Wherever AOS are generated there is the potential for protein damage to occur. Damage is usually minimized through the use of enzymes that convert reactive to less reactive species and antioxidants that ''scavenge'' AOS becoming modified themselves. All cellular components are susceptible to damage if given the chance to interact with AOS, and the problems confronting lipids and DNA have become widely appreciated. Damage to proteins, however, may be widespread even at the early stages of oxidative stress. In this section, the chloroplast is considered, because the origins and nature of protein damage are most widely studied, although still poorly understood.

Case Study; PSII

Chloroplasts face special problems associated with oxidative stress. Several AOS are generated as by-products of the photosynthetic electron transport machinery, but the organelle cannot be made anaerobic without removal of the water-splitting activity of PSII. Thus, nucleic acids, proteins, pigments, and lipids are potentially exposed to AOS. The lipids of the thylakoid have highly unsaturated fatty-acyl chains making them especially susceptible to the peroxidation chain reaction. Highly developed scavenging systems provide effective protection mechanisms, but may be swamped under certain circumstances leading to oxidative damage. Regions with limited access to antioxidants such as the hydrophobic cores of the numerous thylakoid membrane proteins remain especially susceptible to AOS, particularly those that are generated internally. The generation and management of AOS in the chloroplast has been extensively reviewed [32–34]. The focus here will be on molecular protein damage to PSII, since this complex is apparently the site most susceptible to photooxidative damage under normal circumstances.

A number of different manifestations of protein damage within PSII have been identified. Cleavage of the polypeptide backbone was first observed for the rapidly turning over D1 polypeptide, and a 23.5-kDa N-terminal breakdown product was identified that was apparently derived from the N-terminal [63]. More recent studies have equated this fragment with damage derived on the acceptor-side of the reaction center [64]. A 24-kDa fragment derived from the C-terminal of the D1 polypeptide arises under conditions of ''donor-side inhibition'' when the OEC is inactive but electron acceptors are present [65]. Both fragments can be observed after isolation of PSII from photoinhibited pea leaves implying that both mechanisms are significant in vivo [66]. Covalent cross linking of proteins has also been detected after photoinhibitory treatments. Evidence for the formation of a dityrosine cross link within D1 was presented [67], but this modification has not been generally reported. Under moderate illumination, the N-terminal of the α-subunit of cytochrome b_{559} can become linked to D1 in the region 239–244 [68], generating a 41-kDa adduct. Cross linking of D1 to other components, including the CP43 polypeptide, has also been reported [69]. Methionine sulfoxide was detected in low molecular weight polypeptides of PSII after the photoinhibitory treatment of the reaction centers in vitro [17] demonstrating that more subtle oxidative modifications also take place. Most studies have relied on SDS-PAGE for the detection of modifications, so it is unlikely that minor changes in the molecular mass are detected. Thus, it is not clear whether the observed phenomena are related to the earliest events in oxidative damage or whether they are simply the first *observable* events. As described above (see section on molecular characterization using mass spectrometry), MS will be the tool of choice for future studies of PSII damage. Now that the D1 and D2 proteins can be weighed with accuracy exceeding 0.01% [40], it will be possible to identify

Marcel Dekker, Inc.

material showing the characteristic + 16-Da mass shift accompanying the first addition of oxygen to the structure.

Damage to PSII proteins is likely to be caused by AOS which are generated within the complex itself. The potential for PSII to generate singlet oxygen is now well established [70]. Charge recombination in the reaction center ($P680^+$, $Pheo^-$) leads to generation of the P680 chlorophyll triplet that is quenched by oxygen, thereby exciting it to the singlet state [71]. The reactivity of this species has been suggested to underlie the sensitivity of PSII to photodamage [72,73] that demands the turnover of reaction center polypeptides and the repetitive reassembly of the complex [74]. Since singlet oxygen is generated within the hydrophobic core of the complex, it is assumed that local pigments and amino-acyl residues are the sites of damage [71] explaining the necessity for disassembly. It is further conceivable that the pigments and protein around the donor side of PSII are directly oxidized by $P680^+$, particularly if the secondary donor tyrosine Z is also oxidized [51]. Since photoinactivation is faster in the absence of oxygen [75], it could be argued that the production of singlet oxygen is a protective measure. The lifetime of singlet oxygen (μs–ms) may provide enough time for diffusion to a local strategically placed quencher, thus preventing direct oxidation of local protein or chlorophyll by $P680^+$. Carotenoids in the reaction center can probably quench singlet oxygen [76], although they may be oxidized themselves in the process [77–79]. The position of the carotenoids is critical, highlighting the need for a high-resolution structural determination of the reaction center. Unfortunately, the complex has not yet produced highly ordered crystals, which may be due to the heterogeneity displayed by the reaction center subunits [40]. Examination of the sites of damage under conditions of singlet oxygen production will provide important insights into the role of this AOS in vivo.

Superoxide is produced at the acceptor side of PSII via the direct reduction of molecular oxygen by the first quinone acceptor QA^- [80]. Evidence was presented that the high-potential form of cytochrome b_{559}, an intrinsic part of the reaction center itself, is a superoxide dismutase [80]. Thus, photoproduction of hydrogen peroxide at the acceptor side of PSII is observed, although its physiological concentrations are kept low by catalase. During photoinhibitory stress, it is possible that the production of peroxide might exceed the capacity for its removal leading to potential protein damage by this species. If cytochrome b_{559} were converted to its low potential form, the more reactive superoxide might also accumulate as superoxide dismutase activity was lost. Some light-induced modifications to PSII apparently still occur under anaerobic conditions. It could be that these rely on hydroxyl radical species which may be generated in the absence of oxygen by, for example, radiolytic cleavage of water. The role of the bound metal ions of PSII, manganese, and iron may be of significance in this respect.

ENVIRONMENTAL STRESS

Many environmental stresses may be linked to oxidative stress. Pollutants such as ozone contribute directly as an AOS, whereas others such as the oxides of nitrogen may generate reactive nitrogen species (RNS). Reactive chlorine and other halogen-containing species also are predicted to contribute to the protein damage within a similar framework as oxidative stress [81]. Although moderate levels of pollutants may be tolerated under favorable conditions, it is likely that adverse effects will be observed under combinations of multiple stresses. Molecular analysis (see section on Experimental approaches for analysis of Oxidative Damage above) will help to reveal the specific role of environmental pollutants in the exacerbation of oxidative stress. Recent studies with ozone reveal the susceptibility of methionine and aromatic residues to oxidation and the dependence of the modification rate with the tertiary and quaternary structures of the protein [82].

INTRODUCTION

The term *stress* was introduced into the scientific field by the American physiologist Cannon. His student, physician, and biologist, Selye, introduced the general theory of stress to explain the physiological response of an organism to impacts from both external and internal environments. The effect of stress on plants has been defined by Larcher [1,2] as the exposure of plants to extremely unfavorable conditions. Thus, it is not necessarily a threat to the life of a plant, but it alerts the alarm response in the plant organism (defense and adaptation reactions). The problem of stress and its effect on plants has been studied in detail by Levitt [3].

In general, stress factors were divided into natural and anthropic. Stolina [4] has distinguished predispositive, specific, and incidental stressors. From the time effect point of view, stress has been differentiated as short time, medium time, and permanent [5]. Tesche [6] considered the intensity of the stress effect as being important. The plant response to natural stress factors, such as water and nutrient deficiency, has been described in many published reports [7–10]. However, in connection with the widespread forest decline in Europe, it has been shown that natural and antropic stressors act together (especially emissions) [11–17].

EMISSIONS AND HEAVY METALS

In recent decades, plants have been intensively affected by the anthropic permanent acting stressors (emissions). This was compounded by the synergic effects of natural stress factors (extreme temperatures, drought). These factors have led to the widespread deterioration in forest health in Central Europe and North America [18,19]. Although the causes of this phenomenon have not been sufficiently explained, it is generally assumed that the forest decline is due to stress from emissions. Thirteen basic hypotheses have been written to explain the cause of the forest decline in Europe; two of which, ''stress'' [20] and ''ecostress'' [21], explain the forest decline on the basis of the stress theory.

According to the effect of emissions on plants, three basic categories have been distinguished: (a) ''disturbance,'' typical stage of excitatory metabolism without external visually observable symptoms; (b) ''injury,'' involving latent (physiological) injury with no visual symptoms or injury with visual symptoms (chlorosis, necrosis); and (c) dying out or death of plants [22].

Ecophysiological, Biochemical, Anatomical, and Productional Characteristics of Beech (*Fagus sylvatica* L.) Leaves from Regions with Varying Degrees of Emission Impact

Air pollutants influence the physiological processes in woody plants much earlier than in the case of depigmentation or necrosis. Air pollution penetrates into the assimilation organs through the stomata or a damaged cuticle. It also has a negative effect on the photosynthetic activity of woody plants; for example biochemical processes (enzyme activity and chloroplast ultrastructure) as well as chlorophyll content. However, the most frequent statement heard is that pollution induces a decrease in the photosynthetic [e.g., see Refs. 23–27] and transpiration rates [28–30]. In addition, structural and functional changes at the cellular level induce anatomical and morphological changes in tissues and leaves.

In this section of the chapter, the comparison of physiological, anatomical, and productional characteristics of sunlit and shady beech leaves growing under various emission impacts are reported. The results follow up our earlier reports [31–34].

Ecophysiological, biochemical, anatomical, and productional characteristics were estimated on the leaves of branches (about 1.5 m long), which were cut from undergrown and subdominant individuals (shady leaves) or from the dominant tree (sunlit leaves). Three beech experimental sites, situated in Central Slovakia (central Europe), with varying levels of emission impact, distance from emission source (aluminium factory in Žiar nad Hronom), and states of health, were chosen for a comparison study. These were the ecologicoexperimental permanent site, Kremnické vrchy—control site (no emission impact); permanent research site, Jalná—variant 1 (slight emission impact); and research monitoring site, Žiar nad Hronom—variant 2 (strong emission impact). The characteristics of the experimental sites are given in Table 1. The physiological characteristics were measured under both laboratory and outdoor conditions (for details see Ref. 35).

It was found that values in the mean daily net photosynthetic rate (P_N) measured outdoors showed a higher variability (Table 2) caused by variable microclimatic conditions (especially irradiance) during measurement. The mean daily P_N was higher in sunlit leaves than in the leaves of undergrown individuals or in shady leaves. Leaves of the undergrown individuals from variant 2 had approximately a five-times higher P_N than had the shady leaves. From comparison of the sites, it is obvious that the mean daily P_N has a decreasing tendency from the control site to variant 1 and variant 2. The statistical evaluation of the above-mentioned differences is presented in Table 3. However, differences in irradiance values (E_e) were not always statistically significant. These findings confirmed the reality that the leaf photosynthetic activity was influenced by other factors than the light conditions, which was the most important factor for carbon dioxide uptake. We surmise

that in both physiological characteristics, photosynthesis and the function of the stomata apparatus, the decisive factor was the different degree of emission impact.

The mean daily values of the transpiration rate (TR) measured simultaneously with the P_N measurements, are presented in Table 4. The TR values for both leaf types increased from the control site to variant 2. These findings are in agreement with the tendency found for the water loss curves (Figs. 1 and 2). We suppose that in the case of variant 1 and variant 2 in comparison with the control site, the regulatory system for water loss through the stomata as well as physical water loss through the cuticle was disturbed. Significant differences between leaf types were found in all sites studied (Table 5). The water-loss rate in relationship to the transpiration coefficient (TC) rose from the control site to variant 2. The tendency of the TC to increase in relation to the different degree of emission impact was similar to that found for the TR. The only difference was that the TC values of sunlit leaves were lower in comparison with shady leaves, whereas the tendency for the TR was

opposite. From the dynamics of the TC values we can state that the cost of water production increased depending on the degree of the emission load, which means that the leaves from sites with a higher degree of emission impact needed for assimilation of 1 mg CO_2 a higher amount of water for transpiration than leaves from the sites with a lower degree of emission impact. Figures 1 and 2 show that water-loss rate of various leaf types as well as various sites studied using the method of water-loss curves. The water loss was more intensive in the leaves of undergrown individuals than in shady or sunlit leaves (Table 6). On comparing leaf types from the various research sites, the water loss was significantly higher in the case of trees from variant 2 than that in trees from the control site (Table 7). The relationship between the water loss rate and the time was linear, with very high values of correlation coefficient (Table 6; see Figs. 1 and 2).

On analyzing the stomata apparatus, it was found that the smallest stomata were in the leaves of undergrown individuals, but the highest values of stomata density (SD) were estimated in the sunlit leaves of adult trees. At variant 2, it was observed that the leaves of undergrown individuals had higher values of SD than the shady leaves (Table 8). Comparing only the shady leaves, a decreasing tendency for all quantitative parameters of stomata apparatus (SD, SL, SW) was apparent from the control site to variant 1 and variant 2. The shady leaves had at the same time the highest SD variability of all sites studied. The quantitative analysis confirmed that significant differences existed not only between different leaf types but also between sites with different emission impact (Table 9).

Chlorophyll a, b, and $a + b$ contents (expressed per leaf area) as well as the chlorophyll a:b ratio were investigated (see Table 8). The sunlit leaves from variant 1 had the highest values of chlorophyll content and the leaves of undergrown individuals from variant 2 showed the lowest chlorophyll levels. The differences in leaf type as well as in research sites were significant (Table 10). The finding that in shady leaves the chlorophyll content increased, whereas the emission impact increased seems unusual. However, the opposite tendency was observed in the leaves of undergrown individuals. This can possibly be explained when one remembers that saplings at variant 2 had grown in quite different light conditions than the trees at the control site (crown overlighting in consequence of the tree defoliation (see section on Responses in Tree Foliation below and Table 1).

In general, the sunlit leaves of the Control site had the highest values in leaf area (A), and the lowest values for these productional parameters occurred in the leaves of undergrown individuals from the same site; that is, the control site (see Table 8). It was found (variants 1 and variant 2) that the shady leaves always possessed a larger leaf area than the sunlit leaves. The opposite tendency was observed at the control site. In all research sites, the leaves of undergrown individuals had the smallest leaf area. The leaf area of the sunlit leaves decreased from the control site to variant 1 and variant 2, and the leaf area of the shady leaves decreased from variant 1, the Control site to variant 2. In the case of each research area studied, the values of the specific leaf area (SLA) increased from the sunlit and the shady leaves up to the leaves of undergrown individuals (see Table 8). Similarly, as for both the A and SLA of the sunlit leaves and the leaves of undergrown individuals, the values of these parameters (A and SLA) decreased from the control site, variant 1 to variant 2. As follows from the analysis, the values of the specific leaf mass (SLM) in comparison with the values of SLA decreased in the order: sunlit and shady leaves and leaves of undergrown individuals (see Table 8). Comparing the research sites, the SLM values of the sunlit leaves and the leaves of undergrown individuals increased from the control site through variant 1 to variant 2. In the case of shady leaves, the SLM values were relatively steady. Statistical evaluation of A values is stated in Table 11. Analysis of the productional parameters showed that leaf areas in variant 2 were the smallest; however, differences between sunlit and shady leaves were not conspicuous, which was in agreement with the high degree of tree defoliation (see Table 1). This is documented by the fact that these shady leaves do not have a typical shady character as in the case of leaves coming from healthy stands of the Control site where the differences between the leaf types were significant.

Our results confirmed the findings of other investigators [13,36] that the photosynthetic rate is negatively influenced by the air pollutants. In our experience, the leaf damage of trees growing on the forest stand at the Control site was caused by the synergism of air pollution and soil drought (long-term period in summer months without rain). This is borne out by the water-loss curves which characterized leaf (and/or plant) capacity for water maintenance. We also observed cuticle transpiration, which is the most suitable parameter for assessment of water-maintenance capacity. Water-

loss values in this phase are equivalent to the water-loss rate while the plants are stressed by soil drought or plant wilting [28].

Significant differences in the photosynthetic rate between all research sites studied (for both leaf types) were caused by long-term drought (June and July) during the growing season. The most conspicuous negative effect was in the case of trees growing under intensive emission impact (variant 2).

On the basis of our findings, it is possible to conclude that the leaves of trees growing at the Control site had better water-maintenance capacity (or higher resistance to drought) than the leaves of trees growing at variant 2 where this mechanism was disturbed. Furthermore, the highest water-maintenance capacity was observed in sunlit leaves and the lowest in the leaves of undergrown trees. The shady leaves showed a higher water-loss rate than the sunlit leaves (control site and variant 2) which resulted from the different anatomical structure of the leaves as well as (in the case of variant 2) from the greater damage of the subdominant trees in comparison with dominant trees. Similar results were found by others [37,38] using a fumigation chamber for the investigation of F and SO_2 effects. The investigator observed that the fluorine effect caused a decline of the regulatory ability of the stomata resulting in a gradually decreasing stomata and an increasing cuticle transpiration [38]. It is important to emphasize that the transpiration rate in forest trees growing under emission impact depends on tree species, pollutant concentration, and duration of the effect as well as on other ecological factors (e.g., air and soil humidity, air and soil temperature, irradiance, wind). In particular soil drought can be an important predisposing factor and, on the other hand, the water-maintenance capacity may be greatly reduced by emission impact (e.g., see Ref. 39). Our results confirmed these findings.

The stomatal apparatus together with the whole leaf anatomical structure reflect the relatively favorable environmental conditions under which they have grown. In general, the sunlit leaves in comparison with the shady leaves had higher values of SD but the stomata were smaller. This was found in forest trees not only in the present paper but also in the others (e.g., see Refs. 33, 34, 40, and 41). However, absolute values of the stomata number per mm^2 found in our experiments were a little lower than those published in above-cited literature, which could be due to the different age and light conditions or variations in this quantitative leaf parameter [42,43]. Gellini et al. [44] observed in the leaves of damaged beech trees higher values of SD than in the leaves of the control tree. Similarly, Getko and Sergejčik [45] confirmed the effect of air pollutants (compounds of sulfur)

on both the number and size of the stomata in three woody species. This phenomenon is probably caused by an emission impact resulting in stress similar to that caused by drought. Therefore, the leaves adapt anatomically, which means that leaves acquire a xerophilous character (they had higher values of SD). Similarly, undergrown beech individuals in variant 2 showed higher values of SD than the shady leaves of adult trees. This could be explained by injury of the forest stand (decrease in the stocking and crown canopy and a high degree of defoliation). Therefore, the undergrown trees did not receive sufficient shade and the leaves did not exhibit so-called typical shady leaves. This was confirmed by the occurrence of undergrown trees only on overlighted sites. Masarovičová and Minarčic [32] also found that the beech seedlings had leaves with an anatomical structure of an intermediate type; that is, their anatomical structure was between the typical sunlit and shady leaf types. To study the effect of pollutants [46,47] or heavy metals [48] on the chlorophyll content, the leaf anatomical structure should be considered.

Despite the fact that both the leaf growth and the leaf development are determined by internal (genetic) factors, the specific leaf area and the specific leaf mass may be considered to be suitable and sensitive physiological parameters of adaptation to environmental conditions (cf. Ref. 34). Our results show slightly lower values which were probably caused by the natural leaf variability and plant age as well as by the date of sampling. The importance of the correct time for sampling was also confirmed by Gratani et al. [49]. The fact that at variant 2 the sunlit and shady leaves were found with the lowest leaf area was also reported by other investigators [50,51]. Moreover, the sunlit leaves of trees from variant 2 showed a xerophilous character (hard and thin leaves) so their values of SLM were also higher. These results confirmed that the sunlit leaves in comparison with shady leaves were more intensively affected by pollutants, which had been previously observed by Štefančík et al. [52] at the same forest stand.

The growth and leaf photosynthetic activity were also investigated in pollution-damaged oak saplings [27]. Shoots of damaged *Quercus dalechampii* Ten. saplings were shorter and growth lagged behind by more than a week compared with the control shoots. The photosynthetic activity in leaves of damaged trees was significantly reduced. Yet the leaf dark respiration rate was higher in damaged saplings. Changes in both the growth and leaf photosynthetic activities may also be used as a sensitive diagnostic parameter in ascertaining the negative effects of abiotic and/or biotic environmental factors.

Effect of Heavy Metals on Growth and Chlorophyll Content of Some Wild Herbs

The toxic effect of heavy metals is obvious at different levels of the structure and function of the plants: reduction in growth and productivity, changes in membrane structure, metabolic processes, or water and ion uptake. Plants have developed specific mechanisms to enable them to grow and reproduce under contaminated conditions. One of these mechanisms is the presence of barriers such as the production of calose and the efflux of malate and citrate into root surroundings or the production of slime on the root surface (e.g., see Refs. 53–55). Other mechanisms comprise the ability of certain plants to absorb and then immobilize ion uptake by specific proteins (''stress-proteins'' and ''chaperons'') such as phytochelatins and metallothioneins [56–58]. It is accepted [59] that the plant response to metal-enriched soils may involve (a) metal exclusion where there may be either a reduced uptake or restricted transport from root to shoot, (b) a passive uptake where metal concentrations in aerial plant tissues reflect soil concentrations (indicator behavior), or (c) accumulation whereby metals are concentrated in both the root and shoot dry mass after internal complexation and detoxication. It has always been presumed that metal hyperaccumulation must be a mechanism of metal tolerance in which a potentially toxic metal is complexed, translocated, and then compartmentalized in the plant tissues; often being stored as a water-soluble organic acid complex in leaf cell vacuoles. However, metallophytes have evolved several different strategies of physiological response to high soil metal concentrations (e.g., exclusion), in which hyperaccumulation is both an extreme and rare response in serpentine, calamine, and copper/cobalt floras [60]. Tolerance of the plants to heavy metals is either genetically fixed or acquired through adaptation processes. Species of genus. *Agrostis*, *Deschampsia*, or *Silene* produced ecotypes with a tolerance for higher metal concentration (especially Cu, Pb, Zn) in the substrate (e.g., see Refs. 61 and 62). These findings have a practical application in the recultivation of contaminated and degraded soils.

The results of a study on the effect of different Cu concentrations on the growth and chlorophyll content in some wild herb species of tolerant and sensitive populations are presented here. Seeds of *Agrostis stolonifera* L., *Melandrium rubrum* L., and *Rumex acetosela* L. were sampled from the following localities:

Piesky pri Starých horách (region Banská Bystrica, Central Slovakia, tolerant population): piles of soil contaminated by heavy metals.
Staré hory and Borinka (Little Carpathians, SW Slovakia, sensitive population): region with noncontaminated soils.

Soil samples were taken from the same localities as the seeds. Plants grown from seeds were cultivated under controlled conditions in growth chambers (for details see Ref. 63). Concentrations of Cu, Pb, Mn, and Cd in leaves and roots were determined. For plants from tolerant populations, a higher Cu concentration was found in both leaves (1.9 times) and roots (4.2 times) than in plants from the sensitive population. The concentration of Mn was lower in the roots and shoots of plants from tolerant populations (Table 12).

Both the root length and height of the plants decreased steadily with an increasing Cu concentration. For plants from sensitive populations, the greatest decline in the root length occurred at 0.3, 0.6, and 4.0 μM Cu concentrations. For plants from tolerant populations, the decrease in the root length was moderate and most significant at 0.6 and 4.0 μM Cu concentrations. Comparing sensitive and tolerant populations, the most sensitive of all studied species to Cu concentrations was *Agrostis stolonifera* (Table 13). The highest values of index of tolerance, IT (root length of the plant treated with Cu/root length of the plant without Cu and multiplied by 100) were found in all studied species from the tolerant population (Table 14). Pigment analysis confirmed that all chlorophyll components (Chla, Chlb, Chla+b) decreased in *Agrostis stolonifera* leaves of both the sensitive and tolerant populations under Cu treatment. The greatest decrease was found in the Chlb content, which was significantly manifested in the higher values of the Chla:Chlb ratio (Table 15).

Sensitive	125	215
Tolerant	113	170
Cd (mg kg^{-1})		
Sensitive	0.6	0.7
Tolerant	0.6	1.0

Polymetallic ores were mined in the locality of Piesky pri Starých horách from the time of the Middle Ages to the end of the last century. Owing to the mining and processing of metallic ore piles were occupied by the wild herb with herb species (*Agrostis stolonifera* L., *Melandrium rubrum* L., and *Rumex acetosela* L.). Their expansion was limited by deficiencies in humus and nutrients, low soil humidity, and a high content of metals (mainly Cu). One of the first species to be observed was *Agrostis stolonifera*; at present, *Melandrium rubrum* is the dominant species with the highest cover [61,64]. Similarly, Hunter et al. [65] and Karataglis [66] found that species of *Agrostis* are among plants growing in soils contaminated by Cu.

Concentration of 12,700 mg Cu and 70 mg Pb kg^{-1} of soil were estimated at the sites studied. The control samples from Borinka contained only 20–80 mg Cu and 15–50 mg Pb kg^{-1} of soil. Comparable piles of contaminated soil in Europe are found in North Wales at Parys Mountain and Trelogan: 4,360 mg Cu kg^{-1} and 11,900 mg Pb kg^{-1} of soil [66]; Merseyside (NW England): 11,000 mg Cu kg^{-1} of soil [65]; Prescot near Liverpool: maximal concentration 53,000 mg Cu kg^{-1} of soil [67].

The ability of plant populations to tolerate intoxicated substrate depends on their physiological and biochemical adaptation to actual ecological conditions. The basis of this adaptation is ''avoidance'' (barrier against ion uptake) or ''tolerance'' (accumulation and immobilization of ion uptake) (e.g., see Refs. 68 and 69). Our results confirm tolerance as being the basis of plant adaptation.

The metal components also significantly influenced growth processes. Some investigators [61,70,71] found a reduction in biomass production of 40%. The species *Agrostis stolonifera* and *Rumex acetosela* had the lowest height of the aboveground part of the plants on the site studied.

As roots are in primary contact with metal ions, the root growth is influenced faster than shoots. Therefore, Wilkins [72] as well as Macnair [73] suggested the index of tolerance (IT) as the most sensitive parameter for testing root growth processes. It was found that the inhibition of the root growth by Cu ions was greater than in the shoot growth and the reduction of the root length was faster for sensitive plant populations (e.g., see Ref. 74). Our results confirm that all Cu concentrations caused a decrease in the root length and height in tolerant and sensitive plant populations. However, the length reduction was faster and the IT was lower for the plants of sensitive population. The higher IT values for plants in contaminated soil (tolerant population) were also found by others [68,75,76].

The chlorophyll content is one of the most investigated physiological (but not specific) charac-

teristics used for identification of physiological disturbances due to emission impact [35]. The most frequent finding is that both air pollutants [27,46,47] and heavy metals [48,77] cause a decrease in the total chlorophyll content. Our results also confirmed the decrease of the leaf chlorophyll content in the herbs studied, and they therefore agree quite well with the findings of other investigators [78–82]. Since the chlorophyll *b* content after the Cu treatment decreased faster than chlorophyll *a*, the values in the Chla:Chlb ratio were higher. However, the chla:chlb ratio reduction was lower for the plants of the tolerant population. A similar tendency was found by Masarovičová [77] in oak and by Stiborová et al. [78] in barley and maize leaves.

Our results confirm the presence of a different intraspecific tolerance of the population to heavy metals. These plants were able to adapt to high metal concentrations in the soil and to grow, reproduce, and cover anthropic substrates. Therefore, tolerant plant populations could be the key to solving problems concerning recultivation of contaminated and degraded soils.

Responses in Tree Foliation (Defoliation, Phenology)

Defoliation

Since the beginning of 1970s the novel phenomenon—forest damage caused by emissions—has become more obvious. Broad-leaved trees (especially beech) were considered to be more tolerant to emissions in comparison with conifers. However, the symptoms of damage also occurred in broad-

[a] From 1993 to 1996, 39 trees were evaluated.
[b] In 1991, 77 trees were evaluated; in 1992, 76 trees, in 1993 74 trees, and from 1994 to 1996, 72 trees, respectively.

leaved trees, including beech. This was the reason for an early yellowing and leaf fall, shortening of annual shoots, morphological lesions of branches and consequently of whole crowns, their sparsing, and necrosis of leaves and branches. The above-mentioned facts were first observed in Austria, Germany, and Switzerland and later in beech stands in Slovakia, especially in the localities near emission sources. This is an important fact, because European beech (*Fagus sylvatica* L.) is the most widespread tree species (approximately 30%) in Slovakia.

The same method (ICP, International Cooperative Program) [83] for assessment of the state of the health of forests has been used in Europe since 1986 and is based on two criteria: the discoloration and defoliation of assimilatory organs. The assessment is carried out every year in a network of permanent monitoring plots (PMP) in 34 European countries. It is interesting that data related to the extent of the defoliation of beech stands including dynamics are few apart from PMP [84–88]. Deterioration of the state of the health of forests has occurred throughout Europe. This was confirmed by the results of monitoring published in a report in 1995 (Forest Condition in Europe, 1995 [89]). According to this report, in the year 1988, defoliation of assimilatory organs was higher than 25% in only 10.3% of the total evaluated beech trees in 34 European countries. In 1995, it was already 26.1% (in Slovakia 24.4%). The mean defoliation of beech trees in Slovakia in the years 1987–1996 ranged from 17 to 23%. In the year 1991, an exception was recorded when the lowest defoliation (13%) was ascertained [90]. We compared the values of the mean defoliation of nine monitoring cycles of the assessment of the health state of beech trees at three localities in Central Slovakia. They are situated 2, 7, and 18 km (Table 16) from the emission source (aluminium factory).

Increased defoliation was most marked at the permanent research site (PRP), Jalná, and the ecologicoexperimental permanent site (EEPP) Kremnické vrchy, in 1990. This trend occurred not only in Slovakia [84,85,90] but virtually in every country in Europe (Forest Condition in Europe, 1995 [89]). The complex of synergistically affected factors is considered to be one cause of this unfavourable trend. Besides emissions, a significant role is played by changes in climatic parameters (long-term precipitation deficiency and extremely high temperatures during the growing season). This fact was evident at the end of the 1980s and the beginning of the 1990s. Broad-leaved trees responded to the above-mentioned factors by increasing the number of assimilatory apparatuses, which was apparent after several years of evaluation of the defoliation at PRP Jalná and EEPP Kremnické vrchy (see Table 16). In addition to a virtually continuous increase in the mean defoliation values at these sites, there were significant differences in the annual results (Table 17).

Markedly fewer cases of significant annual differences related to the mean values of defoliation were found during the extended period at the RMP Žiar nad Hronom. This could be explained by the fact that the forest stands are more adaptable to long-term negative changes in climatic parameters when subject to a strong emission impact. On the other hand, in stands growing under favorable ecological conditions, gradual but significant changes over a long period of time are con-

spicuously manifested in the foliation of trees. An example of this is the gradual negative changes in foliation at EEPP Kremnické vrchy and PRP Jalná. This was also confirmed by research into the biochemical, physiological, anatomical, and morphological parameters of beech leaves at the same experimental sites [35]. Differences in the mean values of defoliation between sites at different distances from the emission source as well as differences in nine monitoring cycles were also confirmed statistically (Table 18). However, it should be emphasized that the method of visual terrestrial assessment of tree foliation is a subjective method and there is the possibility that the observer may make a subjective error in evaluation and thus influence the accuracy of the results [91–94]. The assessment of defoliation is also influenced by other objective factors such as the number, size, and deformation of leaves (leaf curling), which may cause changes in crown transparency and overestimation of real defoliation. This was observed especially in the sunlit leaves of dominant trees [95,96].

The number of trees and the leaf area are closely related to many environmental factors, moreover, they change every year [97]. It was stated that a decrease in the leaf area is in relation to the frequency of emissions. Glavač [51] found that a decrease in the leaf area of beech leaves was not only related to the emission impact but also to soil type as well. Oswald and Ziegler [50] found that beech trees with mild to severe injuries had leaves about 50% smaller than healthy trees. The higher crown transparency is also partly caused by leaf-eating insects. During mass outbreaks

of certain insect species (e.g., *Calliteara pudibunda*), the leaf area was markedly reduced. This could be estimated indirectly by excrement production (Table 19) [98]. The extremely high temperatures during the summer of 1992 led to a significant increase in crown transparency. This was apparent as early as the end of July and beginning of August with the shedding of green leaves. Thus higher values of defoliation occurred in that year than in previous years (see Table 16). A similar observation was reported by Schütt and Summerer [95] and by Wittig and Werner [99] in a Bavarian forest. They found that some individuals of European beech had lost more than 50% of the total amount of leaves as early as the beginning of September and the other were fully defoliated by the end of September.

The time of year an assessment of beech forest health is carried out also is very important and is closely related to the phenology of evaluated tree species [100,101]. According to the ICP method, broad-leaved trees should be evaluated after the middle of August and that is not always objective as it also depends on weather conditions during the growing season in the actual year, the recommended period for evaluation could influence the accuracy of the obtained results. In

Source: From Ref. 98.

beech stands subject to a heavy emission impact, earlier leaf fall occurred than in stands with a relatively slight emission impact [102,103]. This was confirmed by our 5-year investigation (Table 20) [98].

The foliation of beech trees is also influenced by their fructification [97,100,104]. Some investigators [105–108] have emphasized that yellowing and defoliation of assimilatory organs are nonspecific symptoms for the assessment of tree injuries subject to an emission impact. They argue that leaf yellowing could be the result, not only of emmission impact but also of nutrient deficiency in the soil and/or needles [19,109], drought, and high temperatures during the summer months [110].

Phenology

It is known that differences in the phenological manifestations of individuals such as bud breaking and leaf ageing exist in every population of a particular tree species. Since the 1970s a decrease in interest in phenological investigations has been noted. In this period, the unfavorable effects of emissions on forest stands started to be the most important problem in forestry. The ''novel forest damage'' started a new forest phenological approach in Europe. This was confirmed by the investigation of the air-pollution effect on the shift of tree phenophases, time of vegetative period, lag time

of bud breaking, premature leaf ageing, and leaf fall [99,102,111]. Premature leaf yellowing and leaf fall in connection with the frequency of emission were established outdoors and also under laboratory conditions [112–114]. The shift in the autumn phenophases of beech was observed during our multiyear investigations [113] at the research sites EEPP Kremnické vrchy and RMP Žiar nad Hronom (see Table 1). Figures 3–6 show the climadiagrams for these research sites.

The 95 individuals in the beech parent stand at EEPP Kremnické vrchy and 78 individuals at the RMP Žiar nad Hronom were analyzed every year. Based on the data estimated outdoors, it was found that over 50% of the total number of analyzed individuals reached the given phenophase. The rate of the developmental phenophases was expressed as the number of days of transition from one phenophase to the next one and always to the corresponding date. The data on the time course and the start of partial phenophases were obtained using this methodical approach. Table 21 presents the time course of spring phenophases in the parent stand at both localities. The minimum differences between sites (1–3 days) were estimated. On the other hand, marked differences from year to year, especially in the date of the occurrence of the given phenophase, were found (Figs. 7 and 8).

A very interesting situation was observed in 1991, when the start of vegetation was the latest of the 4-year observations. Similarly, a ''late'' start of phenophases occurred in 1992, although the next phenophases showed a much faster course (mainly phenophases 3 and 5b). The reason for this phenomenon reflected a marked increase in the temperature values (average and maximum) at the end of April and/or the beginning of May. In our climatic conditions, bud breaking lasts from approximately April 20 to the middle of May and/or the full foliation of beech trees lasts from May

7 to the end of May [115]. During our 4-year observations, bud breaking occurred from the middle of April to May 3 depending on the temperature conditions at the beginning of the given year.

The time course of the autumn phenophases in parent stands at both localities is presented in Table 22. The comparison of the autumn phenophases over the 4 years showed that the course of yellowing and leaf fall was faster at RMP Žiar nad Hronom, where leaf yellowing became markedly evident in the first half of August. At RMP Žiar nad Hronom, there were few trees with green leaves (3–15%) in the middle of September, whereas at EEPP Kremnické vrchy, there were 49–99% on the same date. The above-mentioned results correspond with investigations of leaf-fall quantity at both sites as well (see Table 20).

Similarly to the spring phenophases, the autumn phenophases also showed differences in the years studied. From this aspect, the year 1992 is very interesting because of the extreme drought and the long heat wave (above 30°C) during the growing period, which resulted in even the fall of green leaves at the end of July and beginning of August. This effect was best seen at RMP Žiar nad Hronom, where on September 16, 1992, almost half the trees had become totally defoliated. Similar differences in the time and course of yellowing and leaf fall were found by Chalupa [115].

It could be concluded that the course of yellowing and leaf dropping depended on temperature and moisture (precipitation) conditions in a given year together with the synergic effect of air pollution [99,116].

CONCLUSIONS

The widespread contamination of our environment as a result of human activities over many centuries now presents us with the choice of undertaking a monumental clean-up task or leaving the worst problems and a degraded environment to the next generation. Plants are not yet widely used in the removal of organic or inorganic pollutants from the environment, but there is a large potential for this approach. Plants can concentrate metals in their roots and shoots to levels far exceeding those present in either soil or water. The value of metal-accumulating plants for environmental remediation is now being realized with the foundation of a new technology termed ''phytoremediation'' [117]. This is a new and promising approach to the difficult problem of remediating heavy metal–polluted soils. Fundamental to the environmental and economic success of phytoremediation is the existence of plants which hyperaccumulate metals. These are so-called metal hyperaccumulators or hyperaccumulator plants, of which about 400 taxa have been described so far from 35 families of angiosperms [60]. Apart from the interest in elucidating the underlying biochemical mechanism of metal tolerance, metal hyperaccumulators are attracting increasing attention because of their potential application in the decontamination of metal-polluted soils [118]. The use of the roots of terrestrial plants to remove organics or heavy metals from aqueous solutions may provide the foundation for a novel water-treatment technology. Phytoremediation, although still in its infancy, may one day become an established environmental clean-up technology [117].

Extensive biotransformation of pollutants by plants is known to occur, which includes methylation, conjugation, reduction/oxidation, and degradation. The fate of the biotransformation products ranges from incorporation into cellular components, deposition into specialized organs, to excretion and volatilization [119]. The further development of phytoremediation requires an integrated multidisciplinary effort which combines plant biology, soil chemistry, soil microbiology, and agricultural and environmental engineering. Plants that enhance the organic degradation or accumulate toxic metals can be grown and harvested economically leaving the soil or water with a greatly reduced level of toxic chemical contamination [118].

INTRODUCTION

Air is a mixture of gases and is normally colorless, odorless, and tasteless. Its major constituent gases are nitrogen (78%) and oxygen (21%), with the remaining 1% comprises, Ar, CO_2, Ne, He, CH_4, Kr, H_2, CO, Xe, O_3, oxides of S and N, and water vapors [1]. It took about 4.5 billion years of evolution to produce this composition of air, which made this planet, a place capable of supporting life in its present form. Although *Homo sapiens* appeared late in the Earth's history, this species has been dominant in modifying its environment.

The effect of human activity on the global atmosphere has become increasingly evident during the last four decades. There has been a quantum jump in industrialization since the Industrial Revolution, urbanization, nuclear weapons testing, the increasing use of chemicals for optimum crop production to feed the ever-increasing population, especially in the developing countries, and the increasing demands made by humans as their standard of living rises have all contributed. As a consequence, the more eco-friendly composition of the atmosphere was disturbed because the air became polluted.

Air pollution is the contamination of the atmosphere by gaseous, liquid, or solid wastes or by-products that can endanger human or plant health or can attack material, reduce visibility, or produce undesirable odors [2]. It is one of our most serious environmental problems. According to conservative estimates, some 0.2 billion tons of such pollutants are released each year over the United States alone [3]. Many of these come directly from identifiable sources, for example, vehicu-

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

lar exhaust, power generation, and industrial plants, whereas, others are formed through chemical reactions on certain precursors, for example, the production of ozone by the interaction of hydrocarbons, nitrogen oxides, and particulates under the influence of sunlight [4].

Pollutant concentrations are reduced by atmospheric mixing, which is dependent on factors like temperature, wind speed, and movement of high- and low-pressure systems. When a cold layer of air settles under a warm layer producing thermal inversion, atmospheric mixing is retarded and pollutants accumulate near the ground. This inversion may become sustained under a stationary high-pressure system coupled with low wind speeds. A period of only 3 days of poor atmospheric mixing in a high pollution area can lead to high concentrations of hazardous material and can result in severe injuries to all life forms there. For example, such an inversion phenomenon occurred in London in 1952 and 1962 and caused about 4000 and 700 human deaths, respectively.

The combustion of coal, oil, and gasoline accounts for much of the air pollutants. The pollutants thus produced in urban areas may drift to nearby rural areas and cause damage to vegetation there. Such a drift may occur at large distances from the source, as happens, when tall smoke chimneys boost the pollutants from factories higher into the atmosphere, thereby reducing their concentrations at the site of their production. These pollutants may be transported and gradually settle down far from their site of production. Sulfur dioxide (SO_2) and NO_2^- emissions from the Central and Eastern United States are, for instance, causing acid rain over New York State, New England, and eastern Canada. Similar situations have been observed in European countries, which are causing global environmental concern. In Sweden, for instance, according to one estimate, some 15000 lakes have become too acidic to support sensitive species of animals and plants. A large problem with acidic water is that it dissolves metals, both from soil and from water mains and pipes, resulting in higher levels of metal concentrations in drinking water and thereby posing a health hazard.

Research on air pollution damage to plants has been going on for a long time. This research has, however, gathered momentum since the early 1950s, and in addition to research papers, some detailed reviews and books have been published on this subject [5–10]. Thomas, whose paper in the *Annual Review of Plant Physiology* [9], is among the early ones on this topic, quotes some works from where, it is evident that the effect of mercury (Hg) vapors on plants was studied as early as 1797. With the advent of civilization, the oxides of sulfur, carbon, and later on of nitrogen have subsequently received much attention. These studies provided a better understanding of ''acid rains'' produced by sulfur compounds, the ''greenhouse effect,'' and warming of the atmosphere due to an increase in atmospheric CO_2 levels as a result of a worldwide increase in the burning of fossil fuels, coal, natural gas, and petroleum oil.

There has been a continuous increase in the levels of CO_2 in the upper atmosphere resulting in elevated temperatures. It is estimated that there has been an increase of 20% in the CO_2 content of the atmosphere raising the level from 280 parts per million prior to 1900 to the current level of 340 parts per million. As a consequence of the activities of the considerable increased in the human population, about 5.3 gigatons (1 gigaton is equal to 1000 million tons) of carbon dioxide is being added into the atmosphere annually [6], which can play a major role in the heating of the Earth's surface, because the heat which would normally dissipate into space is trapped by the CO_2 and deflected back to ground.

Assuming a rise in the use of fossil fuels by 2% each year, it is estimated that by the year 2000, the CO_2 level would increase to about 360–370 parts per million, and that would raise the Earth's temperature on an average by 1°C [6]. This would bring highly significant and far-reaching changes in the climates of the world. As the world warmed up, the seas would rise by 2.5 inches a decade on the average. They would generally swell by as much as 3 ft by the year 2100, affecting about 224×10^3 miles of the world's coastline [11]. In the absence of any precautionary measures, this would render some island countries uninhabitable, displace 10s of millions of people, seriously threaten low-lying urban areas, flood productive land, and contaminate freshwater supplies. This increase in the average temperature of the planet, therefore, has the potential of changing the overall patterns of food production globally.

The ''ozone scare'' is a comparatively recent event, but it has gained worldwide significance owing to its impact on our ecology. In nature, a region of atmosphere from 20–50 km (12–30 miles) has an ozone concentration of as much as 10 ppm. This level of O_3 is dangerous for all life forms on Earth, but ozone layer in the upper atmosphere, actually protects all forms of life on Earth from the full force of the sun's ultraviolet radiation, which can cause skin cancers, sunburn, snow blindness, wrinkling of the skin, and cataracts, reduce the immune system response, and interfere with plant and oceanic phytoplankton growth.

Ozone is a primary product of the reaction between nitrogen oxides (NO, NO_2), hydrocarbons, and sunlight. Emissions from industries, vehicular exhausts, and refuse incineration are all processes that help to create favorable conditions (i.e. conditions which are favorable for formation of ozone) for the above reaction. Consequently, localized toxicity of ozone may occur. Ozone may, however, be destroyed as well by several chemical reactions. Scientists were therefore concerned when they discovered in 1970 that certain manmade chemicals, called chlorofluorocarbons (CFCs), used as refrigerants in different machineries and in aerosol spray, can pose a threat to the ozone layer. The excessive release of chlorine, Freon, and nitrogen oxides from various human activities, result in the reduction of ozone at high altitudes. Aerosols containing highly reactive chlorofluoromethanes also destroy the ozone layer. Other halocarbons and nitrous oxides may also act similarly.

Initially, it was thought that ozone depletion is on the increase all over the globe, but in 1985, it was revealed that a growing ozone hole concentrated over Antarctica, where 50% or more of ozone above this area was being depleted seasonally beginning in October of each year. This happens on account of heterogeneous reactions on ice particles, which facilitate the catalytic destruction of the ozone layer by chlorine. A 1986 *Newsweek* study predicted a loss of 5–9% of the ozone shield in the next 50 years, whereas a 2.5% decay means 15000 more deaths annually from skin cancers and related diseases. In 1985, 49 countries of the world hence agreed on the United Nations (UN) Convention to protect the ozone layer. This ''Montreal Protocol,'' which was renegotiated in 1990, calls for the gradual phase out of a certain amount of chlorofluorocarbons by the year 2000 and provides aid to developing countries in making this transition.

SALINITY AND PLANT GROWTH

In all arid and semiarid regions of the world, soil salinity is a major agricultural problem. Despite the advanced management technologies available today, salinization of millions of hectares of land continues to reduce crop production severely worldwide. The excess salts present in the root zone impair the growth of many field crops. Stunted growth, leaf-tip burning, and in some cases leaf necrosis, enhanced leaf senescence, and reduced yields are major visible symptoms of this type of injury and are accompanied by a loss in the selective absorption of essential plant nutrients, a decline in the transpiration rate, an altered water potential, and other biochemical changes in the tissue [e.g., see Refs. 12–15].

Plants require mineral nutrients from the root-substrate interface in their native soil environments. Under saline conditions, which are characterized by low-nutrient ion activities, nutritional disorders can develop and crop growth may be reduced. The nutrient availability and uptake by plants grown in saline environments are related to (a) the activity of the nutrient ion in the soil solution, which depends on pH, pE, concentration, and composition; (b) the concentration and ratios of accompanying elements that influence the uptake and transport of these nutrients by roots; and (c) numerous environmental factors.

An overwhelming amount of evidence from laboratory and field studies indicates that Na^+-dominated soils or solutions generally reduce the K^+ and Ca^{2+} uptake by plants and/or affect the internal distribution of these elements. Major ions can influence nutrient absorption by competition or by affecting ion selectivity of membranes. Salinity can also influence the mineral nutrition of plants by affecting the mobility of a nutrient element within the plant or by increasing the nutrient requirement for that element in the cells.

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

Sodium and K uptake, and their distributions in plant parts, play key roles under saline conditions. Potassium has been established to play an important role in stomatal movement (in addition to being an essential macronutrient involved in many vital metabolic processes), and its importance needs no further elaboration. The cellular membranes are the main stress-sensitive sites in the cell. The increased resistance against this stress may be due to the protection of sensitive membranes, which is achieved by structural changes or synthesis of protective compounds. The connection between Na transport (a dominant phenomenon under saline conditions) properties and membrane constituents in a plant system has been reported. Lipids and proteins are the main building blocks of biomembranes and any change in them could be responsible for the sensitivity of a plant to certain potential stresses [16,17].

The demand of food and fiber for the growing world population requires the use of even marginal lands which, with time, are lost to secondary salinizations, a great hazard against which no country can consider itself immune today. On the other hand, the damaging effects of air pollutants are also worldwide and have been reported from the overpopulated cities of Bogota, Sao Paulo, Cologne, Copenhagen, London, Paris, Karachi, Ahmedabad, and Delhi and Baltimore, Los Angeles, New York, Chicago, Philadelphia, and San Francisco in the United States [3,18–21]. In terms of money, the estimates of damage to agricultural crops in California alone amounted to about $8 million annually for field and vegetable crops and about $18 million along the Atlantic seacoast where many highly populated cities of the continents of North and South America and Africa [9] are located.

Sulfur dioxide and ozone are produced mainly in urban areas. These gaseous pollutants produced by industries and the heavy vehicular traffic of cities drift to rural areas and have fallout effects causing injury to plants and resulting in crop losses [22,23]. The ecological implications of these pollutants are hence immense, as their harmful effects are not restricted to a limited area or site of production. Although, a considerable amount of work has been reported on the various aspects of the response of a variety of plants to different pollutants and salinity separately, their combined effects on plant growth and metabolism have remained comparatively less explored. The response of ozone to plant growth and development was reported to be considerably altered in the presence of SO_2 and nitrogen nutrition or low soil moisture [7]. Although carbon dioxide is another air pollutant of importance, it is also an integral part of the process of photosynthesis and has received attention in that context as well. This chapter attempts to highlight some of the effects of SO_2 and O_3 in combination with soil salinity.

EFFECT OF SULFUR DIOXIDE ON PLANT GROWTH

The important physiological processes of plant growth, photosynthesis, respiration, carbon allocation, and stomatal functions are known to be affected by air pollutants. A wide range in the sensitivity of plant growth both within and between species is evident from the literature for pollutants such as SO_2, O_3, N_2O, and HF. The study of the effects of pollutant mixtures on single plants and vegetation has now become a major area of research.

Air pollution by gaseous sulfur dixoide causes the development of soil acidity. The concentration at which atmospheric sulfur dioxide will damage plants have been extensively studied by Zahn [24]. Sulfur dioxide injury to vegetation and forest growth has been observed in the vicinity of several industrial operations, including metal ore concentrators and smelters, petroleum refineries, fossil fuel–burning power plants, and sulfuric acid manufacturing plants [25,26]. Investigations since 1970 in the United Kingdom have indicated that the SO_2 damage to pasture grasses is much more severe in the winter, not only as a result of the seasonal increases in the level of pollutants but also because plant resistance and regrowth are limited by unfavorable environmental conditions (low temperature and irradiance). This has been confirmed by Davies [27], who showed that the sensitivity of *Phleum pratense* plants depends on irradiance, but Davison and Bailey [28] have also demonstrated that fumigation of *Lolium perenne* plants with SO_2 can reduce their ability to tolerate freezing. It is likely that the rather mild effects of SO_2 fumigation on plants are a consequence of the low

S status of the soils used; and under these conditions, atmospheric SO_2 can act as a fertilizer stimulating rather than reducing growth [29].

With the use of SO_2 (0.068 ppm), a pollutant, visible injuries such as reduction in the rates of net photosynthesis and dry matter production and the disruption of water and ionic relations and of cell biochemistry have been observed in grass plants (*Dactylis glomerata, Poa pratensis, Lolium multiflorum, Phleum pratense*) [30]. Any environmental condition that favors stomatal opening increases the absorption of SO_2 and, therefore, injury [22]. SO_2 can cause stomatal opening even when the leaf is subject to water stress leading to increased SO_2 uptake and water loss. Biscoe et al. [31] found that stomatal resistance in the leaves of faba bean (*Vicia faba*) fell by 20% at 140 μg SO_2 m^{-3} and above.

Sulfur concentrations in the tissues of both saline and nonsaline wheat plants were increased greatly by SO_2 fumigation [32]. Increased S from absorbed SO_2 was mostly retained in the aboveground part of the plant, particularly in the leaves. Most of the absorbed SO_2 was oxidized into sulfate, with only a small increase in the concentration of organic sulfur by SO_2 fumigation. The small increase in the organic sulfur concentration may be mainly attributed to an enhanced glutathione content [33]. The NaCl salinity decreased the SO_4 concentration in the leaves of the nonfumigated and SO_2-fumigated plants [34]. Yeo et al. [35] observed that stomatal conductance and photosynthesis decreased in the old leaves of rice as salt accumulation increased over time. The SO_2 treatment of radish (*Raphanus sativus*) plants affected the plant nitrogen balance and subsequently decreased the ability of plants to respond to decreased nitrate availability by affecting resource partitioning to nitrate uptake and root growth [36].

There have been several studies on the interactions between SO_2 and soil salinity on plant growth responses [37,38]. The NaCl salinity might protect plants from SO_2 injury by increasing leaf stomatal resistance and decreasing SO_2 uptake [39]. However, in the long term, SO_2 fumigation increases the sulfur content in plants under salinity stress. Salinity and ozone have been implicated in stomatal closure. The closure of stomata may reduce yield. This closure will also limit the uptake of salt into the plant as a result of reduced transpiration.

Ozone has been implicated in damage to the membrane ion transport system in particular and membrane permeability in general [40]. Salinity and SO_2 have been found to be antagonistic in a number of crop species [41,42]. Long-term exposure to SO_2 can significantly increase the sulfur concentration in the shoot, and the SO_2 absorbed is mostly oxidized into sulfate [43]. Inhibitory effects increased with the duration of the fumigation period up to 8 h using 40 ppm SO_2 and 50–300 ppb ozone. At lower concentration, fumigation of tolerant and sensitive grafts of *Pinus strobus* (eastern white pine) with 50 ppb SO_2 and O_3, singly or in combination, gave no significant inhibition over a 1-week period [44]. A reduction in the stomatal conductance occurred in response to fumigation with ozone and sulfur dioxide [45]. The increased sulfate anion may increase the K^+ content and reduce the Cl^- contents in plants simultaneously exposed to NaCl salinity. This interaction may decrease the sensitivity of NaCl-treated plants to SO_2 pollution because of stomatal and/or mesophyll resistance and decreased SO_2 uptake. Therefore, SO_2 fumigation and NaCl salinity may antagonistically affect the uptake and accumulation of SO_2 and the salt in the plants.

