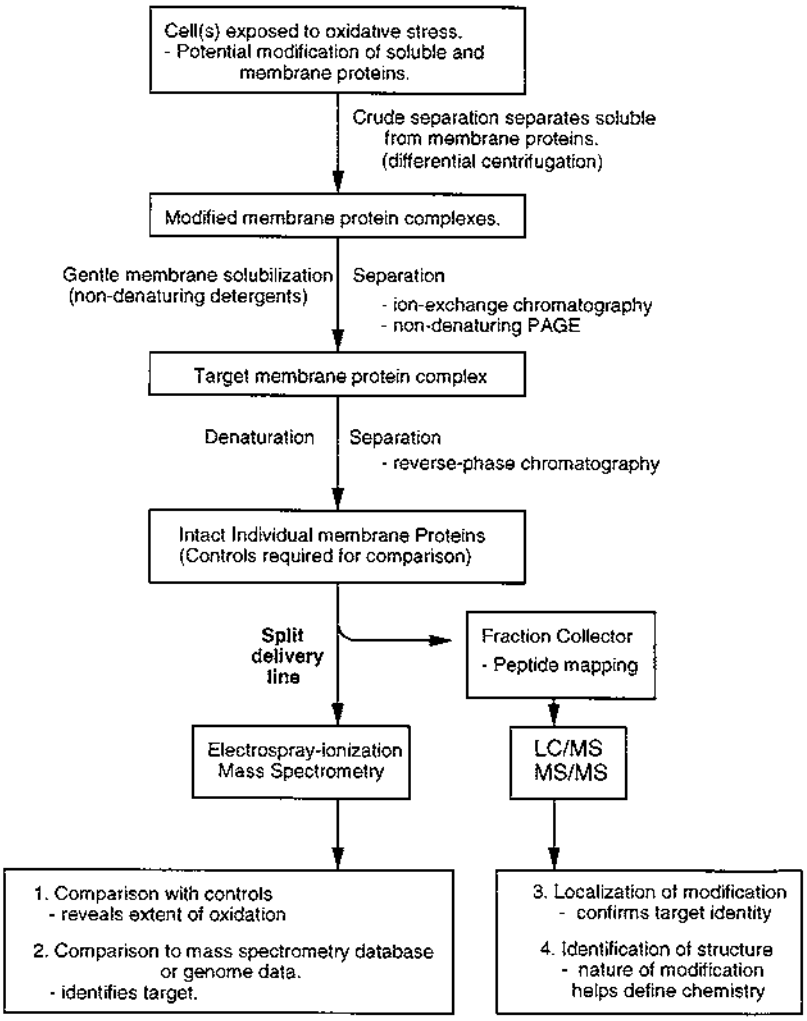

FIGURE 1 Global analysis of the earliest stages of protein oxidation. A flow chart is shown that summarizes an approach that is designed to reveal the identities of the oxidized proteins and their sites of modification. Central to the technique is the use of electrospray-ionization mass spectrometry (ESI-MS). The accuracy and resolution that ESI-MS provides ensure that the earliest stable covalent modifications accompanying oxidative damage to protein can be detected. The scheme that is shown is specifically for the analysis of intrinsic membrane proteins, which have recently yielded to ESI-MS analysis. (From Ref. 40.)

achieve the overall MS goal without the use of SDS-PAGE. Figure 1 depicts a flow chart for the analysis of a sample of oxidatively damaged membrane protein.

High-performance liquid chromatography (HPLC) is considerably more compatible with MS than SDS-PAGE and reverse-phase separations can be directly coupled to ESI (LC/MS). Since buffers and solvents are routinely degassed, the potential for in vitro oxidation is dramatically reduced. A single reverse-phase separation can provide excellent resolution, but it must be combined

with another method to provide the separating power of 2D-PAGE. Ion-exchange chromatography is an excellent candidate (see Fig. 1) to achieve separation in the first dimension prior to multiple reverse-phase LC/MS runs. Unfortunately, these runs are usually performed one at a time, so that 2D-HPLC is more time consuming than 2D-PAGE. After LC/MS has been used to find proteins that appear to be oxidized, it is necessary to identify them and localize the sites of oxidation. By splitting the fluid line that runs from LC to MS (see Fig. 1), it is possible to collect fractions and perform the MS analysis simultaneously. Thus, fractions are available for subsequent enzymatic or chemical cleavage. Cyanogen bromide treatment is especially favored owing to the compatibility of the reaction conditions with solubilization of intrinsic membrane proteins [40,41] as well as the potential to map sites of methionine oxidation in conjunction with mass spectrometry [42].