Wheat (*Triticum aestivum* L.) plants were exposed to a factorial combination of two levels of salinity (control, and 50 mM NaCl) and three levels of SO_2 (10, 231, and 441 nL L^{-1}) in fumigation chambers for 4 h/day^{-1} for up to 42 days. These studies revealed that SO_2 fumigation significantly increased the sulfur concentration in the shoots but not in the roots. The NaCl salinity decreased the sulfate concentration in the leaves. There was an antagonistic interaction between SO_2 fumigation and NaCl salinity on the concentration of sulfate in the leaves. It was also observed that SO_2 fumigation, salinity, and their combinations affected the concentrations of Cl^-, K^+, Na^+, Ca^{2+}, and Mg^{2+} in the plant tissues. The antagonistic interaction between SO_2 fumigation and NaCl salinity on the SO_2 uptake and salt accumulation in the leaves may be responsible for the observed effect on plant growth [46].

The pigment concentration in leaves is an important parameter for determining the photosynthetic efficiency of plants. The chlorophyll content, an index of the photosynthetic potential of plants,

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

is highly susceptible to pollutant action. The pigment interaction with pollutants leads to the destruction of photosynthetic leaf areas and the development of characteristic foliar symptoms. The greater effect of $O_3 + SO_2$ on the pigment concentration suggests their synergistic mode of action. Both O_3 and SO_2 individually are known to reduce the chlorophyll and carotenoid contents in crop plants. The decrease in the chlorophyll content associated with the development of injury symptoms in leaves may inhibit photosynthesis in O_3-and SO_2-treated plants.

Agrawal et al. [47] reported that exposure of rice plants to low concentrations of O_3 (0.08 ppm) and SO_2 (0.5 ppm), singly and in combination, showed foliar injury at different levels. The maximum leaf injury was noted in the case of O_3+SO_2 (0.04 + 0.25 ppm)– treated plants and the minimum in O_3-treated ones. Also, the reductions in chlorophyll *a* and *b* and the total chlorophyll and carotenoid contents in leaves exposed to O_3+SO_2 mixtures were higher than the reduction noted in the case of each individual pollutant. It has been suggested that O_3 by itself affects chlorophyll molecules or it impairs the synthesis of new molecules [48]. It can also affect both cellular and chloroplast structure and levels of chlorophyll in it [49]. The decrease in the carotenoid content in pollutant-treated leaves may be ascribed to the impaired synthesis of pigment. It has been observed that pollutant inactivate carotenoids. Ozone and SO_2 alone may cause the carotene contents to decrease [50]. The pigment reductions and foliar injury may lead to reduced photosynthate production and reduced plant growth.

EFFECT OF OZONE AND SOIL SALINITY ON PLANT GROWTH

Ozone has been proved to be one of the most important air pollutants affecting vegetations [51,52]. Several popular articles have been published concerning the plant responses to ozone and sulfur dioxide separately or in combination [53–57]. Other papers have mentioned that these two gases, both singly and in combination, disrupt various metabolic processes and consequently affect the growth and development of plants [58–60].

Bytnerowicz and Taylor [37] grew bean plants in half-strength Haogland solutions provided with three salinity levels of −40, −240, and −440 kPa and exposed four times to 390 $\mu g\ m^{-3}$ O_3, 520 $\mu gm^{-3}SO_2$, and 390 μgm^{-3} O_3 + 520 μgm^{-3} SO_2. The plants were fumigated with these treatments between 9 a.m. and 4 p.m. Plants fumigated with SO_2 alone showed no injury. Primary leaves of O_3–treated plants were injured more than those of plants fumigated with the combination of O_3 and SO_2. The amount of injury produced by O_3 and (O_3 + SO_2) mixtures decreased when the salinity of the solution increased. The plant growth was suppressed by increased salinity levels. The root growth of O_3 and (O_3 + SO_2)-treated plants was reduced at all salinity levels. Plants fumigated with SO_2 and (O_3 + SO_2) had a higher S content in roots than that of nonfumigated and O_3-treated plants. The highest S content in leaves was found in SO_2 -treated plants at the −40-kPa salinity level. The accumulation of Ca in leaves and of Mg in roots was lowest in plants fumigated with O_3 alone and mixtures of O_3 and SO_2 compared with control.

Maas et al. [61] found a similar decrease in Ca in leaves when bean plants were exposed to a greater dose of O_3. Plants fumigated with O_3 alone and (O_3 + SO_2) accumulated more K in the stems and leaves and more Fe in the roots and leaves compared with nonfumigated and SO_2-treated plants. Physiological explanations for the variation in plants' susceptibility to air pollutants and of the influence of environmental conditions on such a response were not completely understood. However, stomatal closure is considered to be an important factor in inhibiting the penetration of the pollutant. Maas et al. [61] have further stated that the salinity levels, achieved by the addition of NaCl and $CaCl_2$ to the nutrient solution, reduced the amount of visible O_3 injury symptoms. The evidence of membrane permeability involvement in susceptibility has also been presented by many researchers. Presumably, the reduction of injury by O_3 and (O_3 + SO_2) treatments was induced by stomatal closure, but the increase in stomatal resistance observed was much less evident than reported by Ting and Heath [10]. Mansfield [62] also stated that O_3 tends to cause stomatal closure.

Olszyk et al. [63] studied the interaction of ambient photochemical oxidants (primarily ozone,

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

O_3) and salinity on the vegetation of alfalfa (*Medicago sativa* L.) in a field experiment having average electrical conductivities of 0.9, 3.4, and 6.3 dS m^{-1}, which resulted in mean saturated soil extract conductivities in the root zone of approximately 1.5, 5.8, and 8.1 dS m^{-1}, respectively. Plants were exposed in open-top chambers to filtered or unfiltered air at ambient O_3 concentrations. No overall interaction between O_3 and salinity occurred for alfalfa growth or yield. The only general effect of O_3 itself was to increase the percentage of empty nodes at three of the four harvests. The percentage of empty nodes due to ozone tended to decrease with increasing salinity. Salinity by itself was more detrimental to plants than O_3 and caused occasional decreases in dry weight and height. At the levels tested, salinity would affect plants more than O_3 in areas where both stresses occur.

Salinity reduced the O_3 effects on injury and yield for several crops, including alfalfa, pinto bean, and garden beet (*Beta vulgaris* L.) grown under laboratory conditions [64]. Bytnerowiz and Tyalor [37] found that the salinity of the solution decreased O_3 injury in snap bean (*Phaseolus vulgaris* L.). High salinity, however, had no effect on O_3-induced reductions in snap bean dry weight. In these salinity-air pollutant studies, the beneficial effects of salinity in reducing air pollutant effects were attributed to salinity-pollutant interactions in causing stomatal closure and, therefore, less pollutant uptake.

In most species, ozone stress reduces the root growth more than the shoot growth. The root growth of three grasses—orchard grass (*Dactylis glomerata*), rye grass (*Lolium prenne*), and canary grass (*Phalaris aquatica*)—was impaired more than the shoot growth by O_3 stress. The dry weight reductions were shown to be the result of the reduced net assimilation rate. At higher O_3 levels (greater than approximately 0.10 ppm), photosynthesis was drastically reduced and partitioning to all sinks fell, causing dramatic growth reductions in all organs. At these higher ozone concentrations, differential partitioning between organs is not as obvious as at lower concentrations [65].

The root growth in carrot (*Daucus carota*) decreased tremendously under O_3 stress, whereas the foliar growth actually increased [66]. Controlled fumigations of 0.19 and 0.25 ppm O_3 decreased the root weight 32–46%, whereas the leaf weight rose slightly. As the O_3 dose increased, the shoot weight of tall fescue (*Festuca arundinacea*) decreased and the root weight fell even more. Rising O_3 concentrations further reduced both the shoot and root weight and always decreased the root weight more.

It has been reported that senescence was enhanced in flag leaves of wheat by ozone, which was reflected in the time course of the oxidant stress biomarkers. The plant protein content decreased and the nonspecific peroxidase activity, ascorbic acid content, and malondialdehyde content increased only after the leaves had experienced high doses of ozone, whereas the ascorbic acid content levels were raised in ozone-treated plants after only a short exposure period. The catalase activity did not significantly respond to the ozone treatment [67]. Many crops such as rice [68], wheat [69], tobacco (*Nicotiana tabacum*), and legume plants [70] have been found to be more susceptible to elevated O_3 levels. Recently, in Germany, a 35% wheat yield reduction was observed. It is believed that if precautionary measures are not taken well ahead of time to reduce the anthropogenic emissions of photochemical oxidants, a gradual imbalance in the vegetation may occur and susceptible crop/grass species may become extinct in the long run.

Welfare et al. [71] reported that five varieties of rice (*Oryza sativa* L.) of varying salinity resistance were grown in nonsaline and in saline conditions with and without a repeated exposure to ozone at a concentration of 88 nmol mol^{-1} giving an AOT40 (cumulative exposure above 40 nmol mol^{-1}) of 3600 nmol mol^{-1} h. Salinity caused a substantial reduction in the shoot and root dry weights in all varieties, but the effect on the root growth was proportionately less than on the shoot growth, transpiration, and stomatal conductance. The potassium concentration in the leaves of all five varieties was reduced by salinity and by ozone in both saline and nonsaline treatments. Ozone reduced the Na concentration in plants grown at 50 mMol NaCl but had no effect on the Cl concentration. Ozone reduced the root dry weight, but the treatment used did not significantly affect the shoot dry weight. Both salinity and ozone reduced the plant height and carbon dioxide assimilation, transpiration, and stomatal conductance were all reduced by salinity and by ozone, and there was a close quantitative similarity between the effects of ozone and/or salinity on assimilation,

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

stomatal conductance, and transpiration. There were some antagonistic effects, but there were additive effects of salinity and of ozone on the root dry weight, plant height, photosynthesis, transpiration, and stomatal conductance.

Nouchi et al. [72] reported a 50% decrease in the whole plant dry weight in rice plants that were continuously exposed to ozone at 100 nmol mol^{-1} for 6 weeks, although the effect on the dry weight of an exposure of 50 nmol mol^{-1} was not significant. Other studies have reported greater sensitivity of the roots than the shoots in response to moderate ozone pollution [73,74]. Ozone in the lower atmosphere originates predominantly from oxidation and photolysis of nitrogen oxides emitted from vehicular exhaust fumes in urban areas. The sensitivity of plants to atmospheric oxidants is conditioned by a number of environmental factors, including nutritional level, humidity, soil water stress, and root-medium aeration. Many of those vital factors affect the stomata aperature. Ozone, a major air pollutant, decreases the yield of some oxidant-sensitive crops more under nonsaline than saline conditions. Plant sensitivity to ozone is usually evaluated in terms of the visual indices of the foliar injury. This method has been proven to be satisfactory for general leaf crops such as lettuce (*Lactuca sativa* L.), spinach (*Spinacia oleracea* L.), alfalfa (*Medicago sativa* L.), and other forage crops and tobacco (*Nicotiana tabacum* L.). However, some studies now show that the ozone effects on crop yields may not be proportional to the leaf injury [75].

Salinity also is an environmental factor affecting the sensitivity of crop plants to atmospheric oxidants. This abberation has the tendency to make many crops grown in air-polluted regions appear to be more salt tolerant than they really are. The salinity-ozone interaction may be agronomically important in air-polluted areas. However, the increased ozone tolerance induced by salinity may be more than offset by the detrimental effects of salinity on the marketable yields of pinto bean and garden beet and other crops.

Oertli [76] studied the interaction of salinity and atmospheric oxidants. He grew sunflower (*Helianthus annuus* L.) plants in unfiltered air in different concentrations of nutrient solution and found the symptoms of oxidant damage to be greatest on plants growing in the more dilute solutions. However, Heck [77] raises the question of whether this is a salinity interaction or a nutritional interaction. Nonsaline treatments in outdoor experiments show more evidence of leaf damage than saline treatments. This raises a question as to whether the rising level of atmospheric oxidants causes an erroneous increase in the apparent salt tolerance of crops by selectively damaging the control treatments. Because plant sensitivity to ozone is known to depend on the physiological age of leaves and plants repeatedly exposed to ozone throughout their vegetative growth stage exhibit cumulative damage not only to a few leaves but also eventually to all leaves as they become susceptible to ozone injury.

The influence of ozone on pinto bean has been evaluated on a visible leaf damage percentage or an apparent photosynthesis basis. Hill and Littlefield [78] reported that fumigating 8-week-old pinto bean plants with 0.45 ppm of ozone for 1.5 h reduced the apparent photosynthesis rate to half the rate of the control. Likewise, Todd and Propst [79] found that photosynthesis of a single bean leaf exposed to 0.34 ppm of ozone for 11.5 h was half that of an ozone-free leaf.

The effect of ozone on the forage yield of alfalfa (*Medicago sativa* L.) at four controlled salinity levels (-40, -200, -400, and -600 kPa) and ozone levels of 10, 15, and 20 parts per hundred million (pphm) was studied in controlled climate chambers. It was observed that as salinity increased, ozone had less of an effect on yield. Alfalfa exposed to 20 pphm of ozone for 2 h daily yielded 25% more at -200 kPa osmotic potential than that at the nonsaline level, -40 kPa. The residual effect of ozone treatments reduced yield in the next cutting. Salinity at all levels or ozone at 20 pphm increased the water-use efficiency of alfalfa. Both ozone and salinity were required to increase the leaf diffusion resistance [80]. Their experimental findings further demonstrated the strong interactive effects of salinity and ozone on alfalfa.

In a later study, Hoffman et al. [81] studied the interaction of salinity (osmotic potentials of -0.4, -2.0, and -4.0 bars) and ozone (0, 0.15, 0.25, and 0.35 ppm) on the growth of pinto bean (*Phaseolus vulgaris* L.) in a controlled temperature light room with 2-h daily exposures to the treatments. They found that ozone at 0.15 ppm decreased the yield of nonsaline plants nearly 50%,

and at 0.25 ppm and higher, no significant yield was obtained. At −4.0 bars, the yield at 0.25 ppm was only reduced to half that of the ozone-free treatment. The results indicated no interaction between salinity and ozone below 0.15 ppm. Above 0.15 ppm, however, there was a large interaction. Plants grown in saline media show an increased resistance to ozone injury. Mass et al. [61] reported that definite tolerance thresholds exist for both the ozone concentration and the duration of exposure whether plants receive a single or more exposures as reported by Heck et al. [82].

Ogata and Maas [83] studied the interactive effects of the root media salinity and ambient ozone on injury, growth, and yield of garden beet (*Beta vulgaris* L.) under controlled environmental conditions. Plants were grown in nonsaline and saline nutrient solution cultures having osmotic potentials of −0.4, −4.4, and −8.4 bars, respectively, and were exposed to 5 weeks of 0.20 ppm ozone for 0–3 hs/day. They found that the growth of the nonsaline beet plants was not significantly affected by 0.20 ppm ozone until exposure times exceeded 1 h/day, although foliar injury in the form of a reddish purple stipple had developed on mature leaves. Longer ozone exposures produced severe leaf necrosis and reduced the growth of tops and storage and fibrous roots as much as 50, 40, and 67%, respectively. They further observed that, in contrast, foliar ozone injury on plants grown in saline media developed more slowly and the growth of both tops and roots were relatively unaffected by ozone exposure of up to 3 hs/day. Some reduction in the yield of storage roots did occur at −4.4 bars of osmotic potential when plants were exposed to ozone for 3 h/day. The interactive effects of salinity and ozone are apparent for both top and root growth. Like the findings of the pinto bean study [81], these results indicate that the beneficial effects of salinity in reducing ozone damage occur at salinity and ozone levels too high to allow economical beet production. The vegetative growth data, on the other hand, suggest that the interaction of these factors might be economically important for forage crops.

Ozone reduced photosynthesis in many plant species, for example, wheat [84], oats (*Avena sativa* L.) [85], common bean [86], and broad bean [87], although the degree of sensitivity varies between species. The reduction in photosynthesis and the breakdown of chlorophyll molecules are very similar to changes which occur during leaf senescence. Ozone appears to advance the onset of leaf senescence, which is accompanied by a reduced carbon fixation, the breakdown of the chloroplast envelope, the loss of associated proteins and chlorophyll [88], and a reduced ribulose bisphosphate carboxylase/oxygenase (Rubisco) activity [89].

The mechanism by which salinity (osmotic stress) increases the plant tolerance to ozone remains speculative. Essentially, any factor that increases water stress in the plant increases stomatal resistance and, presumably, reduces ozone diffusion into the leaves. Ting and Dugger [90] concluded from a comparative study of ozone-sensitive and ozone-resistant varieties of tobacco that differences in sensitivity were due in part to significant differences in the plant water potentials of the two varieties. Of course, other biochemical and physiological mechanisms may also be involved. For instance, salinity is known to increase the sugar content in some plants [91], and evidence indicates that high sugar levels are associated with an increased resistance of ozone injury to plants [5].

Miller et al. [92] have demonstrated that ozone and a water deficit can suppress photosynthesis, growth, and yield of crops, and both may alter the plant carbohydrate status. Ozone stress generally suppressed leaflet concentrations of total soluble carbohydrate (TSCs) and starch on most sampling dates in soybean (*Glycine max* L.). Impacts of a water deficit were less consistent, but starch concenrations usually increased when effects were significant. Interactions between the two stresses occurred infrequently, although water stress reduced the negative effects of O_3 on sucrose and TSCs when the data were analyzed over the season. The ozone treatment also slightly increased the proportion of sucrose compared with starch in the total nonstructural carbohydrate (TNC) pool.

There are several known mechanisms for alteration of the soluble sugar and starch content of plant leaves by O_3. The most obvious is suppression of photosynthesis by O_3, which is due in part to the reduction of chlorophyll and the decline in the activity and quantity of Rubisco. Ozone has also been shown to interfere with the translocation of soluble carbohydrates from the leaves which would tend to increase concentrations in those tissues. No indication was found that O_3 elevated carbohydrate concentrations in the leaflets. It is likely that the reduction of photosyntehsis

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

by O_3 would more than counteract the reduced translocation resulting in lower levels of carbohydrates in leaves in most cases [93].

CONCLUSIONS

In the vicinity of urban and industrial areas, pollution of atmospheric air by vehicles and industries is a recurring and persistent environmental health hazard. Toxic gases such as carbon dioxide, carbon monoxide, sulfur dioxide, nitrogen oxides, unburnt hydrocarbons, particulate matter, and soot are generally found in abundant quantities and causing serious health hazards to humans and damage to crops and animals.

The global population growth also is considered to be one of the major driving forces of global climatic change. The effects of human activities on the global atmosphere have become increasingly evident during the last decades. As a result of the population explosion, accelerated urbanization, and continuous industrialization new environmental problems like those of greenhouse effects, ozone layer depletion, acid rains, and the increased use of pesticides are being created tremendously.

The ecological implications of pollutants are quite serious for crop growth and development. The gaseous pollutants such as sulfur dioxide, carbon dioxide, ozone, and nitrogen oxides produced by industries and the heavy vehicular traffic of cities drift to rural areas and have fallout effects causing injury to plants and resulting in crop losses. In addition, SO_2 and O_3 in combination with soil salinity have far-reaching effects on crop growth.

Air pollution by gaseous sulfur dioxide causes the development of soil acidity. Sulfur dioxide injury to vegetation and forest growth has been noted near industrial areas. Salinity and SO_2 have been found to be antagonistic in a number of crop species. Similarly, SO_2 in combination with ozone (O_3) has substantially reduced the crop growth and biochemical composition of plants.

Ozone in the lower atmosphere originates predominantly from oxidation and photolysis of nitrogen oxides emitted from vehicular exhaust fumes in urban areas. Ozone has been proven to be one of the most dangerous air pollutants affecting the physiology, growth, yield, and biochemical composition of many crops at present. Ozone and SO_2 are likely combinations in many areas. These two gases, both singly and in combination, disrupt various metabolic processes and consequently affect the growth and development of plants.

Similarly, salinity and O_3 combinations also have drastic effects on the growth of plants. However, salinity reduced O_3 effects on injury and yield for several crops. Reports indicated that the beneficial effects of salinity in reducing ozone injury does not appear to be of any economical importance in crop production.

There is a great risk of higher air pollution effluents due to the lack of effective control measures through catalyzers in the vehicles and filters in chimneys of the industries. There is an urgent need to survey the extent of air pollutants at the surface level, especially adjacent to areas of traffic and industries, and if it is beyond the critical level, we should formulate the structures (i.e., take necessary measures to reduce pollutant emission or introduce filters, etc.), so that air pollutant levels in the affected areas remain within the tolerance range in order to keep the environment pure and healthy for humans to live in.

Herbicide-Mediated Changes in the Population and Activity of Root-Associated Microorganisms: A Potential Cause of Plant Stress

ASGHAR HEYDARI* AND IRAJ J. MISAGHI
University of Arizona
Tucson, Arizona

INTRODUCTION

There has been a great deal of increase in the use of herbicides in the world during the past 30 years [1–3]. New and more effective herbicides are continuously being developed to replace the old ones. In the course of their development, herbicides are routinely screened for the absence of phytotoxicity to crops. However, little attention is given to the possibility that they may also be toxic to plant-associated microorganisms such as those that cause disease stress and those that protect crops against diseases [4]. Consequently, most herbicides are biologically active against microorganisms [5]. Some herbicides have been shown to cause changes in populations of some bacteria in the soil [6,7] and in the rhizosphere [8]. Herbicides are also known to cause changes in the incidence and severity of some types of pathogen-induced stress possibly by affecting plant pathogens [1,2,9–11].

In this chapter, we discuss the impact of herbicides on soil-residing plant pathogenic microorganisms that cause disease in plants and on root-associated beneficial microorganisms that suppress the activity of plant pathogens (biocontrol agents). We show that herbicide-mediated changes in the activity of plant pathogens and biocontrol agents may result in an increase or a decrease in pathogen-induced stress in plants.

We have been interested in the impact of herbicides on the activity of biocontrol microorganisms and on the intensity of pathogen-induced stress because (a) the herbicide concentration varies drastically in the soil, (b) microorganisms and plants are sensitive to changes in the levels of herbicides, and (c) unlike other soil factors (e.g., temperature, moisture), the impact of herbicides on the activity of biocontrol microorganisms has virtually been neglected by students of plant health.

PLANT PATHOGENS AND THE DISEASES THEY CAUSE

Plants, like other organisms, have natural enemies that are capable of reducing their vigor and/or destroying them completely. These enemies are among both prokaryotic and eukaryotic groups, including plants, fungi, bacteria, viruses, nematodes, and a few other microorganisms. These pathogens attack plants at the aboveground and belowground levels. The damage to plants caused by insects is not traditionally considered to be a disease problem.

In a typical scenario, a pathogen is disseminated by wind, irrigation, or flood water and/or by insects and is deposited near a plant. Some pathogens, like nematodes and flagella-equipped bacteria and fungi, are attracted to the plant surfaces using chemotactic responses. Other pathogens are deposited passively on the plant surfaces. The first step in the infection process is penetration of the pathogen into plants through wounds and natural openings such as stomata. Some pathogens are capable of penetrating plant surfaces actively by enzymatically dissolving physical barriers. The penetration into the plant tissue often is followed by a rapid development and spread of the pathogen inside the plant.

The outcome of plant-pathogen interaction, that is, whether the pathogen succeeded or fails to cause disease, depends on a number of factors, including the virulence of the pathogen, the susceptibility of the plant, and the prevailing environmental factors [12]. All of the stages in disease development discussed earlier are sensitive to changes in the environmental conditions, including temperature, moisture, soil texture, pH, soil atmospheric composition, and the presence of chemicals, such as insecticides, fungicides, and herbicides in the soil. Environmental factors impact disease development by modulating the growth and the activity of pathogens, by interfering with the plant's ability to defend itself against pathogenic invasion, and by affecting the development and the activity of microorganisms that compete with pathogens for food resources and for microsites on and around plants.

PATHOGEN-INDUCED STRESS IN PLANTS

Plants often suffer from mild and acute forms of stress in response to pathogenic invasion. The stress is manifested by a variety of symptoms such as wilting as a consequence of water stress, chlorosis mainly due to chlorophyll breakdown, and necrosis as a consequence of the action of pathogen-produced toxins. Water stress can be induced by the destruction of the root systems, pathogen-induced change in the permeability of root and/or leaf cells, and by blocking of xylem elements. Pathogen-induced stress may also be manifested as abnormal growth and malformation due to hormonal imbalances. Most pathogens rob plants of vital nutrients creating nutritional stress. Some of these stress conditions may be reversed when environmental conditions are altered in ways that are no longer conducive to the growth and pathogenesis of pathogens. However, most plants suffering from acute forms of pathogen-induced stress often fail to recover.

BIOCONTROL OF PLANT DISEASES

Plant diseases are being controlled mainly by the use of chemicals (e.g., fungicides, nematicides, bactericides) and in some cases by cultural practices. Chemical approaches to managing plant diseases have in recent years been the subject of public concern, because of the harmful effect of chemicals on the environment, the effect on nontarget organisms, and the possible carcinogenicity of some chemicals. Other problems include the appearance of new races of pathogens that are resistant to chemicals, a gradual elimination and phasing out of some pesticides, and the reluctance of some chemical companies to develop and test new chemicals owing to the long registration process and escalating costs.

A promising new approach to controlling plant diseases is the use of biological agents and/

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

or their products, which is an approach known as biocontrol [13]. Biocontrol is environmentally safe and in some cases is the only option available for protecting plants against diseases [4,13–15].

Unfortunately, the development of biocontrol strategies to combat plant diseases has been painfully slow. Many biocontrol agents perform consistently and efficiently under laboratory conditions but fail to do so in the field [4,13–15]. This is perhaps because the environmental conditions in the laboratory are often artificially selected to be conducive to the development and functioning of biocontrol agents [13]. The environmental conditions in the field, on the other hand, are too complex and exert an influence on the activity and performance of microbial biocontrol agents as well as disease incidence and disease development. Moreover, bacteria, fungi, and nematodes are highly sensitive to changes in environmental factors [16–20]. These observations are the basis for the generally accepted view that a better understanding of the impact of soil and environmental factors on biocontrol microorganisms is the prerequisite for transferring plant disease biocontrol strategies from the laboratory to the field [4,13,14,21]. Soil environmental factors that can potentially affect the intensity of stress induced by soil-residing pathogens, and biocontrol activity of microbial biocontrol agents in the field include moisture, temperature, pH, texture, organic content, atmospheric composition, and the presence of agricultural chemicals in the soil such as herbicides [12,18,22–25].

In this chapter, evidence is presented that preplant herbicides, which are being used heavily on a variety of crops throughout the world, may change the intensity of pathogen-induced stress (in the presence and absence of biocontrol agents) by influencing plants, pathogens, and/or microbial biocontrol agents. We have previously provided evidence that oxygen and carbon dioxide concentrations affect pathogen-induced stress levels by affecting the activity of biocontrol agents [18].

EFFECT OF HERBICIDES ON PATHOGEN-INDUCED STRESS

Herbicides are known to alter the incidence and severity of pathogen-induced stress in plants [1,2,5,11,26–33]. Altman and Campbell [1] showed that the incidence of sugar beet seedling death caused by *Rhizoctonia solani* increased significantly after application of cycolate to the field soil. Rovira and McDonald [11] showed that the application of chlorsulfuron to the field soil caused a significant increase in the level of disease stress to wheat and barley caused by *R. solani* and *Gauemannomyces graminis var. tritici*. The severity of stress in cereals due to infection by *Heterodera avenae* increased after application of trifluralin to the field soil [2]. Disease stress in wheat caused by *G. graminis var.* tritici infection [11] and in sugar beet caused by *R. solani* infection [1] increased after application of trifluralin, chlorsulfuron, and cycolate. Application of trifluralin and dinitramine to the field soil also increased *R. solani*–induced stress in cotton seedlings [26,31,32]. In contrast, the severity of *Fusarium oxysporum vasinfectum*–induced stress in cotton plants decreased following application of trifluralin, fluometuron, diuron, dalapon, and prometryn to the field soil, whereas the incidence of *R. solani*–induced cotton seedling death was not significantly affected by these herbicides [27].

We have studied the impact of three preplant herbicides, pendimethalin, prometryn, and trifluralin, on *R. solani*–induced stress in cotton seedlings in the microcosm and in the field in Arizona at two locations (Safford and Tucson). Plants attacked by this pathogen may be killed prior to or after emergence. In our microcosm experiments, preemergence and postemergence seedling death were increased in soils treated with two of the three herbicides. In a preemergence seedling death experiment in the microcosm, the stand count (number of emerged seedlings) in the soil treated with prometryn was significantly ($P < .05$) dropped by 21, 36, and 67% relative to the control 1, 2, and 3 weeks after sowing, respectively [24]. The stand count in the soil treated with pendimethalin and trifluralin were not significantly ($P > .05$) different from that in the control. In the postemergence seedling death experiment in the microcosm, the disease incidence in soils treated with pendimethalin and prometryn increased significantly ($P < .05$) by 64, 60, and 50% and by 64, 59, and 57%

relative to the control 1, 2, and 3 weeks after inoculation, respectively. The disease incidence in the soil treated with trifluralin was not significantly ($P > .05$) different from the control [24].

The results of field experiments corresponded with those of microcosm experiments (Tables 1 and 2). The stand count in plots treated with pendimethalin and prometryn at Safford significantly ($P < .05$) decreased between 30 and 28%, 39 and 30%, and 47 and 39% for 15, 25, and 50 days after sowing, respectively (Table 1). The difference in the amount of disease in plots treated with trifluralin and in nontreated plots at Safford was not significant ($P > .05$) relative to the control. The stand count in plots treated with prometryn at Tucson significantly ($P < .05$) decreased by, 41, 49, and 54% relative to the control, 15, 25, and 50 days after sowing, respectively (Table 2). Pendimethalin and trifluralin did not cause significant changes in the stand count at the Tucson location (Table 2).

The reported impact of herbicides on the intensity of pathogen-induced stress is not always the same in different studies. For example, prometryn, which increased cotton seedling death in our studies, did not do so in a previous study [27]. Moreover, trifluralin, which has been reported to increase *R. solani*–induced cotton seedling death [28,30,32], did not affect the disease in our study and in a previous study [27]. The differential responses may be due to the differences in the soil

moisture, soil temperature, herbicide concentration, races of pathogens, plant varieties, composition of rhizosphere microflora, and rate of herbicide inactivation in various experiments. The development of tolerance to herbicides by pathogens as a result of a long-term herbicide use may also be a contributing factor.

EFFECT OF HERBICIDES ON POPULATION OF BIOCONTROL BACTERIA IN THE RHIZOSPHERE

To assess the impact of herbicides on the activity of biocontrol bacteria, it is necessary to examine the impact of herbicides on rhizosphere populations of biocontrol bacteria. This is because the ability of these bacteria to develop in the rhizosphere of target plants is a prerequisite for their biocontrol activity [34]. Any soil factors which can potentially interfere with the ability of biocontrol bacteria to develop in the rhizosphere is expected to affect their biocontrol activity as well. However, despite its importance and as far as we have been able to determine, the impact of herbicides on the population of biocontrol bacteria in the rhizosphere has not been studied except for our study (to be discussed below).

We studied the potential impact of three widely used herbicides, pendimethalin, prometryn, and trifluralin, on populations of five plant disease–suppressing bacterial isolates (three isolates of *Pseudomonas fluorescens* and two isolates of *Burkholderia cepacia*) in the rhizosphere of cotton seedlings [23]. All isolates are efficient cotton root colonizers and are capable of suppressing pathogen-induced stress. All five isolates were used in microcosm experiments and one isolate (D1) was tested in the field.

In microcosm experiments, the population sizes of most of the bacterial isolates in the rhizosphere of cotton seedlings in soils treated with each of the three herbicides were significantly ($P < .05$) lower than those in the untreated soils 2 weeks after sowing [23].

The ability of all three test herbicides to reduce isolate D1 population in the rhizosphere declined with time over a 4-week period of monitoring [23]. The population of the bacterium recovered from roots in the herbicide-treated soils were significantly ($P < .05$) lower than those recovered from controls after 1 and 2 weeks but were equivalent to the controls 3 and 4 weeks after sowing [23].

The results of the field experiments were similar to those of the microcosm experiments (Tables 3 and 4). Pendimethalin and prometryn caused a significant ($P < .05$) decrease in the D1 population in the rhizosphere 15 and 25 days after sowing at the Safford location (Table 3). Trifluralin

had no significant effect on the D1 population at this location (Table 3). Pendimethalin and prometryn caused a significant ($P < .05$) decrease in the D1 population in the rhizosphere 15 and 25 days after sowing but not 50 days at the Tucson location (Table 4). The trifluralin-induced decline in the D1 population was significant only 25 days after sowing (Table 4). Isolate D1, which was originally recovered from cotton plants in the field, may have developed tolerance to trifluralin as a result of the continuous exposure to this herbicide in the field.

EFFECT OF HERBICIDES ON BIOCONTROL ACTIVITY OF BACTERIA IN THE RHIZOSPHERE

Our earlier finding that the soil atmsopheric composition can modulate the biocontrol activity of selected bacteria [18] spurred us to examine the impact of other soil factors on the activity of biocontrol bacteria in the rhizosphere. We therefore examined the impact of three widely used herbicides, pendimethalin, prometryn, and trifluralin, on the efficacy of isolate D1 (a biocontrol bacterium) to reduce the severity of *R. solani*–induced seedling death. Isolate D1 is capable of reducing the incidence of *R. solani*–induced seedling death in the field [35]. In both field and microcosm experiments, the efficacy of isolate D1 was reduced in the presence of two of the three test herbicides. In the Safford field experiment, isolate D1 reduced seedling death severity significantly ($P < .05$) compared with the control (not treated with D1) 15, 25, and 50 days after sowing only in non–herbicide-treated plots and in plots treated with trifluralin and not in plots treated with pendimethalin and prometryn (Table 5). In a Tucson field experiment, the biocontrol bacterium (isolate D1) significantly reduced cotton seedling death in plots not treated with herbicides and in those treated with trifluralin compared with the control (not treated with D1) 15, 25, and 50 days after sowing (Table 6). Pendimethalin and prometryn both significantly ($P < 0.05$) decreased the efficacy of isolate D1 in reducing cotton seedling death 25 and 50 days after sowing in a Tucson experiment (Table 6).

In contrast to our findings, the herbicides pendimethalin and metribuzin have been reported to enhance the biocontrol activity of *Streptomyces corchorusii* and *S. mutabilis* in greenhouse tests [36].

MECHANISM OF HERBICIDE-MEDIATED CHANGE IN PATHOGEN-INDUCED STRESS

The mechanism of the observed herbicide-mediated change in the intensity of pathogen-induced stress is not known. The phenomenon may be due to the effect of herbicides on the plant, on the

pathogen, on the activity of indigenous microbial competitors, and/or on the interactions among these entities.

Herbicides may cause changes in the plant root physiology such as root exudation [2,37]. These changes, in turn, may alter microbial community structures in the rhizosphere in ways which may encourage or discourage the development of competitors of an introduced biocontrol bacterium. Such changes may enhance or depress the activity of biocontrol bacteria. Herbicides may alter the intensity of pathogen-induced stress by changing the plant's resistance levels to pathogens. Starratt and Lazarovits [38] showed that the application of dinitroaniline herbicides induced resistance in tomato seedlings to the pathogen *Fusarium oxysporum* f. sp. *lycopersici*. Herbicides also may cause changes in crop plants which may influence the outcome of plant-pathogen interactions [1,39–41]. Herbicides have been reported to cause alterations in the growth, lignin-containing substances,

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

β-glucoside [41], and waxy layer on leaves [39,40] and in the release of glucose from roots [1,42]. Although the height, biomass, and root densities of cotton seedlings grown in soils treated with pendimethalin or prometryn were generally lower than those of control (untreated soil) in our studies, the differences were not statistically significant ($P > .05$) indicating that the physical characteristics of cotton seedlings were not affected by test herbicides [25].

The observed herbicide-mediated change in the intensity of pathogen-induced stress may be due to the effect of herbicides on the pathogen [1,26,31,43]. Such an effect may be stimulatory or inhibitory. For example, in the *R. solani*–sugar beet combination, the herbicide cycolate may interfere with the growth of the fungus and at the same time may enhance root exudates [1]. In such cases, the impact of the herbicide on the intensity of pathogen-induced stress is determined by the balance of stimulatory and inhibitory effects [1]. In our study, the growth of *R. solani* in vitro was not significantly affected by pendimethalin, prometryn, or trifluralin [25].

Herbicide-mediated alterations in pathogen-induced stress may also be due to the effect of herbicides on indigenous microbial antagonists of pathogens [23,25,36,44]. The observed absence of soilborne diseases in some fields in the presence of susceptible hosts and virulent pathogens is most likely due to the presence of indigenous microbial antagonists of the pathogen [13]. As pointed out earlier, we found that the herbicides, pendimethalin, prometryn, and trifluralin, decreased the populations of some biocontrol bacteria in the rhizosphere of cotton [23].

Finally, herbicides may change the intensity of pathogen-induced stress by interfering with the activity of fungicides used to curb the pathogenic activity of pathogens [26,30,45,46]. Application of fluchlovalin and alachlor to the soil altered the effectiveness of fungicides to control the condition in cowpea known as damping-off [45]. Application of nurflurazon, pendimethalin, fluometuron, prometryn, fomesafen, and oxyfluorfen to the field soil significantly reduced the efficacy of the fungicides tolclofos-methyl, pencycuron, carboxin, flutonalit, metalaxyl, and chloroneb against cotton seedling diseases [30]. In contrast, the antifungal activity of the fungicides captan and mounsrin was shown to be increased in the presence of herbicides, paraquat, and simazine [47].

Although plants, pathogens, and antagonistic microorganisms are perhaps the primary target of herbicides, the possibility of other herbicide-mediated changes cannot be overlooked. One such possibility is an alteration of the microclimate as a consequence of the removal of weeds, as suggested by Heitefuss [39]. We agree with Altman and Campbell [1] that no single factor may be solely responsible for the observed herbicidal effect on the outcome of plant-pathogen interactions.

MECHANISM OF HERBICIDE-MEDIATED CHANGE IN BIOCONTROL ACTIVITY OF BACTERIA

The observed herbicides' interference with the biocontrol activity of isolate D1 [25] and *Streptomyces* sp. [36] is most likely due to the effect of herbicides on the biocontrol agents. The sensitivity of microorganisms to herbicides has been demonstrated [6,17,23]. The results of our preliminary studies also have shown that the growth of isolate D1 in a liquid medium was reduced by 48, 44, and 32% 24 h after exposure to pendimethalin, prometryn, or trifluralin, respectively. The herbicide-mediated change in the performance of biocontrol agents may also be a consequence of a herbicide-induced change in the pathogen and the plant which was discussed earlier. For example, the increased activity of a pathogen (in terms of growth and aggressiveness) in the presence of a herbicide may tip the balance in favor of the pathogen reducing the effectiveness of the biocontrol agent. Herbicides may also provide a favorable environment for some indigenous competitors of the biocontrol agent. Herbicide-induced changes in plant may cause changes in the microbial community structures encouraging or discouraging biocontrol activity. Another possibility is the herbicide-mediated shift in the quality and the quantity of the root exudate and/or border cells in plants [48] which can alter the microbial community structure. Finally, herbicides may affect cross communication among microorganisms and plant roots causing drastic changes in the activity of the introduced biocontrol

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

agents and their indigenous competitors. Cross communication among microorganisms and between plants and microorganisms has been demonstrated [49,50].

CONCLUSION

The results of studies presented here clearly show that herbicides which are being used extensively throughout the world (a) may alter the severity of pathogen-induced stress, (b) may affect the efficacy of biocontrol agents used to curb pathogen-induced stress. Herbicides may vary in effectiveness, as microorganisms are differentially sensitive to herbicides. In our study, trifluralin did not cause any significant change in the incidence of cotton seedling death both in the microcosm and in the field experiments. Rhizosphere-associated microorganisms, including *R. solani*, may have developed some levels of tolerance to this herbicide owing to its widespread and long-term use in cotton fields.

The results presented have important implications for disease management. This is particularly true for seedling diseases in which plants are vulnerable to attack by pathogens when most herbicides may still be present in the soil at biologically active levels. The selection of an herbicide must be done cautiously in areas where plant diseases are important. Ideally, herbicides available for a particular crop need to be screened for their effect on pathogen-induced stress and on the biocontrol activity of the selected biocontrol agents. Since bacterial isolates are differentially sensitive to herbicide, it may also be possible to first select an herbicide and then to choose a biocontrol agent whose activity is not adversely affected by the presence of the selected herbicide. It may also be possible to construct bacterial isolates with increased tolerance to herbicides.

The sensitivity of some microorganisms, including biocontrol-active *Burkholderia cepacia*, to herbicides [7,17,23] and the herbicides' ability to increase the incidence of some diseases [1,2,11,36,51] provide additional support in favor of the concept of the integrated pest management (IPM) strategy. This strategy encourages crop specialists to base their decision regarding the use of a pesticide not only on the effectiveness of the pesticide against the target pest but also on its potential impact on all crop pests in the region. The selection of an ideal pesticide (one which is not harmful to the crop, to the non-target microorganisms, and to the beneficial insects) is difficult because of the number and diversity of pests involved in any one crop in any region. For example, in addition to insects and weeds, cotton seedlings are damaged by a number of soilborne pathogens besides *R. solani*. Despite these problems, IPM strategies need to be developed for specific crops in specific regions. The development of IPM requires a knowledge of the impact of a selected pesticide not only on its intended target but also on plants as well as on beneficial and harmful microorganisms and insects. Application of the IPM strategy also requires major changes in agricultural development policies and institutions [52].

Although many herbicides are readily biodegraded within a week, others may remain active for up to 2 months following application to the soil [2]. We found that the ability of all three test herbicides to reduce the biocontrol bacterium (isolate D1) populations in the rhizosphere decreased with time perhaps owing to degradation of the herbicides. However, all three herbicides tested in the Safford field experiment were biologically active up to 25 days after sowing. The persistence of herbicides in the soil depends on several factors, including soil moisture, temperature, pH, organic matter content, clay content, and the chemical structure of the herbicides [2].

Photodynamic Herbicides Affecting Structure and Function of the Photosynthetic Apparatus

AGNIESZKA MOSTOWSKA
Warsaw University
Warsaw, Poland

INTRODUCTION

For centuries humans have endeavored to increase the productivity of crop plants. Plant productivity is closely related to photosynthesis. Most crops achieve less than 50% of their photosynthetic potential owing to limiting factors such as, for example, shading, water supply, or air pollution [1]. Therefore, one of the main goals to improve bioproductivity is to increase the transformation of solar energy to chemical energy and to improve the quality of plants and their resistance to unfavorable environmental factors [2]. With the advent of genetic engineering, one can believe that crop productivity can be improved using methods of biotechnology. One of these methods is to introduce biotechnologically improved plants of better quality to modify crop plants for higher photosynthesis [3].

The application of herbicides to control weed growth is another very common and important agricultural practice. The demand for rapid biodegradable and highly effective herbicides that are nontoxic to animals and humans opens ways for the production of new herbicide-resistant crops [3] and for the development of new highly selective groups of herbicides.

In searching for highly selective and environmentally safe herbicides in the 1980s, Rebeiz and coworkers [4] used compounds which induce the accumulation of chlorophyll (Chl) precursors in the darkness and cause photooxidative damage of plants during subsequent illumination. These investigators named this group of compounds photodynamic herbicides.

Since photodynamic herbicides interfere with the biosynthesis of chlorophyll and cause photodynamic destruction in the light, we decided to analyze in more detail the influence of these compounds on the structure and development of the photodynamic apparatus.

We expected that photodynamic herbicides could change the normal development of the photosynthetic apparatus and to cause some destruction of the photosynthetic and cellular membranes in already developed chloroplasts.

CONCEPT OF PHOTODYNAMIC HERBICIDES

Rebeiz and coworkers [4] had an idea to combine the following phenomena: (a) the capability of accumulating chlorophyll (Chl) precursors in the darkness induced by δ-aminolevulinic acid (ALA) or complexing agents (e.g., 2,2′-bipyridyl (2,2′-B), (b) the fact that tissues which accumulate tetrapyrrole intermediates become very sensitive to light, (c) the species-dependent biosynthetic heterogeneity of the Chl biosynthetic pathway.

Higher plants treated during the dark period with ALA or with complexing agents such as 1,10-phenanthroline (Phe), 2,2′-B, and 8-hydroxyquinoline (8-H) accumulate large amounts of Chl precursors [5–9]. Aromatic heterocyclic components that bind iron inhibit heme biosynthesis and lead to inhibition of the tetrapyrrole pathway at the level of ALA formation or at the later stages. The complexing of iron could also inhibit the enzymatic processes of the Chl biosynthesis [10,11]. One of these mechanisms, or a combination of them, leads to the accumulation of Chl precursors in dark-grown plants. During subsequent illumination, the accumulated tetrapyrrole intermediates act as photodynamic sensitizers. As mentioned previously, compounds which act via this mechanism were named photodynamic herbicides by Rebeiz and coworkers [4]. The photodynamic effects are manifested by bleaching of leaves, a severe loss of turgidity of affected plant tissues, and finally by death of susceptible plants [4]. These effects were mainly due to the accumulation of protochlorophyllide (Pchlide) [4]; or, as was established later, they are mainly due to the accumulation of protoporphyrin IX, Mg-protoporphyrin, and its monomethyl ester rather than of Pchlide [6].

It is believed that the action of photodynamic herbicides is based on a photooxidative mechanism: Accumulated porphyrins photosensitize the formation of singlet oxygen, which in a free radical chain reaction oxidizes the lipoprotein components of cellular membranes [12,13].

Rebeiz and coworkers [4] found that various plant species respond differently to ALA and 2,2′-B treatment exhibiting a very pronounced organ-, age-, and species-dependent selectivity [4] (Fig. 1a–c). The first group of plants, represented by some dicotyledonous weeds such as mustard, lambsquarter, common purslane, and red-root pigweed, accumulated a significant amount of tetrapyrroles in the leaves and stems, and they were subject to severe photodynamic damages after exposure to light (Fig. 1a). The second group of dicotyledonous plants, such as soybean, kidney bean, and cotton, accumulated a significant amount of tetrapyrroles in the leaf tissues but not in the stems. The leaves exhibited severe photodynamic damage and died within a few hours, although the stems remained unaffected. These plants usually recovered from photooxidative damage and produced new leaves (Fig. 1b). The third group of plants, monocotyledonous agricultural plants (corn, barley, oat, or wheat), responded differently to ALA and 2,2′-B treatment. They accumulated a significant amount of tetrapyrroles, but the photodynamic damage was either imperceptible or consisted of small necrotic regions only. These plants (Fig. 1c) developed into healthy ones.

The selectivity of the photodynamic herbicide action seems to be based on (a) different capabilities of tetrapyrrole accumulation by various plant tissues (e.g., see Fig. 1a–c), (b) uneven distribution of various Chl biosynthetic routes, and (c) simultaneous application of different modulators [14–16].

Regarding the second point, there are differences among various angiosperms in Chlorophyll *a* (Chla) biosynthesis. Most of Chla is formed via two parallel biosynthetic routes: divinyl (DV) and monovinyl (MV) [17]. However, the endproducts in higher plants are MV not DV Chla and Chlb except probably for the lethal maize mutant which forms only DV Chla and Chlb [18]. Depending on which Chla biosynthetic pathway predominates during the dark and light phases of the photoperiodic growth, higher plants have been classified into three groups: dark DV light DV, accumulating mainly DV Pchlide a at night and mainly DV Chla during the day (e.g., cucumber, mustard, and representatives of more primitive plant groups: algae, bryophytes, ferns, and gymnosperms); dark MV light MV, accumulating mainly MV Pchlide a at night and MV Chla during the day (e.g., Johnson grass) and the largest groups of plants; dark MV light DV, accumulating mainly MV Pchlide a at night and mainly DV Chla during the day (e.g., corn, wheat, soybean). This phenomena is species dependent and has evolutionary significance [19].

Regarding the third point, some chemicals can modulate the Chl biosynthetic pathway by

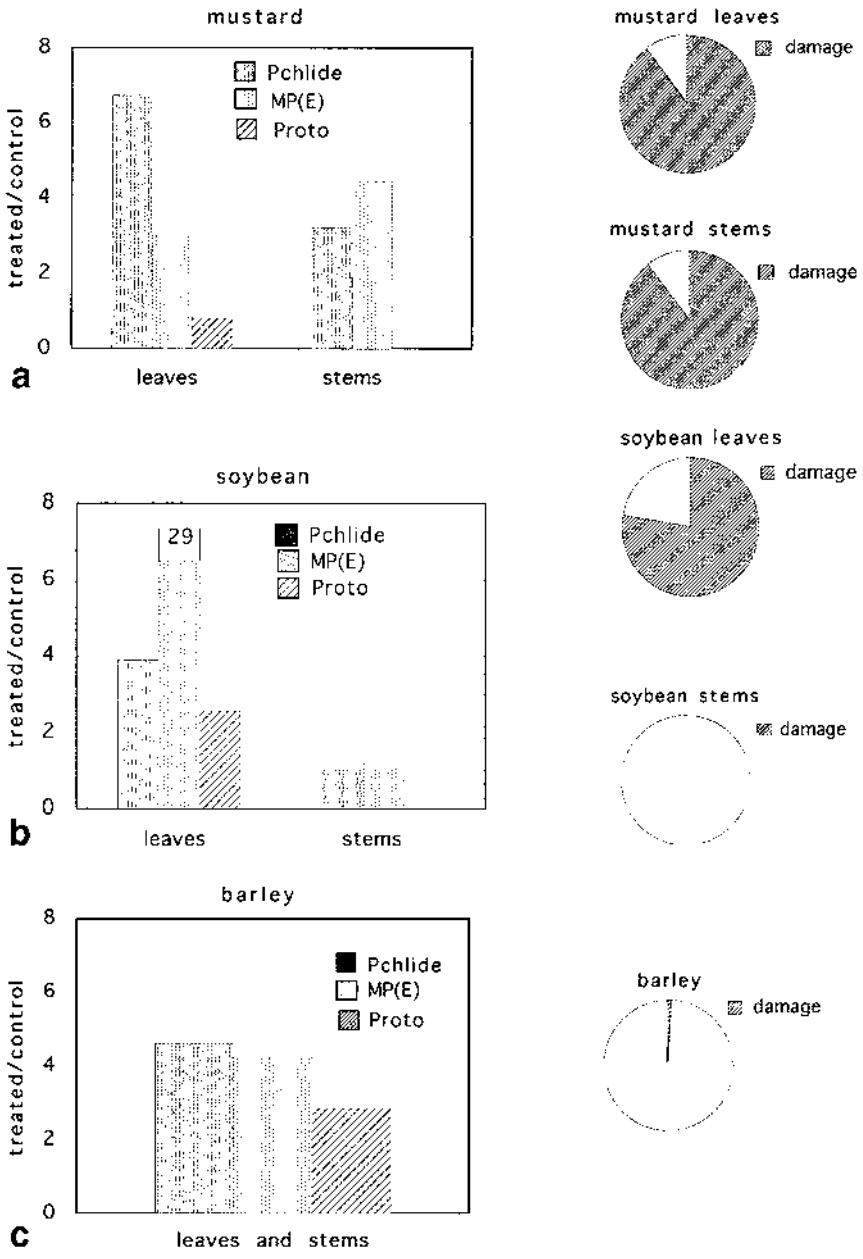

FIGURE 1 Three types of photodynamic herbicidal response of various plants species to ALA + 2,2′-B treatment and subsequent irradiation. The Type I response is represented by mustard (a), type II by soybean (b), and type III by barley (c). (Based on Refs. 4 and 14.)

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

forcing the treated plants to accumulate a type of MV or DV tetrapyrrole that is not produced in the natural Chl biosynthetic routes of this plant species and thus cause a strong photodynamic effect [14,15,20].

It was recently shown that evolution under domestication as manifested in selection for higher plant yields has favored, in certain cases, the MV route and not the DV route [21]. Recent results also showed that the treatment of plants with a low concentration of ALA, the main precursor of all tetrapyrroles including Chl, enhanced the accumulation of MV Pchlide in darkness, especially in dark DV plant species such as cucumber and velvetleaf [21].

INFLUENCE OF PHOTODYNAMIC HERBICIDES ON CHLOROPLAST DEVELOPMENT IN ETIOLATED AND SUBSEQUENTLY ILLUMINATED PLANTS

Plants in Toto

First detailed analysis of a reaction of a single plant species, cress (*Lepidium sativum*), to photodynamic herbicides, with special attention to pigment accumulation and the ultrastructure of plastids during the greening process, was made by Kittsteiner and coworkers [7,8]. Etiolated cress seedlings fed with low (2–5 mM) doses of metal chelators (Phe, 2,2′-B, 8-H) or ALA to accumulate Chl precursors and subsequently irradiated had damage to the upper part of the hypocotyl. The place of photooxidative damage did not coincide with the area of the highest porphyrin accumulation detected by fluorescence microscopy [7,8].

Pea (*Pisum sativum* L.) was another plant species analyzed after treatment with photodynamic herbicides and subsequent illumination. In etiolated pea seedlings, the strongest photooxidative damage was caused by 2 mM Phe and by 2–5 mM 2,2′-B. In the case of pea seedlings, the place of damage was the upper part of the epicotyl [22,23].

According to Rebeiz and coworkers [4], compounds such as ALA and 2,2′-B do not affect monocotyledonous plants. Therefore, it was interesting to find out whether Phe, a photodynamic herbicide, causes photooxidative damage in maize (*Zea mays* L.), a monocotyledonous plant, and whether it inhibits the normal development of chloroplasts during maize plant ontogenesis. Etiolated and then irradiated maize plants were resistant to 2–5 mM of Phe with respect to morphology (A.M., unpublished results).

Pigment Content

In cress, the large accumulation of Pchlide in the dark and its disappearance after 2 h of illumination was reported [7,8]. The rate of greening (after 2 and 12 h) was strongly reduced in cress seedlings. This applied to Chlb to the same extent as Chla but not to carotenoids (Car) [8]. A much stronger effect was achieved after application of complexing agents and subsequent irradiation than after ALA treatment [8]. Only trace amounts of Chla and Chlb were detected with 2,2′-B administration. In contrast to the strong synergistic effect of ALA and complexing agents described by Rebeiz and coworkers [4], the combination of ALA and 2,2′-B (2,2′-B caused the strongest inhibition effect) did not lead to increased inhibition of Chl accumulation. On the contrary, ALA reduced the effect of 2,2′-B [8]. Flash irradiation of cress cotyledons revealed that photoconversion of Pchlide to chlorophyllide (Chlide) was not influenced by chelator treatment. However, the esterification of Chlide was inhibited [8].

Pigment analysis of leaves taken from Phe- or 2,2′-B -treated and subsequently irradiated pea plants indicated an inhibition of both Chla and Chlb accumulation (Fig. 2) similar to cress plants 8,22,23]. After the treatment with the highest dose (3 mM) of 2,2′-B and subsequent 6 h of illumination, the Chla + Chlb content was only 7% of that in control plants (Fig. 2) [23]. The Car level

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

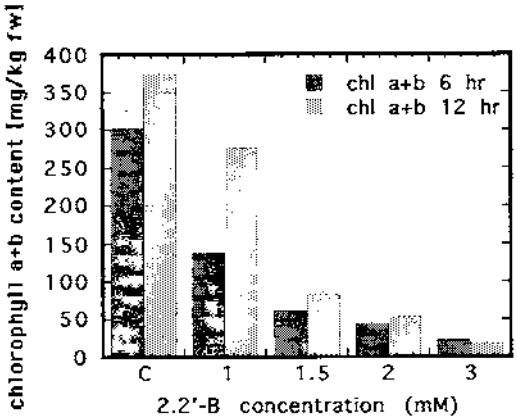

FIGURE 2 Chlorophyll a + b content of control, 1.0, 1.5, 2.0, or 3.0 mM of 2,2′-B-treated pea seedlings, etiolated, and subsequently illuminated for 6 or 12 h. Mean + SE. (From Ref. 23.)

was lower in 2,2′-B–treated pea seedlings and subsequent 6 and 12 h of illumination. It is not consistent with the unchanged level of Car in cress plants [8,23].

Mesophyll Cell Ultrastructure

Dark incubation of etiolated plants with ALA, Phe, 2,2′-B, or 8-H in low doses (1.5–5 mM) did not significantly change the ultrastructure of cells of cress cotyledons [8] nor of pea leaves pretreated with Phe (Fig. 3a) or 2,2′-B [22,23]. The plastids of pea cells treated with Phe had normal paracrystalline prolamellar bodies (PBs) and normal arrangements of prothylakoids. The ultrastructure of the mesophyll cells of maize leaves was not changed after pretreatment with Phe compared with control plants (A.M. unpublished results).

Two to 6 h of irradiation of etiolated plants pretreated with ALA or complexing agents was sufficient to cause photooxidative damage in the cotyledon cells of cress seedlings as well as in the mesophyll cells of pea seedlings, but it was not long enough to change markedly the ultrastructure [8,22,23]. The transformation of PBs and the formation of thylakoids were very similar in treated and control plants both in cress and pea. In pea, the thylakoid length increased in the same way in control and Phe-treated plants as in dark-treated plants.

The first ultrastructural change on illumination in both the Phe- or 2,2′-B–treated pea mesophyll cells was a strong dilation of endoplasmic reticulum (ER) cisternae which persisted during prolonged irradiation (see Fig. 3b,e–g); [22,23]. Phe-dark treatment and subsequent irradiation also caused structural changes of the mitochondria in cress and pea cells (see Fig. 3c); [8,22,23]. Most of mitochondria became vacuolized. In pea cells, they contained dark deposits mostly in crystalline form after treatment with Phe (see Fig. 3c) [22].

In control plants, extension of the irradiation time up to 12 h caused the development of grana with two to seven thylakoids in the plastids of the mesophyll pea cells (see Figs. 3d and 4a) and with three to five thylakoids in cress plastids [8,22,23]. The treatments of pea seedlings with a very low 2,2′-B concentration (1.5 mM) did not cause a strong inhibition of the grana formation (Fig. 4b); however, after 12 h of illumination, the number of thylakoids in the grana was on the average smaller than in control ones (Fig. 4b). The ultrastructure of plants treated with 3–5 mM of Phe or 2,2′-B irradiated for 12 h differed significantly from control plants. Plastids from such plants *did not form grana* (see Figs. 3e,g and 4c). These treatments, however, did not significantly influence

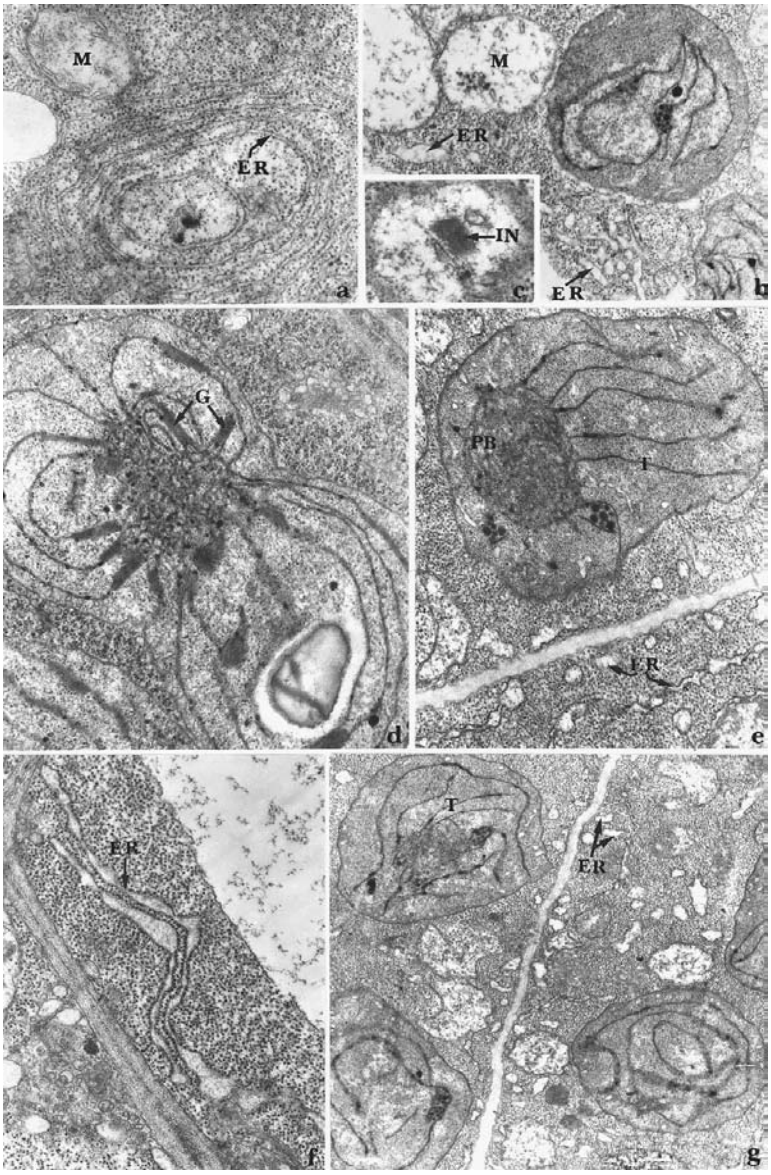

FIGURE 3 Portions of mesophyll cells of dark-grown pea seedlings treated with 2 mM Phe in darkness (a), or treated with 2 mM Phe in darkness and illuminated for 2 h (b,c), or untreated and illuminated for 12 h (d), or treated with 2 mM Phe in darkness and illuminated for 12 h (e–g). the development of single thylakoids. The total length of the thylakoids in treated plants increased after 12 h of irradiation but did not reach the level of control plants [22,23].

Although maize plants in toto were resistant to a low (5 mM) dose of Phe, treatment with Phe in this concentration inhibited the greening and grana formation after exposure to light. Similar to cress and pea plastids, in the case of maize plastids, Phe treatment did not influence the normal transformation of the prolamellar bodies nor formation of single thylakoids on illumination (A.M., unpublished results). Higher Phe concentrations (10–20 mM applied mainly to register the sites of damage) followed by exposure to light caused not only total inhibition of greening but also dilation of the thylakoids, swelling of plastids, and finally total destruction of the plastid structure (A.M., unpublished results).

Conclusions

In cress and pea plants treated with complexing agents and subsequently irradiated, the ultrastructural changes such as the inhibition of grana formation and the dilation of ER cisternae together with the inhibition of Chl accumulation may be due to the inhibition of the transport of certain proteins to the plastids, diminished accumulation of chlorophyll proteins (e.g., light-harvesting complex proteins [LHCP]), and a decrease in the activity of the chlorophyll synthetase. A decreased LHCP level and an inhibition of chlorophyllide esterification has been described in Kittsteiner et al. [7].

EFFECT OF PHOTODYNAMIC HERBICIDES ON THE ULTRASTRUCTURE OF CHLOROPLASTS, PIGMENT CONTENT, AND CO_2 EXCHANGE IN GREEN PLANTS

Plants In Toto

It was interesting to determine if and how photodynamic herbicides induce changes in the structure of chloroplasts in green plants with an already developed photosynthetic apparatus.

The first experiments were done on pea plants, which are sensitive to Phe when applied on etiolated and subsequently illuminated plants [24]. Treatment of green pea plants with Phe in experimental conditions corresponding to a natural field environment would determine if pea is resistant to this photodynamic herbicide. In toto pea plants treated with 2 mM Phe were resistant to low doses (2 mM) of Phe during 9 h of illumination as opposed to the 10- and 20-mM Phe-treated and subsequently illuminated plants. During 9 h of irradiation, both Phe 10 and 20 plants were strongly faded and lost about 40% of their water content [24].

Experiments on the effect of another photodynamic herbicide,-2,2′-B, on green pea seedlings showed similar effects to those in pea plants. Pea seedlings in toto were resistant to a low dose (5 mM) of 2,2′-B, however, 10 and 30 mM 2,2′-B and illumination caused the loss of turgor of treated plants and photooxidative perturbations [25].

Similarly green maize seedlings were resistant to a low dose (5 mM) of Phe with respect to morphology, however, 10 and 20 mM Phe and illumination caused the loss of turgor of treated plants (A.M., unpublished results).

Pigment Content

The influence of photodynamic herbicides on the structure and function of the photosynthetic apparatus in already green pea plants, especially on the pigment content, chlorophyll fluorescence, CO_2 exchange, and the ultrastructure of mesophyll cells, was also examined [24,25]. It was interesting to know if Phe influences or destroys differentiated chloroplasts with well-developed photosynthetic membranes and thereby affects photosynthesis. Since we did not expect low doses (2–5 mM) of Phe or 2,2′-B to destroy chloroplasts, we also applied higher (10–30 mM) doses to determine the sites of damage [24,25].

270 Madison Avenue, New York, New York 10016

The changes in the pigment content, both the Chl and Car in 2,2′-B–treated and subsequently illuminated green plants corresponded to the reaction of plants in toto with such treatment. This means that, in plants treated with 5 mM 2,2′-B, the Chl content remained unchanged during 9 h of illumination (Fig. 5a) and the Car content did not decrease much on longer illumination (Fig. 5b); however, in 10- and 30-mM 2,2′-B–treated plants, these values decreased by about 30% during the 9-hr illumination period (Fig. 5a,b) [25].

In 2- to 20-mM Phe-treated pea plants, the Chl content and the Chla/b ratio did not differ from these values in control plants and did not change significantly during 9 h of illumination [24].

Chlorophyll Fluorescence and Photosynthesis

The results obtained on the Chl fluorescence measurements and on the net photosynthesis rate (P_N) indicated dysfunction of the photosynthetic apparatus already caused by the lowest (5 mM) 2,2′-B concentration and subsequent illumination. Rapid fluorescence already changed after 20 min of light treatment, which indicated that the function of photosystem II (PSII) was strongly affected by 2,2′-B and that the action of 2,2′-B probably began during the dark period. Thus, PSII is a primary target of the 2,2′-B action [25]. The P_N of 5 mM 2,2′-B–treated plants was almost half that of control plants, already after 1 h of illumination and decreased additionally by about 20% during the next 5 h (see Fig. 5c). A dramatic (more than fivefold) decrease of P_N took place after 1 h of illumination in plants treated with 10 or 30 mM of 2,2′-B; after 3–4 h of illumination, the P_N in these plants was essentially zero (see Fig. 5c) [25].

In Phe-treated plants, the P_N was similar in control and 2-mM Phe-treated plants, but it was extremely low after treatment with 10 and 20 mM Phe [24]. At the beginning of the experiment with CO_2 exchange, this value in 10-mM Phe-treated plants was only 22% of that of control plants, and during 9 h of irradiation it decreased to 8%. The inhibition of photosynthesis was not due to the decreased Chl content. The Chla and Chlb content did not differ in control and Phe plants and did not change significantly during the whole experiment [24].

Mesophyll Cell Ultrastructure

Similar to plant in toto, the ultrastructure of the mesophyll cell was the same in control and 2- to 20-mM Phe-treated or 5- to 30-mM 2,2′-B–treated pea and maize plants if the plants were not transfered, to light after administration of the herbicide [24,25] (A.M., unpublished results).

Both pea and maize seedlings treated with low Phe or 2,2′-B doses and subsequently illuminated had a comparable ultrastructure of the mesopyll cells and chloroplasts, in particular, with that of control plants (Figs. 6a, c and 7a); [24,25] (A.M., unpublished results).

However, 10- and 20-mM Phe treatment or 10- and 30-mM 2,2′-B treatment followed by irradiation caused not only a severe loss of turgidity and the inhibition of photosynthesis but also changes in the cell structure. The difference between control and 2,2′-B–or Phe-treated plants became visible after 4 h of irradiation and intensified throughout 9 h of irradiation. This difference was mostly manifested in thylakoid swelling (see Figs. 6b, d and 7c), in dilation of the ER cisternae (see Fig. 7b), in degeneration of the internal mitochondrial membrane, and even in the disruption of the chloroplast envelope (see Figs. 6d and 7c) [24,25]. In green plants, like in etiolated ones, 2,2′-B or Phe treatment and subsequent irradiation did not much affect the formation of new thylakoids, although it destroyed the existing ones. During 6 h of illumination, the length of granal thylakoids and the total length of thylakoids per 1 mm^2 of a plastid section, as well as the number of grana, the number of thylakoids per granum (eight on average) increased to the same extent in control as in Phe-treated plants [24]. However, extended irradiation (between 6 and 9 h) in Phe-treated plants inhibited this development as compared with the control plants [24].

The number and size of starch grains in the chloroplasts of control pea plants continued to increase throughout 9 h of illumination. Finally, especially in Phe-treated pea seedlings followed by 9 h of illumination, grana and intergranal thylakoids were squeezed between large starch grains

or pushed toward the chloroplast envelope (see Fig. 6c). As opposed to the chloroplasts of control plants, starch grains were not seen in any chloroplasts of 2,2′-B or Phe-treated plants after a long period of illumination (see Figs. 6b,d and 7c) [24,25].

There was a difference in the changes in the ultrastructure after high doses of Phe or 2,2′-B and illumination. During the first 4 h of illumination, 20 mM Phe induced stronger ultrastructural changes than did 10 mM Phe. After a longer illumination period, there was no significant difference between the intensity of the ultrastructural changes in Phe 10 and Phe 20 plants [24]. However, 30 mM of 2,2′-B induced stronger than 10-mM 2,2′-B changes during the whole experiment leading finally to strong destruction and deformation of the chloroplasts [25].

The 10 and 20 mM Phe applied to maize seedlings followed by exposure to light caused the strong destruction of chloroplasts and whole mesopyll cells comparable with the reaction of pea chloroplasts on 30 mM 2,2′-B and illumination (A.M., unpublished results).

We tried to find some links between the rapid inhibition of photosynthesis and the ultrastructural changes. Since the 2,2′-B or Phe dark treatment did not influence the ultrastructure of the mesophyll cells, the inhibition of the photosynthetic processes during the first minutes of illumination could not be the result of structural changes. Thus, increasing the structural and functional alteration on illumination might have the same basis [24,25].

The chelating properties of Phe and 2,2′-B could be related to its inhibition of photosynthesis as well as with ultrastructural changes. Phe and 2,2′-B are strong chelators and easily form complexes with iron. However, complexing agents also can bond other ions, for example, bivalent ones, and thus cause membrane depolarization leading to a change of its permeability. The amount of Mg^{2+} ions might be reduced among to the chelating properties of 2,2′-B or Phe. Thus, immediately after the exposure to light, there is no sufficient amount of Mg^{2+} for carboxylase activation and thus photosynthesis is inhibited [26].

A similar interpretation is possible for ultrastructural changes on illumination. Swelling of ER cisternae, thylakoid swelling, and disruption of the chloroplast envelope should be a consequence of an increase in the space between the membranes which might be due to changes of membrane permeability based on the chelating properties of Phe. The changes of membrane permeability could

explain swelling of the ER cisternae and mitochondria [24,25]. Similar changes of the ER and mitochondria were previously described in etiolated Phe-treated plants [22].

Conclusions

The results of applying a low concentration (2 mM) of Phe to green pea and maize plants grown in normal field conditions indicated that these plant species have a high resistance to this herbicide. From application of higher Phe concentrations to pea and maize plants, sites of damage in the cell, particularly the destruction of cell membranes, were shown. The results of applying a low concentration (5 mM) of 2,2′-B to green pea plants indicated that they were resistant to this dose of 2,2′-B with respect to the morphology, pigment level, and structure of the mesophyll cells. However, dysfunction of PSII as well as P_N was already observed with low (5 mM) 2,2′-B treatment. Higher 2,2′-B doses and illumination caused photooxidative perturbations at the structural and functional level in the chloroplasts.

The destruction caused by Phe and 2,2′-B and subsequent illumination, especially the damage caused by longer illumination, might be caused by a standard photoinhibition mechanism, as proposed by Rebeiz and coworkers [4]. However, we have presented some other possible interpretations of the effect of Phe on the structure and function of the photosynthetic apparatus. It is difficult to determine without further experiments which mechanism is the leading one.

FINAL CONCLUSIONS

Photodynamic herbicides represent a group of compounds which induce the accumulation of chlorophyll precursors in darkness and cause photooxidative damage to plants during subsequent illumination. Photodynamic herbicides, particularly 2,2′-bipyridyl and 1, 10-phenanthroline in low concentrations inhibit grana formation, chlorophyll, and carotenoid accumulation, cause a strong dilation of the endoplasmic reticulum cisternae and delays the transformation of prolamellar bodies in etiolated pea and maize seedlings that are subsequently illuminated. The reasons for the reduced greening process are related to the chelating properties of 2,2′-B, a standard photooxidative mechanism, and/or LHCP accumulation within the ER cisternae.

Applications of low and higher 2,2′-B or Phe concentrations on green pea and maize plants revealed that these plants were resistant to low doses with respect to the morphology, pigment level, and structure of the mesophyll cells, but high doses with illumination caused the loss of turgor and photooxidative damages seen at the ultrastructural level and a decrease of the pigment contents.

Both Phe and 2,2′-B caused two types of reactions. The rapid reaction occurs directly after exposure to light. It is probably effected by processes which took place during the dark period and is monitored by changes of Chl fluorescence and of the photosynthetic activity rate. The slow reaction consists of destructive changes in the mesophyll cell ultrastructure: dilation of the thylakoid membranes and ER cisternae, disruption of the chloroplast envelope, and a decrease in the pigment content. Slow reactions are induced by light and require a longer illumination time. We consider PSII as a primary target of photodynamic herbicide action. Other dysfunctions are the result of the PSII damage; however, they also are induced by light and are based on the mechanism of photosensitizing of porphyrins.

INTRODUCTION

The establishment and productivity of forest trees are drastically affected by various environmental stresses [1] of which water deficit is the principal stress [2]. Similarly, water availability is a primary factor affecting the growth and survival of shrubs in desert areas of the world. Water is very significant to trees and shrubs because of its biological roles as a solvent and as a transport medium, as an electron donor in biochemical reactions, and as an evaporative coolant [3]. Water balance is very often impaired by external water-deficit stress (WDS) conditions which affect trees and shrubs in all populations across all geographical and climatic areas. Whether it is episodic or perennial, WDS impairs growth and development and renders woody plants susceptible to secondary, normally sublethal insults. In the extreme case, WDS will destroy large areas of forest and shrublands; thus contributing to land erosion and to desertification. Of the three main climatic factors, moisture, temperature, and wind, moisture is the most variable and definitive for the formation and well-being of shrublands [4].

Water-deficit stress is a common cause of seedling mortality in both naturally regenerated and planted stands of loblolly pine (*Pinus taeda* L.) in the United States [5]. Dry weights of four-winged saltbush (*Atriplex canescens*) more than 2 years after planting are directly correlated with

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

moisture availability at three sites in west Texas [6]. Williston [7] notes that over a 16-year period, as much as 60% of the first-year mortality in pine plantations is due to water deficit. Extensive research has been expended toward the production of genotypes that are morphologically targeted for severe drought-prone areas [8] and contain a genetically determined drought tolerance [9]. In established stands, WDS accounts for 80% of the variation in annual ring width of conifers in humid temperate climates [10] and up to 90% in semiarid regions [11].

Before visual damage is evident owing to WDS, there is a preceding alteration in the woody plant metabolism and gene expression [12–16]. Changes in gene expression are fundamental to both short- and long-term WDS responses. In numerous plant species, the imposition of stress results in the production of new proteins or the elevated synthesis of certain others [17–23] which may prevent cellular damage in various tissues [24–28] and detrimental changes in plasma membrane properties [29,30]. As with most plants, an osmotic adjustment in response to WDS occurs in woody plants, including both pine [31–34] and saltbush [35] and solutes such as proline [31,32] and sucrose [22] accumulate. With a prolonged WDS, a reduction in the tissue elasticity also can result [34,35]. These changes in the tissue properties and solute accumulation are a result of an altered gene expression, which has become the focus of research in many plant species, including woody crops. This chapter focuses on the molecular events associated with the tissue and metabolic changes in trees and shrubs. Numerous reports have been published on the effects of WDS on the molecular responses in many herbaceous crop plants [3,36,37]. The results of these investigations have been included and discussed when they provide more understanding of the general mechanisms and models of the molecular responses which can be applied to woody plants. Our goal is to provide more understanding of how woody plants respond to WDS at the molecular level which will allow researchers genetically to improve these important perennials and eventually overcome the severe economic losses associated with WDS. First, a generalized conceptual model of WDS perception and gene induction is discussed; second, woody plant physiological responses and tissue changes during WDS are presented; and finally, individual gene isolations and characterizations and gene products from several woody plant species are described.

PERCEPTION OF WATER-DEFICIT STRESS AND INDUCTION OF GENE EXPRESSION

Responses to WDS begin with its perception at the cellular level (Fig. 1). It is still not definitively known how a cell perceives WDS, but once it does, a complex cascade of events ensues [38]. Many of the steps of these events have not been elucidated, but one of the most significant observations in the WDS response is the increase in the levels of abscisic acid (ABA) [39–42].

Abscisic Acid Mediates the WDS Response

It has been shown that exogenously applied ABA can mimic many of the responses elicited by WDS; thus ABA is considered to be an essential mediator between WDS and the plant responses [42,43]. Transcription and translation are required for ABA biosynthesis during stress [44] indicating that proteins involved in the biosynthetic pathway must be synthesized in order for elevated levels of ABA to accumulate. The loss of the cell turgor and distortion of the cell membrane as a result of dehydration precede the increase of bulk ABA in the tissues, and the increase is correlated with an induced gene expression [45]. Both rapid and slow responses to ABA have been observed. Rapid responses include the early events of gene expression, including membrane-initiated signal transduction as occurring with guard cells, whereas slow responses include both the repression and expression of genes by ABA. The rapid response is not a prerequisite for the slow response, and the two responses may require different ABA receptor proteins [45].

Although genetic approaches using ABA-deficient and ABA-insensitive mutants (*abi*) have clearly indicated that ABA plays an important role in the WDS response [46,47], its specific mode of action, and its pathway leading to such a response remains unclear [36–38]. In a cascade of many

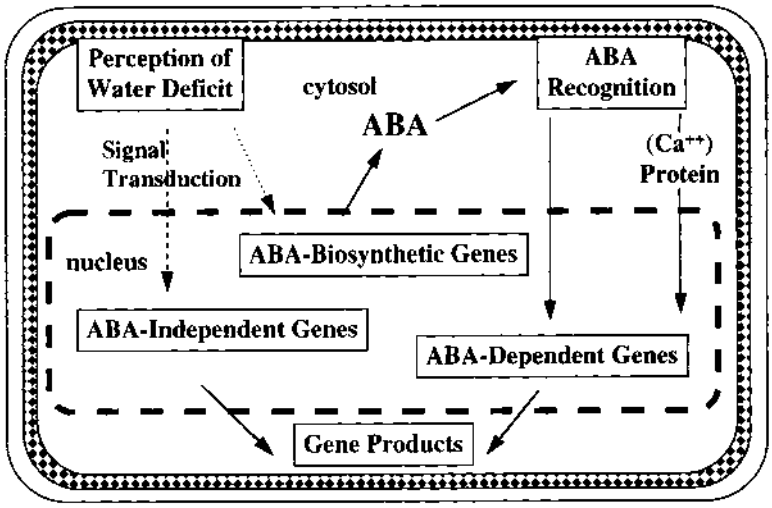

FIGURE 1 Generalized, conceptual model of cellular perception of water deficit stress and gene induction. (Modified from Ref. 38.)

events known to be involved in this response, the function of calcium as a second messenger has been established (see Fig. 1). Abscisic acid induces an increase in the cytoplasmic calcium in a variety of cell types, and, in guard cells, calcium acts as an intracellular second messenger in the ABA regulation of the stomatal aperture [48,49]. In *Arabidopsis*, the ABA-responsive *abil* gene mediates various responses, including the stomatal aperture, seed dormancy maintenance, and the inhibition of plant growth [46,47]. The *abil* gene codes for a phosphatase with novel calcium-binding site called EF-hands. These are protein domains each consisting of 29 amino acids arranged in a helix-loop-helix conformation which allows for the reversible binding of calcium. EF-hands appear to have the function of integrating ABA and calcium signals with phosphorylation events [46,47].

Gene Expression is Modulated by ABA via Transcription Factors

The transcriptional regulation of expressed genes (see Fig. 1) is accomplished by the sequence-specific interaction of *trans*-acting protein factors that bind regulatory *cis*-elements [50–53]. Many WDS-inducible/ABA-responsive genes contain conserved *cis*-acting sequences within the 5′ regulatory region to which transcription factors bind directly or indirectly in order to regulate gene expression. These sequences are usually identified either by exodeletion or mutation analysis [54–56]. The presence of short elements called ABA-responsive elements (ABREs) in the 5′ upstream region of the transcription initiation sites of the *em* gene of wheat [50] and in genes of several other species [55–57] have been reported. In wheat, these elements bind to the cloned transcription factor, EmBP1, and therefore regulate expression. Most of the transcription factors involved in stress responses belong to the bZip protein class [58,59] and can be induced by ABA [60]. In addition to ABREs, AS-1 and E8 *cis*-acting elements in the 5′ upstream sequence of the osmotin gene have been reported as well as enhancer-like and negative regulatory elements [55].

In the barley ABA-responsive gene, *hva22*, ABREs are necessary but not sufficient for the ABA response [56]. However, an ABRE complexed with a novel coupling element confers a high level of ABA responsiveness. In contrast, genes have been characterized whose expression is induced by ABA, but they lack the ABRE factor in their promoters [21]. Another novel 9-bp *cis*-acting element called DRE (dehydration-responsive element) has been isolated from *Arabidopsis* [61,62].

Although not specifically related to WDS, it has also been shown that not only the 5′ upstream region but also the 3′ untranslated region and/or a leader intron are also important in conferring both the temporal and spatial expression of genes [63]. Furthermore, expression enhancers in the introns [64] and in the 3′ untranslated region have a significant effect on mRNA stability [65].

Calcium-Binding Proteins Operate in the ABA-Signaling Cascade

Calcium modulates many physiological processes as a second messenger in a number of signal transduction pathways [66–69]. Calcium is involved in such processes as mitosis, cell elongation, cytoplasmic streaming, polarized cell growth, enzyme secretion, turgor regulation, hormone action, gravitropism, and enzymatic activities [67,68]. Proteins that have calcium-binding capabilities include calmodulin, troponin C, myosin regulatory light chain, calcineurin, sarcoplasmic calcium–binding protein, calpain small and large chains, aequorin, parvalbumin, and α-actinin [70]. Many of these have calcium-binding domains called EF-hands each consisting of 29 amino acids arranged in a helix-loop-helix conformation which allow for the reversible binding of calcium. Calcium binding to the protein stimulates a change in conformation resulting in a change in activity [71].

There appear to be plasma membrane receptors for ABA (see Fig. 1) that act as intermediates between ABA and calcium ion accumulation [72–74]. An increase in the cytosolic calcium ion content has been observed in response to inositol triphosphate treatments [75], one of the early intermediates in the signal transduction pathway. Calcium ions, acting as secondary signal transducers, have been implicated in the activation/deactivation of certain proteins by phosphorylation/dephosphorylation mediated by calmodulin [70]. These proteins lead to the transcription of specific genes followed by translation of new proteins [73]. The ABI1 phosphatase of *arabidopsis* with calcium-binding domains appears to be involved in phosphorylation events initiated by ABA and calcium [46,47]. Frandsen et al. [76] have isolated a calcium-binding protein gene from rice that is responsive to both ABA and osmotic stress. Dias [13] and Padmanabhan [77] have identified a WDS-ABA–responsive pine gene encoding a calcium-binding protein.

CELLULAR AND PHYSIOLOGICAL RESPONSES TO WATER-DEFICIT STRESS

Different orders of complexity in the WDS response pathway exist [3]. Low-complex mechanisms are WDS-response changes involving a single biochemical pathway [3]. They include mechanisms such as compatible solute production, ion uptake and partitioning, and facilitated water uptake [55]. These mechanisms of low complexity could be involved in physiological processes such as cellular protection and osmotic adjustment [36].

High-complexity mechanisms of response to WDS involve changes of many biochemical pathways [3]. These pathways are modified during stress to protect major processes such as photosynthesis and respiration and to preserve structures such as the cytoskeleton and the cell wall [78]. Another example of a high-complexity mechanism is the change in DNA content (79,80).

Cellular Protection

A number of genes whose translational products may be involved in cellular protection have been identified in several plant species. The functions of these genes are mostly predicted from the amino acid sequence of the proteins they encode. They encode hydrophillic proteins which possess a specific amino acid composition as well as conserved repeats of specific amino acids. The predicted functions of these proteins are the sequestration of ions, protection of other proteins or membranes, renaturation of unfolded proteins, or molecular chaperoning. Prominent examples of these types of genes are *lea* in cotton [26,81], *rab* from rice [25] and maize [82], *em* from wheat [83], dehydrin

from barley [27], *asr* from tomato [84–86], *rd22* [87] and *erd* [88] from arabidopsis, *pum* in alfalfa [89], and *le* in tomato [90]. The *lp3* gene, similar to the *asr* gene from tomato, has been identified in loblolly pine [91]. In tomato, ASR2 is localized in the nucleus [86] and is induced by WDS, ABA, and ethylene in ripening fruits [92]. The BspA protein from poplar has been suggested to have a protective role during WDS [93].

Osmotic Adjustment

In both herbaceous and woody species, it has been well demonstrated that they respond to WDS conditions by lowering their osmotic potential through the accumulation of osmolytes in the cytoplasm. This accumulation has been demonstrated in a large number of plants and appears to be related to turgor maintenance. An increase in solutes such as sucrose [22,23] and proline [32–34] has been observed in woody plants, and genes involved in the biosynthesis of WDS-induced osmolytes have been cloned [3]. A few genes encoding membrane channel proteins, called membrane intrinsic proteins (MIPs), are induced in response to a loss in turgor [94–98] and are hypothesized to form water-specific ion or solute channels. During stress, these proteins are predicted to modulate the movement of water or solutes from the vacuole to the cytosol, altering either the water content or the osmotic potential of the cytosol.

In yeast, an enhanced production and accumulation of intracellular glycerol occurs in response to a high external osmolarity [99]. The gene *gpdl*, which encodes the enzyme glycerol 3-phosphate dehydrogenase, is involved in glycerol biosynthesis [100], and its expression is regulated by the *high-osmolarity glycerol* (HOG) signal transduction pathway, which is defined by *pbs2* and *hog1* genes belonging to the MAP (mitogen-activated protein) kinase and MAP kinase groups, respectively [101]. A phosphorylation of HOG1, resulting from the expression of *hog1*, dependent on the protein product (PBS2) produced by the expression of *pbs2*, is necessary for the response to high external osmolarity [102]. Another gene, *spc1*, encoding a MAP kinase which is closely related to the *hog1* and mammalian p38 kinases, is activated by several forms of stress and regulates the expression of both *gpd1* and *tps1*, the latter of which codes for trehalose-6-phosphate synthase. The activation of *spc1* itself requires phosphorylation by another MAP kinase called WIS1. This SPC1 MAP kinase signal transduction pathway links to the G2/M control of the cell cycle with changes in the extracellular environment such as high osmolarity and nutrient depletion [103].

Modifying the Cell Wall

Shoot tissue elasticity is reduced in water-deficit–stressed pine seedlings [104], suggesting that structural changes in the cell walls have been induced. WDS-induced genes whose products have apparent cell wall functions in loblolly pine encode for proteins such as O-methyl transferase and S-adenosylmethionine (SAM) synthetase, enzymes which are involved in lignin biosynthesis as well as encoding copper-binding and glycine-rich proteins (GRPs) [14] which have presumed structural roles in the cell walls.

GRPs are characterized by their repetitive primary structure which contains up to 70% glycine arranged in short repeat units. Genes encoding GRPs have been isolated from a variety of plants, including tomato, arabidopsis, petunia, tobacco, carrot, pumpkin, bean, maize [105], pine [13], and saltbush [16]. Many GRP clones predict a common feature of an amino-terminal signal peptide suggesting that they are localized in the cell wall; however, cytoplasmic GRPs have also been identified. Generally speaking, those found in the cell wall are thought to be developmentally regulated, whereas the cytoplasmic GRPs are regulated by stress conditions such as ABA and WDS [105]. However, an exception to this may be the putative cell wall protein from pine [13] whereby the GRP is induced by WDS. GRPs are most often associated with vascular tissues, including the protoxylem and metaxylem, primary and secondary xylem, vessel elements, phloem, and fibers. Secondary structure prediction of GRPs indicate that they exist as β-pleated sheets with a varying number of antiparallel strands (Fig. 2), a structure that could provide elasticity as well as tensile

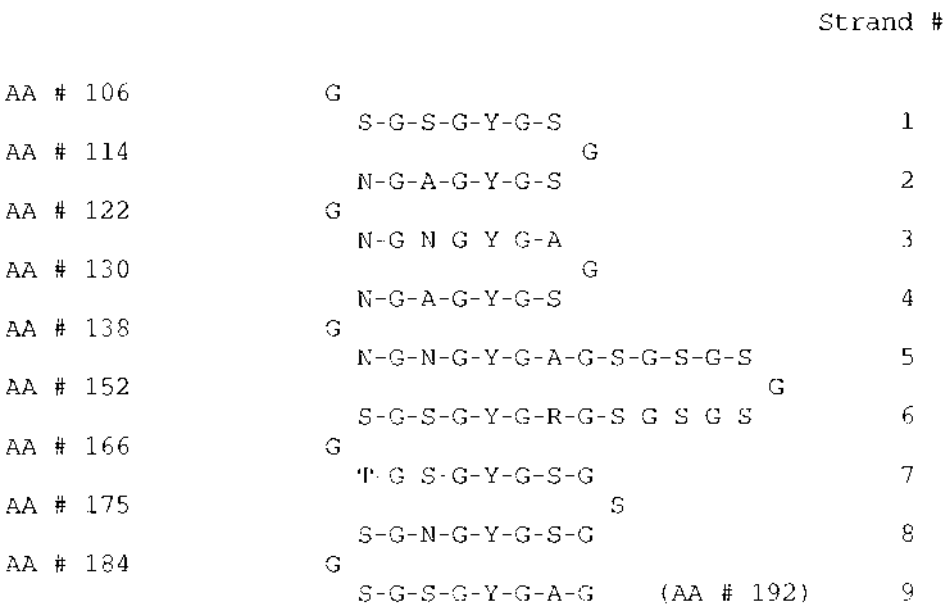

FIGURE 2 The proposed anti-parallel strand structure of the LP5 protein from loblolly pine [13].

strength during vascular development [105]. It has been suggested that GRPs provide a ''nucleation site'' for lignin biosynthesis [106] or a link with other cell wall proteins [105]. Non–cell wall cytoplasmic GRPs may have a role in WDS tolerance [105].

GENES INDUCED BY WATER-DEFICIT STRESS IN PINE

Molecular events leading to the WDS response have been characterized in several woody plants. In most cases, the putative functions for those genes that have identified are predicted based on their homology with genes from herbaceous species, but, in a few cases such as in pines, the genes have been studied in some detail with further characterization of their roles in response to WDS. Genes and gene products from pine are discussed in the following sections.

cDNA Clones from Pine

The synthesis of new proteins in *Pinus taeda* during WDS indicates that gene induction has occurred [19]. To identify these genes, a cDNA library was constructed from *P. taeda* roots which were stressed to a plant water potential of −1.5 MPa. The cDNAs were differentially hybridized to messages present in the roots of water-deficit–stressed and irrigated control trees. Several DNA clones were isolated. These genes were induced in *P. taeda* subjected to a progressive WDS which mimicked that of the natural environment (Fig. 3). When sequenced and characterized, the clones revealed a high homology with different WDS-inducible genes in other plants [14].

The protein encoded by *lp2* [14] shows a high identity with SAM synthetase from a number of plants [107–109]. This enzyme catalyzes the biosynthesis of SAM from methionine and ATP [110]. SAM is a cofactor in numerous biochemical reactions, acting as a methyl donor to proteins,

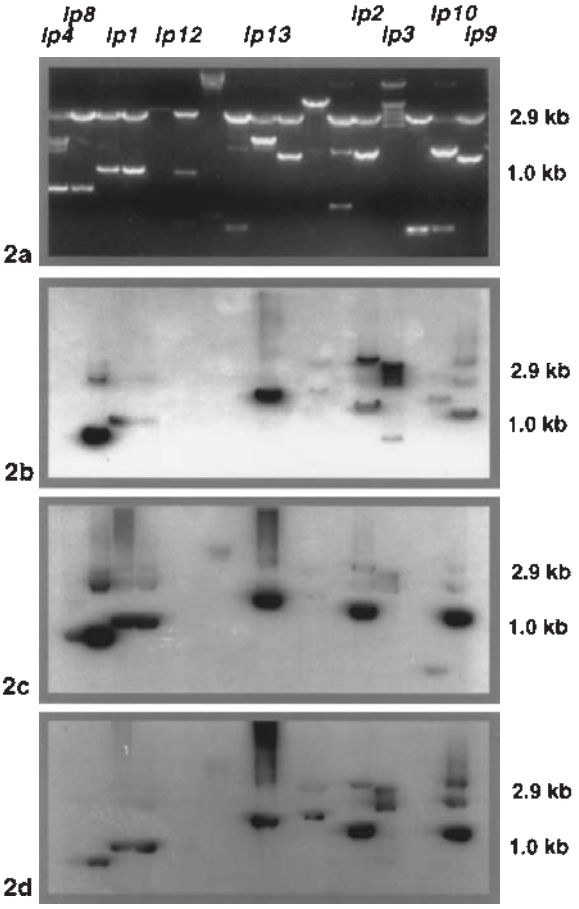

FIGURE 3 Plasmid screening for water-deficit stress (WDS)–responsive clones from loblolly pine [13]. (a) Ethidium bromide–stained gel. (b–d) Autoradiograms of the membranes hybridized with the indicated probe. The size of the DNA fragments is given on the right.

lipids, polysaccharides, nucleic acids [110], and intermediates in lignin [111] and ethylene [112] synthesis.

The *lp3* clone is preferentially expressed during WDS in roots and has very low to nonexistent expression in stems and needles [77]. The expression is also modified by ABA [77]. There are at least four members of the *lp3* gene family, and these members have distinct expression patterns in different tissues under WDS conditions. The predicted protein encoded by *lp3* is highly hydrophilic, and it shows a very high homology with clones from *Lycopersicon* [85,86,92], *Solanum* [113], *Oryza* (nonpublished results) and *Citrus* (nonpublished results). The homology is more than 89% at the C-terminal region, and it is variable in the N-terminal region in all the homologues. The *lp3* clone has a putative nuclear-targeting signal in the C-terminal region similar to its homologues. The protein counterpart of LP3 in tomato, ASR2, is localized in the nucleus [86] and is induced in leaves by ABA and WDS and in fruits during ripening. The expression of *lp3* homologues in other species varies.

Picton et al. [92] observed that the levels of the tomato ERT16b protein, homologous with the LP3 protein, increased during the latter stages of fruit ripening, but the message was not present

in the leaf before and after wounding. In a fruit-ripening, mutant, *rin*, very high levels of ERT16b expression were observed when fruit treated with ethylene were compared with air-stored control fruits. Interestingly, there were no transcripts detected in the leaf. In *Solanum chacoense*, DS2 was induced to very high levels in response to WDS, but it was constitutive to ABA application [113]. In response to wounding, no transcript was detected either in control or wounded leaves. Interestingly, this transcript also was not present in roots, tubers, or flowers. Since *lp3* is homologous with these genes with pleiotropic effects having a consensus nuclear-targeted signal, it could be that *lp3* codes for a transcription factor acting with ABA in the pathway of events induced by WDS.

Clone *lp4* codes for a protein that is similar to stellacyanin, a copper-binding glycoprotein from the Japanese lacquer tree [114] and to copper-containing glycoproteins from cucumber [115] and *Arabidopsis* [116]. *lp5* is preferentially expressed during WDS in roots, and its expression is very low to nonexistent in stems and needles. Genomic Southern analysis indicates that *lp5* belongs to a small multigene family [13]. The *lp5* cDNA codes for a novel putative glycine and serine-rich (41% glycine and 20% serine) cell wall protein with a distinct hydrophobic signal peptide in the N-terminal region suggesting that this could be a cell wall targeted structural protein. The accumulation of glycine-rich proteins in stressed plants has been well documented [24,78,117]. LP5 has nine repeats of GGXYXGG which are postulated to form antiparallel strands forming a β-pleated sheet in the secondary structure (see Fig. 2) with side chains of bulky residues exposed on one side of the sheet [118,119]. The rigid tyrosine residues are in the center of the strand, whereas folding occurs at the flexible glycines except where serine is present (see Fig. 2). There is also the possibility of cross linking between LP5 and other proteins or components of the cell wall via the tyrosine residues in the β-pleated sheet structure. In this way, the putative LP5 protein appears to function in strengthening the cell wall during WDS conditions.

The transcripts of *lp8* were induced to very high levels in root tissues and in stems to a very small degree during WDS [77]. The expression of *lp8* is also modulated by ABA [77]. The predicted product of *lp8* contains a very high degree of homology to several calcium-binding proteins in various organisms. It has four possible calcium-binding sites called EF-hands, which agrees quite well with the consensus model from various species. Therefore, the apparent function of LP8 is to bind to the elevated cytosolic calcium level during WDS and modulate the expression of other genes. Genomic Southern analysis indicates that *lp8* belongs to a small multigene family. Clone *lp9* is induced in stems only under moderate WDS (−1.6 MPa), whereas its expression is downregulated in needles and is constitutive in roots. No significant homologies were observed with the sequences of *lp9* and *lp10* when compared with those from Genbank.

Promoter Analyses of Pine Genes

Genomic clones for *lp3*, *lp5* (a glycine-serine–rich cell wall protein homologue), and *lp8* (a calcium-binding protein), which are induced preferentially in roots during WDS, have been isolated. The genomic clones of both *lp3* (V. Padmanabhan, nonpublished) and *lp5* [13] have been sequenced and the upstream regions of both contain ABA-responsive elements at different positions [120], with *lp3* also having a root-responsive element (V. Padmanabhan, nonpublished results). No consensus sequence for ethylene responsiveness was found. Segments of the two promoters with different amounts of their upstream sequences fused in front of the *uidA* reporter gene encoding β-glucuronidase have been cloned. Preliminary experiments with *lp3* and *lp5* promoter-driven *uidA* expression in bombarded *Pinus elliottii* (slash pine) cell suspension culture cells indicate that both promoters are active. In transient expression analysis, both of these promoters were observed to be induced in response to mannitol (5.5%) which simulated WDS equivalent to −1.1 MPa (Fig. 4). The promoters have been cloned in plasmids pBI121 and p35SmGFP, inserted into *Agrobacterium*, and transferred into tobacco. *lp3* DNA driven by the 35S promoter in tandem with *uidA* driven by the *lp3* promoter have been inserted into *Agrobacterium* and also transferred into tobacco (R.J. Newton, M.A.D.L. Dias, and V. Padmanabhan, nonpublished results).

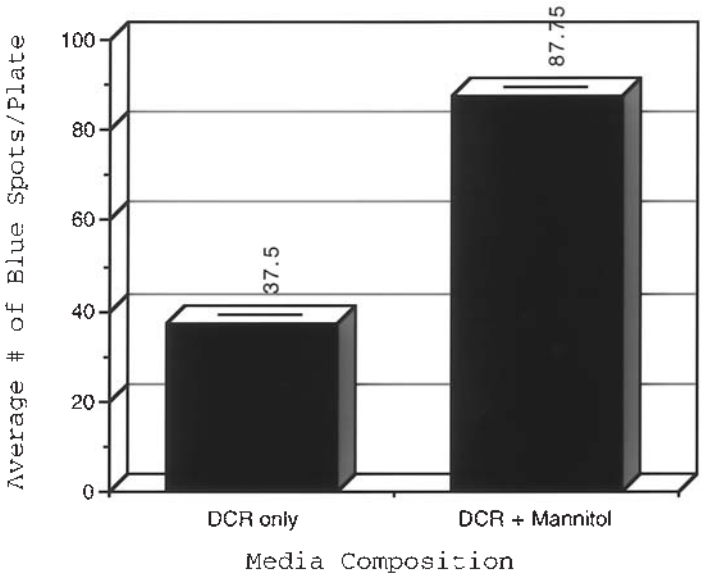

FIGURE 4 Average number of blue spots obtained indicating GUS activity driven by the loblolly pine *lp5* promoter. Expression in slash pine suspension cells subjected to osmotic stress with mannitol after biolistic transformation with *plp5*(p)GUS-SK [13].

GENES DOWNREGULATED BY WATER-DEFICIT STRESS IN LOBLOLLY PINE

Besides several upregulated genes, a few downregulated cDNAs such as *lp6* [121], *lp15*, and *lp20* also were isolated [77]. Even though the expression of *lp10* is downregulated under WDS, the transcripts of this gene are very abundant in roots. The translational *lp6* product bears a strong resemblance to class I chitinases [121]. However, LP*6* lacks the signal peptide, the cysteine-rich chitin-binding domain, and the glycine-proline–rich ''hinge'' region typical of class I chitinases. It is not known whether LP6 possesses chitinase activity. Benhamou and Asselin [122] have speculated that an alternate substrate for chitinases may be glycolipids in the cell walls of plants.

GENES INDUCED BY WATER-DEFICIT STRESS IN OTHER WOODY PLANTS

Saltbush (*Atriplex* spp.)

Through construction of a cDNA library [123], several clones of WDS-inducible genes have been isolated from saltbush, *Atriplex canescens* [15]. Two homologous cDNA clones (*p19-3* and *p27-3*) are nearly identical and encode for a small hydrophillic polypeptide of 95 amino acids (11 kDa) similar to one in rice, but whose function is yet to be determined [15]. Two additional clones, *p8-3* and *p23-3* (D. Villalon, nonpublished results), are similar to proteinase inhibitor I from potato [124]. Also in *A. canescens*, two other clones (OI2-2, OI14-3) putatively encode GRPs with cell wall–targeting signal peptides, which are induced by sulfur dioxide as well as WDS [16]. They have homologous amino acid alignments with ABA-inducible GRPs from alfalfa [89].

The saltbush GRPs induced by stress (ozone, sulfur dioxide, and WDS) also appear to be

arranged in β-pleated sheets. This predicted secondary structure has two specific conformations whereby tyrosine residues are exposed for cross linking with GRPs and other cell wall components, and whereby the spacing of the tyrosine residues determines the potential pore size of an intermolecularly cross-linked network. Genes encoding for GRPs are activated by a variety of stress conditions such as wounding, pathogen infection, WDS, heat, sulfur dioxide, and ozone [16,105]. A possible role for GRPs in these responses may be inferred from studies about cross linking of the extensin protein in the cell wall [125]. Wound-induced plant defense involves H_2O_2 oxidative cross linking and insolubilization of extensin which strengthens the cell wall in the initial stages of plant defense [125]. Similarly, the changes in the cell wall GRPs of both pine and saltbush could be associated with a decrease in the cell wall elasticity as induced by both ozone [126] and WDS [34].

A 59-KDa peptide, similar to the tobacco osmotin, has been detected in the cells of *A. nummularia* [127]. Two cDNA clones encoding osmotin-like proteins have been isolated, and the *pA9* clone is induced by NaCl [127]. Compared with glycophytes, the proteins of the halophytic *A. nummalaria* appear to be unique. Although these genes are similar to osmotin genes, they have different regulatory properties.

Cotton (*Gossypium* spp.)

Seeds of the woody cotton shrub have been the source of the late embryogenesis–abundant genes (*lea*) which encode for proteins which are expressed during the final stages of seed development at the onset of desiccation, and their expression dominates the mRNA population in dehydrated embryo tissues [71]. During dehydration, water loss leads to crystallization of cellular components resulting in cellular damage. LEA proteins can counteract these processes by maintaining the integrity of cellular structures in the absence of water. They are predominantly cytosolic proteins with hydrophilic residues, and their coiled nature is consistent with their proposed role of binding to water [37]. Some LEA proteins could be involved in the ''solvation'' of cytosolic structures during desiccation and/or in mitigating the damaging effects of an ever-increasing ionic strength in the desiccated cytosol [128], whereas others may have a regulatory role [129]. However, data which support these protective roles for LEA proteins during dehydration have not yet been obtained.

Poplar (*Populus*)

A novel 66-kDa protein (BspA) accumulates in the shoots of cultured aspen (*Populus tremula* L.) in response to gradual WDS [93]. Slash pine (*Pinus elliottii* Engelm.) callus cultures exposed to mannitol-induced water stress also express a 66-kDa protein [17]. BspA is the major WDS-responsive protein in aspen. It accumulates in response to ABA application as well as cold and osmotic stress, and it is boiling-stable. It accumulates as early as 1 h after initiation of the WDS treatment and decreases on rehydration. The N-terminal amino acid sequence shows a high homology with the wheat germins GF-2.8 and GF-3.8 [130]. Wheat germins also share a homology with spherulin, a putative cell wall protein in the slime mold, *Physarum polycephalum*, that increases during spherulation in response to osmotic stress [130]. An additional similarity was detected between BspA and a barley cold-responsive protein (pA086) [131] and a protein found in salt-stressed barley roots [132]. The wheat germins appear to be similar to the amino acid sequence of barley oxalate oxidase [133].

The differential accumulation of BspA in two *Populus* species may be related to their tolerance to WDS [23]. When subjected to WDS the detached leaves of *P. popularis* lost less water, had less ion leakage, and accumulated more BspA than did those of *P. tomentosa*. It is suggested that BspA is ''dehydrin-like'' and contributes to membrane stability. The dehydrins [134,135] are polypeptides which are highly hydrophilic, remain soluble after boiling [27], and are suggested to prevent cellular damage during desiccation by binding to macromolecular structures [136]. Dehydrin homologues of 43 and 31 kDa were induced in the shoots and roots of aspen [22], and they are similar to dsp-16, a dehydrin from the resurrection plant, *Craterostima plantagineum* [137].

Sucrose synthase and glyceraldehyde-3-phosphate dehydrogenase (GAPDH) also accumulate in aspen shoots in response to WDS, and this is accompanied by increased sucrose and decreased glucose levels [23]. Sucrose synthase accumulates in stressed leaves of *P. popularis* along with a simultaneous increase in the glucose levels, whereas in stressed leaves of *P. tomentosa*, sucrose synthase is nondetectable and glucose levels decrease [23]. Sucrose synthase is a cytosolic enzyme involved in the breakdown of sucrose into fructose and UDP-glucose, and GAPDH is a key enzyme in glycolysis and gluconeogenesis pathways. Thus, both sucrose synthase and GAPDH may play a dominant role in sugar metabolism during WDS.