The oxidation products of methionine resist CNBr treatment providing a facile technique for their localization [43,44]. The loss of the CNBr site leads to the disappearance of two smaller peptides concomitant with the appearance of a larger one derived from the smaller two connected by the modified methionine residue [42]. By using mass spectrometry, it is possible to identify these peptides by mass providing a rigorous test of chemical identity that further distinguishes sulfoxide from sulfone. Occasional CNBr cleavage failure has been noted and used as the grounds not to use CNBr mapping for identifying sites of methionine oxidation [45]. The use of MS effectively overcomes this argument, since oxidized sites of cleavage inhibition are distinguished from those at which failure was due to unmodified methionine which is converted to homoserine during CNBr treatment. Mass-based CNBr mapping represents a powerful means with which to characterize methionine oxidation [42]. Of course, there are other modifications that can accompany oxidative damage. Such modifications would not remove CNBr sites, but would lead to increases in mass of peptides containing oxidized residues. The sites of modification must then be identified by other means. A powerful means of achieving this goal is to use tandem MS. A peptide is selected in the vacuum of the first mass spectrometer and then is directed into a second chamber containing inert gas molecules where collision-induced dissociation (CID) leads to limited fragmentation prior to final analysis of the peptide ion fragments in the second mass spectrometer [46,47]. In a successful experiment, deconvolution of the different fragment ions provides a description of the chemical structure of the peptide revealing its sequence and modification site.

A recent variant of ESI termed ''nanospray'' can be useful for MS and MS/MS analyses of small quantities ($<$1 pmol) of peptide [48]. However, care must be taken during studies of protein oxidation, since it is reported that low-flow electrospray ionization can quite effectively oxidize methionine residues [49]. Controls involving nonoxidized material must be incorporated at all stages of the analysis.

In summary, mass spectrometry of intact proteins is used to identify those that are oxidized. Further analyses involving the extensive use of MS are then used to identify sites of modification. In this way, it is possible directly to monitor the earliest events in oxidation and identify the sites most susceptible to damage.

There are limitations to the application of MS. The approach relies on measurable change of mass, and therefore ''silent'' modifications may go unnoticed. Fortunately, most stable oxidative modifications involve the addition of oxygen and can therefore be observed. Disulfide formation (loss of 2 Da) is unlikely to be detected by analysis of the intact protein, and studies involving this specific type of oxidative modification must use different strategies to detect their formation. Mass-based titration of free thiols with thiol reagents could provide a convenient way to approach such a problem using MS of intact proteins before and after oxidative treatment.

In Vitro Oxidation

Various agents can be used to generate AOS in the test tube allowing in vitro oxidation of plant and other proteins. Such experiments may be performed for comparison with damage occurring in vivo to test the nature of the damaging species in vivo. Studies of the sensitivity of important targets also are performed and may be used to probe structure and function. Any chemical system that

generates AOS or other reactive species can be used to modify proteins. Commonly used reagents are peroxide or cloramine T for methionine oxidation to sulfoxide. Tryptophan and cysteine residues may also be oxidized [21]. Fe(II)/peroxide systems may be useful for hydroxyl radical generation, and illumination of certain dyes such as Rose Bengal may be used to generate singlet oxygen [21,33] with both systems oxidizing a wider range of amino acids. Extreme care must be taken when extrapolating the behavior of AOS from the test tube to the cell.

Reverse Genetics

Reverse genetics provide a powerful tool for the analysis of protein oxidation in plants and other systems. The relative abundance of plant transformation systems has enabled several groups to examine gene function in vivo by targeted mutagenesis. Such studies range from site-directed mutagenesis studies that alter a single specific amino-acyl side chain (with potentially dramatic changes in the level of expression) to studies that delete genes. A useful approach involves the upregulation or downregulation of the expression of a gene such that the overall level of accumulation of a specific protein is changed providing the chance to observe the importance of that protein and the ability of others to be upregulated in the light of deficit. Examples of these techniques follow.

Site-Directed Mutagensis

In this example, the electron transport pathway through the photosystem II (PSII) membrane pigment–protein complex was manipulated such that the supply of electrons for reduction of the photooxidized primary donor $P680^+$ was limited. Under these conditions, it may be postulated that protein is oxidized to provide electrons leading to covalent modification after reaction with oxygen or other species. Transformation of the chloroplast genome of the green alga *Chlamydomonas reinhardtii* was used to engineer site-directed mutants of the D1 polypeptide PSII subunit [50]. Where aspartate 170 had been replaced by histidine (D170H), asparagine (D170N), or threonine (D170T), normal levels of the reaction center accumulated, although the ability to evolve oxygen was inhibited by 50, 95, or 100%, respectively. The proline (D170P) mutant only expressed PSII at half the level of the others and also was fully inhibited. Biophysical measurements were consistent with a specific defect in the electron donation to the reaction center, but measurements of oxygen flash yields in D170H showed that those reaction centers capable of oxygen evolution did so normally. Apparently, the alterations inhibit the initial binding of manganese as the functional chloroplast oxygen-evolving complex (OEC) is assembled. Thus, the mutants amplify the problem faced by wild-type PSII, namely, the photosensitivity associated with a fully assembled reaction center lacking a donor, awaiting assembly of the OEC. If proteins are damaged before the OEC is assembled, the complex must be removed and the damaged components replaced contributing to the drain that the photodamage/repair cycle imposes on photosynthetic production. It is predicted that protein damage due to donor-side defects will be exaggerated in the mutants allowing identification of the particular areas of modification by HPLC and mass spectrometry, as described above (see section on molecular characterization using mass spectrometry) 2 [51]. Studies like this will contribute to our understanding of the structure and function of PSII and will provide insight into the weaknesses of the current design. Recently, the secondary donor to the reaction center TyrZ was altered to phenylalanine leading to the accumulation of $P680^+$ [52]. Pigments were bleached under these circumstances, although unfortunately the damage to proteins was not assessed in parallel.