CONCLUSIONS

Many environmental stresses affect the establishment and productivity of trees and shrubs, and water deficit is the principal stress. Water has many roles in woody plants such as turgor maintenance, solute transport, donation of electrons, and cooling of tissues and organs by evaporation. The delicate water balance in trees and shrubs is very often impaired by external WDS conditions. It affects woody plant populations across all geographical and climatic areas, by impairing their growth and development. Extreme cases of WDS destroy large areas of forest and shrubland and contribute to land erosion and to desertification. An understanding of WDS responses is important for evaluating the warming effects of the global climatic changes because WDS is often associated with heat stress. Warmer climates could have consequential effects on tree growth via responses to WDS.

For the last decade, researchers have been investigating the molecular responses to WDS in woody plants. Many clones of genes that are either upregulated or downregulated by WDS have been identified. Those genes that have been studied further and partially characterized appear to be involved in modifications of the cell wall, gene activation, signal transduction, and protection against desiccation. We now have sufficient information, expertise, and knowledge to ascertain in a more definitive vein what the function and role of these genes are in response to WDS. Furthermore, by studying their regulation, we have the potential to identify promoter sequences as well as genes which in the future could be useful in the genetic engineering of trees and shrubs. However, at this point, even though specific WDS-responsive genes have been identified in a large number of plant species, for most of these genes, it is still not known what their specific roles are. In addition, these genes have not been shown to provide tolerance to WDS. These data will be needed before specific WDS-responsive genes can be considered for genetic engineering purposes.

Only a few investigations have focused on the responses in woody plants where the cell walls in wood formation and wood composition are of primary importance. Trees and shrubs, because of their demonstrated adaptation to very diverse environments and their perennial growth habit, may have unique and specialized responses involving gene expression which deserve further investigation. Furthermore, trees and shrubs have large, prolific root systems and other factors which provide for compensating responses to WDS, thus they respond in a very gradual manner, whereas many responses of herbaceous plants may be more sudden and abrupt and may involve a different cadre of genes compared with those induced by WDS in woody plants. In most of the investigations reported here, an experimental system which reflects a gradual, slow response to an increasing severity of WDS was used, and this simulates best what trees and shrubs experience in their native environment.

INTRODUCTION

Most of the theory concerning the evolution of the genome size and the effects of the varying DNA content on the physiology, development, and adaptation of plants has been derived through the study of herbaceous angiosperms. Therefore, a brief introduction to these concepts is necessary before specifically addressing gymnosperms.

Extent of DNA Content Variation

The widespread variability in the genome size (DNA content) among eukaryotic organisms has been extensively documented [1–4]. Among angiosperms, the range in genome size varies several hundredfold from 2C = 0.1 to 254 pg [3]. The DNA content varies up to fortyfold and ninefold within families and among congeneric species, respectively. The DNA content variation among both plants and animals does not correlate with the evolutionary advancement or genetic complexity [5]. Furthermore, only a very small amount of DNA apparently has coding functions, and most of the eukaryotic genome is made up of repetitive sequences [6,7]. The repetitive sequences may be tan-

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

demly arranged and/or dispersed throughout the genome [8–10]. Changes in the genome size primarily involve a variation in the amount of repeated DNA sequences [7,11,12].

Fluidity of the Plant Genome

The current model for genome evolution includes the concept that the plant genome is fluid and has repeatedly undergone amplification and deletion of DNA sequences over evolutionary time [9,13,14]. Repetitive sequences have diverged in base composition, and they apparently have undergone extensive translocation, reamplification, and deletion [9,13,14]. This cycle has apparently resulted in the massive variation in the genome size observed among plants [11,14]. The mechanisms for amplifying and/or deleting repetitive sequences are not understood. Proposed mechanisms include errors in the replication of DNA, saltatory amplification, unequal crossing over, and the actions of transposable elements [6,15–17].

Changes in the DNA content may be triggered by stresses imposed by the genetic and/or physical environment [18–20]. The ability to generate variability in response to stress has been proposed to be part of an evolutionary strategy for adaptation to a changing environment [19]. Examples of the stress-induced variation in the DNA content include the formation of megachromosomes in hybrids of *Nicotiana tabacum* with *N. otophora* and *N. plumbaginifolia* [21,22], the instability of the DNA content in hybrids of *Microseris* [23,24], fertilizer-induced changes in the DNA content in *Linum usitatissimum* [25], and the within-plant variation of the 2C DNA content in sunflower, *Helianthus annuus* [26]. In sunflower, the DNA amount is influenced by the photon flux density and the ratio of the red to the far red portion of the spectrum [27]. The reduction in the DNA content of plants growing under light that is rich in far red suggests that phytochrome may be involved. Since light reflected from vegetation is richer in far red light than unobstructed light, it was further proposed that the far red light–induced reduction in the DNA content in the sunflower may represent an adaptation for shade avoidance in competition with neighboring plants [27]. The extent of environmentally induced changes in the DNA content among plants remains to be determined. However, the examples studied so far indicate that a sizable fraction (up to at least 45%) of the plant genome is potentially unstable and subject to rapid content changes.

Most of the variation in the DNA content is associated with classes of repetitive DNAs [7] composed of retroelements; that is, several classes of mobile DNA that transpose through an RNA intermediate [28]. These elements comprise at least 50% of the maize genome, and they are arranged as nested elements in spaces between genes. Retroelements are highly abundant in plants with large genomes, and this suggests that they account for most of the great variation in the genome size [28]. Because retroelements all transpose without excision, their mobility always increases their copy number, and this would tend to increase the genome size [29]. The question still remains whether woody plants such as the pines, which have a large genome sizes, are moving toward the development of even larger genomes, or if there are active processes for removing the interspersed repetitive sequences. So far, no mechanism has been found for removing them [29], but data from sunflower [26,27] imply that mechanisms for removal of interspersed repetitive sequences must exist.

Nucleotypic Effects

Various hypotheses have been proposed to explain the widespread variation of the DNA content observed among eukaryotes, including several nonadaptive ones such as junk, selfish, or parasitic DNA sequences [30–32]. However, an alternative theory that has garnered much support considers the DNA content to be of adaptive significance through cellular and phenotypic effects owing to its mere bulk [33]. These effects are called the nucleotype. The nucleotype is determined by the total quantity of nuclear DNA, both genetic and nongenetic, and influences cellular and developmental parameters such as chromosome size, nuclear volume, cell volume, mitotic cycle time, and the duration of meiosis. It has been proposed that the nucleotype influences the phenotype so that,

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

under some conditions, selection favors accumulation of nuclear DNA regardless of its nucleotide sequence, and under different conditions, the loss of sequences not necessary for survival may confer considerable adaptive advantage [1,33,34].

It is well established that chromosomes that have more DNA also are larger [35,36]. Strong positive correlations have been established between the DNA amount and the chromosome volume and mass [37,38] and between the DNA content and the total length of the synaptonemal complex [39]. Baetcke et al. [40] established a strong positive correlation (slope = +1) between the DNA content and the nuclear volume, and Price et al. [41] detected a similar relationship between the DNA content, nuclear volume, and cell volume. Price [42] presented the hypothesis that the DNA content determines the fundamental nuclear volume and cell volume which are in turn influenced by developmental, genetic, and environmental factors. Selection for the DNA content may, therefore, be partly through its effects on nuclear and cell size.

A relationship between the nuclear DNA content and the minimum mitotic cycle time is well established among diploid angiosperms [43–45]. Generally, the higher the DNA content, the longer is the mitotic cycle time. The average duration of the mitotic cycle increases at a rate of 0.38 h/pg DNA, and this increase is mainly attributed to a longer duration of the DNA synthesis [46,47]. Bennett [48,49] established a correlation between the duration of meiosis and the DNA content in diploid plants. The increase in the duration of meiosis with an increased DNA amount was attributed to similar increases in all meiotic stages.

DNA Content and Adaptation

Although there is no overall correlation of the genome size and phylogeny in plants, the distribution of the variability in the DNA content is not random. Evolutionary trends are apparent. Andulov [50] detected that plants of grass tribes and genera centered in the tropics, or those that grew only during warm seasons in temperate climates, had uniformly small- to medium-size chromosomes. Those growing in the more temperate northern regions tended to have larger chromosomes. Levin and Funderburg [38] concluded that genome sizes are generally larger in temperate compared with tropical herbs and that families indigenous to tropical and subtropical regions have substantially smaller genomes than those of temperate regions. Bennett [51] concluded from a study of cereal grain crops, cultivated pasture grasses, and legume pulse crops that humans had generally chosen species for cultivation that resulted in a distribution paralleling or exaggerating the natural tropical-temperate cline in the DNA content. A south to north cline of an increasing DNA content has been found for some conifers. Miksche [52,53] detected that the DNA contents of plants from northern populations of *Picea glauca* and *P. sitchensis* were greater than 50% larger than those of southern populations.

From a study of 271 species, Bennett [54] detected a relationship between the growth form of herbaceous angiosperms and the DNA amount. He observed that (a) annual species of both monocots and dicots have a significantly lower mean DNA content than perennials, (b) the range of the nuclear DNA amount is smaller among diploid annuals of both classes, (c) ephemeral annuals have a lower mean DNA content than nonephemeral annuals, and (d) among monocots the mean DNA amount of obligate perennials is greater than that of facultative perennials, and the mean values for facultative perennials and annuals are not significantly different. Bennett [54] proposed that the nuclear DNA content and the minimum generation time are correlated and the DNA content is causally correlated with the rate of development.

Grime and Mowforth [55] suggested that selection may operate on the genome size through a differential effect of temperature on cell division and cell expansion. They proposed that cell expansion is inhibited to a lesser degree than cell division at low temperature, and plants growing in cooler environments should have growth dominated by cell enlargement that would favor larger cells and a higher DNA content. Growth should be facilitated by more rapidly dividing cells with less DNA under warmer conditions where temperature is not adversely affecting the mitotic cycle time. Phenological data collected from British flora [55,56] support this hypothesis. From early

spring to midsummer in the Scheffield region, growth rates were significantly and negatively correlated with the genome size. In a species-rich grassland community in northern England, the DNA content and the rates of leaf elongation of grasses, sedges, forbs, and small herbs were studied in relationship to temperature and chronology [56]. The most rapid rates of leaf expansion occurred in species with relatively high DNA content during the cold early spring. The differences were not apparent under the warmer conditions of early summer.

Strong support for an adaptive nature of a variable DNA content comes from studies of the genome size, speciation, and adaptation in congeneric species and within species. The two most thoroughly studied examples come from the genera *Microseris* and *Zea*.

In the Microseridinae (Asteraceae) of western North America, there are correlations between the ecological adaptation and the DNA amount at the interspecific and intraspecific levels. The more primitive diploid species of *Microseris* occupy cooler and more mesic habitats than do the specialized annual species that are adapted to warmer, more xeric, and time-limited habitats [57]. The evolution of these diploid annuals from their putative perennial ancestor(s) resulted in massive diminution of the DNA sequences so that they have only about 40–60% of the DNA amount of the perennials [57–59].

The DNA amount varies over 20% within the annuals *M. bigelovii* [60] and *M. douglasii* [61]. In *M. bigelovii*, the lower DNA values were detected in plants of geographically disjunctive populations at the low-rainfall, southern extreme of the species range and at the northern high-rainfall extreme on thin soil over a barren rock outcrop. The higher DNA values were detected from plants of habitats at the center of the species range where intermediate amounts of precipitation occur. Price et al. [60] suggested that the low DNA content resulted from selection in stressful and/or time-limited habitats at the extremes of the ecological adaptation of the species.

In *M. douglasii*, from which over two dozen populations have been sampled, high DNA values are restricted to plants growing in more mesic sites, generally on well-developed soil [61]. At some sites that were studied more extensively, temporal changes in the DNA content were observed that correlate with environmental changes; that is, amount of precipitation and the length of time available to complete the life cycle [61,62].

The observed distribution of the DNA amounts among and within species of *Microseris* suggests an adaptive role for the DNA amount. Selection may act on the nucleotypic effects of the DNA content that influence the cell size, mitotic cycle time, and rate of development [1,33,63].

The DNA content varies among North American populations of *Zea mays* representing open-pollinated and inbred lines from Mexico to Nova Scotia [64,65]. The nuclear 4C DNA amount ranged from 9.8 pg in Gaspe Flint to 13.5 pg in Zapolate Chico, or about 38%. Rayburn et al. [65] detected a significant negative correlation between the DNA content and the maturity zones. Since these maturity zones are roughly latitudinal in nature, there exists a latitudinal cline from higher to lower DNA values in North American maize. Maize apparently originated in Mexico or Central America as an obligate cultivar. It was subsequently taken northward by humans until the cooler and shorter growing season restricted maturation. Rayburn et al. [65] suggested that the smaller genomes of maize lines grown at high latitudes resulted from selection by humans for earlier maturation, maximum plant size permitted within climatic constraints, and yield. These more rapidly developing plants may have been achieved in part through selection from a shorter mitotic cycle time and more rapid cell proliferation resulting from less nuclear DNA.

NUCLEAR DNA CONTENT IN GYMNOSPERMS

Survey of Gymnosperms

The DNA content of more than 80 gymnosperm species from 24 genera have been reported [52,53,66–80]. Although real differences occur among species, some of the variability among and within studies is due to the methods, standard, and tissue used. If not properly controlled, the problems historically associated with determining the DNA content from gymnosperm root-tip nuclei result in increased variability and imprecise measurements of the DNA content [69,79]. Gymno-

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

sperm root tips fixed in nonadditive fixatives release tannins from the vacuoles which may interfere with the Feulgen reaction and result in reduced staining [81]. The recent improvement in instrumentation and the emphasis on techniques and careful preparation of tissues should minimize the procedural variability of the DNA values of the same species determined from different laboratories.

Methods

About 75% of the DNA content reported for gymnosperms was derived from Feulgen densitometry with 15% from laser flow cytometry and 10% from chemical extraction [80]. Chemical extraction was the only method for measuring the DNA content prior to the development of microdensitometric techniques. Scanning Feulgen microspectrophotometry is the most frequently used method for determining the relative DNA content. However, laser flow cytometry (LFC) is a recently established method for plants [82] that we have used to determine the DNA content of *Pinus* species [72]. Our results showed that the mean DNA content of samples determined by Feulgen densitometry was significantly linearly correlated with the mean value determined by laser flow cytometry ($y = 0.132 + 1.04 \times r = 0.987$ [72]). Flow cytometric determinations of the DNA content in loblolly pine by two independent laboratories were 21–22 pg/1C [72] and 44–45 pg/2C [73] indicating the reliability of the method.

Standards

Four kinds of standards were used for Feulgen densitometry and laser flow cytometry [80]: *Allium cepa* cv. Ailsa Craig (2C = 33.5 pg), *Zea mays* (L.) ssp. *mays*, inbred line Va35 (4C = 10.32 pg), *Hordeum vulgare* cv. Sultan (2C = 11.12 pg), and chicken erythrocytes (2C = 2.5–3.5 pg). Price et al. [83] have pointed out that plant nuclei instead of chicken erythrocytes should be used as standards for plants. Compared with the values obtained with other standards, plant material using *A. cepa* as a standard have values which are 8–52% smaller than those using chicken erythrocytes. Values obtained using *Z. mays* and *H. vulgare* as standards are 1.2–1.3 times larger than those using *A. cepa*. These differences could be caused by tissue differences as well as differences in methods. Also, the use of a very low DNA content standard is not preferable when measuring nuclei such as those of gymnosperms that have relatively large genomes.

Tissue

Meristematic tissue in the root tips has been mainly used for the DNA content determinations; however, nuclei from leaves or other tissues have sometimes been used. It is often difficult to squash the root tips of woody plants so that nuclei are clearly separated and free of debris. Further, if not fixed properly, the DNA contents of gymnosperms may be underestimated owing to interference of the Feulgen reaction by tannins [81,84]. Uniformly squashed and well-separated nuclei are essential for an accurate DNA determination by scanning densitometry. We have found that the megagametophyte of *Pinus* is soft and easy to squash and can be readily used for precise and accurate measurements of the DNA content by both Feulgen scanning densitometry and flow cytometry using propidium iodide [72].

CONIFER RETROTRANSPOSONS

Although gymnosperms have enormous genome sizes, very little is known about their genomic structure and composition. Reassociation kinetics have shown 75% of the *Pinus* genome to be repetitive DNA [85,86] which apparently contains retrotransposons. Retrotransposons that proliferate by reverse transcription of RNA intermediates are the major class of mobile genetic elements in plants [7,9,11,14]. Retrotransposon elements, IFG7 from *P. radiata* [87] and TPE1 from *P. elliottii* [88], are both highly amplified in their respective genomes. The TPE1 element is uniformly dispersed over all 12 chromosome pairs and appears to be inactive. It is conserved in several *Pinus* species

as well as *Picea*, *Taxodium*, and *Gingko* [88]. Retrotransposon amplification may be the means by which plant genome sizes increase, but the mechanisms by which they decrease are not known [29]. Two mechanisms for reduction, resistance to retroelement amplification, and restricting contact with retroelements have been suggested [29]. Suppression/methylation processes may also be associated with both mechanisms [89]. Although changes in the genome size have been noted in relation to environmental stress, the nature of the repetitive entities and the mechanisms involved have not been well characterized. One of the suggested roles for the amplified repetitive DNA is that of altering gene function [29].

CONIFER DNA CONTENT AND NUCLEOTYPIC DEVELOPMENT

The conifer DNA content correlates to nucleotypic parameters such as nuclear volume and total length of the haploid chromosome complement [90,91]. There also appears to be a direct proportionality between the DNA content and tracheid dimensions such as length and diameter in a ''western'' subset of *Pinus* species [92]. This can be extrapolated further with a consideration of the relationship between these two parameters and the indices of growth and development of individual trees. Bailey [93] found a correlation between tracheid size and stem diameter in conifers, and a similar relationship has been observed in *Pinus*. DNA content data have been related to published data sets of growth and development [94]. There appears to be a direct positive relationship between the DNA content and the duration of tree development [92]. A significant relationship between the DNA content and the seed volume has been observed in several *Pinus* species [66,72].

ENVIRONMENTAL CORRELATES AND CONIFER NUCLEAR DNA CONTENT

Chronic stresses have been important agents in the evolution of conifers [94]. For example, the effects of water-deficit stress (WDS) have a strong influence on the allocation of maternal resources (seed weight) and tree size [94]. The habitats of *Pinus* species cover widely differing ecological areas. Rehfeldt and Lester [95] have suggested that the particularly variable environments to which pioneer tree species are subjected have led to the evolution of genetic systems with a high degree of developmental homeostasis or a fairly constant physiological and morphological response to a range of environments. Such homeostasis has been postulated to be due in part to redundant DNA control systems of high DNA–content species or provenances which activate the same developmental gene systems in response to varied stimuli [67]. However, little is known about the functions of repetitive DNA and any roles it may have in gene regulation. Environmental conditions can greatly alter the nuclear DNA and the phenotype in some plant species, and these are heritable to subsequent generations [20,96,97]. However, in conifers, the relationship of intraspecific variation in the DNA content to the environment is still unresolved [53,66,71,75,78,98,99]. The intraspecific variation has been reported to vary from the lowest to highest by a factor of 1.5–2.2 in five conifer species [49,50,72,84], but the DNA content was uniform and constant in six *Pinus* species [66,69,98]. Furthermore, two provenances of *P. wallichiana* [66] from areas representing extremes in water availability showed no differences in their DNA content.

Latitude and Elevation

The intraspecific DNA content per cell was related to the latitude of distribution among sources of *Picea glauca* [52]. Western sources revealed an inverse relationship between DNA per cell and growth, whereas eastern sources did not. The DNA values of different seed source populations of four conifer species measured along latitudinal gradients showed that populations from high latitudes had more DNA per nucleus than those collected from lower latitudes [52,53,100,101]. For *Picea*

sitchensis, the DNA content increased with latitude, with the more southern provenances having nuclear volumes and DNA contents one-half that of the more northern provenances [53,90]. However, in two *Pinus* species, latitudinal differences in DNA content were not observed [76,98]. Intraspecific variation can also be associated with elevation. Transcending an increase in elevation from 600 to 1500 m in New England, there was a detected increase in the nuclear DNA from 47.5 to 50.7 pg in *Picea rubens* [71]. These data provide evidence for the effects of temperature on the DNA content as theorized [55,63], but the relationships to the tracheid size and conductivity have not been investigated.

In conifers, the DNA content correlates to nucleotypic parameters such as an increase in the nuclear volume and total length of the haploid chromosome complement [90,91]. From an interspecific perspective, gymnosperm species with smaller nuclear volumes and smaller DNA amounts per cell tend to display greater geographical distribution than species with larger amounts of DNA [68]. Plant species from northern latitudes tend to have larger nuclear volumes than plants of the same or closely related species from southern regions [90,102,103]. Cavalier-Smith [63] suggests that this reflects an increased selection for large tracheids and large nuclei in cambial cells in cooler climates with shorter growing seasons. Ohri and Koshoo [66] showed that there is an association between the very high DNA content of *P. gerardiana* with a temperate and xeric habitat. However, these relationships are not always demonstrated in other species. Populations of *Picea rubens*, with a high DNA content, appear less resistant to high elevational environmental stresses than those of *P. mariana*, with a low DNA content [71].

Temperature and Precipitation

Seasonal variations in temperature and precipitation are considered to be the most important climatic factors limiting the geographical distribution of a given species [104]. McCune [105] concluded that convergent evolution had occasionally occurred with *Pinus* species, but shared ancestry and evolutionary divergence produced by a diversity of environments were more important.

Grime and Mowforth [55] suggest that selection operates on the genome size through a differential effect of temperature on cell division and cell expansion, where at low temperature, cell expansion is inhibited to a lesser degree than cell division. According to their thesis, growth should be dominated by large cells and high DNA in cooler environments, whereas growth should be facilitated by more rapidly dividing cells with less DNA in warm conditions [55]. In addition to temperature, Grime and Mowforth [55] hypothesize that natural selection has operated on the nuclear DNA content through differential sensitivity of the cell growth to moisture availability. The cell volume and DNA content may thus be an important parameter in the plant adaptation to WDS environments [42].

Price et al. [106] and Cavalier-Smith [63] suggested that the evolution of xylem tissues has been impacted by the evolution of genome sizes. Angiosperms with vessel elements could maintain good sap flow with smaller cell volumes, whereas gymnosperms continued strong selection for large tracheids. Cavalier-Smith [63] argued further that this change in xylem construction with vessel elements made possible the evolution of herbaceous annual and ephemeral angiosperms with their small, rapidly dividing cells, small-volumed conducting cells, and low DNA content. On the other hand, gymnosperms with their strong selection for large tracheid size maintained a high DNA content and a slower rate of development which prevented them from evolving an annual growth habit [63]. The influence of temperature on the DNA content and cell volumes may be related to the conductive properties of the xylem [63]. In some conifer species, the DNA content has been reported to vary by a factor of two [107], and in many species, there is a continuous cline in the Northern Hemisphere from a low DNA content in the south to a high DNA content in the north [53]. Because the viscosity of water increases by a factor of two as the temperature drops from 25 to 0°C, hydraulic conductivity would decrease unless the diameter of the tracheids increases. In conifer wood, the cambial cells are already quite large [108,109], and the first xylem cells laid down during the cooler spring growth season with ample soil water available are large [110].

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

Temperature

In addition to moisture, it is theorized that natural selection operates on the genome size through temperature influences on cell division and expansion. Grime and Mowforth [55] proposed that growth in cooler climates is dominated by large cells and high DNA. By regression analysis, we have considered the relationship between the DNA content and the minimum daily air temperature for each month of the year in the habitat for each of the 18 *Pinus* species, but no correlation was observed (data not shown). The absence of such a relationship may reflect the limiting effects of extremely cold climates on plant metabolism and growth. However, a significant relationship exists between the nuclear DNA for *Pinus* species [72] and the mean daily maximum air temperature of their habitats [111] if only the four summer months are considered [72]. This relationship indicates that *Pinus* species with a high DNA content are associated with cooler climates.

The inverse relationship between the DNA content and the habitat air temperature supports the hypothesis of Cavalier-Smith [63], who contends that there is selection for a large tracheid volume and for a large nuclei in cambial cells in cooler climates with shorter growing seasons. To address this hypothesis further, a measured *Pinus* DNA–content data base [72] has been related to several published data sets of tracheid dimensions [112–115]. The data for both diameter and length cluster the species in two major groups: group I with DNA content ranging from 21 to 25 pg and group II ranging from 26 to 30 pg. Group I comprises ''eastern pines'' (with the exception of *P. radiata* from a coastal, humid, and cool climate), whereas group II includes the ''western pines'' (with the exception of *P. strobus* from northern latitudes) which experience extremes of low precipitation and low temperatures [116].

Precipitation

The availability of the comprehensive data set obtained by Wakamiya et al. [72] allows one further to address the hypotheses relative to environmental influences on the DNA content. These DNA content data have been related to published precipitation data [117], and there is an inverse relationship between the DNA content of *Pinus* species and habitat annual minimum precipitation. Compared with mesic *Pinus* species where minimum precipitation is over 1400 mm, there is a 25% increase in the amount of DNA per cell in those species adapted to habitats with only 300 mm. *P. eldarica* has a high DNA content of 31 pg [72] and has been adapted to the semiarid climate in the southwestern United States [118]. These data indicate that a high DNA content is an adaptation to WDS environments among the species of *Pinus*. However, intraspecific variation between two *P. taeda* provenances from habitats of varying water availability was not evident [72]. It appears that there is a positive relationship between the DNA content and the tracheid size as long as cell expansion is not limited by low water availability (or perhaps extreme cold temperatures). That is, the relationship between the two variables is highly correlated with species from habitats of moderate to high-rainfall levels. For example, one of the group II species with a large DNA content (*P. lambertiana*, 29 pg, [76]) also has one of the largest tracheid sizes reported for commercial pines (diameter = 52 μm, length = 6 mm [112]). This strong correlation may be due to the fact that the habitat of this species has a high precipitation range of 840–1750 mm [116], and that large tracheids have resulted from large precursor cells expanded by water. Conversely, the high DNA content of one of the group II species, *P. monophylla* (30 pg [72]) associated with very small tracheids (diameter = 32 μm, length = 3 mm [112]), appears to be related to the low precipitation of its habitat (200–460 mm [116]). These cells may have the capacity to be larger, but were unable to expand because of limited water available for expansion. We postulate here that embolism and cavitation [119,120] were important factors which influence the tracheid volume in stressed environments. Nevertheless, it appears that the direct relationship between the DNA content and the tracheid volume as hypothesized by Price et al. [106] and Cavalier-Smith [63] is most demonstrated in *Pinus* species from habitats of moderate to high levels of precipitation, although more data are needed.

Because a direct relationship between the tracheid length and the diameter in *Pinus* is evident, it is reasonable to conclude that the DNA content is most likely proportional to the tracheid volume.

Furthermore, it is appropriate to consider the relationship between the tracheid volume and hydraulic conductivity (L_p), because the adaptive, evolutionary significance of the nuclear DNA content can be more adequately assessed if it is related to the physiological processes of water transport. The Hagen-Poiseuille equation [121] predicts that the volume of water moving in a unit time along a tracheid is proportional to the fourth power of its radius. Measurements of the xylem hydraulic conductivity (L_{px}) in *Pinus* stem axes of 17-month-old seedlings indicated that there is a direct relationship between the L_{px} and the DNA content [122], but this was not observed in 21-month old seedlings [123]. These contradicting observations were related to differences in (a) seedling age, (b) ages of the cell types analyzed, and (c) methodology associated with the determination of the cell dimensions [123]. However, *Pinus* species with large genome sizes had thick cell walls and small ratios of lumen radii to cell wall thickness in their conductive cells, and those species lost their turgor to tissue dehydration at water potentials lower than those of species with a small genome size [123]. These characteristics of WDS tolerance may be contributing factors in establishing the inverse relationship between the genome size in the genus *Pinus* and the lowest mean precipitation in their natural habitats [72].

In addition to the tracheid diameter, the hydraulic conductivity is also related to the number of tracheids per unit of the stem transverse area. In *Cyrtomium falcatum* (holly fern), the overall decrease in the hydraulic conductance was strongly influenced by a decrease in the number of tracheids and the diameters of the largest tracheids [124]. Estimates based on the Hagen-Poiseuille equation consistently overestimated conductance, but this constant relationship supports the assumption that the conduit number and diameter are the principal determinants [124]. In *Psilotum nudum* [125], decreases in both the tracheid number and the lumen diameter were directly related to decreases in the hydraulic conductance. A model based on the Hagen-Poiseuille relation indicated that calculated conductances were in agreement with those measured [124], but for most woods, actual conductivities are 20–100% of the theoretical conductivities [120]. Furthermore, the conductivity advantages acquired by increases in the diameter became smaller as the tracheid diameter increased [125].

A correlation between the conductivity and the xylem cell diameter has not always been found. The hydraulic conductivity was not strongly correlated with the vessel diameter in 10 tree species, nor was it correlated with stem density [126]. In addition, there were no significant differences in the plant hydraulic conductivities (K_{plant}) between *Pinus taeda* seedlings from coastal versus interior ecotypes [127]. The K_{plant} describes the conductivity of water movement from the soil to leaves [128,129]. Large tracheid diameters could also be a detriment in stressful environments of low temperature and water deficits owing to embolism [119,120,130]. However, one of the advantages of gymnosperm tracheids as opposed to angiosperm vessels appears to be their capacity to localize embolisms [131].

CONCLUSIONS

A quantitative variation in the nuclear DNA content is apparently important in plant evolution, including adaptation to stressful environments. Natural selection may operate on the genome size through nucleotypic effects on cellular parameters such as cell volume and mitotic cycle time, and through differential effects of temperature and moisture availability on cell division and expansion. Large differences in the DNA content have spatial and temporal phenotypic consequences which profoundly affect when, where, or how plants grow both in relation to their global distribution and within a local community [132]. The variation in the DNA content may have considerable adaptive significance with far-reaching ecological implications and clearly illustrates that further, widely based comparative studies relating these correlations to the physiological bases of adaptation would be informative. There is a need to address the hypothesis that a quantitative variation in the DNA content is important to plant evolution which includes adaptation to stressed environments.

Data gathered with woody perennial genera indicate that conifer DNA contents do not relate

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

to the environment in the same way as those of annual herbaceous species. Unlike many perennial angiosperms, gymnosperms appear to have adapted to stressed environments by maintaining a large genome and large cells. Large cells are thought to enhance the hydraulic conductivity which then may be related to the DNA content, but the data are conflicting and depend on the age of the plants studied and the methodology used. *Pinus* species with large genome sized maintain their turgor at lower water potentials than do species with a small genome size when subjected to WDS. This property may contribute to the apparent tolerance to low precipitation environments observed with *Pinus* species with a high DNA content.

If there is a positive relationship between the tracheid structural and conductive properties and the genome size in conifers, this would provide credence to the theory that the nuclear DNA content is important in the evolution and natural selection of conifers. This relationship between the DNA content and a physiological parameter would be informative from an adaptive standpoint. It also would provide an additional explanation for the large genomes associated with conifers compared with most other plant species. Better understanding of these relationships would contribute to our knowledge as to how gymnosperms respond and adapt to changes in the environment.

Osmoregulatory Role of Proline in Plants Exposed to Environmental Stresses

Bruria Heuer
Institute of Soils and Water, ARO, The Volcani Center
Bet Dagan, Israel

INTRODUCTION

Plants face frequent periods of environmental stress that impairs their growth and reproductive capacity. Environmental parameters with deleterious effects include unfavorable climates, water stress, and inappropriate soils. Restrictions of plant growth cannot be attributed to one single process, because plant growth is the result of many integrated and regulated physiological and biochemical processes. To survive and maintain a minimal growth potential, plants must conform to these extreme environments entailing adaptive changes in metabolism and cell composition. Of the various mechanisms enabling plants to cope with water stress, the most common is the accumulation of intracellular solutes, such as sugars and free amino acids. The most frequent nitrogen-containing compounds that accumulate in plants subjected to environmental stresses are amides (glutamine and asparagine), amino acids (arginine, proline, citrulline, and ornithine), and polyamines (putrescine) [1]. The accumulation of proline on dehydration due to water deficit or increasing osmotic pressure is the most recent information concerning the osmoregulatory role of proline in environmentally stressed plants.

OSMOREGULATION OR OSMOTIC ADJUSTMENT

Water deficits have been shown to induce a lowering of the osmotic potential in crops as a means of maintaining their turgor [2]. This decline in the osmotic potential as a response to water deficit can be achieved by solute accumulation within the plant cell or by a decreased cell volume leading to an increased concentration of osmotic solutes as water leaves from the vacuole. These phenomena are described as osmoregulation and osmotic adjustment. *Osmoregulation* has been defined as ''the regulation of osmotic potential within a cell by the addition or removal of solutes form solution until the intracellular osmotic potential is approximately equal to the potential of the medium sur-

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

rounding the cell'' [3]. *Osmotic adjustment* refers to the lowering of the osmotic potential due to the net accumulation of solutes in response to water deficits or salinity [3]. Osmotic adjustment is an important mechanism in drought tolerance, because it enables (a) a continuation of cell expansion [4,5]; (b) stomatal and photosynthetic adjustments [6]; (c) better plant growth; and (d) yield production [7]. The compounds involved in osmotic adjustment are mainly soluble sugars, potassium, organic acids, chloride, and free amino acids [8,9]. The degree of the osmoregulatory processes is affected by the rate of stress, stress preconditioning, the organ type and age, and the genetic variation between and within species [10]. It is accepted that the nontoxic compatible organic solutes accumulate in the cytoplasmic compartment of cells and inorganic ions toxic to metabolic processes are restricted to the vacuolar compartment. Considerable research has been conducted to characterize the accumulation of proline, a compound known to contribute to the osmotic adjstment and tolerance of plants exposed to unfavorable environmental conditions. How much of a role it plays is still controversial and is discussed in detail in the following sections.

PROLINE METABOLISM

Proline metabolism is a typical mechanism of the biochemical adaptation in living organisms subjected to stress conditions.

Proline Synthesis

Two pathways of proline biosynthesis are known in higher plants: the glutamate pathway and the ornithine pathway (II). These pathways seem to be identical for all organisms. Most evidence about the roles of particular enzymes in proline biosynthesis or catabolism has been obtained from microorganisms.

Proline Catabolism

The ability of plants to degrade proline through an oxidation process has been shown clearly [11]. The catabolism of proline involves the conversion to glutamic acid via pyrroline-5-carboxylate reductase and a subsequent metabolism of glutamate by the Krebs cycle reactions that release CO_2 as the endproduct. Oxidation of proline is catalyzed by proline oxidase and requires oxygen as an oxidant.

Endproduct Inhibition

Proline manifests a conspicuous ability to control its own biosynthesis. Exogenous application to plant tissues of an amount of proline sufficient to increase the endogenous pools enhanced the rate of proline oxidation as a result of a feedback inhibition process [12,13]. It is known that proline oxidase, one of the enzymes involved in proline degradation, can be induced by high concentrations of proline [14,15]. Feedback inhibition of proline synthesis does not occur under water-stress conditions.

Impact of Environmental Stresses on Proline

Extensive research in this area has revealed proline accumulation as a universal response of plants under stress. Proline accumulation due to water or salt stress results from a stimulated synthesis in the tissue, an inhibited oxidation, or an impaired incorporation of proline into proteins. Clearly, under such conditions, the mechanisms of feedback inhibition cannot function. Indeed, this was proven by Boggess et al. [12], who showed that proline does not inhibit its own synthesis in wilted barley and tobacco leaves. The increased synthesis of proline due to wilting seems to be related to the first step of this synthesis. On the other hand, water stress and salinization inhibit proline oxidation in

TABLE 1 Accumulation of Proline in Water- or Salt-Stressed Tomato Leaves[a]

	Proline content ($\mu M\ g^{-1}$ fresh weight)	
Salinity level	high soil moisture	low soil moisture
Nonsalinized	8.83	13.27
Low salinity	15.64	15.77
High salinity	18.31	21.47

[a] Plants were irrigated with saline water (4 or 10 dS m^{-1}) or irrigation was withheld for 7 or 14 days.

the mitochondria and alter the permeability of the mitochondrial membranes [16–18]. Further, the incorporation of proline into protein is inhibited by water stress, thereby also leading to proline accumulation under stress conditions [19]. The step affected in protein synthesis is probably the translation step [20]; however, this process is not obligatory, because proline accumulation was observed when protein synthesis inhibitors, such as cycloheximide, were applied [21]. The state of the hormonal balance in plants is suggested to play a considerable role in the mediation of proline accumulation under water or salt stress [21]. The key role in the osmotic adaptation of plants has been ascribed to abscisic acid (ABA).

In conclusion, the reduction in turgor is accepted as the primary trigger of proline accumulation in plants subjected to conditions of drought and salinity. The loss of turgor activates a complex sequence of adaptive events correlated to the level of stress, plant tolerances, and plant growth.

PROLINE ACCUMULATION AS AN OSMOREGULATORY RESPONSE

The accumulation of proline seems to be associated with adaptation to temperature stress. Free proline concentrations increased both under high [22] or low temperatures [23,24], and proline could serve as a stress indicator in plants exposed to these unfavorable growth conditions. Heavy metals or herbicides are other environmental factors that induce proline accumulation in plants. *Vicia faba* plants grown in hydrocarbon-polluted soils accumulated high levels of proline [25]. High-Pb concentrations reduced sunflower plants' biomass but increased the concentration of free proline [26]. The leaf proline content also increased in pea plants [27] or *Vigna radiata* [28] grown in nutrient solutions containing high-Cd concentrations. Chlormequat given to soybean plants increased the leaf proline content [29]. The foliar application of paraquat and diquat to *Parthenium hysterophorus* resulted in a reduction of the proline level 48 h after application followed by an increase 72 h after spraying [30]. The foliar application of fomesan, imazaquin, metobromuron, and metolachlor to soybean plants resulted in reduced levels of proline and some other amino acids, probably because of a disturbed protein synthesis [31]. Chlorsulfuron, norflurazon, and tri-allate increased the proline content in pea and *Vicia faba* [32]. Increased levels of proline were also found in barley plants infested with aphids because of low water potentials [33]. It is suggested that the changes in proline could be considered as a protective/adaptive mechanism against expected injuries resulting from pollution or herbicides.

Proline accumulation in dehydrated plant tissues was first noted in 1954 by Kemble and MacPherson [34]. Further experiments showed that the de novo synthesis of proline was involved, as the amounts were greater than those released by proteolysis. Proline accumulation was observed in many species as a result of exposure to water or salt stresses. For example, withholding irrigation or irrigation with saline water increased the proline content in tomato leaves (Table 1). Several

TABLE 2 Proline Accumulation in Sugar Beet Disks as a Function of Exposure Time to Stress[a]

Osmotic potential (MPa)	Proline content ($\mu M\ g^{-1}$ fresh weight) after stress application (h)			
	1	2	6	18
−0.2	0.32	0.34	0.37	0.48
−0.4	0.34	0.32	0.41	0.89
−0.8	0.35	0.27	0.41	1.02
−1.2	0.30	0.33	0.43	1.93
−1.6	0.30	0.35	0.49	4.15

[a] Disks were floated on solutions of different osmotic potentials for several hours and then the proline content was determined. The osmotic potential of the solution was lowered by the addition of PEG (polyethylene glycol) 6000.

reports correlate this phenomenon with stress resistance indicating that a better performance and survival can be expected in species that accumulate proline. Much evidence is available to corroborate the proline action as a compatible solute regulating and reducing water losses from dehydrated cells. The increase in the proline content during water stress is inversely proportional to the initial proline concentrations in plant organs [35]. It was found that the generative parts of bean plants contained considerably lower concentrations of proline than the vegetative parts after withholding water. The accumulation of proline during tissue dehydration is time dependent (Table 2). Diurnal changes in the proline content were also reported [36]. The accumulated proline is lost rapidly as a result of recovery from water stress but not as an immediate response to salt removal from the media.

All of the points just mentioned are addressed in detail in the following sections.

Osmotic Adaptation of Bacteria and Algae

Generally, microbes respond to water potentials by accumulating intracellular compounds that are compatible with the cellular metabolic functions. There is a natural ranking or differing osmolyte preferences among species of bacteria [37]. *Azotobacter chroococcum* accumulates trehalose and glutamate, *Azospirillum brasilense* accumulates proline and glutamate, and *Klebsiella pneumoniae* accumulates proline and trehalose [38]. It was observed that osmotically stressed cells generally favor the shift from glutamate to trehalose or proline as the culture ages or as salt levels increase, because they provide better protection for long-term adaptation to the new growth conditions. The mechanism of osmotic adaptation in these organisms can be attributed to an enhanced osmolyte uptake from the medium or to an increased net osmolyte biosynthesis. Partial alleviation of salt stress was obtained by adding low concentrations of proline or betaine to the growth medium of *Thiobacillus ferroxidans* [39]. Similar results were obtained for *Rhizobium* species [40]. In response to increased salt concentrations, algae also synthesize osmoregulatory solutes to counterbalance the low water potential of the growth media. Proline plays a key role in the osmoregulatory mechanism of *Chlorella autotrophica* (a marine microalga) when exposed to high salinities [41]. In this alga, proline accumulation begins immediately after an osmotic shock without a lag phase. This alga is not dependent on protein synthesis and requires light, because photosynthesis supplies the required energy for proline biosynthesis.

Accumulation of Proline in Callus Cultures and Isolated Cells

Callus cultures of rice, adapted to grow under increasing levels of NaCl, accumulated considerable amounts of free proline compared with unadapted cells [42]. This trait was not lost when the cells were transferred through 10 passages in the absence of selection pressure and regrown on salt.

On the other hand, mature embryo-derived calli from rice cultivars differing in their salt tolerance also accumulated proline when exposed to NaCl, KCl, or mannitol [43]. This accumulation did not depend on the nature of the stressing agent or the stress intensity and did not appear to be involved in osmotic adjustment; therefore, it was considered to be a symptom of injury in the stressed rice calli and not an indicator of resistance. In an embryogenic callus culture of lemon, selected for resistance to salinity, the proline concentration significantly increased as compared with control cells [44]. The transfer of salt-tolerant cell cultures of alfalfa to NaCl-containing medium resulted in a 10-fold increase in proline concentrations [45]. In *Brassica napus*, both unselected and tolerant calli responded to water stress by osmotic adjustment and proline accumulation [46]. Increases in proline concentrations were approximately linear in tolerant calli, reaching a maximum of 175 dry weight and 520 μM in unselected calli. This accumulation was correlated with growth inhibition and negatively correlated with the culture age for tolerant calli. Callus cultures of *Medicago sativa* accumulated proline in response to NaCl [47]. This accumulation was enhanced by calcium and was positively correlated with salt tolerance. The salt tolerance of sugar beet calli was also accompanied by a significant increase in the proline concentration under conditions of high salinity [48]. The proline content in a callus culture of pearl millet grown in 1% NaCl increased more than 20-fold compared with nonsalinized controls [49]. Exposure of tobacco callus cultures to osmotic shock greatly enhanced the proline accumulation in proportion to the amount of absorbed sorbitol [50]. NaCl-resistant cell lines of tobacco increased the proline content within 5–10 h after transplantation to a selective medium. In the wild strain, the proline content remained unchanged over a 24-h period [51,52]. A correlation between the viability of cells in a saline environment and the proline content was observed [52]. The intracellular proline concentration was positively correlated with the osmotic potential indicating that proline was a component of the osmotic adjustment of the cells [53]. Glutamate was the main source of the newly produced proline, and the relative contribution of the catabolic pathway was small. Cell lines selected for resistance to salt stress responded to water stress by accumulating markedly more proline than the wild type [52]. This response was stable through at least eight generations and was fully reversible. Similar results were obtained with cultured cells of a salt marsh grass (*Distichlis spicata* L.) [54]. Most of the accumulated proline effective in osmoregulation was found in the cytoplasm. Therefore, it plays a minor role in the osmotic adjustment of the vacuole. Cells maintained a cytoplasmic proline concentration at least one order of magnitude greater than that of the vacuole. Proline accumulation was inhibited by cycloheximide but not by actinomycin D. This indicates that mRNA translation, not mRNA transcription, is required before proline production. Reports are also available on a preferential accumulation of proline in nontolerant cells, as opposed to tolerant cells, indicating a dependence on a salinity threshold [55].

Cultured cells of sorghum exposed to water stress by the addition of polyethylene glycol (PEG) to the growing media increased the proline content significantly [56]. The magnitude of this increase was not correlated with the drought tolerance of the individual varieties ruling out the role of proline as an osmoprotectant in sorghum, as well as in other cereal crops.

Proline Levels in Germinating Seeds

Most of research on proline as an osmoregulatory compound has been carried out on the vegetative parts of the plants. Little attention has been paid to the reproductive organs, especially seeds. Recently, information was released on the existence of osmotic adjustment of seeds under stress conditions. Salt stress increased proline accumulation in the cotyledons and roots of germinating ground-

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

nut seeds [57]. Proline accumulated in the endosperm and radicles of germinating barley seeds with increasing NaCl concentrations in the growing media [58]. This proline probably originated from the degradation of stored protein in the endosperm. Under increasing levels of salinity, germinating seeds from salt-tolerant cultivars of rice contained higher levels of free amino acids than salt-sensitive cultivars [59]. In contrast, irrigation of Cajeme wheat with saline water resulted in a continuous decrease in free proline in the grains [60]. This decrease was associated with increased protein concentrations suggesting either that the rate of protein incorporation was accelerated under salinity or that free proline accumulation was stunted in other parts of the plant.

Osmotic Adjustment in Halophytes

Halophytes are plants capable of growing and reproducing in highly saline environments. These plants usually absorb large amounts of NaCl, which is believed to be sequestered in the cell vacuoles; otherwise, enzymatic activity would be impaired. Proline, known to accumulate in the cytoplasm to balance the osmotic potential of the accumulated salt in the vacuole, does not play a role in the osmotic regulation of halophytes. For example, in halophytic Chenopodiaceae, such as *Suaeda monoica*, *Atriplex spongiosa*, and *Arthrocnemum fructicosum*, proline accumulation was observed only at high inhibitory salinities, not at low salinities, promoting normal growth [61,62]. Similar results were obtained with the halophyte *Mesembryanthemum crystallinum* grown at 400 mM NaCl [63]. Proline accumulation preceded the shift of CAM in these plants but only under light [64]. The results suggested that, in *Mesembryanthemum*, proline has a bifunctional role in the acclimation to high salt stress: an osmoregulatory role in the light and as a substrate for dark respiration to supply energy to the compartmentation of ions into vacuoles in the dark. Proline concentrations in *Spartina* varied with N availability, although the higher accumulation could not alleviate the growth inhibition caused by the high salinity level [65].

Changes in Proline Concentration in Cultivated Crops Induced by Water and Salt Stresses

The short- or long-term exposure of crops to conditions of water or salt stress are very common. Besides diurnal variations in environmental factors, approximately 30% of the agricultural area is affected by drought or salinity. This entails an adaptation of crops to these deleterious conditions to survive. As mentioned previously, one way to achieve this goal is by undergoing osmotic adjustment through a net accumulation of organic compatible solutes, such as proline. Much research has been devoted to this issue, and many reports on proline accumulation in plants under stress conditions are available. In this section, the most recent knowledge about the response of cultivated crops to stress, with respect to proline accumulation, is presented.

Wheat

Progressive water stress imposed on wheat resulted in proline and glycinebetaine accumulation [66]. This was the case for water stress encountered in the field or in laboratory experiments, particularly when developing gradually rather than all at once [66,67]. The accumulated proline was completely metabolized on rewatering. As far as salt stress is concerned, free proline accumulation was related to the salt tolerance of the wheat cultivar as well as to the nature of the salinity imposed [68]. Thus, the free proline content in *Triticum aestivum* decreased with NaCl salinity but increased with $CaCl_2$ and $MgCl_2$, salinities [69,70]. On the other hand, other studies reported an increase in the proline content following increased levels of NaCl [71]. Cultivar Kharchia-65, considered a salt-tolerant genotype, showed a higher level of proline than other cultivars at all growth stages except the mid grain filling stage [72,73]. Irrespective of the kind and concentration of salts, the free proline accumulation in wheat leaves increased with the plant age and occurred during the day, peaking toward evening [69].

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

Barley

The exposure of barley seedlings to mild or moderate concentrations of PEG for extended periods resulted in a proline increase in all tissues proportional to a reduction in water and osmotic potential [74,75]. Nevertheless, the findings showed that this increase was not the reason but the consequence of osmotic adjustment. As for wheat, when water stress was relieved, the proline concentration decreased [76]. On the other hand, the proline concentration in salt-shocked barley leaves remained high even after salt stress was relieved. As a result of salt stress, proline accumulated only when a threshold value was reached, and its concentration was directly proportional to the sodium concentration. Salinity increased proline synthesis from glutamate and decreased the rate of proline oxidation, a process known to take place in the mitochondria [77]. It was reported that the properties of mitochondria from NaCl-treated barley were modified [78], also contributing to the production of intermediary compounds that could be precursors of solutes such as proline. Correlations between the accumulation of abscisic acid (ABA) and proline were observed in water-stressed barley plants [79]. During water stress, plants lost their turgor inducing ABA production. When ABA levels exceeded a threshold level, they induced proline accumulation. In salt-stressed barley plants, turgor was maintained and therefore proline accumulation was induced without precursory ABA accumulation. Thus, the mechanisms that initiate proline accumulation in barley in response to water and salt stresses are probably different.

Sorghum

A correlation between a growth delay and proline accumulation was observed for sorghum seedlings exposed to salinity [80]. As in other plants, proline did not start to accumulate until a considerable amount of inorganic solutes was already present in the leaf cells, presumably in the vacuolar compartment [81]. The threshold value was 200 $\mu M\ K^+ + Na^+\ g^{-1}$ fresh weight, implying the involvement of proline in the osmotic adjustment of sorghum under severe conditions of stress. Water stress of sorghum plants, imposed by withholding irrigation [82] or by polyethylene glycol [83] induced proline accumulation in the leaves. Plant relief from water stress decreased its levels, although proline remained relatively high when compared with nonstressed controls.

Rice

The free proline content increased in 5-day-old rice seedlings subjected to salt treatments [84]. This was an increase of approximately 400% compared with nontreated controls and was more pronounced in the susceptible than in the resistant cultivar, although young leaves of all cultivars accumulated proline [85]. Similar results were obtained with a rice cultivar grown in sand cultures in the presence of NaCl [86], although in the latter case the salt-tolerant cultivars maintained higher concentrations of protein amino acids.

Thinopyrum, Agropyrum, and Pascopyrum

For *Thinopyrum, Agropyrum*, and *Pascopyrum*, an increase in the glycinebetaine and proline content is a common response to salinity [87]. Proline content was higher in older than in young, expanding leaves. The proline concentration increased in both *Agropyron* and *Pascopyron* as water stress increased [88]. It decreased in *Agropyron* but increased in *Pascopyron* as plant development advanced.

Pearl Millet

The proline content in pearl millet seedlings increased with increasing salt concentrations [89]. This was true for all salts tested: NaCl, KCl, Na_2SO_4, and K_2SO_4. The combination of sodium with chloride and sulfate was more effective in accumulating proline. It is suggested that the increased content of proline under conditions of chloride salinity may be due to an increased water deficit, whereas under conditions of sulfate salinity, plants may undergo complete osmotic adjustment.

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

Maize

The free proline levels increased significantly in response to water stress, favoring osmotic adjustment in maize seedlings [90], and mainly in the primary root tips [91]. The exposure of seedlings to NaCl induced a lower accumulation of proline than the exposure to PEG [92]. This is probably because of a decreased necessity to perform osmotic adjustment. It also depends on the way the plants were exposed to salt stress: gradually, leading to salt acclimation, or in one step, leading to a salt shock [93].

Cotton

Cotton plants subjected to water stress by withholding irrigation accumulated free proline to about 100 times the concentration of well-watered controls [94]. A high water potential threshold of about 1.7 MPa was required before proline started to accumulate. Both leaves and roots accumulated proline [95]. Within 48 h after watering, concentrations dropped to the control level. It is possible that proline is capable of functioning as a source of respiratory energy and N during the rewatering phase.

Sunflower

In sunflower, the free proline levels increased in response to water stress, contributing to osmotic adjustment, but their absolute values were very low [96]. Considerable variations were detected among different genotypes. Similar to many other plants, accumulation levels were much lower in NaCl-treated sunflower plants.

Safflower

Salt-tolerant accessions of safflower grown in salinized sand cultures accumulated significantly more proline in their leaves than salt-sensitive accessions [97]. This suggested that the salt tolerance of safflower is associated with a high accumulation of free amino acids in the leaves.

Soybean

The proline accumulation in soybean plants exposed to NaCl concentrations, increasing up to 100 mM, was culture specific [98]. The proline levels were inversely correlated with the tolerability of the salinity stress. Moreover, their accumulation was associated with chlorosis and plant injury and was therefore of no protective value.

Pea

Exposure of pea plants to 120 mM NaCl in the nutrient solution increased the amount of free proline in the roots [99]. The proline content represented approximately 3% of the total content of free amino acids. In pea shoots, potassium mediates proline accumulation [100], since an excess of endogenous K or a low Na/K ratio favor this phenomenon.

Chickpea

Both chloride and sulfate salinities enhanced proline accumulation in chickpea leaves [101]. However, the proline content was higher under conditions of chloride than sulfate salinity. Salinity also favored proline accumulation in pod shells and seeds [102].

Indian Mustard

Salt-tolerant cultivars of Indian mustard accumulated almost 80% more proline than nonsalinized controls, but this increase was only 64% higher in salt-sensitive than in salt-tolerant cultivars [103].

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

Perhaps the higher accumulation of proline observed in salt-tolerant plants contributed to a better resistance to severe salt shock by lowering cell osmotic potentials and by maintaining turgor.

Oilseed Rape

Nutrient, salt, and osmotic stresses caused proline accumulation in oilseed rape plants [104]. The highest proline accumulation resulting from nutrient stress was demonstrated in the leaves and stems grown under conditions of Ca deficiency. For example, the proline levels in the stems were 50 times higher then in controls. Potassium, P, and Fe deficiencies caused a much lower proline accumulation. Nitrogen deficiency did not stimulate proline accumulation. The function of proline in nutrient-stressed plants is not clear. It was suggested that proline is capable of preventing protein degradation and enzyme inactivation. Salt stress caused differential enhancement in the proline level in *Brassica juncea* L. seedlings and leaf tissues at different developmental stages [105] as a result of the activities of proline biosynthesis of enzymes. At the same time, the activity of the proline-degrading enzyme, proline oxidase, decreased under salt stress.

Alfalfa

Water stress imposed on alfalfa plants by withholding irrigation stimulated proline accumulation in leaves and nodules [106]. The threshold water potential triggering such an accumulation was higher in nodular tissues, suggesting that, under severe water stress, nodular metabolic enzymes and structural proteins may be protected by this process. The proline accumulation in plant tissues also can be considered a soluble N sink, because it coincided with a decline in soluble protein. Salt application to alfalfa plants yielded only a slight accumulation of proline [107].

Tomato

The proline content increased by 40% in tomato plants growing in salinized nutrient solutions [108]. Short-term exposure to salinity resulted in increased uptake rates of ions and proline production in the salt-tolerant wild type of tomato but not in the salt-sensitive domesticated plants [109]. During long-term salt exposure, both species were able to adjust osmotically and both exhibited decreases in proline levels. A specific effect of nitrate on proline accumulation at high salinities was observed by Heuer and Feigin [110]. Less resistant forms of three tomato species showed a greater increase in the free proline content under saline conditions. Tomato plants subjected to drought by withholding irrigation adjusted osmotically by accumulating reducing sugars and proline (111) indicating a glycophytic response involving a high energy cost.

Sugar Beet

Osmotic and drought-induced stresses of sugar beets resulted in a rapid increase in the proline content while the growth rate and fresh weight decreased [112]. Salt stress also induced proline accumulation, but the fresh weight remained unchanged at the beginning and increased with continuous incubation.

Potatoes

The proline content increased in the leaves and tubers concomitantly of potato plants with a rise in the osmotic potentials [113] indicating a possible role for proline in the plants' adaptation to salinity.

Teff

Salinity induced a 20-fold increase in the leaf proline concentrations in teff, probably because of tissue dehydration [114]. When teff plants were subjected to drought, proline increased sharply only below 28% soil saturation.

Lolium

Acclimation of *Lolium perenne* to drought and low temperatures increased concentrations of proline and amino acids [115].

Arabidopsis

In *Arabidopsis thaliana* plants subjected to low water potentials, the proline accumulation was significant as a result of a de novo synthesis [116]. Proline formed 17–26% of the total amino acid concentration in reproductive tissues but only 1–3% in vegetative ones.

Pistachio

A significant increase in the bulk pistachio leaf proline concentration was reported by Walker et al. [117] inplying its involvement in plant osmotic adjustment under salinity.

Eucalyptus

The proline content in the leaves of *Eucalyptus* plants varied according to the salinity level [118]. It increased under 300 mM saline stress but decreased under 600 mM stress and represented up to 25% of the total amino acids.

Aspen

Drought stress applied to three aspen (*Populus tremuloides*) clones caused both organ-specific and clone-specific changes in the amino acid concentrations, but proline was a minor constituent [119].

Conifers

Pinus sylvestris and *Larix sibirica* grown under drought conditions had a lower protein content but higher proline in their cambial zone or in the assimilating organs and tissues than normally irrigated trees [120]. In conifers, young shoots can be used as test subjects to indicate moisture deficit by the composition of their free amino acids.

Coffee

Water-stressed coffee plants accumulated proline mainly in mature leaves [121]. Its concentration was related to the osmotic potential at zero turgor and to the osmotic adjustment of the plants.

Mulberry

The accumulation of total amino acids and proline was observed in the roots and leaves of mulberry plants exposed to water stress [122]. The activity of the enzymes responsible for proline degradation, proline oxidase, and proline dehydrogenase were inhibited under stress conditions mainly in the roots.

Trigonella

Fenugreek plants (*Trigonella*) grown in nutrient solutions containing NaCl or PEG-4000 increased the proline content in their leaves (123).

Artemisia

No osmotic adjustment was found in *Artemisia*, a drought-tolerant shrub [124]. A small increase in proline was observed with rapid recovery following rewatering. It was concluded that, depending on cell elasticity, the differences in the osmotic potential of nonirrigated shrubs could be attributed entirely to changes in leaf water volumes.

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

Jojoba

Free proline was accumulated in high amounts in leaves of NaCl-treated jojoba plants [125]. The proline content increased with an increase in salt concentration in the growth medium, which decreased rapidly after the plant was restored to optimal growth conditions. The level of proline that accumulated in salt-treated jojoba plants was of a magnitude similar to that found in salt-treated halophytes.

Flowers

Azadirachta indica (Neem) and *Melia azedarach* (Persian lilac) irrigated with high concentrations of saline water showed an increase in the moisture and proline contents [126]. Proline also accumulated in poplar cuttings subjected to NaCl or PEG [127]. The most damaged cuttings showed the highest accumulation of proline. The increase in free proline was proportional to the temperature rise. Water- or salt-stress induced proline accumulation of *Dodonaea* [128], probably as a mechanism of drought resistance or salt tolerance. *Melanthera biflora*, a moderately salt-tolerant plant, accumulated proline in response to salt or water stress, which was mainly due to a decrease in the fresh weight/dry weight ratio [129].

Transgenic Plants

Proline production and accumulation has been correlated with tolerance to water and salt stresses. Consequently, the overproduction of proline in plants may lead to an increased tolerance against abiotic stress. To test this hypothesis, genes encoding relevant enzymatic activity were transformed into different species, mainly tobacco. The mothbean Δ^1-pyrroline-5-carboxylate synthetase, a bifunctional enzyme able to catalyze the conversion of glutamate to Δ^1-pyrroline-5-carboxylate, which in turn is reduced to proline, was overexpressed in tobacco [130]. The transgenic plants produced a high level of the enzyme and synthesized 10- to 18-fold more proline than control plants and the osmotic potentials of their leaf sap was less negative under water-stressed conditions. Transformation of the gene *ipt* from *Agrobacterium tumefaciens*, encoding isopentenyl transferase, into tobacco also resulted in increased levels of proline [131].

Varietal Differences in Osmoregulation

Many reports on the variation in genotypic resistance to environmental stresses are available. This response differs between cultivars adapted to certain growth conditions or regions as well as within species more or less tolerant to drought or salinity. One of the physiological mechanisms of tolerance is related to the ability to accumulate proline in plant tissue. Major differences in osmotic adjustment through proline accumulation were found in crop cultivars despite identical water potentials, implying genetic variations. Wheat varieties subjected to either drought or salinity accumulated proline in their leaves, stems, and roots [132]. This process was more obvious in the more sensitive cultivar, which maintained a lower relative water content in its tissues [133]. Compared with other wheat varieties, a higher accumulation of proline was found in the salt-tolerant genotype [72]. A total of 20 barley genotypes differing in their resistance to salinity, as well as chickpea plant types, showed no correlation between tolerance and proline accumulation [134]. In the F_1 generation of barley, the accumulation of free proline was significantly lower than in their parents [135]. The F_1 pearl millet hybrids revealed a significant negative correlation between yield and proline accumulation at a specified salinity level. Varietal differences in concentrations of Na, K, and proline within forage sorghum were not correlated with their differences in salt tolerance [136]. Most of the research carried out with rice varieties subjected to salt stress showed higher levels of proline in tolerant than in susceptible genotypes [137–139], although contradictory results are also available [50,140]. Significant differences in the proline concentration between the root tips of two corn cultivars were observed, but not as a result of salinity or calcium application [141]. No relation between the proline content in the leaves or tubers of potatoes and their relative tolerance or susceptibility to salinity

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

was found [86]. Two cultivars of black gram irrigated with saline water significantly increased the proline content in leaves [142]. However, the proline levels in the leaves were too low to play any significant osmoregulatory role in these cultivars. The leaf proline content was negatively correlated with salt tolerance in black gram. A total of 15 species of *Melalenca* tested for proline content after their exposure to stress conditions varied in response [143]. Accordingly, they could be classified into five groups based on the presence of proline analogues in addition to proline. In alfalfa plants, the most tolerant species exhibited the highest potential for proline accumulation in response to salinity [107,144] suggesting its involvement in the osmotic adjustment of salt-stressed alfalfa plants. The F_1 hybrids of wheatgrass (*Thinopyrum*) contained only trace amounts of proline, and this was also beyond a threshold of 200 μM Na + K g^{-1} fresh weight [145]. Proline was detected in the extracts of plants at dusk only under severe conditions of stress. As already mentioned, this threshold was also reported in sorghum and barley. Brassica somaclones, selected in vitro for salt tolerance, contained higher amounts of proline than the nonselected somaclones or the parent genotype [146]. The salt-tolerant somaclones had a stable genetic change for proline overproduction, which is possibly responsible for their survival when subjected to lethal salt levels.

In conclusion, the accumulation of proline in cultivars differing in their tolerance to stress is not universal and covers a wide spectrum of responses. Therefore, it is not always advisable to look for a specific selection criterion based on the proline content for purposes of selection and breeding.

Negative Response

Despite the abundance of reports on proline accumulation in plants growing under drought or salinity, a few others demonstrate a negative response as far as osmoregulation is concerned. For example, the contribution of proline to osmotic adjustment in legumes is of minor importance [147]. No significant accumulation of proline in the leaves of green gram seedlings [148] or maize plants [149] was observed when grown in sodium bicarbonate or sodium carbonate salts. Increased concentrations of chloride or sulfate salts or of PEG could not effectively stimulate proline accumulation in sugar cane leaves of a salt-sensitive variety [150]. Similarly, pigeon pea plants failed to accumulate proline at high-salinity levels [151]. The lack of this adaptive mechanism may explain the failure to develop salt tolerance in cultivated pigeon pea or sugar cane. In a more recent work, however, salt tolerance could be found in wild relatives of pigeon pea belonging to the genera *Atylosia*, *Dunbaria*, and *Rynchosia* but without correlation between salinity tolerance and proline accumulation [152]. In *Andropogon glomeratus*, a C_4 nonhalophytic salt marsh grass, proline played no role in osmotic adjustment, since very high levels of salinity are required to increase its concentrations [153]. One of the adaptive mechanisms suggested as being associated with osmotic adjustment is a restriction in cell expansion [154]. Extensin, a major plant cell wall glycoprotein in dicots, was found to be a hydroxyproline-rich glycoprotein [155]. Therefore, some work was carried out to determine changes in cell wall proteins induced by salt stress and expressed as changes in proline and hydroxyproline concentrations. No significant effect of stress on the proline and hyroxyproline contents was found in a purified cell wall fraction of sunflower [156]. Therefore, changes in the physicochemical properties of the cell wall accompanying osmotic adjustment appear to lie in other posttransitional modifications of extensin. Cell membrane stability of four *Arachis* cultivars exposed to PEG was tested in response to drought tolerance [157]. It was found that proline was not effective in controlling the physiological status of the cell membrane and its stability.

EXOGENOUS PROLINE APPLICATION

One approach to assess the metabolic consequences of proline accumulation in response to stress is to examine its exogenous application to whole organisms or tissues. Exogenously applied proline stimulated the growth of bacteria subjected to osmotic stress [158,159]. Proline has also been applied to higher plants to determine its ability to counteract the inhibitory effects of environmental stress, mainly water, or salt stresses. The addition of 100 mM proline to a Hoagland solution containing

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

120 mM NaCl neutralized the effect of salinity on pea plants [99]. Incubation of *Commelina communis* epidermal tissue in proline inhibited stomatal opening [160]. Exogenous proline had no effect on the germination of tomato seeds under water or salt stress [161] or on the ribosome stability in the presence of 250 or 500 mM KCl [163], but it increased pollen germination when exposed to brief temperature stress [162]. The addition of 10 mM proline to cultured barley embryos increased shoot elongation under saline conditions [164]. This effect was attributed to the ability of proline to decrease the leaf salt load. Proline allowed an enhanced K/Na discrimination in transport to the shoots and a better salt exclusion from the shoots with retention in the roots. The callus lines of *Cicer arietinum* grown in a medium containing 100 mM NaCl and 10 mM proline increased their fresh and dry weights [165]. Higher concentrations of proline (50 and 100 mM) inhibited the growth of NaCl-stressed as well as NaCl-nonstressed callus cultures of mung bean [166]. Optimal concentrations of proline increased the cellular levels of K and decreased Na and Cl levels. The presence of 1 or 10 mM proline in media containing 100 or 200 mM NaCl had little effect on the growth of the salt-adapted callus of rice [167]. Some concentrations significantly increased the growth of salt-unadapted callus. Spraying cotton plants grown under conditions of low soil water potential with proline solutions counteracted the effects of stress, especially at moderate and high stresses [168]. Proline (10 mM) inhibited the growth of salt grass suspension cultures in the presence of 260 mM NaCl [169]. Exogenous [^{13}C]proline inhibited the normal biosynthesis of proline that would have occurred in suspensions grown at this salinity level. Plants growing in saline environments usually accumulate large amounts of NaCl in their tissue. Because Na and Cl are inhibitory to a large number of enzymes, their presence in the cytoplasm should be minimal. Evidence of the compartmentation of electrolytes between the cytosol and the vacuole is available. The necessary osmotic balance between the two compartments is achieved through the accumulation of organic solutes in the cytoplasm. Proline is one of these compatible solutes. Besides playing an osmotic role, it should protect enzymes against denaturation or inhibition of activity. This could be determined easily by adding exogenous proline to the assay media or to crude extracts. Contradictory reports for differing plant species are known. For example, full protection of PEP carboxylase against NaCl inhibition was obtained in two Poaceae species with a proline concentration between 200–800 mM, and proline behaved as a competitive inhibitor in Chenopodiaceae [170]. Similar results were obtained from the activities of NAD-malate dehydrogenase, glucose-6-phosphate dehydrogenase, NADP-isocitrate dehydrogenase, and glyceraldehyde phosphate dehydrogenase [171]. Almost full protection of enzyme activities was obtained when proline was added at a molar ratio of 2:1 (protectant to salt) simultaneously with the addition of salt to the reaction media. No protection was found when proline was added after a 1-h preincubation of enzyme extracts with high salt concentrations. Extracts from air-dried leaves recovered almost fully after more than 5 h of preincubation in 1 M proline. Exogenous proline supplied to radish seedlings reduced tissue Hg levels owing to the inhibition of Hg uptake [172].

The method of using exogenous proline proved that mechanism of feedback inhibition of proline synthesis exists in fully turgid plant tissues but not in stressed tissues [12]. At this point, enhanced proline oxidation also cannot be ignored. Moreover, this technique emphasized the role of proline as a compatible solute involved in the process of the osmotic adjustment of living organisms.

PROLINE CONTENT AS AN INDICATOR FOR BREEDING PROGRAMS

The existence in plants of quantitative variations in the physiological trait of proline accumulation in response to water or salt stresses has suggested its possible consideration as a selection criterion for breeding programs. This was indeed recommended for cereals growing in Mediterranean environments [173]. Research performed with 12 paddy genotypes showed a stimulation of proline accumulation in the leaves of plants exposed to salinity [137]. The salinity index of yield showed a significant positive association with proline accumulation, prompting the suggestion of this physio-

logical trait as one of the promising indices for breeding salt-tolerant genotypes in rice. The magnitude of the proline response also was suggested for screening alfalfa plants for salt tolerance [144]. On the other hand, Ashraf [142] concluded that proline accumulation cannot be used as an indicator for salt tolerance in black gram and is thus unsuitable for breeding programs. The same is true for soybeans [174] and pearl millet [134]. It can be concluded that, in general, proline accumulation is specific to a genotype, and generalization over different varieties of a crop is not always possible.

CONCLUSIONS

The accumulation of proline in plants subjected to water or salt stress has been observed widely, although not universally. Several possible physiological functions have been ascribed to induced proline accumulation by water shortage. These functions include osmoregulation, a soluble N sink, a signal of senescence, and an indicator of plant resistance to stress. Proline may affect the solubility of various proteins, thus protecting them against denaturation under water-stressed conditions. An increase in the proline content may be associated with either enhanced biosynthesis, with stimulated proline oxidation, or an impaired protein synthesis. In general, proline concentrations are directly proportional to the salinity level or to the intensity of water stress. Genotype variations are very common; however, a positive correlation cannot always be found between the proline content and a plant's relative tolerance or susceptibility. Restoring plants to optimal growth conditions results in a rapid decline in the proline content. Additional studies are required to elucidate conclusively the role of proline in plant adaptation to stress.

Glutathione and Its Central Role in Mitigating Plant Stress

Chengbin Xiang and David J. Oliver
Iowa State University
Ames, Iowa

INTRODUCTION

Glutathione (GSH) is a tripeptide (γ-glutamylcysteinylglycine) composed of glutamate, cysteine, and glycine. Plants, like their animal and microbial counterparts, have evolved to rely on the unique properties of this chemical to protect themselves from a broad range of environmental stresses. The ability of GSH to protect plants from stress is dependent on the two chemical properties of the thiol group of cysteine. The thiol group can be oxidized and thus provides a source of reducing equivalents to buffer the plants from a number of oxidative stresses, including active oxygen species and air pollutants. In addition, the chemical reactivity of the thiol allows glutathione to complex with a range of organic and inorganic chemicals and thus protects plants from their potentially toxic effects. We will consider these two roles separately.

Role of GSH in Protection from Active Oxygen

Many environmental stresses cause plants to produce a family of reactive oxygen species (ROS), including superoxide ($O_2^{\cdot-}$), hydrogen peroxide (H_2O_2), and hydroxide radical ($^{\cdot}OH$) [1–5]. These reactive molecules are interconvertible and have the ability to react with and damage membranes, proteins, and nucleic acids. These reactive oxygen species can form when plants are exposed to radical-forming air pollutants, including ozone (O_3), peroxyacyl nitrates (PAN), SO_2, some halogenated hydrocarbons, NO, and NO_2. In addition, active oxygen can be generated when environmental stresses cause overreduction of the chloroplast or mitochondrial electron transport chains. Chloroplasts, for example, produce active oxygen under conditions of high illumination and low temperature [1–3]. Chilling conditions also appear to restrict the activity of the cytochrome portion of the mitochondrial electron transport chain and may result in H_2O_2 formation.

Glutathione is involved both directly and indirectly in quenching these free radicals [4–6]. The indirect reaction involves the ascorbate/GSH cycle where ascorbate is the ultimate electron donor for reduction of H_2O_2 to water and GSH is an intermediate electron carrier, as shown in

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

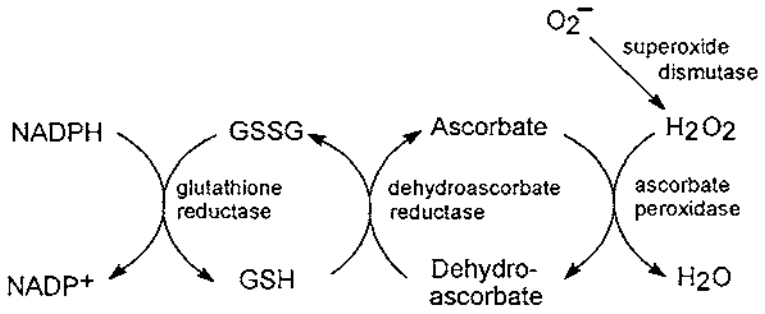

FIGURE 1 The ascorbate/glutathione cycle for quenching reactive oxygen species.

Figure 1 [6,7]. Ascorbate is also important in maintaining tocopherol (vitamin E) in the reduced state and, therefore, links GSH to the dominant free radical scavenger in membranes [8]. Direct reactions between GSH and ozone, PAN, and activated oxygen species have been documented and are implicated in GSH-based protection systems. It should be noted, however, there is substantial controversy about the role of GSH in protection from active oxygen and air pollutants [9], and some authors have even suggested that thiyl radicals produced by a single electron reactions with glutathione ($GS^{\bullet}$ and $GSSG^{\dot{-}}$ are a strong oxidant and reductant, respectively) might be involved in radical propagation and cell damage [10].

Role of GSH in Detoxification of Xenobiotics and Heavy Metals

Plants respond to a range of organic contaminants (herbicides are the best studied) by conjugating either contaminants or metabolites derived from them to GSH [11–13]. These chemicals, usually electrophilic alkylating agents, are then either stored or further metabolized into less toxic forms. The GSH conjugation reaction is catalyzed by one or more members of a family of proteins called glutathione S-transferases (GSTs). GSTs have been identified in a broad range of different plants and each plant probably has 5–10 different forms of the enzyme (isozymes) [14]. Each isoform will apparently conjugate a range of different organic compounds. GSTs are inducible. Exposure of the plant to an organic compound will result in a 3- to 10-fold increase in the level of the GST that conjugates that organic compound. Where investigated, the increase is transcriptionally controlled. A group of agrochemicals, Safeners, include chemicals that are capable of inducing GST isoforms that catalyze the formation of GSH conjugates with specific herbicides [14,15]. Treatment with Safeners, therefore, decreases the sensitivity of the plant to the herbicide (while presumably having little or no effect on weeds). It is assumed that these enzymes evolved to conjugate naturally occurring organics (e.g., hormones, cinnamic acid, anthocyanins) and thereby regulate their physiological effects or transport to the vacuole [11].

Perhaps one of the most fascinating aspects of the protection GSH affords plants is its ability to confer moderate levels of resistance to heavy metals, particularly cadmium and copper. Many heavy metals are toxic to plants. As a result, plants have a number of mechanisms for reducing heavy metal toxicity. These include limiting metal uptake, increasing metal efflux, and sequestering metals within the plants (usually in the vacuole) so that their interaction with enzymes is minimized [16]. These mechanisms are essential for plants to survive on land containing elevated levels of toxic metals. More recently, the ability of plants to concentrate some toxic metals has received renewed attention with the realization that it might be possible to use plants to remove metals from polluted soil. This process has been dubbed phytoremediation. The plants with the highest capacity

for bioaccumulation of metals are the hyperaccumulators. *Thlaspi caerulescens* has received the most study [17].

Metal sequestering within plant cells is usually carried out by organic or amino acids in the vacuole or by one of two groups of metal-binding, cysteine-rich polypeptides, metallothioneins and phytochelatins. Plants clearly contain metallothioneins [18–20] and overexpression of mammalian metallothionein genes in plants does confer some level of resistance to heavy metals [21]. Although the role of metallothionein in metal resistance in plants is still being debated, most scientists seem convinced that phytochelatins are important in conferring some level of metal (particularly cadmium and copper) resistance in plants [22,23].

Glutathione acts as a precursor for the synthesis of phytochelatins. Phytochelatins are composed of two or more repeating γ-glutamylcysteine units with a terminal glycine residue $(\gamma\text{-glu-cys})_n$ gly [22,23]. The structures of GSH and phytochelatins are shown in Figure 2. Plants synthesize phytochelatins in response to heavy metal (particularly cadmium) exposure (the mechanism of phytochelatin synthesis and the control of its synthesis is discussed later). Phytochelatins bind cadmium with a ratio of 1 Cd^{2+} per 2 SH groups [24,25]. The cadmium-phytochelatin complex is deposited within the vacuole. Work in Ow's laboratory has identified the phytochelatin transporter in the fission yeast *Schizosaccharomyces pombe* [26,27]. This transporter either works by itself to transport the cadmium-phytochelatin complex across the tonoplast or it transports the phytochelatin while a separate Cd^{2+}/H^+ counterport loads the vacuole with cadmium [26–28]. The complex would then form spontaneously within the vacuole. Experimental evidence seems to support the cytosolic formation of the cadmium-phytochelatin complex followed by its transport intact across the vacuole (Fig. 3). In rich medium or high cadmium concentrations, a larger molecular weight complex is formed that contains cadmium, phytochelatin, and sulfide. This complex has a Cd^{2+} thiol ratio of about 1:1 [24,29,30].

The role of phytochelatins in providing a level of resistance to cadmium was demonstrated initially with *S. pombe* and more recently with *Arabidopsis*. Hayashi's group [31] selected *S. pombe* mutants that were unable to grow in the presence of 0.5 mM Cd^{2+} (wild-type yeast grow normally at this Cd^{2+} concentration). Analysis of these mutants showed that they were blocked in the synthesis of GSH and phytochelatins. Howden et al. [32,33] have done the same experiments with *Arabidopsis*. Mutant plants were selected that were unable to grow in the presence of 0.09 mM $CdSO_4$. One set of plants, the *cad1* mutants, were missing the enzyme responsible for phytochelatin synthesis from GSH and the second group of plants, the *cad2* mutants, were deficient in one of the enzymes essential for GSH biosynthesis, γ-glutamylcysteine synthetase. Although a good deal of circumstantial evidence supports the role of phytochelatins in cadmium resistance in plants and fission yeast, the sensitivity of single-site mutants that are deficient in phytochelatins is the definitive evidence that these γ-glutamyl peptides are important in providing some level of resistance to cadmium. Chen and Goldsbrough [34] have provided information that strongly suggests that not only are mutants that are unable to make phytochelatins Cd^{2+} sensitive, but that overproduction of glutathione can create plants that are exceptionally Cd^{2+} tolerant. These investigators selected tomato tissue culture lines that could grow in elevated cadmium. Biochemical analysis revealed that the cadmium-tolerant lines had elevated γ-glutamylcysteine synthetase activity. This indicates that higher GSH and phytochelatin synthesis can result in increased cadmium resistance.

SYNTHESIS OF GSH AND PHYTOCHELATIONS

Mechanism of GSH and Phytochelatin Biosynthesis

Glutathione is synthesized by a two-step reaction beginning with the common amino acids, glutamate, cysteine, and glycine, and two moles of ATP (see Fig. 2). The first reaction is the formation of an amide bond between the γ-carboxyl group of glutamate and the α-amino group of cysteine to form γ-glutamylcysteine. This reaction requires Mg-ATP and is catalyzed by the enzyme γ-glutamylcysteine synthetase [35]. The cDNA for γ-glutamylcysteine synthetase (*gsh1*) was recently

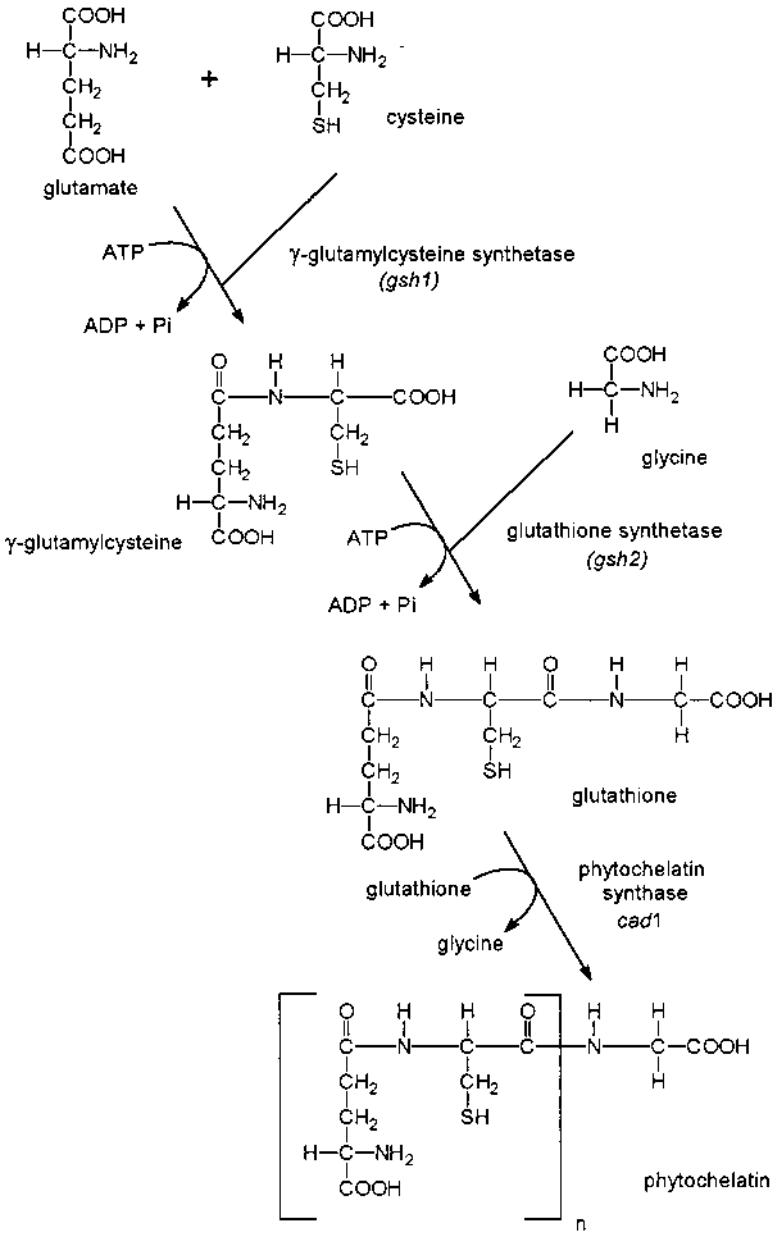

FIGURE 2 The biosynthetic pathway for glutathione and phytochelatins.

MARCEL DEKKER, INC.

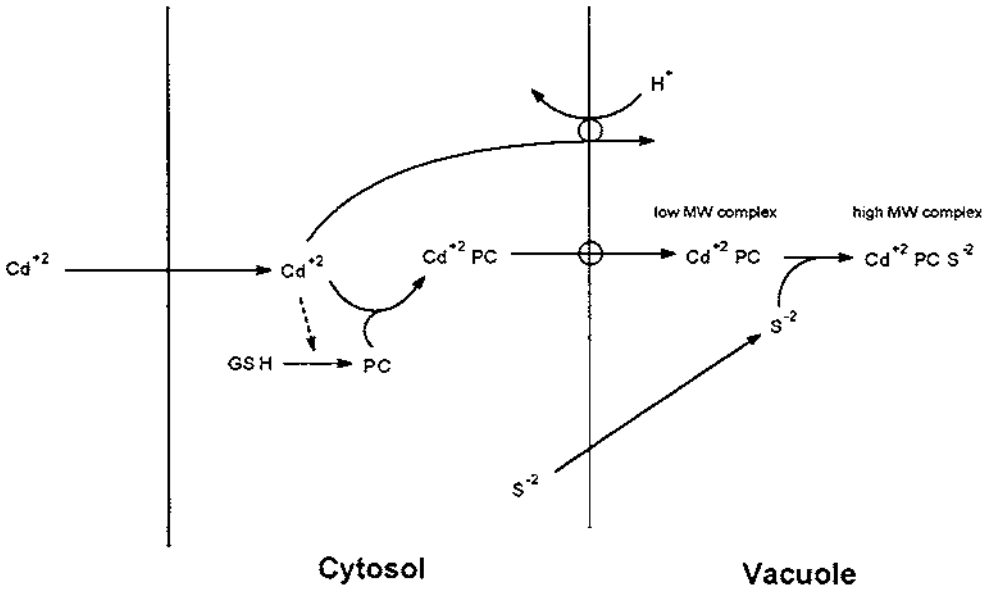

FIGURE 3 A model for Cd^{2+} uptake and sequestration in plant cells. Cadmium enters the cell and triggers phytochelatin (PC) synthesis. The phytochelatin binds the Cd^{2+} and this complex is transported into the vacuole. Additional Cd^{2+} enters the vacuole by a proton antiport. Sulfide and cadmium addition causes formation of a high molecular weight complex.

cloned by May and Leaver [36]. Glutathione is then synthesized by the formation of a second amide bond between the α-carboxyl of the cysteine residue and the α-amino group of glycine. This reaction also requires Mg-ATP and is catalyzed by the enzyme GSH synthetase. The cDNA [37,38] and gene [38] for this enzyme has recently been cloned from *Arabidopsis*. The *Arabidopsis gsh2* gene is capable of complementing *S. pombe* mutants that are cadmium sensitive owing to their inability to produce GSH synthetase [38]. The protein is also expressed in *Escherichia coli* and this system has been used to identify an essential flexible loop in the plant protein [39] as well as to clarify the role of the N-terminus region of the protein from higher eukaryotes [40] The GSH reductase (see Fig. 1) is needed to maintain GSH in the reduced form. Foyer et al. [41] have presented data suggesting that GSH is much more stable than GSSG and have presented preliminary data showing the effects of expressing bacterial *gsh1* and *gsh2* in poplar [41,42].

Phytochelatins are synthesized by the condensation of multiple GSH molecules to form a molecule with repeating γ-glutamylcysteine residues with a terminal glycine (see Fig. 2). The general structure is $(\gamma\text{-glu-cys})_n$ gly or $(\gamma\text{-EC})_nG$ and in plants n ranges from 2 to 8 with 3 to 5 being the most common. The enzyme that catalyzed this condensation is called γ-glutamylcysteine dipeptidyl transpeptidase or, more commonly, phytochelatin synthase [43,44]. The phytochelatins grow by the sequential addition of GSH molecules, $(\gamma\text{-EC})_nG + GSH \rightarrow (\gamma EC)_{n+1}G + G$.

The synthesis of phytochelatins is controlled posttranslationally. The activity of the enzyme is strictly dependent on the presence of heavy metals [43] with a preference order of Cd > Ag > Bi > Pb > Zn > Cu > Hg > Au (Al, Ca, Fe, Mg, Mn, Na, and K had no effect). Incubation of the enzyme with GSH causes no reaction. On addition of Cd^{2+}, the transpeptidase condenses two glutathione molecules to form $(\gamma\text{-EC})_2G$ followed by the sequential addition of GSH residues to form in sequence $(\gamma\text{-EC})_3G$ and $(\gamma\text{-EC})_4G$. As the phytochelatins accumulated in the reaction vessel,

they chelated the metal and the enzyme became inactive. The addition of more metal turned the phytochelatin synthase back on and phytochelatins continued to accumulate. The first level of control of phytochelatin synthesis is the direct activation of the enzyme phytochelatin synthase by heavy metals.

Control of GSH Synthesis

GSH synthesis is primarily controlled by feedback inhibition of γ-glutamylcysteine synthetase by glutathione [45]. Thus, the rate of GSH consumption controls its rate of formation. In addition, longer term controls are present where the plants can increase their overall capacity to produce GSH.

Exposing plants to cadmium causes a rapid drop in GSH levels. Several hours later, however, the plants develop an increased capacity for glutathione synthesis and the steady-state GSH levels return to near normal. Table 1 shows that when *Arabidopsis* plants are exposed to 50 μM Cd^{2+}, there is a rapid conversion of GSH to phytochelatins. Following 2 hs of Cd^{+2} exposure, there is a decrease in the GSH pool and an increase in the level of phytochelatins. After 24 hs of Cd^{2+} exposure, the level of GSH has returned to about 75% of its level in control tissues. Meanwhile, phytochelatin synthesis has continued at a high rate. After a 24-h exposure to cadmium, the total thiol pool (GSH and phytochelatins) increased about sevenfold in this experiment. Scheller et al. [46] have used their tomato suspension culture system to present more detailed kinetic analysis showing very similar results. The only way to explain the data in Table 1 and those of Scheller et al. [46] is that the rate of GSH synthesis is elevated, thus increasing the GSH pool at the same time as the rate of its conversion to phytochelatins is accelerated. Two mechanisms are possible. The enzyme γ-glutamylcysteine synthetase is inhibited by GSH in vitro. If this also is true in vivo, then the drop in the glutathione level that occurs with the activation of phytochelatin synthase would be expected to increase the activity level of γ-glutamylcysteine synthetase. This effect, however, should be fairly rapid and was insufficient to prevent the drop in the GSH levels during the first 2 hrs of Cd^{2+} exposure (see Table 1). The observation that the GSH levels do return within a day suggests that some additional control mechanisms are involved, probably at the level of the expression of the genes that control GSH biosynthesis.

Some published data provide support for the view that cadmium treatment increases the level of activity of the proteins for GSH biosynthesis and that this increase is controlled at the genetic level. Ruegsegger et al. [47] reported that Cd^{2+} treatment increased the level of GSH synthetase activity measured in vitro by three-to four-fold in peas. Schlunz (reported in Ref. 48) also has demonstrated a time-dependent increase in glutathione synthetase activity in vitro in peas following exposure to cadmium. Schneider (reported in Ref. 48) calculated that the rate of GSH synthetase

Table 1 Effect of 50 μM Cadmium on Glutathione and Phytochelatin Levels in Arabidopsis Plants Grown in Liquid Culture

Cd^{2+} Exposure (hs)	GSH Concentration (μmol/g)	Phytochelatins (μmol/g)
0	0.86	0.15
2 hr	0.05	1.40
24 hr	0.75	5.42

Arabidopsis seedlings in liquid shaker cultures were exposed to 50 μM $CdSO_4$ for 24 h before the entire seedlings were harvested and washed and GSH and phytochelatin levels determined.

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

activity increased 8-fold and that γ-glutamylcysteine synthetase increased 10-fold when tobacco suspension culture cells were exposed to cadmium. Clearly Cd^{2+} increases the in vitro activity and probably the level of the proteins of GSH synthesis.

Other researchers have shown that the enzymes of GSH synthesis are also regulated by oxidative stress. Work by Smith [49] and Smith et al. [50] and May and Leaver [51] have shown that H_2O_2 can induce GSH synthesis. Smith's work showed that catalase inhibitors (or plants with mutations in the catalase gene) result in increased photorespiratory H_2O_2 concentrations. The elevated H_2O_2 concentrations result in increased GSH levels. In a catalase-deficient barley clone [49], the GSH level increased 5- to 10-fold when the plants were transferred to photorespiratory conditions. May and Leaver [51] inhibited catalase activity in an *Arabidopsis* suspension culture with aminothiazole. The increased H_2O_2 concentration caused a four-fold increase in the GSH level. The elevation in GSH protected the cells from oxidative damage caused by H_2O_2. Inhibition of GSH synthesis with buthionine sulfoximine (BSO, an inhibitor of γ-glutamylcysteine synthetase) allows the H_2O_2 concentration to rise and oxidative damage to the cell results. These observations [49,50,51] suggest that H_2O_2 induces GSH synthesis and that GSH protects the cells from oxidative damage.

Given this indirect evidence that the capacity for GSH synthesis was regulated in plants, we decided to address the possibility that exposure to metals would result in the increased expression of the genes needed for GSH biosynthesis. *Arabidopsis* seedlings grown in liquid culture were exposed to either 100 μM cadmium for up to 4 days or to varying concentrations of cadmium for 1 day. mRNA was isolated from the plants and probed with the cDNA clones for *gsh1* (γ-glutamylcysteine synthetase), *gsh2* (GSH synthetase), and *gr1* (cytosolic isoform of glutathione reductase). As shown in Figure 4, a 12-h exposure to 100 μM cadmium causes a substantial increase in the level of mRNA for all of the genes necessary for glutathione biosynthesis. These high mRNA levels were maintained for 96 h. The system is sensitive to low-cadmium concentrations with 1 μM Cd^{2+} causing a measurable increase in mRNA level. The amount of mRNA increased to about 100 μM cadmium. At 1000 μM Cd^{2+}, the level of mRNA dropped below the detection limit of the blot. This may represent a specific response to high-metal levels or a general toxic effect of the metal. Copper is the only other monovalent or divalent cation that causes similar increases. Run-on transcription experiments have demonstrated that this increase in the mRNA level results from an increase in the transcription rate. Clearly, the plants responded to cadmium (as well as copper) exposure by increasing the expression of the genes necessary for elevated rates of GSH synthesis.

It is interesting to speculate how plants perceive the exposure to heavy metals and what the signal transduction pathway is between cadmium (and possibly other environmental stresses) and the induction of the genes for GSH synthesis. A very generalized model is shown in Figure 5. Metal

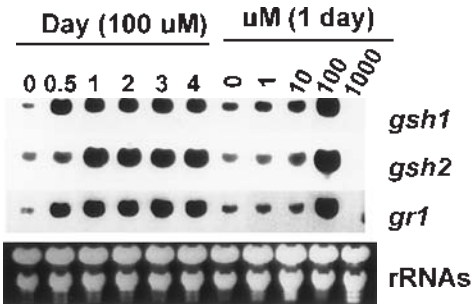

FIGURE 4 The effect of Cd^{2+} treatment on the level of mRNA for *gsh1*, *gsh2*, and *gr1*. *Arabidopsis* seedlings were grown in liquid shaker cultures and exposed to the indicated concentrations of $CdCl_2$ for the times shown. The seedlings were harvested, washed, and total mRNA extracted and analyzed by Northern blotting.

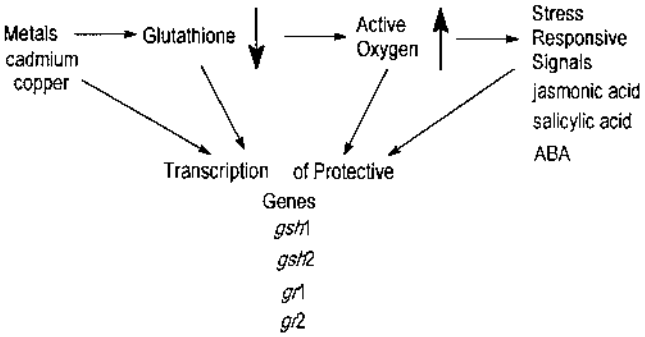

FIGURE 5 A model for the signal transduction pathway by which plants respond to cadmium and copper. Metal uptake causes a decrease in GSH levels which may result in an increase in reactive oxygen species and triggers the synthesis of signal molecules. One or more of these factors may trigger transcription of the genes for GSH synthesis.

treatments cause a decrease in the steady-state levels of GSH. This decrease in GSH causes an increase in the level of activated oxygen species as demonstrated in the case of H_2O_2 by May and Leaver [51]. Increased oxidative stress has been shown to elicit the synthesis of a number of stress-responsive chemicals, including jasmonic acid [52], salicylic acid, and abscisic acid. It is possible that one of these latter chemicals causes the activation of the genes needed for GSH biosynthesis. It could also be that the increase in active oxygen species or the decrease in glutathione induces these genes. It is even possible that the metals themselves induce gene expression directly in a manner that is directly analogous to the case with the metallothionein gene from bacteria [53] and mammals [54]. Given the central role of glutathione in mitigating a rnage of different environmental stresses, it will be essential to determine if these other stresses also alter GSH synthesis and how these responses are intergrated with those induced by metal exposure.

CONCLUSIONS

Glutathione seems to occupy a central role in protecting plants from a broad range of environmental stresses. The control of GSH biosynthesis is manifested in several steps. γ-Glutamylcysteine synthetase is feedback regulated by the concentration of GSH and works to maintain a steady-state level of this chemical. In addition, the expression of all genes essential in glutathione biosynthesis is regulated at the transcriptional level. The mechanisms by which environmental stresses control expression of these genes is unknown and the signal transduction pathway needs to be resolved.

Plant Hormones and Stress Phenomena

INTRODUCTION

Theophrastus is quoted to have said, ''For growth and nourishment, the climate is one of the most important factors.'' There is an apt proverbial saying that it is the year which bears and not the field. Plants growing in nature and crops in an agricultural system complete their life cycle in environments that are, to a considerable degree, unfavorable for expressing their genetic potential for reproduction. For completing various stages of development, that is, from seed germination to seed production, plants/crops experience a constantly fluctuating environment. Physical and chemical systems respond in accordance with the pressure exerted on them, but the fundamental characteristics of the living system is to resist change, and thus they are self-regulating. Therefore, for their survival the sessile plants/crops, must be highly responsive and self-regulating to changes in their physicochemical environment. There is, however, flexibility in this regulation, which appears to be governed by Shelford's *law of tolerance* [1]. According to this law, as long as the increase in the factor enhances response, it is considered to be *deficient*, and when no further response is elicited, it is optimum. When the response starts declining, it is *inhibitory* or at the toxic level. It is thus obvious that plants are stressed at the levels of both *deficiency* and *inhibitory/toxicity*. But plants/crops seldom experience variation in a single environmental factor, and covariation of and interactions between them is a norm rather than an exception. Thus, plants/crops growing under limiting (biotic or abiotic) environments are ''stressed.'' Stress can therefore be defined as any change in the environment that decreases plant growth and reproduction below the genotype's potential until productivity becomes uneconomical and ultimately ceases. Thus, the term *stress* is measurable and meaningful to agriculture.

The estimation and impact of environmental stress on crop productivity varies with the source. It has been suggested that only 10% of the world's arable land may be classified as nonstressed, and about 20% is under mineral stress, 26% is drought stress, and 15% is freezing stress [2]. On the other hand, Boyer [3] has estimated that environmental stress limited the productivity of U.S. agriculture to 25% of the potential.

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

Any environmental perturbance, regardless of its nature, that influences water and carbon balance unfavorably affects productivity. It is now generally accepted that drought, salinity, and temperature extremes disturb the water balance of plants. Besides water stress caused by salt acting as an osmoticum, a physical effect, salinity stress also causes ion toxicity by excess amounts of ion, particularly Na^+ and Cl^-, and in obtaining the required ions despite the predominance of other ions in the external media, a chemical effect. This classification is, however, artificial, because all the processes interact with each other. It has been suggested that in many plant/crop species, water stress causes an initial decrease in growth, whereas ion effects are responsible for a further reduction in plant growth. Therefore, plants exposed to saline environments need to adjust to three basic problems.

Most of the water in the hydrosphere is salty and much of the fresh water is frozen. Todd [4] estimated that oceans contain 97% of the planet's water, continents about 2.8%, and the atmosphere about 0.001%. About 77% of the water associated with land is found in ice caps and glaciers and about 22% is found in ground waters, much of which is uneconomical to retrieve. This leaves only a small percentage of readily manageable fresh water as a resource of the water supply.

Plants take up water from the soil to maintain cell turgidity and fix CO_2 from the atmosphere to provide, for example, food, fuel, fiber, drugs, and forest products, to humankind and animals. Stomates, representing a unique adaptation of terrestrial plants, play a key role in coupling leaf gas exchange to water availability. Plants transpire 100–300 times more water during the assimilation of CO_2 than is required for their growth and the production of a usable yield. It has been estimated that 600 kg of water is transpired to produce 1 kg of dry maize, and to produce 1 kg dry biomass, 225 kg of water is transpired [5]. It was further reported that to produce 1 kg of sucrose, sugar beet plants transpire 465 kg of water, and to produce 1 kg dried biomass, they transpire 230 kg of water [6]. Therefore, depending on the photosynthetic pathway, for every gram of C fixed, 250–600 g of water is lost through transpiration. Thus, a small fraction of 1% of the water that moved through the plant from the soil to the atmosphere became the part of the biomass. Therefore, optimum productivity is mainly dependent on a favorable balance between water and carbon.

The world's land surface occupies about 13.2×10^9 ha, of which 7×10^9 ha is arable, only 1.5×10^9 ha of which is cultivated [7]. Of the cultivated lands, about 0.34×10^9 ha (23%) is saline and another 0.56×10^9 ha (37%) is sodic. Salt-affected soils are not limited to semiarid and arid regions and cover nearly 10% of the total land surface in around 100 countries of the continents and subcontinents [8]. A salinity problem develops in a number of ways: seawater intrusion, saline irrigation and drainage waters, saline ground waters, brines from natural salt deposits or geological formations, brines from gas and oil fields, and saline and sodic soils. As elaborated by Tanji [9], the primary source of salts in waters and soils is the chemical weathering of earth materials; that is, minerals that are constituents of rocks and soils. Evaporative salinization, i.e., surface of evaporation of water and transpiration by plants, and dilution, e.g., snow melt waters, irrigation waters, rainfall, influence the concentration of dissolved mineral salts. Mineral solubility principally regulates the extent to which salts dissolve or accumulate.

Plants do modify their development in response to the above- or underground environmental stimuli, including gravity, light, water, salts, and pathogens. The modifications in their development frequently take the form of changes in the direction of growth. For example, as the salinity stress increases, it approaches a *threshold* above which the productivity starts declining until it becomes toxic (Fig. 1) [10]. In order to cope with the salinity stress, plants have devised strategies and they have accordingly been classified as *halophytes/mangroves* and *glycophytes*. Many halophytes are Na^+ includers, but they effectively keep this ion away from the growing cells. On the other hand, glycophytes (many of our agricultural crops) are Na^+ excluders (or K^+ includers), but variations do occur: *Spergularia marina* is a Na^+ includer at low salt levels and a Na^+ excluder at high salt levels[11]. Thus, the distinction between halophytes and glycophytes is relative one.

Being sessile, plants/crops respond to a stressful environment by a number of morphological and physiological changes which include the reduced growth of leaves, stems, and hairy roots;

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

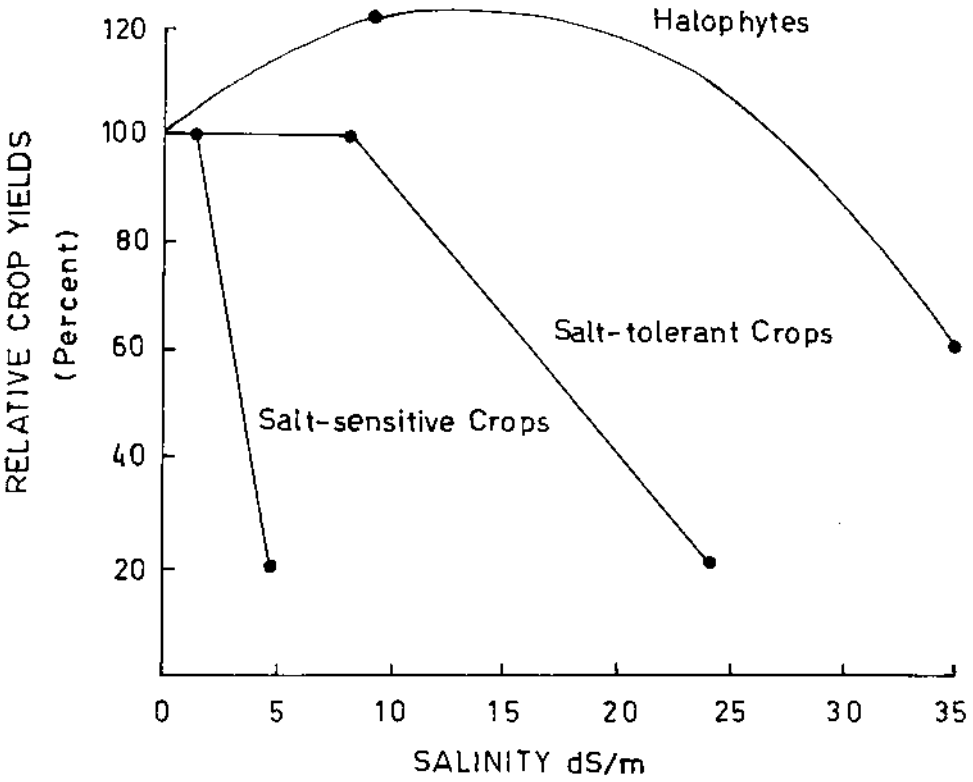

FIGURE 1 Growth response of plants and crops to salinity stress. (Reproduced from Ref. 10.)

stomatal closure; a reduction in the rate of photosynthesis; hormonal disbalance; and a low capacity for nutrient uptake [12]. Two novel approaches were made to break the link between soil drying and reduced water uptake. As the soil dried, Passioura [13] used a pressure vessel around the roots of wheat and increased the pressure to balance the increase in soil suction. Under these conditions, the water relations of pressurized plants was similar to those of normally watered plant but the leaf growth and stomatal conductance was reduced. In another experiment, Gowing et al. [14] split the roots of young apple trees into two containers. Leaf expansion and leaf initiation were reduced by soil drying in one container, which was restored by severing the root. Both these novel approaches indicated that the water status of the shoot was not related to the observed growth reduction under soil drying, and a signal from the root regulated the shoot growth and the gas exchange. The logical explanation for the restriction in shoot growth is the unbalanced supply of growth promotors and inhibitors originating from a root experiencing soil drying. Stress effects on leaf growth and stomates are obvious in even the short term, before solutes have built up to the high levels for osmotic adjustments, to the changes in the water balance of the tissues [15,16]. It has been demonstrated that without any noticeable change in leaf water status, the plant's growth and stomatal closure can apparently be affected by a message (hormonal) received by the leaves or sent from the roots experiencing osmotic stress [17]. Similarly, it has been shown that shoot turgor was not the limiting factor to plant growth under salinity stress [18,19]. Therefore, the earlier the response, the more likely

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

that it had to do with the primary response of stress itself rather than a consequence of one or more of the early events. For such stimulus-response coupling, most of the models proposed consist of a sequential four-component system that includes perception of the stimulus, transduction of the signal, alteration of gene expression leading to a cascade and amplification of the message in the form of a network of biochemical/molecular events, and a physiological response in the form of a morphological adjustment/modification in the growth form. At present, we know nothing about the response of plant/crops growing in a stressful environment, and we have some understanding of the hormonal mode of transduction, but information about the perception mechansim is lacking. It has been suggested that, in eukaryotic cells, the major mechanism of signal transduction is via protein phosphorylation and dephosphorylation (via kinases and phosphorylases, respectively) [20,21].