Deletion Mutagenesis

The PSII complex is made up of many different proteins and the product of the chloroplast *psb*I gene is known to be intimately associated with the reaction center core [53]. To investigate the role of this low molecular weight membrane protein, expression of the gene was disrupted by insertional mutagenesis effectively deleting it. An *aad*A expression cassette that confers resistance to spectinomycin was introduced through biolistic transformation of *Chlamydomonas reinhardtii* [54]. The

mutants could grow photoautotrophically in dim light, but their sensitivity to high light implies superphotosensitivity of PSII. Exposure of low-light–grown cells to high light and molecular examination of the resulting damage will reveal specific details of the role of this protein in photoprotection of PSII.

Inhibition of Expression

Some of the most revealing studies arise when the expression of a gene is limited rather than eliminated. Transformation of tobacco plants allowed the production of plants containing about 10% of the wild-type level of catalase [55]. Just like the psbI mutants, the plants grew well under low-light conditions. High-light stress, however, leads to the development of white necrotic lesions on the leaves. Although accumulation of H_2O_2 was not detected, leaf necrosis was accompanied by the accumulation of oxidized glutathione and a fourfold decrease in ascorbate suggesting that protective mechanisms were seriously compromised. Increased ascorbate peroxidase and glutathione peroxidase levels indicate that alternative pathways for relief of oxidative stress could be upregulated. Indeed, the elevated expression of ascorbate peroxidase and glutathione reductase has been noted after photoinhibitory insult to *Arabidopsis* [56]. High-light–induced damage to the tobacco plants was prevented under elevated CO_2 illustrating the contribution that photorespiration makes toward oxidative stress.

Elevation of Expression

A common approach to the study of oxidative stress involves the elevation of the amount of a target enzyme followed by tests to investigate whether the resistance to insult is improved. Tobacco plants overexpressing chloroplast Cu-Zn superoxide dismutase were especially resistant to photoinhibition under chilling stress implying a role for superoxide in damage under these conditions [57]. Overexpression of glutathione reductase in poplar chloroplasts generated plants with an increased resistance to photoinhibition apparently due to increased levels of the scavengers glutathione and ascorbate [58]. The expression of mannitol via the introduction of bacterial genes to tobacco chloroplasts increased resistance to oxidative stress by supplementing endogenous antioxidants [59]. Progress toward generating crop plants with an increased stress tolerance is encouraging [60], and it should be possible to diminish oxidative damage to proteins provided they are accessible to scavengers and the aqueous milieu.

Acclimation and Synergy

The expression of many of the components involved in the protection from oxidative stress varies with the acclimation state of the plant. Thus, it is impossible to consider oxidative stress without careful consideration of growth conditions and the recent history of the plant. Furthermore, it is becoming apparent that many factors may contribute to oxidative stress with certain combinations showing considerable synergy. It will be necessary to consider the acclimatory state of plants and the synergistic nature of stress factors in future studies of protein damage.

Nonintrusive Imaging

A long-term goal is the development of systems that allow the remote observation of protein damage without any disturbance of the cell or whole plant. Electron spin resonance was used to monitor the loss of free thiol during heart ischemia [61] providing an early example of this type of work. Other approaches might involve the identification of specific magnetic resonance signals for mapping experiments using magnetic resonance imaging (MRI) or the development of specific probes compatible with positron emission tomography (PET).

Structural Biology

The interpretation of detailed molecular studies on protein oxidation is greatly aided if a high-resolution structure has been determined. Structural information is especially useful when the mecha-

nisms of the reactions are to be considered. By using x-ray crystallography, it was possible to characterize two sites of metal-catalyzed protein oxidation on the enzyme glutamine synthetase [62]. The first oxidation modified the active site, thereby inactivating the enzyme, whereas the second inhibited substrate binding and loosened the structure presumably enhancing its protease sensitivity and turnover [62].

ENDOGENOUS OXIDATIVE STRESS