Under a stressful environment, marked and often rapid changes in the hormonal balance of plants are commonly observed. Since a given stress induces resistance to unrelated stress(es) [12,22], and hormones also influence a stress response, changes in their relative levels may enable the plant to adjust its growth despite suboptimal conditions [23]. Our current understanding of plant growth processes from seed germination through vegetative growth, reproductive development, maturity, senescence, and seed production is influenced by hormones (Table 1). Since plants/crops lack a rapid communication system similar to the central nervous system of animals, they adjust their hormonal balance to regulate growth in response to environmental perturbations. Of the five commonly acknowledged hormones, auxins, gibberellins, cytokinins, ethylene, and abscisic acid, the

levels of auxin and cytokinins are reduced, whereas that of abscisic acid is enhanced; there is not enough available information to generalize about the status of gibberellins and ethylene. It is known that ethylene causes a reduction in abscisic acid (ABA) which antagonizes the action of gibberellins; and gibberellins are the key hormone promoting internodal growth [24]. Therefore, a commonly observed enhancement in the ABA level would suggest that the levels of ethylene and gibberellins may not be as important as the other three hormones in playing a significant role in the overall stress physiology.

Plant hormones (also called *phytohormone*) are *organic compounds*, *synthesized in one part of a plant and translocated to another part that*, *in very low concentrations*, *cause a physiological response*. This definition sets forth three criteria which separate plant hormones from other nutrients and metabolites: they are endogenously produced, transported to a target area from the site of synthesis, and act in low concentrations. From the outset, plant hormones have been heavily involved with ''action at a distance'' and their ability to move within the plant body has been a paramount consideration. Their transport characteristics are unlike those of most other substances. Water moves up from the root hairs to the transpiring surface along a gradient of (negative) hydrostatic pressure; sugars move from the leaf chlorenchyma down to the cambium or roots along a gradient of both (positive) hydrostatic pressure and sucrose concentration. Ions can be accumulated against concentration gradients, but these are not considered to be growth substances. Auxin does not appear to move along an auxin gradient, but what really is a morphological gradient: polarly and predominantly from the apex to the base in leaves and shoots and from the apex to a short distance behind the apex in roots in most of plant species. As a rule, only slight polarity is shown by gibberellins, which in most concentrations travel freely in both directions in plants. Cytokinins may be carried in small amounts in the transpiration stream or in the bleeding sap, but they mostly appear to remain close to the site of their formation. ABA also seems to move with only slight directionality. In a large number of instances, it appears that the levels of hormones in a tissue/organ relative to one another are a more important consideration than are their absolute concentrations. They exist in plants at concentrations lower than 10^{-6} M [25], and an endogenous concentration above this is generally considered to be supraoptimal. It is also known that not only does each hormone affect the response of a number of plant parts, but that these responses also depend on the species, the plant organs, its developmental stage, cell and tissue sensitivity, concentration and interaction among the hormones, and the environmental factors.

The mechanism(s) by which hormones trigger a response is still far from clear. Specific receptors have been suggested, but no convincing evidence for their function in mediating hormone action has been given. There is, however, considerable evidence that these hormones induce gene expression, but how this is done biochemically is not well understood [1]. These hormones are detectable in all actively growing plant organs; younger leaves and apical buds are paticularly high in auxin, whereas root apices are high in cytokinins, gibberellins, and ABA. Fruits and seeds are generally rich in plant/crop hormones. Therefore, plant/crop hormones are ubiquitous and generally not species specific.

To demonstrate the hormonal control of a physiological process/response, either the balance of the test hormone must be experimentally manipulated (as by excising young organ[s], supplying the hormone exogenously, or using a hormone-deficient or overproducing mutant) to establish its control. In this respect, the Mitscharlich law of diminishing returns [26] can be modified as follows: the increase in plant response produced by a unit increment of a deficient (limiting) hormone is proportional to the decrement of that hormone from the maximum. In this chapter, we cover the hormonal relations of plant hormones elicited under moderate stresses and not at the levels that cause injury/toxicity.

HORMONES

Plant hormones are not only involved in cell division and/or cell differentiation, but there is also a wealth of information about many other processes, including induced gene expression and bio-

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

chemical changes (see Table 1). These changes point to the nature of the control exercised by hormones at the subcellular or molecular level. Unlike most animal hormones, which usually have relatively specific types of physiological regulatory functions, plant hormones have considerable interplay between the various groups in the overall regulatory process. Owing to their inherent flexibility, plants/crops adapt to fluctuating environments to complete their life cycle. But when environmental conditions become stressful, plants/crops cope with this pressure by adapting a strategy of reducing leaf expansion and closing their stomates to limit water loss. These adaptive responses are elicited before any measurable change in the water or turgor potential is detected [15–18]. The reduction in leaf expansive growth to stressful environmental conditions has a profound effect on crop production independent of stomatal or biochemical effects. It has been suggested that the rate at which any cell enlarges is determined by the product of two cellular parameters: wall extensibility and effective turgor [27]. Hormonal modulation of the rate of cell enlargement is affected by altering one or both of these parameters. Cell differentiation and enlargement proceed concurrently with division during much of the period of leaf expansion. Stress-induced growth inhibition in the apical meristematic region and the expanding leaves may also be dependent on events external to these regions. Owing to the complexity of the control mechanisms of leaf growth by endogenous hormone(s), the issue remains unresolved. It has, however, been demonstrated that cell enlargement rather than cell division and auxin transport was reduced in coleoptiles (a leaf structure) subjected to salinity stress [28,29]. These observations along with that of Virk et al. [30] and the proposed model based on the auxin-cytokinin countercurrent [31], to explain the basic mechanism underlying plant axial growth, suggest that the reduction of plant/crop growth in response to a stressful environment may have been due to an impaired hormonal balance. The commonly accepted plant/crop hormones are identified as auxins, gibberellins, cytokinins, ethylene, and abscisic acid; jasmonic acid and salicylic acid have also been proposed to be included in this group of organic compounds.

Auxins

Auxin is a term derived from the Greek word *auxein*, meaning ''to increase.'' It is a generic name for chemicals which typically stimulate cell elongation, but auxins also influence a wide range of other growth and developmental processes (see Table 1). The existence of growth-regulating chemicals that control plant/crop growth, and the interrelations between their parts, was the outcome of experiments on the root and shoot responses to external stimuli. In some plant/crop species, a perceptible reduction in the root and shoot growth could be observed when the external water potential is reduced to -0.1 MPa [32,33]. Considering the importance of the auxin indole-3-acetic acid (IAA), it is surprising that very little attention has been paid in elucidating its role in the hormonal balance under a stressful environment. Since we completed this same chapter in the previous edition of this volume in 1993, it is surprising that no further advancement to our knowledge has become available since then [34].

To recollect, it is known that salinity stress reduces the recovery of the free or diffusible IAA from maize (*Zea mays*) coleoptile tips [35]. Similarly, water stress has also been shown to reduce the recovery of this hormone in *Helianthus annuus* (sunflower) and *Anastatica hierochuntica* [36] and from the abscission zone of *Gossypium hirsutum* (cotton) fruits [37,38]. The explanation for the reduction in the recovery of the free IAA was considered to be due to enhanced conjugation. Kannangara et al. [39] observed fluctuations of auxin concentration in the field-grown sorghum (Sorghum bicolar) and concluded that the change in the concentration could not be correlated with the diurnal changes in the ABA or in the leaf water status. Contrary to these observations, Sakurai et al. [40] reported an increase in the auxin level in the squash (*Cucurbita maxima*) hypocotyls subjected to a decreasing leaf water potential. Compacted soil [41,42] or shaking [43] as a source of mechanical stress enhanced or reduced, respectively, the auxin level in maize. Similarly, reduced recovery of auxin was observed from the leaves of tobacco (*Nicotiana tabacum*) subjected to wounding stress [44].

The above findings indicate that the observed reduction in diffusible auxin under a stressful environment may have either been due to a reduction in the biosynthesis, an enhancement in its metabolism, or an affect on the transport kinetics. There is reasonable amount of work on the biosynthetic pathway of auxin available, but we are not aware of any work conducted with plants raised under a stressful environment. Therefore, the only option left to have an understanding about this parameter is to rely on the studies reported on the other two parameters: metabolism and transport kinetics.

In critically evaluating the published work, we see that decreasing the water potential increased the in vitro IAA-oxidase activity in pea (*Pisum sativum*) which correlated with the endogenous auxin level [45,46]. On the other hand, the IAA-oxidase activity decreased with increasing the water deficit in wheat (*Triticum aestivum*) [47]. Similar results were obtained when oat (*Avena sativa*) seeds were imbibed for 48 h in various Na^+-salt solutions; that is, a decrease in the in vitro enzyme activity at all the concentrations tested. However, exposure for longer time periods caused a sharp enhancement in the IAA-oxidase activity proportional to an increase in the Na^+-salt concentrations [48]. Contrary to these results, Naqvi et al. [31] did not find any change in the in vitro endogenous enzyme activity in the coleoptiles (leaf structures) of salinity-stressed maize seedlings. These observations support the hypothesis that the organization of the cytosol is such that enzymes in vivo do not respond to osmotic/ionic environment as they do in vitro [49].

Naqvi [50] studied the absorption and transport properties of ^{14}C-labeled indole-3-acetic acid (^{14}C-IAA) in coleoptile segments excised from salinity-stressed maize seedlings. Using the classic donor:tissue:receiver system, it was demonstrated that the above two parameters were not influenced by the stress. Further studies on the kinetics of ^{14}C-IAA in the same system showed that 0.5 or 1.0% salinity did not materially affect either the velocity or the intensity (capacity) even though the seedling growth was adversely affected.

Kaldewey et al. [51] using internode segments of water-stressed pea seedlings observed that stress did not affect the velocity but did reduce the capacity of ^{14}C-IAA transport. Studies using cotton cotyledonary petioles also showed a reduction in auxin transport capacity by 50% when water stress was enhanced from -8 to -12 bar [52]. Testing the effect of aging, Davenport et al. [53] excised petiole segments from the upper, middle, and lower canopy of mature water-stressed cotton plants and obtained similar results regardless of the age of the petioles. Critical examination of their data, however, indicates that, contrary to their conclusion, no material effect of stress up to -20 bar was observed. Sheldrake [54] raised oat seedlings under nonstressed conditions for 4–6 days and isolated mesocotyl segments which were osmotically stressed (0.5 M sorbitol) for 2 h. These stressed segments when used for auxin transport studies indicated an enhancement in this parameter. However, in the absence of an effect on either the absorption or the transport velocity, the results could not be logically explained.

Nullifying the gravitational force by using Clinostat, it was demonstrated that gravity compensation did not affect either the auxin biosynthesis or the absorption and transport of exogenously supplied ^{14}C-IAA [55].

From a practical point of view, treatments with auxin have been reported to alleviate some of the adverse effects of stress on germination, seedling growth, and the yield of a number of crop species as well as fresh- and seawater algae [56–65].

Gibberellins

In 1926, Kurosawa discovered that gibberellins increase the growth of plants by greatly elongating the cells [66]. Studying the symptoms of the rice disease *bakanaebyo* (''foolish seedling disease''), Takahashi [67] observed that the causal pathogen was a soilborne fungus, *Gibberella fujikorai*, the sexual or perfect stage of *Fusarium moniliforme*, which caused infected seedlings to grow abnormally taller and to fall over owing to a spindly stem structure. He further observed that when a pure culture filterate was sprayed onto rice seedlings, it produced the same abnormal growth. This suggested that the filterate contained some soluble substance which caused the growth abnormality.

Other Japanese workers demonstrated that the effect was not confined to rice but could be reproduced in many other species. However, in 1938, Yabuta and Sumiki isolated two crystalline active substances from the culture filterates of the fungus and named them gibberellin A and B. Currently, 84 gibberellins (i.e., GA_1, GA_2, GA_3–GA_{84}) have been characterized from fungi, plants, and crops and all of them are active on plants/crops [1].

Besides other effects, the primary action of gibberellins is on stem elongation, which is a consequence of both increased cell division and cell elongation. Depending on the intensity and duration of water stress, excised lettuce (*Lactuca sativa*) leaves exhibited a rapid decline in gibberellin-like activity [68]. The reduction was also closely related to the increase in the leaf water saturation deficit and a concomitant elevation in the ABA level. The gibberellin-like activity was barely detectable after 6 h of stress, but after 4 h of relief from the stress, it returned to the normal level. It was further shown that a 10% decrease in the relative water content (RWC) of the detached leaves did indeed accelerate the decline in the gibberellin level [69]. Water-stress studies on gladiolus (*Gladiolus psittacinus*) flower bud growth also indicated a reduction in the level of gibberellin [70]. Similarly, when bean (*Phaseolus vulgaris*) seedlings were subjected to mechanical stress, a decline in the gibberellin content as well as in the stem growth was observed [71]. But studies using aeroponically grown sunflower plants did not show any change in the total gibberellin level or in their distribution when subjected to high-pressure liquid chromatography (HPLC) analysis or to dwarf rice (*Oryza sativa*) bioassay [72]. Gibberellic acid (GA_3) transport through cotton petiole segments has not been found to be influenced by either water or anaerobic stress [73], and the velocity remained at 1 mm/h.

Improvement in germination and seedling growth of onion (*Allium cepa*), sesame (*Sesamum indicum*), flax (*Linum usitatissimum*) [74], lettuce [75], and the polymorphic seeds and seedlings of atriplex (*Atriplex triangularis*) [76] under stressful environments has been observed. Similarly, treatment with GA_3 effectively enhanced the α-amylase activity and the coleoptile lengths in wheat [77,78] and seed germination as well as the seedling growth in barley (*Hordeum vulgare*) [79]. Rao and Ram [70] have demonstrated that bud opening in gladiolus was sensitive to stress which was alleviated by GA_3 indicating stress affected the hormone supply adversely. In addition to these beneficial effects, GA_3 treatment increased the nutrient uptake and enhanced the yield of field-grown wheat [80]. Starck and Kozinska [81] have concluded that gibberellin-treated bean absorbed more P and Ca^{2+} and less Na^+ and partially reestablished the monovalent/divalent ion ratio, which increased in the apical organs of salinity-stressed plants.

Ethylene

Ethylene is the simplest organic compound and is biologically active in trace amounts. Since ethylene is biosynthesized and emitted as gas by plant tissues directly into the atmosphere, it is easily detected by gas chromatography in nanoliter amount in less than 1 min without going through extraction and purification protocols. Besides, the classic *triple response*, characterized by growth retardation, an increase in diameter, and horizontal growth of shoots, is still used as a bioassay to identify and measure ethylene. There is increasing evidence that ethylene influences many plant growth and developmental processes and interacts with all the other plant hormones (see Table 1).

Plant tissues subjected to injury by a variety of stresses, for example, wounding; chemical; mechanical, and temperature extremes; and pathogens, are the site of enhanced ethylene biosynthesis. However, it is not the injured or dead cell but the cell adjacent to it which produces ethylene. Since it is a gaseous hormone, its emission has been detected to increase from 2 to 50 times or more depending on the intensity of the stress and the sensitivity of the tissue. However, this surge is short lived, peaking rapidly and returning to normal level within 24 h or less [82]. No work is available which suggests any deviation in the normal biosynthetic pathway of the stress ethylene surge. However, Kacperska and Kubacka-Zebalska [83] suggested two prerequisites for such stress-induced endogenous ethylene biosynthesis; (a) the promotion of 1-aminocyclopropane-1-carboxylic

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

acid (ACC) synthesis and (b) activation of a free radical–generating system. The latter system was needed for the nonenzymatic conversion of ACC to ethylene and depended on the activation of the membrane-associated lipoxygenase caused by stress-induced alterations in cell membrane properties.

When intact plants of sunflower, bean, cotton, and miniature rose (*Rosa hybrida*) were moderately water stressed, no enhancement in ethylene emission was observed [72,84]. But whenever detached plant organs were stressed, ethylene production was enhanced [85,86]. When detached wheat leaves were subjected to dehydration to loose 9% of water of the initial fresh weight, a 30-fold enhancement in ethylene emission was detected within 4 h; thereafter it rapidly declined at or even higher water-stress [85].

The detection of ACC as a water-soluble precursor of ethylene helps to answer some unresolved questions referring to the movement of ethylene in plants. ACC was found to be present in the xylem sap of tomato plants. Its concentration was higher in the sap from waterlogged than from aerated control plants. The appearance of ACC in the sap preceded the onset of epinastic curvature of the petioles, and its concentration correlated with the production of ethylene in the shoot. Therefore, it seems that instead of ethylene, its precursor, ACC, moves within the plants/crops [87].

Ethylene promotes cell extensibility as well as elongation and has been shown to play an important role in many water plants with aerial parts to adjust to the water level. When plants are submerged, elongation is greatly accelerated until the aerial parts regain the water surface. The organs which elongate may be the stem, petioles, or flower stalks [87,88]. But generally the hormone is known to inhibit elongation growth [89,90] and to accelerate senescence [91]. By manipulating the endogenous levels of ethylene and auxin, cells of different shapes and sizes can be produced [92]. This hormone has also been suggested as a marker for screening stress-tolerant lines, because it correlated well with its seedling growth [93]. However, ethylene is well known to play an important role against pathogenic stress [20].

Cytokinins

The discovery of cytokinins was an outgrowth of in vitro technology of plant regeneration developed by Skoog and associates [10]. The isolation and identification of kinetin (6-furfurylaminopurine) from aged or autoclaved herring sperm DNA and its promotion of cytokinesis (cell division) at concentrations as low as 1 μM greatly stimulated research on plant growth and development. Although kinetin does not occur naturally, its discovery greatly supported the concept of the existence of a cell division factor postulated by Wiesener in 1892 [94] and experimentally demonstrated by Haberlandt [95]. However, it was later isolated from immature maize kernel and was named zeatin (Z) [96]. Since then 25 free cytokinins have been isolated and identified from plants/crops among which some are active in inducing maximum tobacco callus growth at concentrations as low as 4 nM [96]. The active cytokinins have not been clearly identified, mainly because mutants or inhibitors that block particular metabolic steps are not availabe. Therefore, it may have been a problem as to which of the 25 cytokinin(s) should be measured under stressful conditions. Cytokinins are a group of compounds that stimulate water uptake, increase cell division, promote organ development, and lead to regeneration and proliferation of shoots [97].

Cytokinins have been classified by a substituted base into three groups: zeatin (Z), dihydrozeatin ([diHZ]), and N^6-(Δ-isopentenyl) adenine (2ip). In many species, the zeatin-type cytokinins are the most active and most prevalent forms of cytokinin [97]. McGaw [98] has concluded that of the hormonally active cytokinins, the nucleotides are probably associated with uptake, with the ''active'' form comprising the ribosides and the bases. Letham and Palni [97] observed that the ribosides were the major forms transported through the xylem and phloem. But O-glucosides and nucleotides were observed to be the major constituents in bean xylem exudate [99]. Thus, there is little doubt that vascular exudate contains cytokinins [100,101]. Benzyladenine (BA), a synthetic cytokinin, is readily taken up by roots, and within 60 min after its addition, the internal cytokinin level was 30%

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

of the external concentration [102]. It has also been demonstrated that if the internal BA concentrations were raised by external supply, the adverse effects on various growth parameters were compensated [103].

In an elegant experiment, Carmi and Van Staden [104] demonstrated that the growth of the primary leaves of decapitated and partially defoliated bean plants was strongly influenced by the roots. Partial excision of the roots reduced the leaf area and weight as well as the mesophyll thickening. Metabolic activities such as chlorophyll and protein biosynthesis were dramatically reduced by partial root excision. The balance between the root and shoot systems and the ratio between the dry weights of the root to the leaves also were affected. These effects could be correlated with the lower levels of cytokinin in the leaves, stems, and roots of the partially excised root plants. Actively dividing regions of plants are the sites of cytokinin synthesis [98,99,105], and because of the root morphology, there are more actively dividing tips in the root system; therefore, the major portion of the cytokinins is biosynthesized there and transported to the shoot [105,106]. These root-originated cytokinins along with shoot-synthesized ones influence the control of both the development and senescence of the whole plant [107]. Generally, the growth-enhancing effects of BA are considered to occur via an increase in the protein content [97] by stimulating the RNA polymerase activity [108] and reinforcing the binding of RNA to ribosomes by a higher rate of incorporation of BA nucleotides [97]. This increase in the protein content is reflected in a higher photosynthetic activity [109] and in an enhanced nitrate reductase activity [110]. Besides BA retards the protein degradation by inhibiting ribonucleases [111] and senescence [112].

Vascular exudates and/or leaves of stressed plants exhibit a reduced cytokinin activity, and the response is known to be rapid [16,34,72,98,106,113]. After the exposure to nutrient stress, transfer from 100 to 2%, the cytokinin concentrations of the shoot and root of *Plantago major ssp. pleiosperma* dropped to 50% in a 2-day period, whereas the mineral contents decreased much later [113]. Similarly, a rapid drop in the cytokinin concentration was correlated with a reduction in barley growth paraments [114]. Contrary to the general consideration that a reduction in growth under stressful environment signifies sensitivity, Kuiper and associates interpret it as an strategy for tolerance [103,113,114]. Treatments with exogenous BA or relieving of stress enhanced the internal cytokinin concentration and alleviated growth reduction in both the species. Similarly, tomato plants recorded reduced cytokinin activity 8 days after they were subjected to salinity stress, which was correlated with growth reduction. When the stress was relieved, the cytokinin activity reached the normal level in the next 4 days (Fig. 2) [10]. Hubick et al. [72] water stressed aeroponically grown sunflower plants and observed a rapid decrease in the cytokinin activity. Neuman et al. [115] reported that root hypoxia reduced cytokinin in the xylem sap, but zeatin riboside (ZR), dihydrozeatin riboside (diHZR), and their equivalents were not reduced in the leaves of bean and poplar (*Populus tricocarpa* x *P. deltoides*). However, Bano et al. [15] have observed that rice seedling roots experiencing 30 h of drying exhibited a reduced level of cytokinins, isopentenyladenine (2ip) + isopentenyladenosine (2iPA), and zeatin (t-Z)+zeatin riboside (t-ZR) in the xylem sap which increased after the relief of stress by rewatering.

Despite their established role in plant/crop development, information as to how endogenous cytokinins are reduced under stressful conditions is meager. The reduction in the cytokinin level raises the question whether the hormones' biological activity was minimized by enhancing temporary storage or whether it was metabolized. Studies show that N-glycosides are very stable and have a low biological activity in vitro and may withdraw cytokinin from the potential pool [97]. On the other hand, the O-glycosides are deglycosylated readily and may be involved in homeostatic control of the hormone levels [97,98]. A reduction in the cytokinin activity under stressful conditions may have been either due to reduced biosynthesis or enhanced metabolism. Binns [116] has defined cytokinin metabolism as the conversion of (9R-5′P)iP to any other N^6-substituted adenine derivative cytokinin. Accordingly, the major conversions are the dephosphorylation and deribosylation yielding the riboside and free base, respectively. The hydroxylation of the side chain produces the trans-zeatin (t-Z) derivatives (9R-5′P)t-Z, (9R)t-Z, (9R-5′P)-diHZ, (9R)diHZ, and diHZ. These derivatives can be further metabolized; often by O-glycosylation of Z or diHZ and N-glycosylation at the 7 and

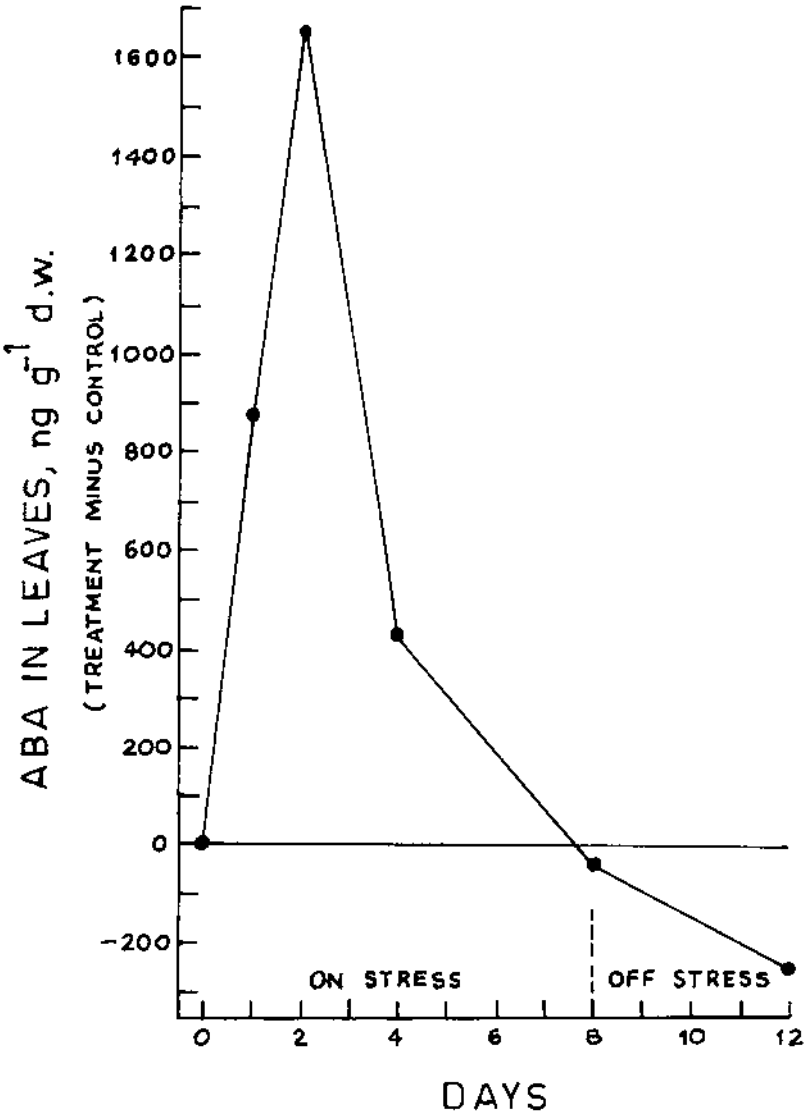

FIGURE 2 Effect of salt stress on the free ABA content of tomato leaves. (Reproduced from Ref. 10.)

9 positions of the adenine base. However, such studies under stressful conditions are not available to answer similar questions. Thus, basic questions regarding the biosynthesis, metabolism, and activities of cytokinins remain unanswered. Kuiper [103] has, however, observed that *Plantago* plants exposed to low salts had reduced cytokinins and had a limited number of active root tips.

Kinetin treatment enhanced seed germination and seedling growth in tomato and pea under salinity stress [117,118]. Under salinity stress, wheat seedling growth retardation was partially alleviated by kinetin treatment [119]. That alleviation of salinity induced a reduction in the germination and seedling growth by kinetin treatment seems to be well documented [120]. Kuiper and associates [11,103,113,114,121] have reported that mineral and salinity stress induced a reduction in the endog-

enous cytokinin concentration and the growth parameters of *Plantago major* ssp. *pleiosperma*, species of wheat and barley, were effectively enhanced by cytokinin. Treatments with cytokinin have been reported to enhance transpiration by causing maximum stomatal opening in a number of plant/crop species [122,123]. Saunders [124] has shown that cytokinin exerts at least part of its effect by stimulating Ca^{2+} uptake by responsive cells.

Certain cytokinins (6-benzylaminopurine, zeatin, 2-isopentyladenine) have also been shown to be efficient elicitors in inducing phosphoenolpyruvate carboxylase (PEPCase), the key enzyme in crasssulacean acid metabolism (CAM); proline and pinitol accumulation, and an osmotin-like protein in *Mesembryanthemum crystallimum* [125–127], a *halophyte*, and PEPCase and carbonic dehydrogenase in maize, a *glycophyte* [128]. Similarly, another cytokinin (BA) enhanced the accumulation of nitrate reductase (NR) mRNA in etiolated barley leaves [129]. This cytokinin (BA) also has been shown to regulate the accumulation of jasmonic and salicylic acids caused by mechanical wounding and pathogenic signals, respectively. As a consequence of these observations, in wild-type and transgenic tobacco plants, Sano et al. [130] concluded that cytokinins were indispensable for the control of jasmonic and salicylic acids, elicitors of wounding and pathogenic stresses.

Abscisic Acid

Hemberg is credited with being the pioneer who advanced the idea that plant growth and development are regulated by endogenous levels of both a promotor (auxin) and an inhibitor. Employing an *Avena* bioassay, he observed that potato peels contained a high level of growth inhibitors. He further demonstrated the presence of a similar inhibitor which was correlated with the degree and levels of bud dormancy in *Fraxinus excelsior* (ash) [131].

Bennet-Clark and Kefford [132], using paper chromatography to analyze plant extracts for growth substances, observed the inhibitory activity at R_f 0.6 and 0.7. This was later shown to be present in a number of plant species and the levels responded to environmental changes. After diverse approaches, that is, dormancy (dormin) and abscission (abscisin I and II), it converged that ABA was the hormone responsible for both the physiological states [133]. Like other plant/crop hormones, ABA also is ubiquitous among vascular plants/crops besides being present in some algae, fungi, and mosses, and it is known to influence many physiological functions (see Table 1).

The naturally occurring enantiomorph of ABA is (S)-ABA, which is sesquiterpenoid (a 15-carbon compound), and by its biogenesis is related to monoterpenes, diterpenes (gibberellins), carotenoids, and triterpenes. Endogenous (S)-ABA is optically active, having one center of asymmetry at C-I′, whereas synthetic ABA is recemic and composed of equal amounts of (S)-and (R)-enantiomers. The synthetic (R)-ABA accounts for 50% of the recemic mixtures of ABA and has a biological activity equal to that of the natural (S)-ABA in most cases; except in stomatal closure where it is inactive. Since the observation that the endogenous ABA level increases under environmental stress and that it causes stomatal closure reducing transpirational water loss [134], later workers named it the ''stress hormone''. However, the total content of ''free'' ABA per unit leaf area does not increase before stomata close under stress [135]. ABA influences many physiological processes (see Table 1), and its enhancement under stressful environments convinced Quarrie [136] to remark that, '' a plant that cannot make abscisic acid (ABA) is in trouble.'' Wright [137] surveyed over 70 plant/crop species and observed an increase in the ABA levels when their excised leaves were subjected to a period of wilting. Besides, it also accumulates in the absence of water deficit [15]. ABA also has been reported to increase under pathogenic stress [138,139] and enhances resistance to pathogens [140]. It is a typical sesquiterpene, consisting of three isoprene units, and is known to be synthesized through carotenoid pathways with xanthophylls being immediate precursors [141].

During the past 20 years or so the endogenous level of ABA has been reported to rapidly increase 5- to 100-fold or more under stressful conditions. Therefore, ABA is considered to be involved in stress signal transduction and to serve to coordinate the physiology and development of plants/crops experiencing a stressful environment [10,141]. However, gene analysis has revealed that both ABA-independent as well as ABA-dependent signal transduction cascades operate between

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

the initial signal and the gene expression under drought stress [142]. It has further been suggested that factors other than ABA may be involved in the osmotic signal transduction pathway [143].

ABA is synthesized in the shoots and roots and moves bidirectionally and not polarly in plants/crops and is also transported rapidly from cell to cell. Under water stress, Hoad [14] observed that ABA was actively translocated out of the mature leaves in the phloem and transported to the stem apices, fruits, and seeds in white lupin (*Lupinus albus*). It has, however, been reported that, under a stressful environment, translocation of ABA form the shoot to the root is inhibited causing the hormone to accumulate in the aerial parts [145].

ABA reduces seedling growth, but Sharp and associates [146–149] conclude that it affected the shoot and root growth differentially; that is, maintaining primary root elongation and inhibiting shoot elongation in maize seedlings. The inhibition of shoot growth is unequivocal, but the maintenance of root elongation is contradictory and needs a satisfactory resolution. In short-term experiments (100 h), using variously moist vermiculite, they concluded that the accumulation of ABA under water-stress conditions functioned both to maintain the primary root elongation and to inhibit the shoot elongation of maize seedlings. Analysis of their data [148] reveals that seedlings raised under −0.03 MPa (control) had an ABA content of 15 ng^{-1} H_2O and a root length of 210 mm. Reducing the water potential to an order of magnitude (−0.30 MPa) enhanced the endogenous level to 37 ng g^{-1} H_2O (2.5×) but reduced the root length to 179 mm (−15%), and an exogenous ABA treatment of 2×10^{-6}M (−0.03 MPa) raised the endogenous level to 44 ng g^{-1} H_2O (3×) and also reduced the root length to 175 mm (−17%). Similarly, the data presented by Sharp et al. [149] (Fig. 1A, B) clearly indicate that in -FLU (fluridone, inhibitor of ABA biosynthesis) treatment, the increase in the root lengths between 50 and 100 h was independent of the ABA content. On the other hand workers using hydroponic [150–156], aeroponic [157], and soil [154,158–160] culture system to raise seedlings or mature plants have reported inhibition of both the shoot and root growth. It is therefore possible that maintenance of root elongation in the absence of calcium in such short-term experiments may not sustain it in long-duration studies. It is also known that roots are strongly hydrotropic in nature and grow in the direction of increasing soil moisture. This was elegantly demonstrated by raising cotton seedlings in soils of differing water content [161,162] and the hydrotropic response studies with mutant pea *Ageotropum* [163]. The threshold of osmotic perception was observed to be less than 2 min, and the transduction and transmission of the stimulus to the basal growing zone required 90–120 min to elicit the response [164]. Besides, parallel variation in the maintenance of the root growth to the varying ABA concentration has yet to be demonstrated.

During the last 30 years, the role of ABA in the control of stomatal closing in the context of the plant water relation has been established. Therefore, enhanced levels of ABA were very conveniently correlated with the closing of stomata as an initial response to the water-limiting environment. But recent reports by Davies and associates [17,165] suggest that stomata may start closing before changes in the xylem ABA level are detected unless it is modified by the influence of the leaf. ABA has been shown to act indirectly by increasing the cytosolic Ca^{2+} [166]. This observation is consistent with the long-known fact that external Ca^{2+} depresses the stomatal aperture [167].

Proline is probably the most widely distributed compatible osmolyte which accumulates in living organisms, including plants, under stressful environments [168,169]. The enhanced accumulation of proline was shown to be induced by ABA [170,171], but other workers using ABA-deficient plants [172,173] or maize cultured cells [174] have demonstrated that stress-enhanced proline was independent of ABA.

ABA has been reported to suppress the accumulation of nitrate reductase (NR) mRNA by inhibiting the level of transcription in etiolated barley leaves [129]. Similarly, it has been observed that ABA treatment did not lead to an increase in the osmotin protein in ice plants (*Mesembryanthemum cystallinum*) [127].

HORMONE INTERACTIONS

The growth-regulatory activities of plant hormones depend on their interactions, but the mechanisms by which interactions control the physiological processes and development is unknown. Some might

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

consider this to be a pessimistic description of our state of knowledge which comes from the difficulty of carrying out genetic studies in this area [116].

In plants, cytokinin interacts with auxin to produce the callus and regenerate the shoot and/or root; it opposes auxin in lateral bud development (apical dominance or compensatory growth); it resembles auxin in inhibiting root elongation; it does strongly what auxin does weakly in promoting protein synthesis; and it acts in the same way as auxin to cause cell division. Similarly, gibberellin acts like auxin in promoting the elongation of etiolated stems and the formation of parthenocarpic fruit (although it generally delays fruit set); it reacts with auxin in producing the elongation of isolated green stems; it acts far more powerfully than auxin in the elongation of intact stems; and it does what auxin cannot do in causing flowering of long-day plants on noninductive photoperiods and the elongation of monocotyledonous leave sheaths. Yet gibberellin acts in the opposite direction of auxin regarding root formation by leaves and stem cuttings. It was suggested that auxin exerted its influence on lateral bud growth via enhanced ethylene synthesis, but recent evidence using transgenic overproducing auxin, cytokinin, or ethylene tobacco and *Arabidopsis thaliana* plants has shown that it was the auxin/cytokinin ratio and not ethylene which controlled the lateral bud growth [175,176]. The auxin-cytokinin countercurrent seems to be the basic regulatory mechanism controlling the plant axial growth [31]. Ethylene causes a reduction in the level of ABA, which is an antagonist of gibberellin's action, and gibberellin is the hormone that promotes internodal growth.

Gibberellic acid reverses the ABA induction of aldolase reductase, *rab/lea* genes, and α-amylase mRNA inhibition, and cytokinin enhances the accumulation of NR mRNA, which is suppressed by ABA, and the hormonal influence on NR gene expression was concentration dependent in the range of 10^{-7}–10^{-4} M [131]. ABA inhibits and cytokinin promotes the opening of leaf stomata and cotyledon expansion [129]. Plant senescence involves the interaction among auxins, cytokinins, ethylene, and ABA, and the accumulation of chlorophyll caused by cytokinin is an opposite effect of the senescence resulting from ABA treatment.

CONCLUSIONS

Early work on the environmental effects on plant/crop growth and production concentrated on the aspects of shoot growth and functioning. But some elegant experiments demonstrated that hormonal signals from stressed roots controlled leaf growth and stomatal behavior. The models suggested have a sequential four-component system that includes the perception of the stimulus, the transduction of the signal, the alteration of gene expression, and the physiological/morphological response. We now have some understanding of the hormonal mode of transduction, but information about the perception mechanism is lacking. Under a stressful environment, particularly in the root zone, hormonal imbalance in the form of enhanced ABA (inhibitor) and reduced cytokinins (promotors) seems to be coupled. These two hormones have an opposite influence on the leaf growth, stomatal behavior, senescence, and some important enzymes of the photosynthetic pathway. Recent molecular studies have shown that ABA-independent and ABA-dependent signal transduction systems operate under a stressful environment. Therefore, an important goal for future research needs will be to understand the influence of cytokinin and ABA on the early events of perception and transduction, by uncoupling their response. These studies may not be possible until suitable mutants or a chemical(s) are available to interfere with the biosynthetic pathways of the hormones. Attention also is needed to further explore the role of indole acetic acid in order to achieve the hormonal balance and ameliorate plant growth to enhance crop productivity under a stressful environment.

ABSCISIC ACID AS A STRESS HORMONE IN PLANTS

When abscisic acid (ABA) is applied externally to plants, their water relations are improved. ABA reduces water loss by promoting stomatal closure and can increase water uptake into roots. ABA application also promotes characteristic developmental changes that can help the plant cope with a range of environmental stresses. Examples of such changes are the restricted growth of shoots, the reduction in leaf surface area, a stimulation of root extension, lateral root growth, and root hair development. All these effects of ABA application, together with the observation that environmental stress stimulates ABA biosynthesis and ABA release from sites of synthesis to the sites of action, suggest a role for ABA as a stress hormone in plants.

MECHANISMS TO INCREASE THE ABA CONCENTRATION AT THE PRIMARY SITE OF ACTION AT THE STOMATA

It was shown previously [1] that the biosynthesis and metabolism of ABA are stimulated by the plant water deficit when the bulk leaf turgor is reduced close to zero. Stomatal reactions, however,

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

can be observed at much smaller water deficits. It was also observed [2] that increases in ABA concentrations in leaves and in epidermal tissues are seen only after a lag phase of 30–60 min after the onset of stress, a time period within which stomatal reactions to the initiation of the stress have often been completed.

We must therefore ask how ABA concentrations can be increased at the primary site of action under conditions in which ABA biosynthesis is not affected? The primary site of action for ABA on the stomata was shown to be the outer surface of the plasmalemma of the guard cells [3–5]. Even if we assume that ABA may be recognized by cytosolic structures of the guard cells [6], the apoplast surrounding the guard cells is regarded as the relevant compartment so far as ABA action is concerned, because this is the only compartment from which ABA can be taken up into the guard cells.

Several possible mechanisms explain the ABA-dependent closure of guard cells under these special conditions:

1. ABA may be released rapidly from the mesophyll cells to the apoplast.
2. ABA may be transported from the roots in the transpiration stream to the leaves and to the stomata. In this respect, it may be important that under certain specialized conditions, only a few roots in the shallow soil layers, which dry out more rapidly than other parts of the root system, may be sufficient to supply the leaves with sufficient ABA to promote stomatal closure. This may occur even when the water relations of the shoot are unaffected by the soil-drying treatment.
3. Guard cell sensitivity and responsiveness to ABA may be changed by environmental stress, which could result in rapid and sensitive ABA responses.

Redistribution of ABA in Leaves Under Environmental Stress

ABA is the only one of the known acid plant hormones that distributes across the mesophyll cell compartments according to the anion trap concept [7]. The undissociated abscisic acid ABAH is the only permanent ABA species that passes the membranes by diffusion and is trapped in alkaline compartments (cytosol and chloroplast) as the almost completely nonpermeant anion ABA. Alterations of intracellular pH gradients therefore redistribute ABA between the leaf cell compartments. From the stress physiological perspective, apoplastic alkalization accompanied by a slight cytoplasmic acidification, as observed by Hartung et al. [8], is of particular interest.

This flattening of pH gradients, which occurs before turgor is reduced to zero, results in a substantial and rapid increase in the ABA concentration in the apoplast. Hartung and Slovik [7,9] performed a computer simulation of ABA redistribution and confirmed that this can be a rapid and sensitive process.

ABA AS A MESSENGER FROM THE ROOT SYSTEM TO THE STOMATA

It is now clear that, under many circumstances, stomatal behavior can be closely related to changes in the soil water conditions even when leaf water relations are not affected by these changes. Blackman and Davies [10] showed with split root experiments with maize (in which one part of the root is well watered but the other suffers from drought stress) that stomata close despite the maintenance of a high water potential in the leaves. These results, together with many other findings (for references see the review of Davies and Zhang [11]) strongly indicate that roots can sense some aspect of the soil water status. Stomatal behavior can be regulated as a function of the strength of these signals.

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

ABA Biosynthesis in Roots

It was shown by several research groups that dehydration of isolated root systems increased ABA biosynthesis. Zhang and Davies [12] showed this for isolated maize root segments, Cornish and Zeevaart [13] and Cornish and Radin [14] for tomato and cotton roots, and Hartung and Abou-Mandour [15] for bean roots. Roots contain all the necessary precursors for ABA biosynthesis via the indirect violaxanthin pathway [16]. Burbridge et al. [17] have studied the gene expression of zeaxathin epoxidase (ZE), an enzyme that is believed to catalyze two early steps of the indirect ABA biosynthetic pathway. Drought treatment showed no effect on the abundance of ZE mRNA in tomato leaves. More recently, Burbidge et al. [18] have isolated a cDNA encoding a protein capable of catalyzing the oxidative cleavage of a 9-cis xanthophyll. They note that this is probably a key regulatory step in ABA biosynthesis. Northern analysis showed that there was a substantial drought stress–induced rise in the transcript level. The upregulation of gene expression is consistent with the proposed role of the cleavage enzyme as a key regulatory step in the ABA biosynthesis pathway. Nevertheless, the exact target of stress in the ABA biosynthesis pathway is still not known.

Carandang and Hartung (unpublished data) reinvestigated the increase in the ABA concentration in dehydrated maize and bean roots and observed the strongest capacity of a biosynthesis in root tips indicating that ABA synthesis occurs mainly in the cytosol of nonvacuolated cells (Fig. 1). Cortical and stelar tissues exhibit a comparable capacity for ABA biosynthesis (Fig. 2). As reported by other investigators [13,14], however, a quite drastic loss of water is required to stimulate ABA biosynthesis. As discussed, sensitive mechanisms are necessary to meet our postulations. It is therefore necessary to consider whether stress-dependent ABA redistribution in roots can play a role in stress signaling.

ABA Redistribution in Roots Under Stress

The question arises of whether mechanisms of ABA compartmentation and redistribution, which were found to be valid in leaves, can also be applied to root systems. Although, in leaves, stress

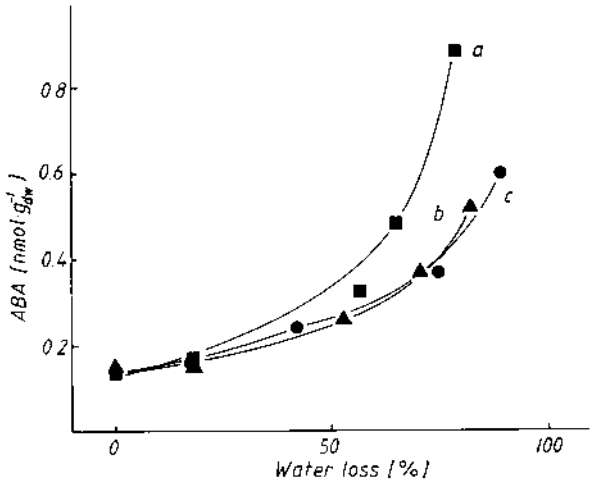

FIGURE 1 Accumulation of ABA in isolated root tip segments of *Zea mays* dependent on the percentage of water loss. Root segments (a, 0–3 mm; b, 3–6 mm; c, 6–9 mm behind the tip) were allowed to lose water to a certain percentage. The segments were then kept for 2 h under these conditions and then extracted and analyzed for ABA. (From J. Carandang and W. Hartung, unpublished data.)

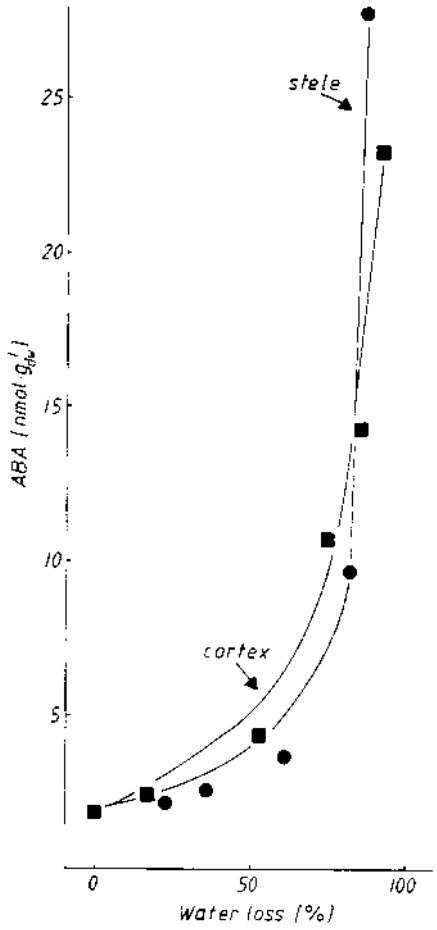

FIGURE 2 Accumulation of ABA in isolated 15-mm long cortical and stelar sections of *Phaseolus coccineus* dependent on the percentage of water loss. For further details see Figure 1.

must increase the apoplastic ABA concentration by an enhanced release of ABA from the mesophyll cells, the situation in roots is more complex.

Assuming that radial ABA transport in roots is symplastic predominantly, the ABA concentrations should be increased in the cytoplasm of cortical cells. This allows transport symplastically via the passage cells of the endodermis to the stele. Having arrived in the stele, ABA should be released easily from the xylem parenchymal cells to the xylem vessels.

To explain this process by the anion trap concept, which works perfectly in leaf tissues, we must postulate an increase in the pH gradients in the cortical tissues rather than a flattening, as occurs in the mesophyll. Thus, stress should acidify the apoplast of the cortex or alkalize the cortical cytosol, or both.

In fact, ^{31}P nuclear magnetic resonance (^{31}P-NMR) investigations [19] have shown that osmotic stress (caused by polyethylene glycol) and salt stress alkalize both the root tip cytosol and the vacuoles of maize. Daeter et al. [20] also determined the permeability the coefficients of the cortex root plasma membranes of maize for ABA and found them to be lower by one to two orders

of magnitude than those of plasma membranes from other tissue types. This would diminish loss of cytoplasmic ABA during symplastic transport to the stele. Incorporation of these findings into a computer model of Slovik et al. [21] predicts only small changes in the ABA concentration in the leaf apoplast. However, when the pH_{cyt} of the xylem parenchymal cells in the model is reduced by only 0.1 unit ABA_{xyl} is significantly increased by drought stress. Armstrong et al. [22] have shown that stelar tissues form an anoxic core even in well-aerated roots. Anoxic conditions can reduce pH_{cyt} by 0.2 unit for at least 16 h [23].

FACTORS AFFECTING ABA CONCENTRATION IN THE XYLEM SAP

Soil Water Content

Zhang and Davies [24,25] have convincingly shown that soil drying increases the ABA concentrations in both the root tissue and the xylem sap ascending from the roots. Presumably, a reduction in the root turgor volume will increase ABA synthesis in the roots. There are, however, characteristics of a drying soil that may also be responsible for increased ABA biosynthesis. Soils from extreme habitats like deserts exhibit, besides a reduced water content, an increased salt concentration, alkaline pH values, reduced nutrient supply, and high soil strength [26].

Salt Factor

High concentrations of NaCl in the soil solution can significantly increase the ABA concentrations in plant organs and transport fluids. Wolf et al. [27] studied the long-distance transport of ABA in salt-stressed lupins (*Lupinus albus*) and showed that the salt stress increased the phloem sap ABA by a factor of 5 and the xylem sap ABA by a factor of 10. Mathematical analysis of their data led to the conclusion that a significant portion of the xylem sap ABA was derived from the leaves and was transported from there to the roots and then retranslocated in the xylem back to the leaves. This recirculation of ABA also was stimulated significantly under conditions of salt stress.

Peuke et al. [28] and Jeschke et al. [29] have studied ABA flows in mildly stressed *Ricinus communis*. The strongest effect could again be observed on ABA accumulation in the roots and the ABA transport in the xylem. The stimulation of ABA accumulation in the tissues and the ABA export in the phloem were observed predominantly in fully mature but nonsenescent leaves.

Effects of Salts Different from NaCl

The effect of different cations and anions on ABA accumulation in wheat leaves has been studied by Varma [30]. Among cations, excessive sodium and magnesium had the strongest effect and calcium and potassium the weakest effect on ABA accumulation. Chloride salts, on the other hand, proved to be more effective than sulfate, nitrate, and carbonate salts.

Alkaline pH

Soils with high salt concentrations usually have a very alkaline pH. When we apply the anion trap concept to roots growing under these conditions, we should expect a release of ABA into the rhizosphere. Such an increased ABA release to the alkaline soil solution that was predicted by computer simulations of Slovik et al. [21] would result in severely ABA-deficient plants, assuming that the soil solution was free of ABA. According to Slovik's mathematical model, the dramatic loss could be prevented if ABA would be present in the soil solution in the low nanomolar concentration range. Indeed, ABA has been detected in soil solutions of different soil types under different crops in the range of 0.5–5.0 nM [31]. On the other hand, however, many roots acidify their rhizosphere, especially under conditions of nutrient deficiency. This was shown for phosphate-starved members of

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

the *Brassicaceae* [32]. Such a proton release would increase pH gradients between root cytosol and apoplast (which is in direct contact with the rhizosphere) and prevent ABA starvation of roots. From a preliminary series of experiments with *Lupinus angustifolius* (alkali susceptible) and *Cicer arietinum* (alkali tolerant) (W. Hartung and N.C. Turner, unpublished results), it seems that ABA biosynthesis in the roots of the alkali-tolerant chickpea is increased causing a high ABA concentration in both the xylem sap and the soil solution.

Reduced Nutrient Supply

Application of Nitrogen to the Roots

It has been known since the 1930s [33] that nitrogen (N) deficiency mimics drought stress. Nitrogen deficiency also increases ABA concentrations in leaves and roots [34]. In sunflower, concentrations of leaf and root ABA increased following a 60% reduction in nitrate availability [35]. Interestingly, a similar reduction in the nitrate supply reduced the ABA concentration in the xylem of *Ricinus* plants [28].

The source of N may also be important for the stress physiology of the plants. NH_4^+ supplied as the only N source has strong inhibitory effects on leaf and root development. Peuke et al. [28] (Fig. 3) observed a threefold increase in the xylem ABA flow and a twofold increase in the phloem ABA flow of NH_4^+-stressed *Ricinus* plants compared with nitrate-nourished plants. In *Phaseolus vulgaris*, the NH_4^+-dependent increase in the xylem sap (ABA) was five- to sixfold, which is a particularly dramatic increase for this plant.

Foliar Application of Nitrogen

When nitrate or ammonium is sprayed on the leaves of *Ricinus* and the root nutrient medium is kept free of nitrogen, the ABA biosynthesis in the leaves of the nitrate-sprayed plants is stimulated. A high portion of this ABA is loaded to the phloem and translocated to the roots where most of the ABA is metabolized. In ammonium-sprayed plants, a significant ABA net biosynthesis can be observed in the roots resulting in a root to shoot ABA transport in the xylem which is four to five times higher compared with the nitrate-treated plants. Again, a large portion of phloem-transported ABA is recirculated to the shoot. Surprisingly, this resembles strongly the situation of the plants in Figure 3, where roots were supplied with nitrogen. We have to postulate a shoot to root signal of the ammonium-sprayed plants that causes stimulation of ABA biosynthesis in roots and ABA xylem transport. The nature of this signal is unknown.

Phosphate Deficiency

As pointed out above, saline soils can be very alkaline. A high pH of the soil solution causes a reduced availability of phosphate for the roots as long as the roots are not able to acidify their rhizosphere. Radin [36] studied the influence of phosphorus (P) deficiency on the accumulation of ABA in cotton leaves. The ABA levels were only slightly increased at water potentials below -1.5 MPa. The sensitivity of guard cells, however, was greatly enhanced.

In castor bean, P deficiency causes similar effects as mild salt stress as far as C and N flows are concerned. Different from salt-treated castor bean, however, the ABA accumulation in the leaves was very low despite a massively increased import of ABA in the xylem to the leaves [29].

Potassium Deficiency

Only very few data have been published on effects of potassium (K^+) deficiency on ABA in plants. In K^+-deficient wheat plants, the ABA levels in the leaves and the grains are much higher than in the controls, which may be responsible for the premature ripening of grains [37].

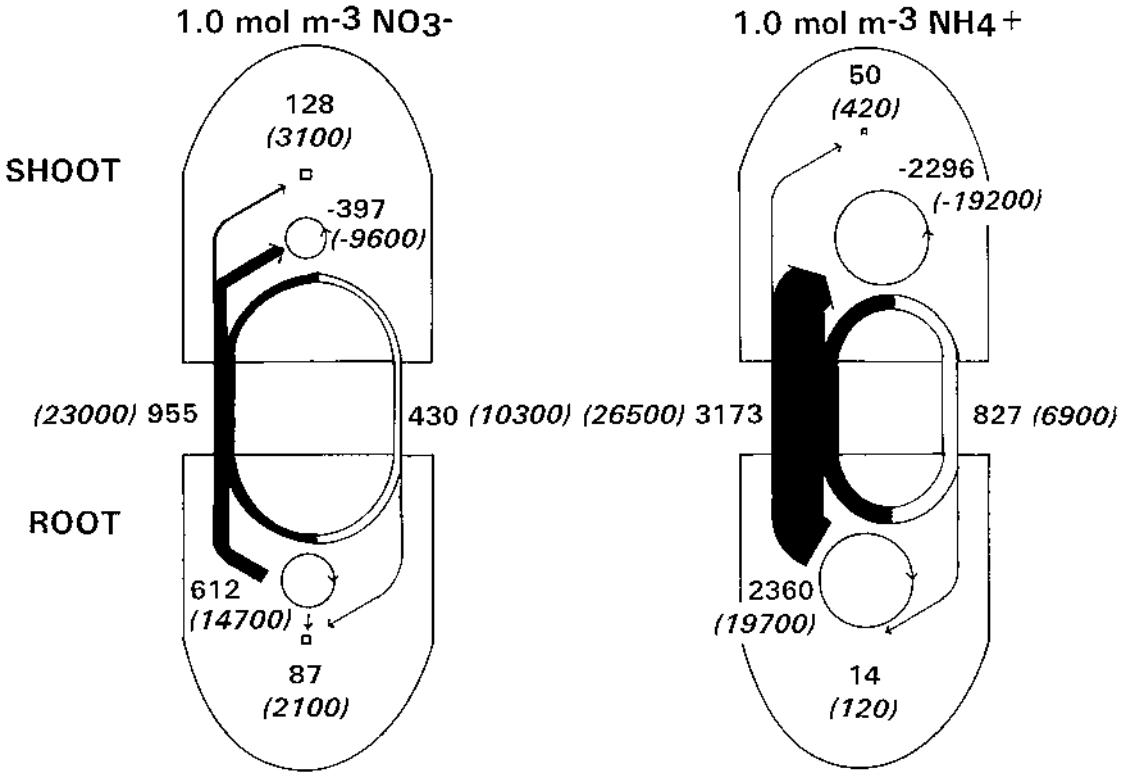

FIGURE 3 Flow profiles for transport, utilization, and net-synthesis or metabolism of ABA in castor bean plants that have been supplied with 1 mM nitrate or ammonium. Open arrows indicate flows in the phloem, black arrows the flows in the xylem. The widths of the arrows (flow in phloem and xylem), the area of squares (deposition), and circles (net synthesis/degradation) are drawn in the relation of the rates of flows. The numbers beneath the arrows, squares, and circles indicate net flows in pmol g^{-1}_{frwt} $(10\ days)^{-1}$. Upward arrows of the circles denote net synthesis, downward arrows net degradation. Numbers in italics show nmol $plant^{-1}$ $(10\ days)^{-1}$. (Redrawn after Ref. 28.)

Micronutrients

It has been shown recently that mutants which are deficient in the molybdenum cofactor (MoCo) also are ABA deficient. The MoCo is not only an important component of the nitrate reductase but also of aldehyde oxidase, the latter of which catalyzes the last step of ABA biosynthesis, the oxidation of ABA aldehyde [38,39]. Indeed, foliar sprays of molybdate to wheat leaves increase the ABA content, responsiveness to applied ABA, and dormancy of embryos significantly [40]. Peuke et al. [28] (see Fig. 4) have shown that an optimal nitrate supply stimulates ABA synthesis in the roots and leaves (foliar spray) of *Ricinus*. Nitrate treatment induces nitrate reductase which includes the MoCo and consequently the oxidation of ABA aldehyde.

High Soil Strength

It has long been known that a high soil strength (or mechanical impedance) inhibits plant growth and development. Masle and Passioura [41] observed that growth-inhibiting effects on shoots can

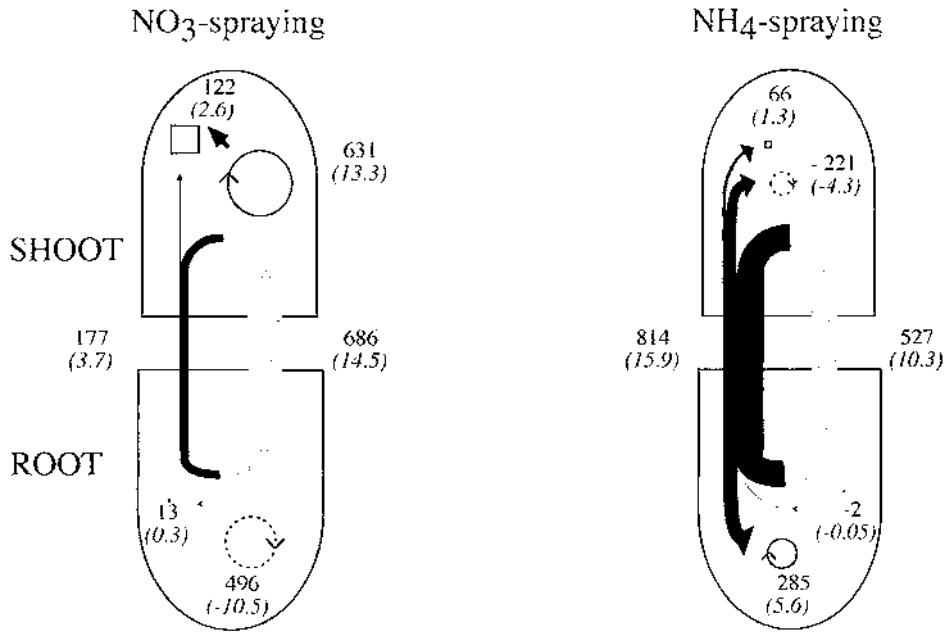

FIGURE 4 Flow profiles for transport, utilization, and net-synthesis or metabolism of ABA in castor bean plants that have been sprayed with nitrate or ammonium. The root nutrient medium was free of nitrogen. For further details see legend of Figure 3. (From A.D. Peuke, W.D. Jeschke, and W. Hartung, unpublished data.)

be greater than those on roots. These responses occur even under conditions in which the water relations of the shoots were not affected by mechanical impedance. These investigators [41] conclude that roots may signal to the shoots the effects of the interaction between the root and the compacted soil. Such a signal may modify the growth and development of the plant. Tardieu and coworkers [42–44] detected increased ABA concentrations in the xylem sap of maize plants growing in compacted soil. This extra ABA apparently reduced stomatal conductance. Enhanced ABA concentrations seemed to be a result of poor water supply and root dehydration in compacted soil rather than a direct effect of compacted soil [45,46]. When roots are forced to penetrate compacted soil, they increase radial growth, the number of root hairs, and the size of the root cap. Root hairs can act as an anchor to facilitate the penetration of the compacted soil. Very similar morphological changes can be observed when seedlings are cultivated in a nutrient medium containing 0.1–1.0 μM ABA. Maize seedlings growing in compacted soil show a 10-fold increase in the xylem sap ABA, especially during the first days after germination. It therefore seems that enhanced ABA can aid root penetration with secondary effects on shoot physiology [45,46].

Recently, Mulholland et al. [47,48] studied the influence of soil compaction on ABA relations in barley plants. They also found a transient increase of ABA_{xyl} as a result of soil compaction. Different from maize [46], however, the investigators concluded that ABA acts as a leaf growth promoter to maintain leaf growth under conditions of compaction stress.

SENSITIVITY OF STOMATA TO ABA

In most plants, leaf water deficit causes ABA concentrations to increase by a factor of 10–30, but the response of bean plants (*P. vulgaris*) to stress is very weak (except ammonium-stressed beans).

Trejo and Davies [49] found that ABA in the xylem sap increased by only a factor of 2, even in particularly stress-resistant varieties that were very severely droughted. Similar observations were made with *Phaseolus coccineus* [50]. Smith and Dale [50] also observed very weak ABA increases in the leaves of bean plants that were stressed by root cooling.

Two conclusions can be drawn from these findings:

1. Guard cells of bean leaves are particularly sensitive to ABA.
2. ABA is not the only chemical regulator generated by environmental stress.

Field experiments with maize [51] and with desert-grown almond trees [52] showed a biphasic relationship between the xylem sap ABA concentration and the leaf conductance (Fig. 5) under circumstances in which other environmental and plant factors (including leaf water status) vary greatly. Within a relatively narrow range of xylem sap ABA concentration, small increases in ABA have a dramatic consequence for leaf conductance, and a further increase is largely ineffective. These results suggest that, in many plants, a highly sensitive stomatal response to ABA can be observed.

In field experiments, Tardieu and Davies [51] observed diurnal variations in the sensitivity of maize stomata to ABA. They provide strong evidence that the leaf water potential modifies sensitivity, with an increased stomatal sensitivity to ABA during the afternoon hours when the leaf water potentials are low. These data are consistent with the findings of Burschka et al. [53], who observed that *Arbutus unedo* guard cells exhibited a diurnal variation in sensitivity to small doses of ABA injected into the transpiration stream. Burschka et al. [53] found that, in their system, sensitivity was also increased during the later afternoon hours. In cotton leaves, nitrate and phosphate deficiency also enhance stomatal sensitivity to ABA [36,54].

Model calculations of Hartung and Slovik [7] may also be important in this context. These investigators concluded that a fivefold increase of ABA in the xylem sap is sufficient to increase

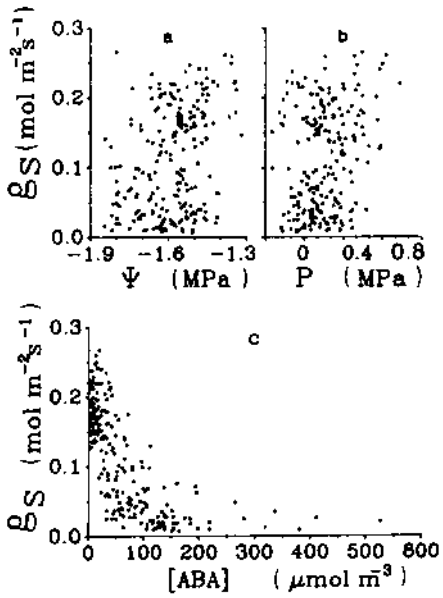

FIGURE 5 Stomatal conductance of maize plants growing in the field as a function of leaf water potential (a), leaf turgor (b), or xylem ABA concentration (c). (From Ref. 44.)

ABA at the primary site of action and that a twofold increase keeps the ABA at a constant high level over several days.

All these data show that small increases in ABA, as observed in beans, can be sufficient to explain the postulated stomatal responses, especially when changes in the ABA sensitivity of guard cells dependent on water and nutritional status are taken into consideration.

Detailed field observations [55] have suggested that the concentration of ABA in the xylem is determined not only by the degree of root dehydration but also by the rate of water movement through the soil-plant-air continuum. A high evaporative demand increases water flux and dilutes the ABA added to the transpiration stream from the drying roots. It is clear that without an increase in stomatal sensitivity to ABA, as the leaves dehydrate at higher fluxes, a chemical signaling system would have a little effect on hot and dry days, precisely the conditions under which it would be of most use.

Recent investigations of Daeter and Hartung [56] and Hartung et al. [57] demonstrated that ABA carriers at the epidermal plasma membranes and the metabolism of ABA in the cytosol of the epidermis and mesophyll cells are important for keeping the apoplastic ABA concentration in unstressed leaves low and for speeding up ABA redistribution under stress.

Recent experiments by Wilkinson (personal communication) suggest that even the very low concentration of ABA found in well-watered plants is important in the regulation of stomatal behavior. This is apparent, because the stomata of ABA-deficient mutants open in response to an alkaline pH treatment. The same treatment closes the stomata of wild-type plants. This means that low ABA concentrations may prevent excessive stomatal opening when conditions are such that an alkalinization of sap is promoted.

ABA Conjugates as Stress Signals

It has been postulated recently [58,59] that ABA-conjugates can act as root/shoot stress signals in a range of plants. Indeed, Bano et al. [60,61] have detected glucose esters of abscisic acid (ABA-GE), phaseic acid, and dihydrophaseic acid in the xylem sap of drought-stressed rice and sunflower plants, and Jeschke et al. [29,62] found ABA conjugates in the xylem sap of castor bean and maize plants.

As an example of ABA-GE as a potential long-distance hormonal signal in castor bean, the data of Figure 6 are shown which originate from the experiment shown in Figure 4, where leaves were sprayed with nitrate and ammonium. Under these conditions, ABA is conjugated in the leaves and deposited there, presumably in the vacuoles. Additionally, a significant part is loaded to the phloem and transported to the roots. There part of the ABA-GE is recirculated to the shoot. Similar to the case of free ABA (see Fig. 4), flows of conjugated ABA are stronger in ammonium-treated than in nitrate-treated plants.

ABA conjugates are believed to be extremely stable. In most cases, investigated conjugated ABA was not hydrolyzed to free ABA, especially when ABA-GE has been deposited in the vacuoles. The question arises of how ABA conjugates are taken up by the mesophyll cells after arrival in the leaf apoplast, because the permeability coefficient of the mesophyll plasma membranes for ABA-GE is extremely small (10^{-11} ms^{-1}) [63]. Additionally, we have to keep in mind that ABA-GE is physiologically inactive [64] and needs to be hydrolyzed before acting on the guard cells. Therefore, we postulate hydrolytic enzymes in the apoplast which may release ABA from the conjugate and allow free ABA to be taken up by the mesophyll cells and to act on the guard cells.

ABA as a Shoot to Root Stress Signal

The computer simulations by Slovik et al. [21] predicted that large quantities of ABA that has been synthesized in the mesophyll tissues should be loaded to the phloem and transported to sinks, mainly

Marcel Dekker, Inc.

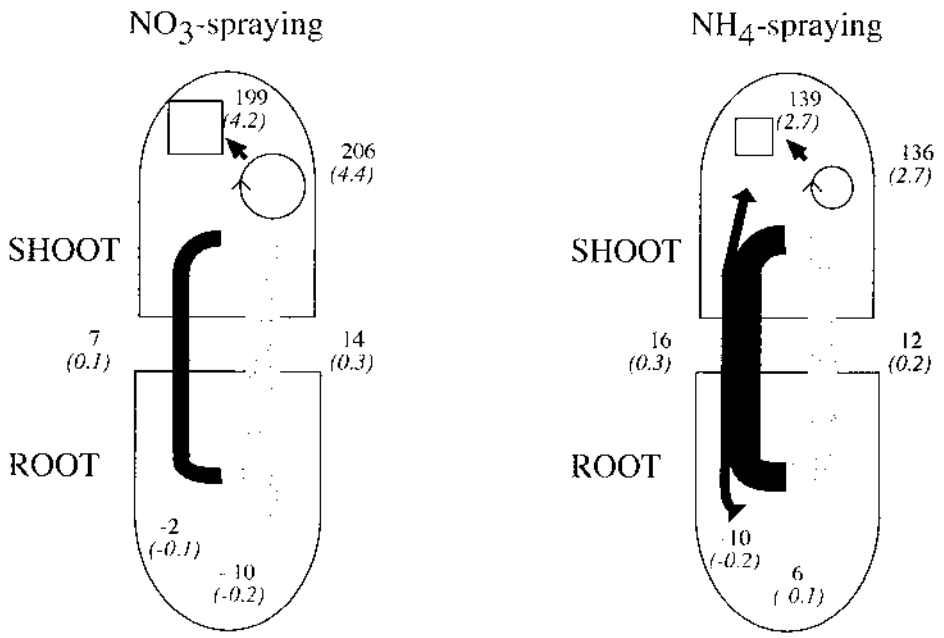

FIGURE 6 Flow profiles for transport, utilization, and net formation/degradation of conjugated ABA in castor bean plants that have been sprayed with nitrate or ammonium. For further details, see legend of Figure 3. (From A.D. Peuke and W. Hartung, unpublished data.)

the roots. As discussed earlier, a significant fraction of this ABA can be recirculated to the shoot again. ABA also can be taken up by the stelar and cortical tissues where developmental processes, such as lateral root and root hair formation, could be initiated.

A role as a shoot to root signal has been postulated for castor bean seedlings by Zhong et al. [65]. They observed that mild reduction of water potential in cotyledonal cells in the direct neighborhood of the phloem elements of *Ricinus* caused an increase of the ABA concentration in the phloem sap up to 50-fold. Our investigations of ABA long-distance transport of salt-stressed lupins and castor beans showed that fully expanded leaves acted as a net ABA donor for other sinks. This was not the case under nutrient deficiency. Neither nitrate- nor phosphorus-deficient *Ricinus* leaves exported significantly increased amounts of ABA to sinks [28,29].

Leaves of maize plants that were cultivated with their seminal roots only experienced drought stress because water flow was restricted by the constant number of xylem vessels in the mesocotyl, although the roots were sufficiently supplied with water and nutrients. The ABA content of the leaves of single-root maize plants were elevated up to 10-fold and leaf conductance was reduced significantly. Surprisingly, however, the ABA concentrations in the roots of single-rooted plants were clearly increased compared with the controls; most likely due to the increased ABA import via the phloem. In this system, ABA as a shoot to root stress signal may stimulate compensatory root growth of the seminal root system and may increase the hydraulic conductivity of the root system [62].

Figure 7 shows the relation between the leaf ABA concentration of castor bean plants and the phloem sap ABA concentration and the ABA phloem flow. These data support a role of the leaf ABA that is loaded predominantly to the phloem vessels and may act as a shoot to root stress signal.

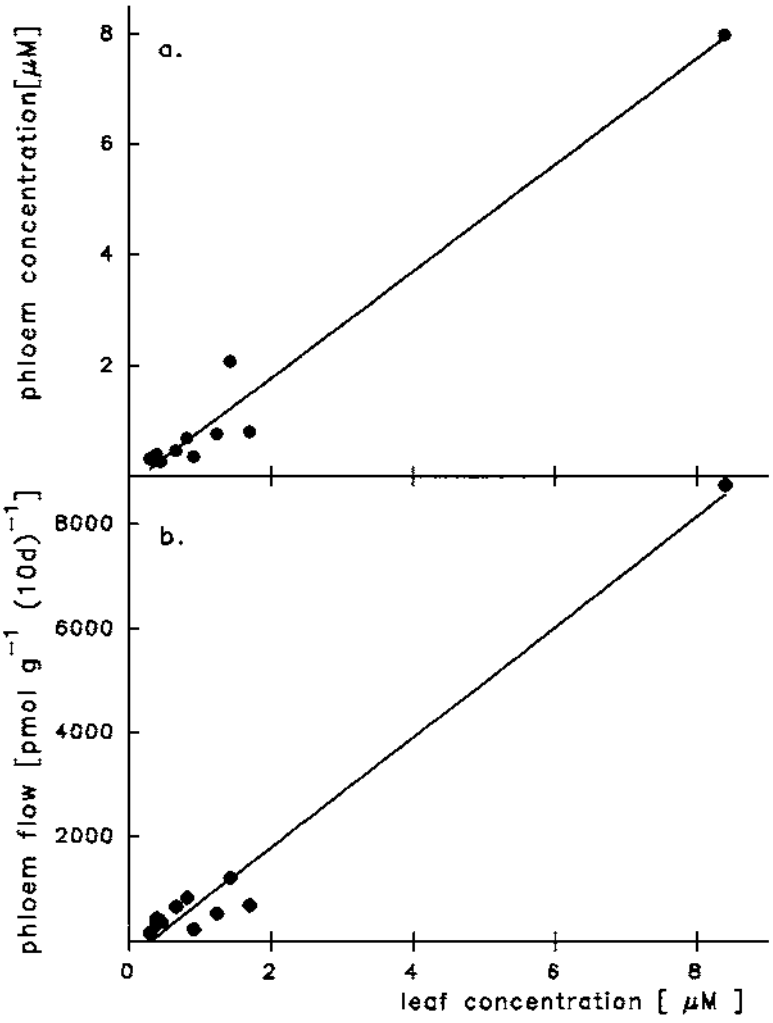

FIGURE 7 Relation between ABA concentration in castor bean leaves and ABA concentration and flows in the phloem. (Data taken from Refs. 28 and 29 and Fig. 4.)

ABA AND NONSTOMATAL REACTIONS

There has recently been much discussion of whether ABA affects nonstomatal processes in leaves, such as photosynthesis. Many conclusions have been drawn from gas-exchange experiments in which internal CO_2 concentrations are calculated before and after the application of ABA to the transpiration stream [66,67]. The results of many of these types of experiments suggest that ABA directly affects the photosynthetic processes in the leaf, but these results must be open to the question, since ABA may cause nonuniform stomatal closure [68], which can cause difficulties in the calculation of intercellular CO_2 concentrations.

ABA effects on the photosynthetic metabolism also have been investigated using the oxygen electrode. These results seem to be far more reliable, and with these techniques, the direct effects of ABA are negligible [69]. Experiments in which measurements of intercellular CO_2 were made

confirm this conclusion but suggest that water deficits may have a rather different effect on photosynthetic processes.

An additional nonstomatal stress physiological role has been suggested recently by Hollenbach et al. [70]. They observed that expression of the lipid transfer protein (LTP) gene (*ltp*) in barley leaves is stimulated when ABA is accumulated. LTPs play an important role in transfer of cutin and wax monomers from the site of synthesis to the cuticle. Thus, again, ABA influences the water relations of plants by increasing the wax layers on the cuticular surface.

ABA AND DEVELOPMENTAL PROCESSES

It has long been known that reduced soil moisture status can change the ratio of shoot to root in favor of the root system [71] and that similar responses and the formation of root-hairs and lateral roots can be stimulated by ABA applications [72,73]. Root growth at a reduced water potential was studied in detail by Sharp and coworkers [74]. This group showed that the tips of primary maize roots continue to grow under a reduced soil water potential when the growth and development of shoots are already inhibited. Maintenance of root growth at a low water potential is associated with a very substantial deposition of proline in the cells in the growing zone [75] and an increased activity of xyloglucan endotransglycosylase (XET) and the expansins. These enzymes may loosen cell walls and thereby sustain cell elongation in roots even when turgors are slightly reduced.

Treatment of roots with the carotenoid synthesis inhibitor fluridone reduces the ABA concentration in the root tips and substantially reduces growth at a low water potential [76] but not at a high water potential. This result suggests that roots have a requirement for ABA to help sustain cell expansion at a low water potential. Interestingly, fluridone treatment reduces proline deposition rates into the growing zone, but deposition rates are increased by ABA application to fluridone-treated roots.

A large number of developmental processes that depend on ABA accumulation under stress are listed by Trewavas and Jones [77].

CONCLUSIONS

There is an interesting parallel between the interacting effects of ABA and low water potential on both the root growth and the stomatal behavior. In both cases, the effects of ABA are increased as water potential falls. These results support the suggestion that there is a central role for ABA in the control of gas exchange and the growth and development of drought plants, but they also show that this chemical regulator cannot be considered to act entirely independently of changes in plant water relationships.

INTRODUCTION

Stratospheric Ozone Depletion and Ultraviolet B Fluxes

Ozone (O_3) is a minor constituent of the earth's upper atmosphere (stratosphere: 20–50 km above the earth's surface) and is produced by the combination of oxygen molecules formed by the breakdown of O_2 by the sun (Fig. 1). It is now well established that ozone concentrations in the stratosphere have declined during the last 25 years as a direct result of anthropogenic pollution of the atmosphere with a variety of chlorine- and bromine-containing compounds [1,2].

The importance of ozone in the stratosphere, with respect to life on earth, is that this is the only gas in the upper atmosphere that appreciably absorbs radiation below 300 nm. The absorption coefficient increases by many orders of magnitude with decreasing wavelength. Only the levels of ultraviolet B (UVB: 280–320 nm) radiation reaching the earth's surface will be affected by ozone loss (Fig. 2).

The detection of slight long-term increases in UVB levels due to ozone loss are difficult because the flux of UVB reaching the earth's surface is influenced by numerous atmospheric conditions apart from ozone content [3]. Nevertheless, increases in the levels of UVB attributed to ozone depletion have been reported over the Swiss Alps (0.7–1.0% increase per annum from 1979 to 1990) [4] and over New Zealand [5]. Although the precise nature of changes in the UV environment are not certain, it is apparent that there is likely to be increased amounts of UVB radiation reaching the earth's surface; an estimated 1.5- to 2.0-fold increase for every 1% loss of ozone. The regions in the Southern Hemisphere, where ozone depletion is most severe and the atmosphere relatively unpolluted, will likely be more significantly affected.

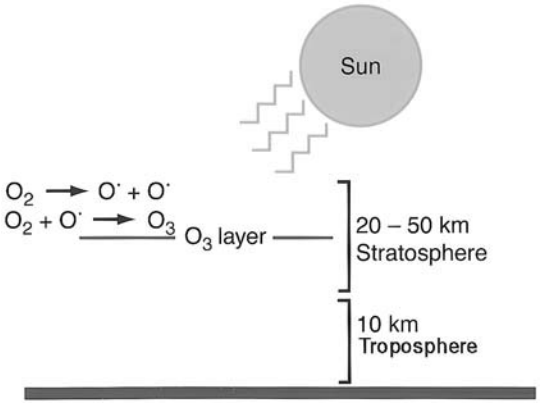

FIGURE 1 A schematic representation of the earth's upper atmosphere. The position of the ozone layer is indicated.

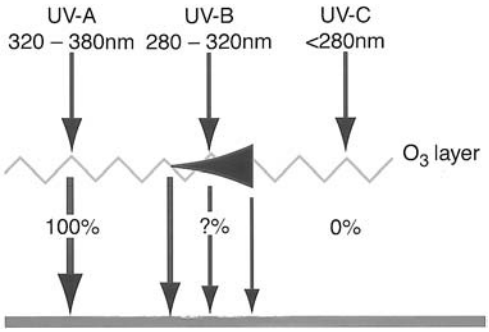

FIGURE 2 Diagrammatic representation of changes in UV penetration to the earth's surface in relation to changes in stratospheric ozone. At shorter wavelengths, <280 nm (UVC), absorption by ozone is so great that a small fraction of the present ozone layer is sufficient to block this radiation completely. At wavelengths >320 nm (UVA: 320–380 nm) absorption by ozone is so weak that changes in ozone are of no consequence. Only the levels of ultraviolet B (UVB: 280–320 nm) radiation reaching the earth's surface will hence be affected by ozone loss.

UVB radiation is potentially damaging to all living organisms, but it is especially so for plants, as they require sunlight for survival and as such are unable to avoid exposure to changes in the UVB environment. There have been many studies on the effects of UVB on plants, and this work has been extensively reviewed [6–8] and the most common effects are summarized in Figure 3. In addition, the exposure of plants to UVB radiation has been more recently shown also to have profound effects on cellular metabolism. These effects include the suppression of primary metabolic functions such as the expression and synthesis of the photosynthetic proteins Rubisco large (*rbcL*) and small (*RbcS*) subunits and chlorophyll *a*/*b*–binding proteins (*Lhcb*) (reviewed in Refs. 9, 10); the induction of elevated antioxidant responses, such as the expression and activity of superoxide dismutase (SOD), glutathione reductase (GR), and ascorbate peroxidase (APX) [11–13]; and the accumulation of phenolic pigments [14,15]. The effects of UVB at this level are likely mediated

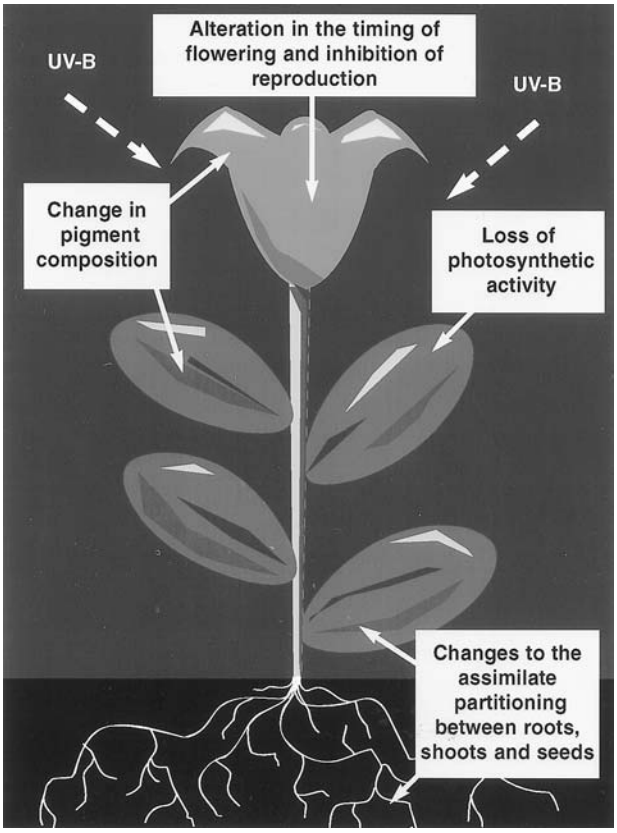

FIGURE 3 Diagrammatic representation of the most common effects of UVB on plant physiology and biochemistry.

through specific photoreceptors and subsequent signal transduction pathways and/or through absorption of UVB by DNA leading to subsequent changes in gene expression.

This chapter reviews the effects of UVB radiation on cellular metabolism, and more specifically gene expression, and the mechanisms and pathways by which UVB mediates these effects.

EFFECTS ON GENE EXPRESSION

In contrast to the physiological and biochemical impacts of UVB on plants, little is known about the effects of UVB on gene expression. The best-characterized genes are those encoding key proteins involved in photosynthesis, which are downregulated in response to UVB, and several genes encoding ''defense'' proteins, which are upregulated. This section will consider these two sets of genes separately.

Chloroplast Proteins

The exposure of plants to supplementary UVB leads to a reduction in photosynthesis, and biochemical studies have shown that chloroplasts are a major site of UVB damage. UVB exposure leads to a reduction in the efficiency of electron transport, photophosphorylation, and carbon fixation, all of

MARCEL DEKKER, INC.

which contribute to the decreases observed in the rate of photosynthesis [16,17]. More recently, it has become clear that UVB radiation also effects the expression of genes encoding key photosynthetic proteins and that UVB effects at this level can account, to some extent, for the overall inhibition of photosynthesis by UVB radiation [17–19]. In these studies, transcripts for key chloroplast proteins decline in response to UVB exposure within hours leading to a subsequent loss of enzyme activity and protein content over a period of days [17,19]. These studies have also highlighted that UVB-induced changes in gene expression are complex and dependent on several parameters, including the developmental stage of tissue studied and the level of background light provided throughout the UVB treatment [17,20]. These points will be discussed in detail in the section on Factors Affecting Gene Expression below.

Chloroplast proteins are encoded on the nuclear and chloroplast genomes. Both nuclear- (*Lhcb, RbcS* and the γ-CF_1-ATPase) and chloroplast-encoded (*rbcL, psbA,* CF_1-ATPaseB-E, cytochrome *b*, and subunit IV of the cytochrome *b*/*f* complex) transcripts are reduced in response to UVB exposure [9]. The actual extent of the downregulation is dependent on the severity of the UVB exposure; however, in general, chloroplast-encoded transcripts are maintained for longer periods than nuclear-encoded transcripts (Fig. 4). Hence, the reduction in the nuclear-encoded *Lhcb* transcript occurs rapidly, with as much as about an 80% reduction after 4 days (Fig. 4a[i]) in contrast to the chloroplast-encoded *psbA* transcripts which remain at about 90% of the control level even after 4 days of UVB exposure (Fig. 4a[ii]) [19,20]. These differences, however, do not necessarily provide a true reflection of the decline in the protein levels or, in fact, the extent of the loss of a particular photosynthetic function.

Nuclear genes are primarily regulated at the transcriptional level, whereas plastid-encoded genes also are subjected to posttranslational regulation [21]. The differences in the response of nuclear- and chloroplast-encoded photosynthetic genes may simply be a reflection of these different regulatory processes. Although there is only limited data available to define at what level the inhibition of UVB on gene expression takes place, studies carried out so far are consistent with this idea. The decline in the steady-state level of the nuclear-encoded *Lhcb* gene corresponded to the loss in the protein concentration of the chlorophyll *a*/*b*-binding protein (see Fig. 4a[i] and b[i]). In addition, the functionality of the mRNA, as determined by in vitro translation assays, was consistent with the mRNA and protein profiles. These results indicate that nuclear-encoded genes appear to be largely regulated at the transcriptional level in response to UVB [19]. The regulation of these genes may, however, be more complex. For instance, in ^{35}S-methionine labeling of pea leaf disks, the

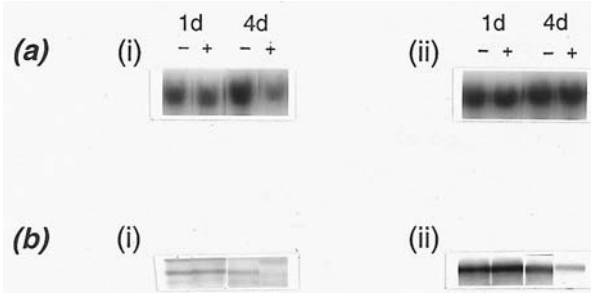

FIGURE 4 Changes in expression and protein levels of photosynthetic genes in response to UVB radiation. (a) Autoradiographs of Northern blot analysis of total RNA from fully expanded leaves of 17-day-old pea seedlings treated with (+) or without (−) supplementary UVB exposure. The RNA was then hybridized to ^{32}P-labeled (i) *Lhcb* and (ii) *psbA* CDNA. (b) Western blot analysis of total protein isolated from fully expanded pea leaves treated with (+) or without (−) supplementary UVB exposure. Antibodies were to (i) chlorophyll *a*/*b*–binding proteins (ii) D1 polypeptide of PSII.

results indicated that the methionine may have been incorporated into the initiation complex (80 S.Met-tRNA.mRNA) without further elongation of the peptide chain [18]. This suggests that there may also be some posttranslational inhibition. In contrast, the picture is very different for chloroplast-encoded proteins. The decline in the level of the chloroplast-encoded D1 polypeptide of photosystem II (PSII) was not in parallel with *psbA* mRNA profiles, with the polypeptide levels declining prior to any loss of mRNA (see Fig. 4a[ii] and b[ii]). ^{35}S-methionine–feeding experiments followed by chase experiments illustrated that UVB exposure enhances both the rate of synthesis and the degradation of these proteins [10,19], as has been demonstrated under conditions of high visible light [22] indicating that the levels of this protein are primarily regulated posttranslationally [19]. Interestingly, the photosensitizers of D1 degradation in the different regions of the spectrum are distinct: the bulk photosynthetic pigments in the visible and red region and plastoquinone in the UV region [23,24].

Defense Genes

Plants have evolved a number of protective mechanisms against UVB-induced damage with the three most important being attenuation of UVB radiation by protective pigments, the production of antioxidants, and the repair of UVB-induced lesions in nucleic acids. The latter will be discussed in detail in the section on DNA Damage and Repair, whereas this section will concentrate on the production of pigments and on the various antioxidant mechanisms.

The most extensively studied defense mechanism in response to UVB stress is the production of protective pigments, flavonoids, a group of secondary products which include the flavones, flavonols, isoflavonoids, and anthocynins [14,15]. These compounds are considered to be major attenuators of UVB radiation. Direct evidence for the protective function of flavonoids has come from the use of *Arabidopsis* transparent testa (*tt*) mutants defective in flavonoid biosynthesis. These studies have illustrated that a few specific flavonoid compounds, including sinapate esters and hydroxycinnamate esters, may be particularly important in UVB tolerance [25,26] and in the protection of photosynthetic transcripts against UVB irradiation (see below) (B.R. Jordan, P.E. James, S. A.-H.-Mackerness, unpublished data). However, it is important to note that flavonoids are effective antioxidants and may play an important role in this respect [27].

The increase in the level of these protective pigments in response to UVB irradiation is due to a dramatic and coordinated increase in the expression and activity of the enzymes of the phenylpropanoid pathway (e.g., chalcone synthase [*Chs*], phenylalanine ammonia lyase [*PAL*], chalcone isomerase [*CHI*], and dihydroflavonol reductase [*DHFR*]) [28]. Studies in pea and *Arabidospsis* have shown that, concomitant with the UVB-induced downregulation of gene expression for photosynthetic proteins (section on Chloroplast Proteins above), there is an increase in *Chs* (Fig. 5a) [18,19] and *PAL* expression [12,29] and a subsequent increase in the composition of protective pigments (Fig. 5b) [18,19,30]. These increases have been shown by run-off transcription assays on isolated nuclei to be caused by changes in transcription [31].

The role of flavonoids in protecting gene expression has only recently been confirmed. Using *tt*-5 mutants, it was demonstrated that flavonoids do play a part in the protection of photosynthetic transcripts against UVB (B.R. Jordan, P.E. James, and S. A.-H.-Mackerness, unpublished data). Transcript levels declined faster in the *tt*-5 mutants than in the wild-type plants on exposure to supplementary UVB radiation (Fig. 6). One of the proposed roles of flavonoids in response to UVB exposure has been shielding of DNA from UV-induced damage [32,33]. Thus, the greater reduction in transcripts in *tt*-5 mutants as compared with wild-type plants in response to UVB was likely due to UV-induced damage to the DNA in the mutants. However, the absence of these pigments did not affect the relative sensitivity of photosynthetic transcripts at different developmental stages; photosynthetic transcripts from older leaves were reduced faster than transcripts in younger leaves in these mutants, as in wild-type plants (Fig. 6; see the section on Factors Affecting Gene Expression below); thus indicating that it is unlikely that DNA damage could be the primary mechanism by which transcripts are regulated in response to UVB in wild-type plants.

The regulation of the flavonoid biosynthetic pathway may be controlled by UVB, UV/blue

photoreceptors, and phytochrome depending on the species and the stage of development [34]. In mature leaves of several species, including *Arabidopsis, Chs* expression is primarily regulated by UVB and UV/blue light, whereas in young or dark-grown seedlings, phytochrome is involved [35–38]. The light-dependent regulatory transcription elements within the *Chs* genes in several species have been characterized. The signal transduction pathways acting via different photoreceptors merge at a small light regulated unit (LRU1) of 52 bp on the *Chs* promoter. LRU1 has been shown to be

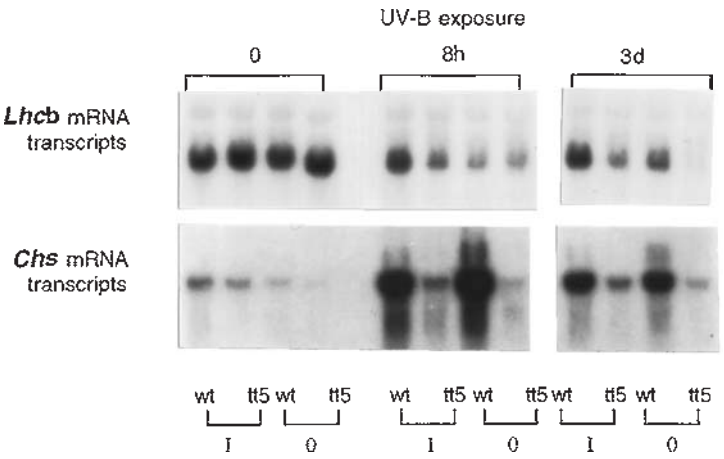

FIGURE 6 Changes in expression of *Lhcb* and *Chs* genes in wild-type and *tt-5* mutants in response to UVB exposure. sufficient to confer a signal to gene expression by activation of transcription factors binding to this element [39,40].

In addition to light, the enzymes of the phenylpropanoid pathway are also induced in response to other abiotic and also biotic stresses, including treatment with fungal elicitors. However, treatment with elicitors, unlike UVB exposure, results in the transcriptional activation of *PAL* but not the *Chs* genes [31]. In fact, the treatment of parsley culture cells with fungal elicitors strongly inhibits transcription of the *Chs* gene and blocks its UVB induction. Interestingly, it has been shown that the same elements within the *Chs* promoter are involved in the downregulation of *Chs* gene expression in response to elicitors and upregulation in response to UVB [39,40].

A common feature in plant responses to different environmental stresses is the rapid generation of reactive oxygen species (ROS) and the rise in intracellular oxidative stress suggesting that different environmental challenges may be linked to induced cellular responses by common signal mechanisms (further details are in the section on Signal Transduction below). Consistent with the induction of oxidative stress, UVB exposure leads to an increase in the concentration of lipid peroxides [41–43] and changes in mRNA transcripts [12,44] and the activities of antioxidant enzymes [11,13,45]. The actual defense mechanism(s) involved remain to be elucidated and do vary between species. In pea, RNA transcripts for cytosolic Cu/Zn-SOD and mitochondrial Mn-SOD increase substantially in response to UVB exposure. Similarly, the mRNA transcripts for all three enzymes of the ascorbate/glutathione cycle increase. In contrast, the transcripts for the chloroplastic Cu/Zn-SOD are decreased [12,46]. It is possible that the reduction of the chloroplastic SOD is either a reflection of the need for the protection of the rest of the cell at the expense of the chloroplasts or an indication of the site of action of UVB, which may be at the cytoplasm or cell exterior and not within the chloroplast. Studies using *gun* mutants have added weight to the later theory. Oxidative damage within the chloroplast, mediated by the chloroplast signal transduction pathway, is frequently cited to explain the downregulation of nuclear-encoded genes for chloroplast proteins [47,48]. The *gun* mutants are defective in this pathway [48]; however, gene expression was still inhibited by UVB exposure in these mutants suggesting that the chloroplast signal is not involved in the downregulation of the nuclear-encoded photosynthetic proteins [9]. However, recent studies have indicated that the ROS generated in response to UVB do play a role in the signal transduction pathway leading to the downregulation of photosynthetic genes [49] (S. A.-H.-Mackerness, L. Surplus, B.R. Jordan,

and B. Thomas, unpublished data). This will be disscussed in more detail in the section on Signal Transduction below.

Stress-mediated changes in the abundance of antioxidant enzyme transcripts do not always correlate with a corresponding change in the antioxidant enzyme protein level/or activity [50,51]. A few studies have looked at the effect of UVB on the activity of antioxidant enzymes. However, the limited information available indicates species differences. For example, in cucumber, SOD and APX activity increases in response to UVB exposure [11], whereas in *Arabidopsis*, only APX [13] and in pea APX, GR, and SOD activity increases [46] (S. A.-H.-Mackerness, L. Surplus, B.R. Jordan, and B. Thomas, unpublished data). The most decisive way to determine the importance of a particular defense response in relation to a stress is to examine its role in over- or underexpressing transgenic plant system. Unfortunatly, studies using these transgenic plants modified in the content of various antioxidant enzymes have highlighted the complexity and perhaps species variablity present in response to various stresses and have not provided definitive answers. In addition, few have been studied with respect to UVB damage [9].

In addition to antioxidant enzymes systems, plants contain an array of nonenzymatic antioxidants, including ascorbic acid (vitamin C), glutathione, α-tocopherol (vitamin E), and carotenoids [52]. An increase in the level of these compounds has been reported in response to UVB exposure [12,43], and the importance of ascorbic acid has been confirmed in UVB tolerance by the use of an ascorbic acid–deficient *Arabidopsis* mutant [53].

From this short review of the mechanisms involved in UVB defense, it is clear that our knowledge remains limited and that further investigation will bring substantial benefits in our understanding of cellular defense mechanisms.

FACTORS AFFECTING GENE EXPRESSION

Little is known about the interaction of UVB with other stresses and the factors that affect the sensitivity or response of plants to UVB radiation. Plants respond to an array of stresses through common defense mechanisms, and therefore exposure to one stress may lead to protection or limited tolerance to another (reviewed in Ref. 9). For example, limited water availablity (water stress) increases the tolerance of some plant species to UVB stress [54]. However, the information available on the effect of various stresses on the sensitivity to UVB is limited and even less is known about the effects on gene expression. This section will therefore concentrate on the influence of the developmental stage of the tissue and high photosynthetically active radiation (PAR) on the UVB-induced effects on gene expression, which have been recently investigated further.

The majority of studies conducted on the molecular impact of UVB have been carried out in pea and using fully expanded leaves. However, recent studies have highlighted the differential sensitivity of plants to UVB irradiation at different developmental stages. In *Arabidopsis*, the older leaves become damaged by UVB faster and to a greater extent than the younger leaves [55]. A similar pattern of sensitivity is noted with respect to mRNA transcripts which are not as severely downregulated in younger leaves as they are in older tissue (see Fig. 6) (B.R. Jordan, P.E. James, and S. A.-H.-Mackerness, unpublished data). In pea, where these differences have been best characterized, the mRNA transcripts for chloroplast genes are maintained in young buds and not downregulated to the same extent as they are in older fully expanded leaves (Fig. 7a, b). In addition, during greening of etiolated buds, gene expression continues apparently unaffected by irradiance with UVB (Fig. 7c) [18]. Similar to *Arabidopsis*, visual assessment of UVB-induced damage correlates with the effects on RNA transcripts. Therefore, the differential sensitivity to UVB at different developmental stages is evident at the physiological, biochemical, and molecular levels.

The mechanism of the differential sensitivity of photosynthetic transcripts to UVB has been recently studied further in pea. Using a highly sensitive gene-specific polymerase chain reaction (PCR) technique [56], the role of individual members of the *Lhcb* genes family in pea was tested for their role in this response (S. A.-H.-Mackerness, L. Liu, B.R. Jordan, B. Thomas, and W.F.

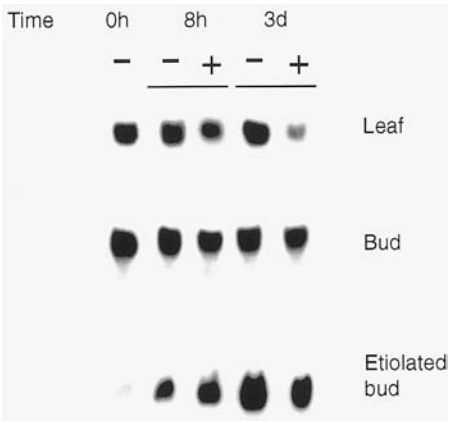

FIGURE 7 Changes in expression of the *Lhcb* gene at different developmental stages. Autoradiographs of Northern blot analysis of total RNA from (a) fully expanded leaves, (b) green buds of 17-day-old pea seedlings, and (c) 6-day-old etiolated buds treated with (+) or without (−) supplementary UVB radiation.

Thompson, M.J. White, unpublished data). The results indicated that the differential sensitivity to UVB at the different developmental stages is not due to the expression of different members of the *Lhcb* multigene family. The results, did, however, show that the genes could be divided into two groups with respect to their response to UVB at different developmental stages. These two groups had been previously identified in pea based on their responses to red and blue light and the differences in their relative levels of expression in buds and leaves [56,57]. These observations therefore indicate that the response of the two *Lhcb* gene groups to different light qualities may involve a common regulatory or signal transduction pathway.

In addition to the developmental stage of the tissue studied, the level of background light provided throughout the UVB treatment has a profound influence on the sensitivity of plants to UVB radiation. A high PAR (400–700 nm) can ameliorate the damaging effects of UVB [58–60] and the reduction in RNA transcripts to some extent [17,20]. Two mechanisms for this protection have been examined: (a) an increase in the repair of DNA damage by an increase in the activity of DNA repair enzymes, photolyases, and (b) an increase in the rate of photosynthesis. Photolyases are light-activated DNA repair enzymes involved in the repair of lesions formed in DNA on UVB exposure [61,62]; these are discussed further in the section on DNA Damage and Repair below. Several studies have indicated that the protective effect of high PAR is primarily due to increases in the activity of these enzymes under these higher light conditions [58,63,64]. However, recent studies in wheat have illustrated that the activities of these enzymes are saturated at very low light levels [65]. Therefore, the effects of PAR noted at much higher light levels are unlikely to be due to increases in the activity of these enzymes. Adamse and Britz [60] were the first to provide an alternative mechanism. They illustrated that increases in photosynthesis alone were sufficient to account for the protection against UVB-induced physiological damage in cucumber leaves under high light conditions. Using a similar approach, A.-H.-Mackerness et al. [20] illustrated that the high PAR protection of gene expression was also related to photosynthetic activity and not photorepair mechanisms (Fig. 8).

The carbohydrate products of photosynthesis are important regulators of chloroplast function, and it is well established that increases in the amount of sugars lead to the feedback inhibition resulting in a reduction in photosynthetic efficiency [66–68]. More specifically, these studies have shown that the decline in RNA transcripts encoding photosynthetic proteins, resulting in decreases in the content and activity of these proteins, leads to the reduction in the rate of photosynthesis

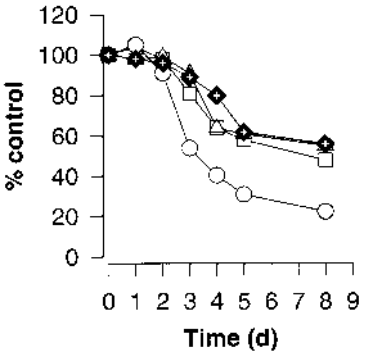

FIGURE 8 Changes in expression of *rbcL* gene under four light treatments in response to UVB radiation. Pea seedlings were grown under low-light conditions (150 μmol $m^{-2}s^{-1}$ PAR) and then exposed to supplementary UVB under low light (LL: ○), high light (HL_w, 350 μmol $m^{-2}s^{-1}$ PAR: □), high CO_2 (H_{CO_2}, 1500 ppm CO_2: △) or HL levels provided by high-pressure sodium lights (HL_{Na}: ◆). H_{CO_2} and HL_{Na} were used to increase photosynthetic rates to HL levels without altering the activity of photolyase. Northern blot probed with ^{32}P-labeled *rbcL* CDNA were quantified by determining the amount of bound radioactivity by liquid scintillation counting. (Modified from Ref. 20.)

[68,69]. In fully expanded leaves of pea seedlings, UVB treatment was reported to increase the levels of soluble sugars and starch [70] suggesting that the rapid decrease in mRNA levels for photosynthetic proteins, in response to UVB, could be regulated through a form of metabolic feedback. The relationship between photosynthesis and the carbohydrate status will vary substantially during chloroplast and organ development (e.g., switch from sink to source.) and at different light intensities. As such, therefore, this was an attractive proposal, as it could account for the differential effect of UVB at various developmental stages and also provide a mechanism for high light protection. However, the levels of UVB used in this study were high, and more detailed studies using more realistic UVB levels have revealed that UVB exposure leads to a decrease in the level of glucose rather than an increase in the response to UVB irradiation [71] (Fig. 9). Furthermore, comparison of the UVB effects on carbohydrates in source and sink organs indicated that changes in carbohydrates in response to UVB are clearly indirect and arise from the effects of UVB on photosynthesis in source organs [71].

Recent studies have highlighted similarities between plant responses to UVB and pathogen stress with generation of ROS being a common feature of both responses (see the section on Signal Transduction below) and have thus provided a starting point for dissecting the UVB-induced signal pathways. Initially by using cell cultures systems [49] and more recently using whole plants (S. A.-H.-Mackerness, L. Surplus, B.R. Jordan, and B. Thomas, unpublished data), it has become clear that UVB regulates photosynthetic genes through an ROS-dependent pathway (further details in the section on Signal Transduction below). As a result of these findings, a common mechanism was postulated to explain developmental sensitivity and high light protection against UVB damage, taking into account the role of photosynthesis and ROS in the sensitivity to UVB radiation.

The level of ROS within a cell is a balance between their generation and removal [72], and recent studies have shown that, consistent with this, the sensitivity of photosynthetic transcripts and the whole plant to UVB radiation is dependant on the antioxidant capacity of the tissue studied (S. A.-H.-Mackerness, L. Surplus, B.R. Jordan, and B. Thomas, unpublished data). The antioxidant capacity of a cell is primarily dependent on the rate of photosynthesis which in turn is dependent on, among other parameters, the developmental stage of the tissue [73,74] and the irradiance levels [75,76]. Therefore, younger tissues and plants under high light have higher antioxidant capacity,

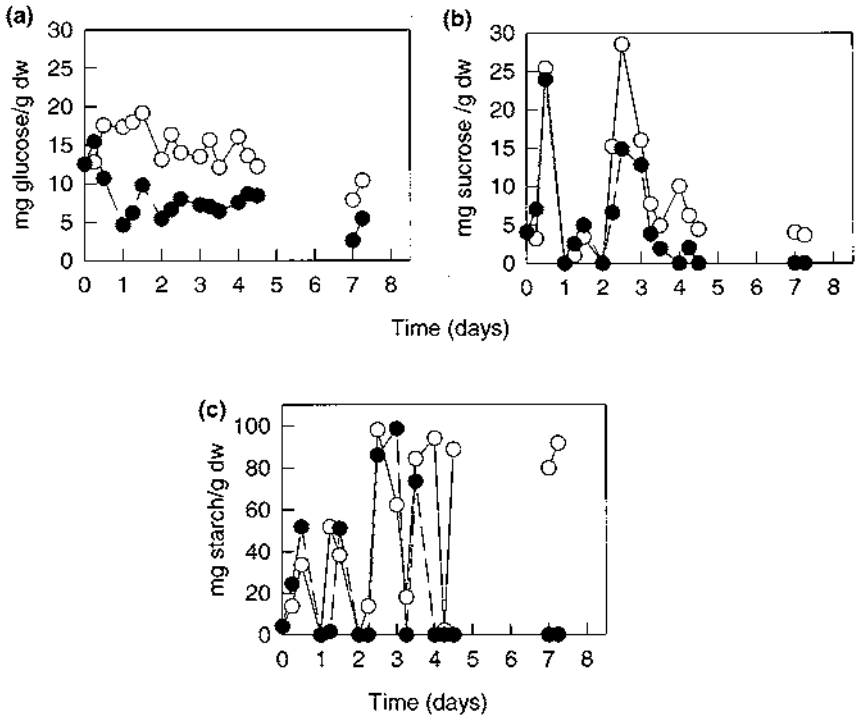

FIGURE 9 Effect of UVB on the carbohydrate status of pea leaves. Carbohydrate levels in the third leaf pair of 17-day-old pea seedlings were determined from plants treated with (●) or without (○) supplementary UVB radiation. (Modified from Ref. 71.)

as their photosynthetic rates are higher, and are thus able to remove ROS more effectively and hence are less sensitive to UVB-induced stress (S. A.-H.-Mackerness, L. Surplus, B.R. Jordan, and B. Thomas, unpublished data).

Further work is required to clarify the role of ROS in UVB-mediated stress and to determine the importance of different antioxidant enzymes in UV resistance. This information could provide potential targets for genetic engineering of plants for UV tolerance.

DNA DAMAGE AND REPAIR

DNA strongly absorbs UVB radiation and is therefore likely to be damaged by this highly energetic radiation. Most studies of UVB-induced damage and repair of DNA have been carried out in animals or microorganisms and the results extrapolated to plants. More recently, however, detailed research on DNA damage and repair in plants has been carried out (for further details see Refs. 9, 61, and 62).

The major DNA damage caused by UVB radiation is the formation of dimeric photoproducts, cyclobutane pyrimidine dimers (CPDs), and pyrimidine (6-4) pyrimidone photoproducts. The (6-4) photoproducts are also readily isomerized to Dewar photoproducts by UVA radiation, and this should be accounted for in the determination of UVB-induced damage. The formation of CPDs is the most common lesion and takes place throughout the DNA molecule. Formation of (6-4) photoproducts, however, takes place in actively transcribed regions of the DNA [77,78]. Consequently, the presence of (6-4) photoproducts may have more deleterious consequences, especially as they do not appear to be repaired as rapidly as CPDs. Although dimeric DNA lesions form the predominant DNA

damage, other lesions can occur, including the formation of monomeric photoproducts, DNA strand breaks and cross linking of DNA to protein [79]. These lesions may still have a significant impact on the biological function of the cell despite being a minor proportion of the DNA damage if the appropriate repair mechanisms are not available.

DNA damage, if not repaired, will have a profound influence on the function of plant cells, pyrimidine dimers are known to inhibit DNA and RNA polymerase in mammalian and microbial systems [78,80]. Consequently, CPDs or (6-4) photoproducts will prevent transcription of the DNA. To overcome this, cells contain a range of repair mechanisms that recognize lesions in the DNA. These repair mechanisms can be grouped as photoreactivation, excision repair, and recombinational repair [61,81].

The photoreactivation of DNA dimers (CPDs and 6-4 photoproducts) is carried out by photolyases that use a range of wavelengths in the UVA and blue region (300–500 nm) depending on the source and the presence of different chromophores within the photolyase [61,82]. Photoreactivation is both economical, efficient, and error free and has now been demonstrated in a range of plant species [79], including *Aradidopsis thaliana* [83,84] and maize pollen [85]. In wheat leaves, photorepair activity was found to be effective even at very low irradiance (2 μmol $m^{-2}s^{-1}$ PAR), with the removal of thymine dimers being much more efficient in the light than in the dark [65]. Photolyase activity, as well as being dependent on light, is also temperature dependant [83], which could be of substantial significance given the predicted scenario of changes in the global temperature. Recently, the first plant CPD photolyase gene was isolated from *Arabidopsis*. This sequence was found to be similar to the mammalian type II photolyases and not the type I photolyases found in bacteria [86]. Expression studies indicated that photolyase was not expressed in etiolated tissues and was inducible by blue and UVB light, which is similar to the photoreactivation activity in plants. Expression levels were highest in flowers, perhaps reflecting a need to protect exposed gametes from DNA damage.

Few plant systems have been studied in great detail with respect to DNA repair, and to date only a handful of studies have been carried out under field conditions. A substantial variation in the levels of DNA damage between different tissues was noted in field-grown maize exposed to ambient levels of UVB radiation [87]. No difference in DNA damage levels was, however, found between green tissue (leaf sheath and leaf blade), suggesting that architecture has no influence, with photoreactivation activity occurring in both the epidermis and inner cell layers of leaves. Although there was a slight increase in DNA damage throughout the day, no accumulation of damage was noted over the growing season.

In *Arabidopsis* seedlings, little or no photolyase activity was observed in the organellar genomes and high levels of DNA damage accumulated on UVB exposure. However, as only marginal effects on growth were noted, it was suggested that *Arabidopsis* must possess very efficient mechanisms for the tolerance of UV-induced DNA damage [84]. Surprisingly, in contrast, studies in maize indicated that all organelles that contain DNA (nucleus, plastid, and mitochondria) also contain the capacity to photorepair DNA [87]. Monocots tend to be more UV resistant than dicots. It is possible that if a more diverse distribution of photorepair enzymes is a general feature of monocots, then this could perhaps explain the difference in UV tolerance between these different plant types.

The mechanisms of excision repair of DNA in plants are not well characterized and are frequently referred to as ''dark repair'' to distinguish them from photorepair. In some species, no excision repair has been detected and in others the levels are significant but are much slower than in the presence of photoreactive light [62]. Interestingly, it has been suggested that the relative contribution of DNA repair mechanisms may differ depending on the levels of UVB damage [88]. Thus, at higher levels of damage to alfalfa seedlings, both photorepair and excision repair made significant contributions to CPD removal. At lower levels, however, only photorepair could be detected. The third type of repair, recombinational repair, has not yet been demonstrated in plants.

The information on DNA repair mechanisms in plants lags greatly behind that of mammalian and microbial systems. However, owing to the concern over increases in UVB radiation, there recently has been considerable effort made to better characterize the repair systems in plants. The

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

information available indicates very efficient repair systems both in the light and dark with genes being rapidly and specifically repaired. Owing to this efficiency, it is unlikely that the effects of UVB on gene expression (see sections on Factors Affecting Gene Expression above) can be due to nonspecific DNA damage.

SIGNAL TRANSDUCTION

Our understanding of the signal transduction pathways leading to various UVB responses is very limited. In recent years, the application of knowledge from mammalian systems has provided some insight into the details of these pathways. In addition, the realization that plant responses to UVB stress have commonalties with plant responses to a variety of other stresses, including pathogen [89,90] and wounding [91] responses, has provided a starting point to allow the elucidation of these complex cascades. For example, in both responses to pathogens and UVB, photosynthetic genes are downregulated and the acidic and basic pathogenesis-related (PR) genes are upregulated (Figs. 10 and 11a).

Salicylic acid (SA) has been recognized as an endogenous regulator in plants and it is now accepted as a component of the signal pathway leading to plant responses to pathogens [92,93]. In addition, ROS generated after pathogen attack are considered to play a role in the regulation of disease resistance [94,95]. Regulation of genes in response to UVB radiation has been shown to involve components of this pathway. UVB exposure can result in the production of ROS [43,96,97] and can lead to increases in SA levels [98].

Numerous studies have demonstrated that SA levels rise after pathogen attack and that SA is the endogenous signal for the induction of several plant defense responses, including the expression of the acid-type PR genes [92,93,99]. The role of this compound in upregulation of the PR genes was confirmed in experiments using transgenic plants (NahG plants). These plants overexpress the salicylic hydrolase gene from *Pseudomonas putida* which catalyzes the conversion of SA to catacol. Therefore, these plants are unable to accumulate significant levels of SA [100]. In these plants, pathogenic infection did not lead to the accumulation of PR transcripts. In similar experiments, using these transgenic plants, it was demonstrated that SA was a component of the UVB signal pathway leading to the upregulation of three acid-type PR transcripts (PR-1, PR-2 and PR-5) (see Fig. 11b). However, photosynthetic genes were still downregulated in response to UVB in these transgenic plants indicating that SA is not involved in this pathway (see Fig. 11b). Feeding/spraying

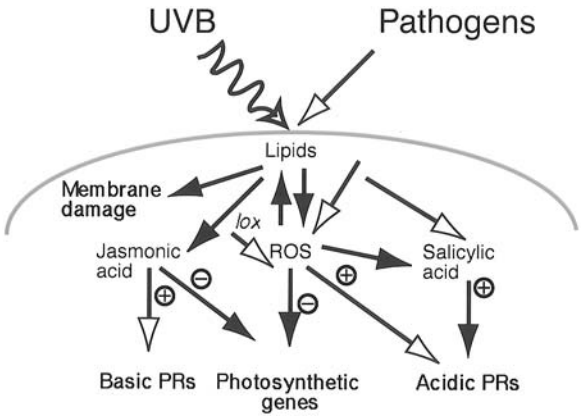

FIGURE 10 Schematic representation of pathogen-induced signal transduction pathways. Possible commonalties with responses to UVB stress are indicated with solid arrows.

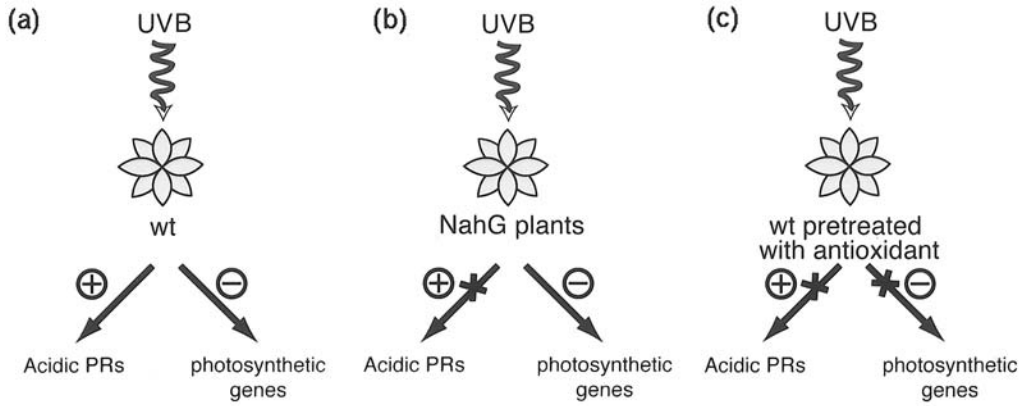

FIGURE 11 Schematic representation of the role of salicylic acid and reactive oxygen species (ROS) in the signal pathway leading to the downregulation of photosynthetic genes and the upregulation of the acid-type PR genes in response to UVB. (a) UV treatment of wild-type (wt) *Arabidopsis* leads to an increase (+) in PR transcripts and a decrease (−) in photosynthetic transcripts. (b) UVB treatment of transgenic NahG plants, which cannot accumulate SA, does not lead to an increase in PR transcripts but the decrease in photosynthetic transcripts still occurs. (c) Treatment of wild-type (wt) plants with antioxidants [e.g., ascorbic acid or pyrrolidine dithiocarbamate (PDTC)], prior to UVB treatment prevents both the increase in PR transcripts and the decrease in photosynthetic transcripts in response to UVB exposure.

experiments using antioxidants and oxidants in wild-type plants have shown that ROS are also involved in the upregulation of PR genes [89] (L. Surplus, B.R. Jordan, B. Thomas, and S. A.-H.-Mackerness, unpublished data) as well as the downregulation of photosynthetic genes in response to UVB radiation (see Fig. 11c) [49]. (L. Surplus, B.R. Jordan, B. Thomas, and S. A.-H.-Mackerness, unpublished data). These studies therefore have illustrated that, as in pathogenic attack, the increase in PR transcripts in response to UVB is via a SA- and ROS-dependant signal transduction pathway. In contrast, a separate UVB signal pathway, which is ROS dependant but SA independent, leads to the decrease in photosynthetic transcripts.

In contrast to SA, which is involved in the signal pathway in response to pathogens, jasmonic acid (JA) is involved in the response to wounding and pathogen attack as well as other important plant physiological responses such as senescence [101]. UVB irradiation also has been shown to lead to an accumulation of JA [91]. UVB leads to the upregulation of a set of genes normally associated with responses to wounding, and the role of JA in the regulation of these genes in response to UVB exposure was confirmed by using a similar approach as that described above by the use of mutants blocked in the octadecanoid pathway [91]. UVB exposure also leads to an increase in ethylene production [102]. Ethylene, like JA, is produced in response to wounding and senescence [103]. The role of ethylene in plant responses to UVB stress has not been studied.

In addition to molecular genetics approaches described above, various studies have taken advantage of the expanse of knowledge on UVB effects on mammalian systems and have used biochemical approaches to dissect these pathways. Initial studies have been carried out using cell cultures and a variety of pharmaceutical compounds with known targets. These studies have concentrated on the mechanism leading to the upregulation of the *Chs* gene in response to UVB. However, although considerable progress has been made in elucidating the steps of the phytochrome-mediated signal transduction pathway, little is at present known about the UVB signal pathways.

Intracellular calcium, calmodulin, and serine/threonine kinases, but not tyrosine kinases, and

phosphatase activity have been shown to be involved in UVB light-dependant *Chs* expression [104,105]. This pathway is distinct from the previously characterized cGMP-dependant pathway utilized by phytochrome to upregulate *Chs* expression [106] and the blue/UVA pathway which does not appear to involve calmodulin. In addition, it is also separate from the ROS-dependant pathway leading to the upregulation of PR genes in response to UVB [105].

Little is known about the components of the UVB-induced pathway at present; nevertheless, it is apparent that plant cells utilize different signal pathways to regulate the same gene (e.g., *Chs*) depending on whether activation is caused by a phytochrome, blue/UVA, or UVB light receptor. In addition, there are distinct signal pathways leading to the regulation of different genes in response to UVB involving ROS, SA, and JA. Although it is clear that these studies are in their infancy, it is quickly becoming evident that UVB-induced signaling is complex and, similar to other stresses, crosstalk between various pathways must occur. A combination of the types of approaches described above should, however, provide us with a wealth of information that was to a great extent out of our reach a few years ago.

CONCLUSIONS

The effects of UVB radiation on plant growth and development have been extensively investigated in the last two decades and a wide range of responses have been reported. However, the mechanisms underlying these UVB responses are poorly understood. It has become more obvious in recent years that, although UVB can directly damage DNA, responses to UVB radiation are not a result of this nonspecific damage. The involvement of specific signal transduction pathways in response to UVB are adding further weight to this argument. Further work will need to be directed toward the identification and further characterization of these and other pathways, which provide the most promising avenue for the identification of potential targets for future engineering of UVB tolerance in important agricultural and horticultural crops.

ACKNOWLEDGMENTS

We would like to thank Dr. Brian Thomas for his continued support and input into the UVB project at HRI, Lynn Surplus for her experimental efforts and her contribution to the research, and Richard Napier for his interest and advise on the project. We would also like to acknowledge the collaboration of Dr. Michael White and Liansen Liu at the University of St. Mary's in Nova Scotia. Finally, we are grateful to the entire Visual Aid Department at HRI, particularly Michael Smith, for preparation of the illustrations.

Molecular Mechanisms of Plant Responses to Elevated Levels of Tropospheric Ozone

Lola Peñarrubia and Joaquín Moreno
Universitat de València, Burjassot, Spain

OZONE STRESS IN PLANTS: ORIGINS AND SYMPTOMS

Atmospheric Ozone and the Biosphere

Ozone, the three-atomic molecular combination of oxygen (O_3), plays the dual role of a friend and a foe to the biosphere, being either protective or damaging to living beings according to the atmospheric height where it accumulates. Stratospheric ozone, produced mainly by photochemical reactions of sunlight with oxygen, attains its highest concentration in a layer, extending from 25 up to 30 km over the earth's surface, that protects the biosphere from the sun's ultraviolet radiation [1]. The progressive thinning of this layer due to chemical pollution is currently giving rise to an ozone ''hole'' with the subsequent damages to life produced by exposure to intense low wavelength (potentially mutagenic) radiation. However, this chapter focuses on ozone at the troposphere, the lowest region of the atmosphere in contact with earth's surface, where it is an important component of the photochemical air pollution associated with human activities, and causes direct damage to terrestrial animals and plants (among them agricultural crops) owing to its high reactivity and oxidizing nature. Both ozone stores, the bigger stratospheric one (holding about 90% of total ozone), and the smaller tropospheric one (with the remaining 10%) are fairly well delimited and isolated by the colder tropopause barrier, which is thought to prevent convection between them. However, upward transport of tropospheric air is known to occur through equatorial deep convective systems, whereas evidence for transient downward inputs of stratospheric ozone-rich air into the troposphere also has been recently found in tropical zones of the Atlantic Ocean [2]. Even if locally significant, the global contribution of these exchanges to tropospheric ozone levels is uncertain.

Origin of Tropospheric Ozone

Most of the current tropospheric ozone is thought to be a result of human pollution, and it has accordingly increased during the last century with the development of the industrial civilization.

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

Ozone is spontaneously synthesized from volatile air pollutants, mainly nitrogen oxides (NO and NO_2), which are primary components of ''smog'' [3,4]. Nitrogen oxides are generated by burning organic matter (mostly fossil fuels), being present in most industrial and motor vehicle exhausts. NO_2 is readily photolyzed to give atomic oxygen:

$$NO_2 + h\nu(\lambda < 400 \text{ nm}) \rightarrow NO + O$$

whereas atomic oxygen combines with molecular dioxygen to produce ozone:

$$O + O_2 \rightarrow O_3$$

Furthermore, NO is usually oxidized back to NO_2 through photochemically generated oxidants, thereby closing an ozone-producing cycle. These oxidants arise from organic air pollutants (such as volatile hydrocarbons) in a cyclic chain reaction involving the hydroxyl free radical ($OH^{\bullet}$), which is itself a photochemical product of ozone [1].

In addition, ozone can also be generated in the presence of molecular oxygen by many ''high-energy'' events, such as intense low-wavelength radiation or high-voltage electric discharges. The sources for these processes may be artificial (among those well known for scientists are spectrofluorimeter lamps, photocopying machines, and laser printers) or natural (such as thunderstorms).

The irregular geographical distribution of the ozone sources (highly correlated with human population density and industrial activity) together with climatic trends (such as wind cycles) account for the observed spatial variability of ozone levels [4]. However, temporal patterns of variation also have been observed, with the highest ozone peaks being achieved during warm and sunny days. These changes have been attributed to the higher overall pollution induced by intense solar irradiance and high temperatures due to easier volatilization and photochemical transformation of many organic compounds that contribute, either directly or indirectly (by oxidizing NO to NO_2), to ozone production. As a result, ozone levels show a seasonal variation, being higher during the summer, when short peak episodes of high ozone levels have been described in industrialized countries [4,5].

Evidence of Plant Damage by Ozone

Although the nature of the initial chemical damage of ozone to plant tissues has proven elusive and controversial (see section on Ozone Injury: First Events below), there is an overwhelming amount of data supporting a correlation between exposure to high levels of ambient ozone and plant growth decay. The physiological and anatomical effects of ozone exposure were early described in the cigar wrapper varieties of tobacco, in which elevated levels of ozone cause the necrosis of leaves known as ''weather flecks.'' A careful work carried out during the late 1950s led to the selection of ozone-tolerant varieties of tobacco, and also to the isolation of the hypersensitive Bel W3 line. This mutant responds to ambient (subcritical) concentrations of ozone-producing necrotic flecks in presenescent mature tobacco leaves, and it has been used as an ozone biomonitor for more than 30 years [6].

Even at doses similar to those of moderately polluted air (such as occurs over much of the United States during the summer), ozone has been shown to reduce the photosynthetic activity of several tree and crop species, thereby limiting plant growth and crop yield [7]. Other studies have correlated plant exposure to ozone with other changes at the physiological and metabolic level, such as leaf yellowing (i.e., photosynthetic pigments loss) and abscission, stimulation of dark respiration, phloem unloading, and alterations in the patterns of assimilate distribution (reviewed in Refs. 8 and 9). Since most of these symptoms are also characteristic of the natural decay processes of plants, ozone is often reported to accelerate senescence.

In general, a threshold ozone concentration for the adverse effects on plant growth can be only approximately defined owing to the significant dependence of the induced damage on the plant species, the presence of other pollutants, soil moisture, and other environmental conditions. However, the figure of 40 nL/L (or 40 ppb) has been acknowledged as a convenient (if rough) consensus value in order to express ozone treatments as a cumulative dose over a critical threshold. Thus, an

exposure index has been defined, being referred to as AOT40 (accumulated ozone exposure over a threshold of 40 ppb) [10]. AOT40 is computed as the product of the ozone concentration (ppb) by the time (hours) that it exceeded the threshold value. Nevertheless, the generalized use of this threshold in the prospective evaluation or economic assessment of crop or forest damage by ozone is strongly discouraged in favor of detailed approaches that take into account the characteristics of the particular species and environmental modifying factors [10].

Most studies devoted to ozone effects on plants have been carried out in controlled ambients either in the laboratory or in open-top chambers in the field. In the latter case, experiments monitored the ambient ozone levels while appropriate controls were run in parallel under the lower ozone concentration achieved through charcoal filtering of the air or by the addition of the protective antioxidant ethylene-diurea, N-(2-(2-oxo-1-imidazolidinyl)ethyl)-N′-phenylurea [5]. Under more controlled conditions in the laboratory, experiments are usually performed either with acute treatments (i.e., short moderate to high [>200 nL/L] doses of ozone [similar to transient peak episodes which occur naturally during the summer]) or chronic treatments (i.e., long-term exposure to low [40–60 nL/L] doses [closer to seasonal means]). Plants subjected to chronic treatments are usually affected at the physiological and metabolic level, undergoing restricted growth and premature senescence but without visible anatomical injuries. Symptoms of ozone damage under such moderate conditions may be difficult to recognize in the field because of their similarity to natural senescence or to the effects of other stress factors [5]. In contrast, acute treatments habitually produce symptoms which are readily perceptible such as yellowing, necrotic wounds, and leaf abscission even if the integrated dose (ozone concentration multiplied by exposure time) in these experiments is habitually much lower than the natural one corresponding to ambient levels sustained throughout a growing season [11].

In addition to the evidence obtained in laboratory (or tightly controlled) experiments, the incidence of ozone exposure on plant growth also has been evaluated under natural field conditions, in forest pine trees subjected to ambient ozone levels, by simultaneously monitoring the stem circumference of 28 trees and the local ozone level over a period of 5 years. Analysis of the collected data indicated that a high ozone concentration (above 40 nL/L) interacted with low soil moisture and high temperatures as one of the critical factors that reduced the short-term rate of stem expansion [12].

Summing up, exposure of plants to ozone causes dose-dependent metabolic, physiological, and anatomical alterations that result in diminished growth and crop yield, enhanced senescence, and generalized decay (which may eventually lead to abscission and death). The whole of this behavior, which includes cell and tissue deterioration as well as plant defense processes in a complex cross-talk (showing even species-specific features), is known as the ozone stress syndrome. In the following section, we will further analyze the characteristics of this complex response aiming to find explanations for the observed changes at the molecular level.

OZONE INJURY: FIRST EVENTS

Ozone Penetration

The nature of the primary interaction of ozone with plants that leads to its damaging effects is still a disputed matter, but the way by which ozone penetrates into plants is fairly well established. A comparative study between several tree and crop plants indicated that those species with a higher stomatal conductance exhibited more intense deleterious response (as measured by photosynthesis reduction) [7]. Accordingly, a study of ozone penetration in sunflower leaves [13] showed that stomatal diffusion was indeed the main path of entrance. In fact, the ozone uptake rate (Q) may be anticipated from the following formula [13]:

$$Q = C \cdot \frac{g_w}{1.68}$$

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

where C is the ambient concentration of ozone, g_w is the gas phase (stomatal + boundary layer) conductance of the plant for water vapor, and 1.68 is the estimated ratio of the diffusion rates for water vapor and O_3.

Direct measurement at intercellular spaces indicated that the ozone concentration is extremely low there irrespectively of the ambient (external) concentration (up to 1500 nL/L) [13]. This was interpreted as that ozone is absorbed and rapidly decomposed in the cell wall and plasmalemma of the cells surrounding the substomatal chambers and it does not penetrate into the deeper layers of cells [13]. If this is so, the direct effect of ozone would be highly restricted to the cell walls and plasma membranes of a few cells.

Free Radicals

It has been long suspected that the direct damaging effects of ozone may be due to the generation of free radicals. Oxygen-derived radicals belong to a group of reactive species, known as ROIs (reactive oxygen intermediates), which are naturally produced in plants as a result of the partial reduction of molecular dioxygen. In order of increasing reduction of oxygen, ROIs include the superoxide anion ($O_2^{-\bullet}$) and its protonated form, the hydroperoxyl radical ($O_2H^\bullet$), hydrogen peroxide (H_2O_2), and the hydroxyl radical ($OH^\bullet$) (Fig. 1A). The latter is the most active and potentially damaging to biological structures, whereas hydrogen peroxide, and even superoxide, are comparatively much less reactive in aqueous solution [14]. Nevertheless, hydroxyl radicals can be generated

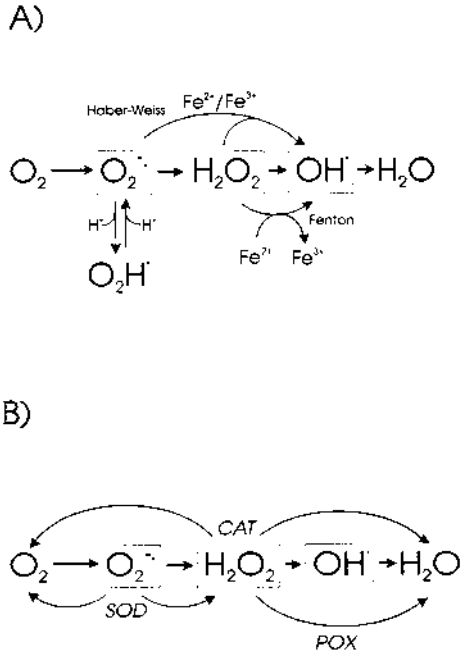

FIGURE 1 Reactive oxygen intermediates (ROIs). (A) Main ROIs and exchange reactions. ROIs produced by progressive oxygen reduction: superoxide anion ($O_2^{-\bullet}$) (the protonated [peroxyl] radical form is also shown [$O_2H^\bullet$]), hydrogen peroxide (H_2O_2), hydroxyl radical ($OH^\bullet$). The transition metal–induced Haber-Weiss and Fenton reactions also are indicated. (B) ROIs scavenging reactions and enzymes implicated in them: superoxide dismutase (SOD), peroxidase (POX), and catalase (CAT).

from hydrogen peroxide in the presence of transition metal ions in the reduced state (specially Fe^{2+} and Cu^{+}) by means of the Fenton reaction:

$$H_2O_2 + Fe^{2+} \rightarrow OH^- + OH^{\bullet} + Fe^{3+}$$

The oxidized metal ion can be reduced back in the presence of superoxide:

$$O_2^{-\bullet} + Fe^{3+} \rightarrow O_2 + Fe^{2+}$$

The net results of these two reactions

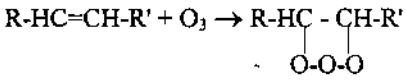
$$H_2O_2 + O_2^{-\bullet} \rightarrow O_2 + OH^- + OH^{\bullet}$$

is known as the Haber-Weiss reaction and by which hydrogen peroxide and superoxide anions are converted to the highly reactive hydroxyl radical through the catalytic effect of metal traces. Free metal ions are scarce inside cells, but they can be released from metal-protein complexes found in vivo through the oxidative attack of hydroxyl radicals. Thus, the production of hydroxyl radicals may become autocatalytic in vivo provided that other ROIs are present [14]. ROIs, which may arise naturally in plants as a by-product of mitochondrial respiration or photosynthetic activity in the chloroplast, are usually damaging to the cell functions. Therefore, they are habitually disposed off by an array of enzyme-catalyzed protective reactions [15]. However, under certain conditions, the cellular production of ROIs may be topically allowed, or even stimulated, as a part of a defensive strategy against pathogens [16]. In addition, ROIs also are known to act as cellular messengers triggering manifold protective and defensive responses [17]. Just because of their signaling role, oxygen radicals are good candidates to mediate the elicitation of the diversified effects that constitute the plant's response to ozone. Actually, induction of free radicals inside intact leaves of legumes by ozone treatment has been demonstrated in situ by means of electron spin resonance spectroscopy [18]. Unfortunately, the chemical nature of the radicals could not be unambiguously identified because of the need of a spin trap to enhance sensitivity. Ozone is known to decompose spontaneously in aqueous solution in a chain reaction that involves the ozonide radical ion ($O_3^{-\bullet}$) and produces hydroxyl radicals and superoxide anions. The reaction is initiated by hydroxide ions through the following sequence [19]:

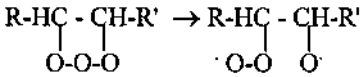
$$O_3 + OH^- \rightarrow O_2 + HO_2^-$$
$$HO_2^- + O_3 \rightarrow O_3^{-\bullet} + HO_2^{\bullet} \leftrightarrow O_3^{-\bullet} + H^+ + O_2^{-\bullet}$$
$$O_3^{-\bullet} \rightarrow O_2 + O^{-\bullet}$$
$$O^{-\bullet} + H_2O \rightarrow OH^- + OH^{\bullet}$$

However, owing to its dependence on hydroxide ions, the decay of ozone in aqueous medium takes place at a significant rate only at relatively high pHs. Thus, ozone decomposition has been deemed to be too slow at physiological pH, at least under laboratory conditions (half-life of about 5 min), compared with other competing reactions of ozone with biological molecules, such as singlet oxygen production [20].

Alternatively, ozone may also produce other free radicals as a result of its reaction with a number of compounds, such as phenolics and other organic molecules containing carbon-carbon double bonds. The reaction appears to proceed through ozone addition to the double bond:



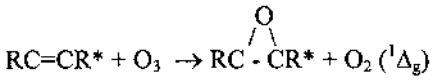
yielding an unstable ozonide, which may break down to radicals (among other possible outcomes):



Other free radicals (including ROIs) may secondarily arise from these as a result of electron propagation reactions. This mechanism may explain the observed effect of phenolics, enhancing the production of hydroxyl radicals in aqueous solutions exposed to ozone [21]. In order to explain the synergistic effect of ozone with the gaseous plant hormone ethylene (see section on Ethylene and Polyamine Bioynthesis below), Melhorn et al. [18] proposed that ozone toxicity may result from the production of free radicals on reaction with stress ethylene (presumably by adding on across the carbon-carbon double bond, as above), which is produced by the plant and is present in intercellular spaces. This would explain why inhibitors of endogenous ethylene production supress or reduce the deleterious effects in plants exposed to ozone [22]. Even if ethylene cannot account quantitatively for the rapid disappearance of ozone once it penetrates into the plant [23], it is plausible that most damaging effects could arise from ethylene-induced free radical production, whereas the excess ozone could be almost immediately consumed by reaction with the abundant phenolic acids bound to cell walls [18]. Alternatively, other investigators propose a direct ozone damage to membranes or even to intracellular molecules.

Singlet Oxygen Production

Ozone may combine with several organic functional groups in a reaction in which one oxygen atom is incorporated to an oxidized product, whereas the remaining two atoms are released as singlet oxygen ($O_2[^1\Delta_g]$), a highly reactive overenergized state of molecular dioxygen, which may easily oxidize a variety of biological compounds [14]. Kanofsky and Sima [20] have carried out a study on a number of biological molecules as potential targets of ozone reactivity and found that several amino acids (especially methionine and cysteine), redox protective compounds (ascorbic acid, uric acid, reduced glutathione), and coenzymes (NADH and NADPH) as well as proteins (human serum albumin) do indeed react in vitro with ozone producing singlet oxygen in high yield. Reaction with molecules containing carbon-carbon double bonds (such as NADH, NADPH, ascorbic, and uric acids) apparently proceeds via the formation of an unstable epoxide:



which may further hydrolize spontaneously to a diol or break down to different subproducts. On the other hand, the reaction with sulfur-containing molecules (methionine, cysteine, glutathione) leads to a sulfoxide:

$$RSR^* + O_3 \rightarrow RSOR^* + O_2(^1\Delta_g)$$

which, in the case of thiols (R* = H; such as cysteine or reduced glutathione), may turn to a disulfide by condensation with another thiol molecule:

$$RSOH + R'SH \rightarrow RSSR' + H_2O$$

Thereafter, the original thiol group may be restored by disulfide exchange:

$$RSSR' + R''SH \rightarrow RSH + R'SSR''$$

This could explain why the activity of some cysteine-containing enzymes, which is lost through ozone exposure, can be regained by treatment with an excess of low molecular weight thiols [24,25].

Singlet oxygen released in these reactions may in turn react with lipids to give peroxide derivatives or oxidize other amino acid residues (such as tryptophans or histidines) [14]. These reactions (together with the generation of free radicals) are likely to be involved in the oxidative modification of certain amino acid residues observed on treatment of purified proteins from plants [26], bacteria, and animals [27] with ozone. In these experiments, histidines were converted to aspartic acid residues, tyrosines to 3,4-dihydroxyphenylalanines, and other side chains to carbonyl derivatives (apparently generated by a direct attack of ozone to ethylenic double bonds) in a protein-dependent manner, indicating that susceptibility of the residues to oxidative modification is subjected to sequence and/or structural constraints [27]. By means of these (or similar) reactions, ozone could plausibly inactivate membrane proteins through modification of functional residues. Indeed, Dominy and Heath [25] have reported that ozone inhibits the K^+-stimulated ATPase from bean plasma membranes by oxidizing a critical sulfhydryl group. Thus, damaging of membrane pumps (thereby altering the ionic balance inside the cell) is a possible mechanism by which ozone could elicit a diversified cellular response [9]. The case of the abundant photosynthetic enzyme ribulose 1,5-bisphosphate carboxylase/oxygenase (Rubisco), which is a preferred target for proteolysis during natural and stress-induced senescence [28], and whose inactivation and degradation are thought to be regulated by oxidation of critical residues [29,30] also is relevant owing to the habitual use of its turnover to monitor plant senescence in photosynthetic organs. Rubisco levels have been shown to decline in several plants on exposure to ozone [31–33]. Indeed, treatment of the purified potato Rubisco with ozone results in modification of residues to carbonyl derivatives, with subsequent inactivation and aggregation of the enzyme [26]. Moreover, the potato enzyme also inactivates and aggregates inside isolated intact chloroplasts (kept at low temperature to prevent proteolysis of the aggregates) as a result of exposure to ozone [33]. Even if Rubisco modifications are not detected in vivo when the whole plant foliage is treated with ozone, it is plausible that they are nevertheless taking place provided that oxidation targets the protein for degradation and the modified Rubisco is efficiently removed in vivo [26,34]. However, since the chloroplastic localization of the enzyme makes unlikely its direct interaction by ozone, it appears that Rubisco modifications may result from the production of secondary oxidants (such as singlet oxygen or ROIs) [26] or other specific signals, elicited by ozone damage, which may trigger redox imbalance inside the chloroplast [34].

Lipid Peroxidation

The deterioration of membrane structure through lipid peroxidation is a common process typically associated with senescence and decay processes in plants. It usually results from the oxidative modification of polyunsaturated lipids in a radical chain reaction that involves molecular dioxygen and propagates from an initial event triggered by a free radical [14]. The process is initiated by the removal of a hydrogen atom from a methylene group (usually one weakened by adjacent double bonds) by a reactive free radical such as hydroxyl:

$$—CH{=}CH—CH_2—CH{=}CH— + OH^{\bullet} \rightarrow —CH{=}CH—{}^{\bullet}CH—CH{=}CH— + H_2O$$

The resulting carbon radical rearranges to a more stable conjugated diene:

$$—CH{=}CH—{}^{\bullet}CH—CH{=}CH— \rightarrow —{}^{\bullet}CH—CH{=}CH—CH{=}CH—$$

which then reacts with molecular oxygen to give a peroxyl radical:

$$—{}^{\bullet}CH—CH{=}CH—CH{=}CH— + O_2 \rightarrow —{}^{\bullet}OOCH—CH{=}CH—CH{=}CH—$$

In turn, the resulting peroxyl radical can abstract another hydrogen atom (thereby becoming a peroxide) from a neighboring lipid molecule. Thus, the process is reinitiated and propagated as a chain

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

reaction. Ozone treatments are known to induce lipid peroxidation in membranes [35]. From the chemical point of view, the reaction with ozone could proceed following three different paths. First, ozone can initiate lipid peroxidation as a secondary effect of generating free radicals (specially hydroxyl ones). Second, peroxidation of lipids can also result from the production of singlet oxygen, since this species can directly react with unsaturated lipids to give hydroperoxides [14]. Nevertheless, the latter is not a chain reaction and hence does not propagate (a molecule of singlet oxygen is needed for each oxidized double bond). Third, ozone could directly add on across double bonds of lipids, yielding an unstable ozonide, which could decompose to give free radicals, thereby initiating peroxidation [14]. Whatever the mechanism, lipid peroxidation (together with oxidative modification of membrane proteins) is expected to alter membrane permeability and function, thereby initiating a diversity of cellular responses. On the other hand, peroxidized lipids can be further metabolized through different pathways to compounds (such as volatile aldehydes, hydroxy acids, or jasmonates) that may act as diffusible signals [36]. For these reasons, and given the easy accesibility of membranes from the intercellular space, lipid peroxidation is also a likely candidate to be the critical primary effect of ozone that mediates the subsequent complex response.

In summary, ozone damages cellular structures by oxidative modification of key molecules, most likely at the membrane and cell wall level. This oxidative injury may result either from direct combination with ozone or as a secondary result from free radical or singlet oxygen production. It is plausible that all the above paths of oxidation occur simultaneously, the qualitative and quantitative relevance of each of them being dictated by the physical, chemical, and anatomical constraints of the particular case. At any rate, there is little doubt that this primary effect of ozone is the origin of chemical signals that are able to trigger secondary responses at the genetic, metabolic, and hormonal level.

PLANT RESPONSES TO OZONE

Ozone exposure modulates plant gene expression both inducing and repressing specific messages [36,37]. All ozone-repressed genes described to date code for chloroplastic proteins, such as photosynthetic components and antioxidative enzymes [38,39]. This fact may reflect the special sensibility of the chloroplast to cellular redox changes. However, not all nuclear genes encoding chloroplast proteins are repressed by ozone indicating that downregulation of chloroplast gene expression is not a generalized trend [38]. Table 1 lists some of the genes regulated by ozone exposure and its abbreviations (intended for quick reference here). Most of these genes have been shown also to be regulated by other stresses, such as pathogen attack, drought, and exposure to ultraviolet (UV) irradiation as well as other air pollutants and heavy metals. Moreover, oxidative stress caused by treatments with copper or aluminum results in a gene-induction pattern which is very similar to the ozone response [34,40].

Reactive Oxygen Intermediates Scavenging

Plants produce ROIs (see Fig. 1A) under normal developmental conditions mainly through the mitochondrial respiratory and photosynthetic electron transport chains. Although plants make use of ROIs in several metabolic processes, such as lignin formation in the cell walls, ROIs are very reactive, instantaneously damaging proteins, lipids, and DNA. In order to deal with ROIs, plants have a battery of constitutive antioxidative defense mechanisms that include metabolites and enzymatic systems.

Ascorbate (vitamin C), glutathione, α-tocopherol, and β-carotenes are among the metabolites implicated in scavenging ROIs [11]. Besides, and since transition metals ions promote the production of ROIs through the Haber-Weiss and Fenton reactions (see Fig. 1A), metal chelators (fitochelatins and metalothioneins) have been shown also to have antioxidant properties [41]. Similarly, proteins

that participate in the homeostasis of metals in yeast also have been implicated in protection against oxidative stress [42].

The antioxidative enzymatic system (Figs. 1B and 2) is composed of superoxide dismutases (SODs) that convert the superoxide anion into H_2O_2 and O_2, catalases (CATs) that eliminate H_2O_2, and peroxidases (POXs) that reduce H_2O_2 into water using electron donors, such as ascorbic acid in the case of ascorbate peroxidases (APXs), or reduced glutathione in glutathione peroxidases (GPXs). Ascorbate is recycled back at the expense of NADPH in the ascorbate-glutathione or Halliwell-Asada cycle (Fig. 2A). The enzymes that participate in this pathway are APX, dehydroascorbate reductase (DHAR), monodehydroascorbate reductase (MDHAR), and glutathione reductase (GR).

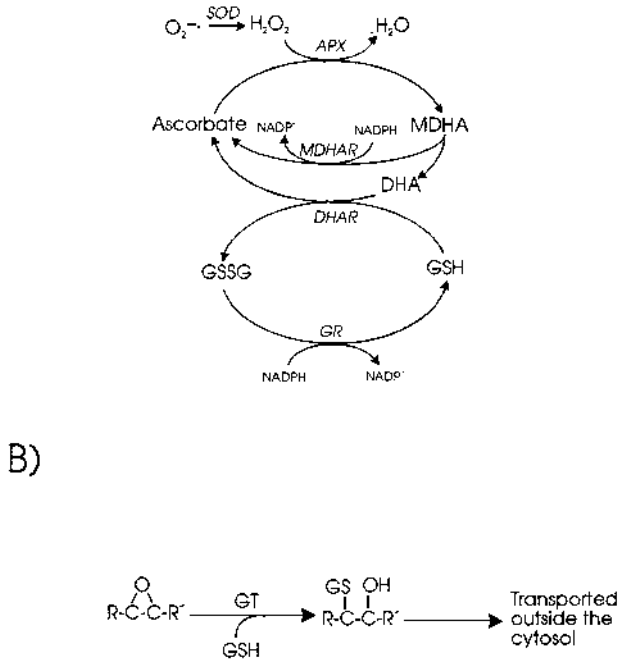

FIGURE 2 Some antioxidant plant enzymes. (A) The ascorbate-glutathione, or Halliwell-Asada, cycle connects the photosynthetic reductive power of NADPH to the scavenging of ROIs using glutathione and ascorbate as intermediates. Enzymes participating in the pathway are superoxide dismutase (SOD), ascorbate peroxidase (APX), dehydroascorbate reductase (DHAR), monodehydroascorbate reductase (MDHAR), and glutathione reductase (GR). Other abbreviations are MDHA, monodehydroascorbate; DHA, dehydroascorbate; GSH, reduced glutathione; and GSSG, oxidized glutathione. (B) Glutathione transferase (GT) conjugates glutathione to oxidative damaged molecules (an epoxide is shown as an example) targeting it for transport outside the cytosol.

In addition, glutathione S-transferase (GST) plays an important role in detoxifying oxidative products by catalyzing its conjugation with reduced glutathion (Fig. 2B). After further chemical modification, these conjugates are transported out of the cytosol by specialized pumps [43]. Several isoforms with different cellular locations have been described for most of the antioxidative enzymes suggesting that isoenzymes could reduce ROIs to a different permisive level in each compartment [44].

In general, both reductant metabolites and antioxidant enzymatic activities decline in plant tissues with age, and this may be one of the main factors that promote the onset of oxidative processes associated with senescence [45].

Exposure to different stresses may cause a localized and pronounced rise in ROIs, which in some cases is due to the activation of a plasma membrane NADPH-oxidase enzyme [46]. This sudden local increase in ROIs, known as ''oxidative burst,'' is part of a defensive strategy against pathogens and elicits an array of plant responses, including an increase in the biosynthesis of the antioxidative enzymes in the surrounding cells.

Since ozone may generate ROIs by several pathways (see section on Free Radicals above),

it is likely that the overlapping responses of ozone with other stresses at the gene-induction level (the so-called cross induction [47]) are due to the initial production of ROIs which can mimic the oxidative burst. In turn, this may trigger signaling events leading to a variety of plant responses that are common to these stresses [11].

Antioxidant responses include the synthesis of metabolites such as ascorbic acid that aids cells to detoxify lipid peroxides caused by ROIs. In this regard, apoplastic ascorbate levels have been found to increase in response to ozone exposure in different plants [48–51]. An ascorbic acid–deficient mutant, which accumulates only 30% of the normal ascorbate concentration as a result of a biosynthetic deffect [52], has been shown to be ozone sensitive demonstrating the important role that ascorbate plays in resistance to oxidative stress [53]. Glutathione, which is connected to ascorbate through the Halliwell-Asada cycle (see Fig. 2), also increase both in the reduced and oxidized forms during ozone treatment [54–56]. Perhaps the presence of elevated levels of antioxidant compounds in ripe fruits is the cause of their extraordinary resistance to the high doses of ozone used as fungicidal in post-harvest technology [57].

Contradictory results have been obtained with regard to the effect of ozone on the activities and expression levels of antioxidant enzymes; maybe as a result of differences between plant systems and ozone treatments utilized by several investigators. An extensive study on mRNA accumulation of antioxidant genes after ozone, sulfur dioxide, and UVB light exposure has been performed in *Nicotiana* by Willekens et al. [58]. Their results suggest that CAT and GPX activities, but not SODs and cytosolic APX, contribute to the antioxidant response in tobacco. However, other studies have shown that both the APX transcript and the derived enzymatic activity increase after ozone exposure [38,59–61] presumably enhancing plant tolerance to ROIs. Accordingly, the reduction of endogenous cytosolic APX mRNA levels in transgenic tobacco plants by antisense technology made these plants significantly more susceptible to ozone injury than control plants [62]. These results indeed demonstrate the importance of cytosolic APX in relieving the oxidative stress generated by ozone.

Ozone exposure correlates with a decline in chloroplastic GR transcripts [38]. The role of GR activity in oxidative stress responses is also rather controversial. Experiences with tobacco plants transformed with a pea GR expressed either in the cytosol, chloroplasts, or chloroplast plus mitochondria indicated that only certain lines of the latter combination were more resistant to ozone [63]. In addition, tobacco plants expressing the GR coding sequence from *Escherichia coli*, both in cytosol and chloroplasts, improve their tolerance to paraquat but show no differences in the response to ozone [64,65]. This may reflect the different location of ROIs induced by paraquat (chloroplast) and ozone (apoplast).

In contrast, transcription of GST is dramatically affected during ozone stress. Its mRNA increases rapidly and transiently about 20-fold within 3–6 h of ozone treatment suggesting that GST could play an important role in detoxifying cells [38,56]. Owing to this prominent change, GST is considered to be a sensitive molecular marker of ozone.

Ozone treatment has been shown to increase both SOD transcript [56] and SOD activity [54]. This appears to be due to enhanced transcription of the cytosolic Cu/Zn SOD, since mitochondrial Mn SOD remained unchanged and the chloroplastic Fe SOD transcript declined in ozone-treated plants [38]. The general increase of reduced glutathione in plants exposed to oxidative stress [66] has been proposed to influence the expression of cytosolic SOD in tobacco, which is thought to be under redox control [67,68].

Results of overexpressing SODs in transgenic plants are controversial with regard to ozone resistance. Engineered tobacco plants producing elevated levels of chloroplastic Cu/Zn SOD activity display the same sensitivity than control plants to superoxide toxicity caused by paraquat [69] or ozone [70]. However, tobacco plants overexpressing chloroplast-directed MnSOD show enhanced protection against oxygen radical and ozone damage [71,72]. In addition, transgenic tobacco plants that overproduce chloroplast-located pea Cu/Zn SOD have a higher resistance to oxidative stress and also exhibit an increase in APX activity [73]. These discrepancies could be explained by differences in the levels of SOD overproduction, in the extent of inhibition of Cu/Zn SOD by hydrogen peroxide, or in the ozone dosage among different experiments [72].

Ethylene and Polyamine Biosynthesis

Ethylene and polyamines play antagonistic prosenescent and antisenescent roles, respectively [74]. Their synthetic pathways (Fig. 3) share the same precursor metabolite, S-adenosyl methionine (SAM); a fact that could explain in part their competing interactions. SAM also acts as a methyl group donor in numerous methyl transferase reactions, including the biosynthesis of lignin. The key regulatory step in the ethylene biosynthetic pathway is the conversion of SAM to 1-aminocyclopropane-1-carboxylic acid (ACC) catalyzed by the ACC synthase (ACS) [75]. The final reaction in the pathway is the conversion of ACC to ethylene, which is catalyzed by the ACC oxidase (ACO) (Fig. 3).

Ethylene production is involved in many physiological processes throughout the plant life cycle [75]. Besides, most plants synthesize ethylene when subjected to different stress conditions, including ozone exposure [76,77]. Tobacco and tomato plants subjected to ozone treatment show increased levels of the ethylene precursor ACC [78,79]. Accordingly, two genes encoding ACS from tobacco have been found to be transcriptionally activated after ozone exposure, thereby increasing ethylene production [80,81]. In a recent study, Tuomainen et al. [79] have compared the expression of different genes involved in ethylene biosynthesis on exposure of tomato plants to ozone. Their conclusions are that specific genes from the families of the SAM synthase, ACS and ACO are indeed induced by ozone, but postranslational modification (phosphorylation) of ACS also contribute to the activity rise, especially during the early stages of response.

A remarkable correlation between stress ethylene synthesized in response to ozone and plant sensitivity to ozone has been detected by analyzing the levels of ethylene in ozone-sensitive and ozone-insensitive plant varieties [77,82]. When ozone-sensitive tobacco plants were exposed to ozone, ethylene synthesis increased considerably in parallel with leaf injury, whereas levels of ethylene remained low in the insensitive variety Bel B. Moreover, younger tobacco plants are more

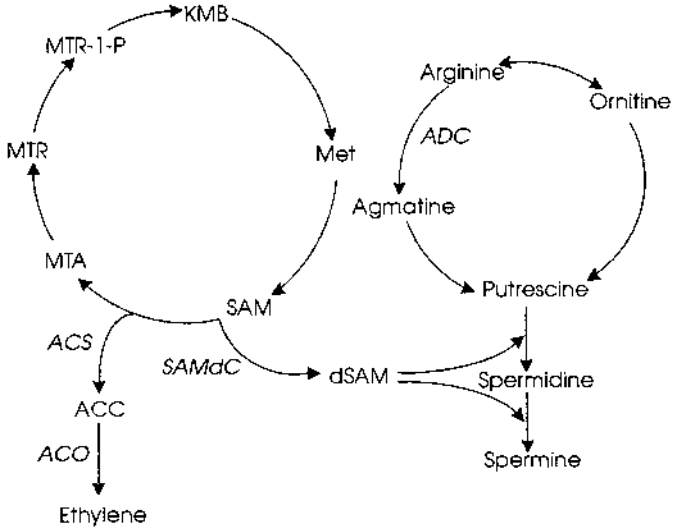

FIGURE 3 Biosynthetic pathways of ethylene and polyamines in plants. Only main intermediary metabolites and key enzymes are indicated. Metabolites: ACC, 1-amino-cyclopropane-1-carboxylic acid; KMB, 2-keto-4-methylthiobutyric acid; MTA, 5′-methylthioadenosine; MTR, 5-methylthioribose; SAM, S-adenosyl-methionine; dSAM, decarboxylated SAM. Enzymes: ACS, ACC synthase; ACO, ACC oxidase; ADC, arginine decarboxylase; SAMdC, SAM decarboxylase.

resistant than older plants to ozone injury correlating with their ability of producing stress ethylene. Furthermore, ozone toxicity is reduced in mung bean plants when pretreated with different inhibitors of ethylene biosynthesis acting at different metabolic steps. It also has been demonstrated that these inhibitors prevent ozone injury without affecting stomatal opening [22]. These results illustrate a synergic effect between stress ethylene and ozone, which has been attributed to the nonenzymatic reaction between them in the gas phase of the substomatal chambers to produce free radicals and reactive aldehydes that might be responsible for plant damage [76].

Contrarily, ethylene treatment, previous to ozone exposure, has been shown to minimize the subsequent damage to plants [18,83] probably through the induction of defense systems which protect plants from the toxic effects of ROIs [59].

ADC is the key enzyme regulating polyamine synthesis during plant stress [74]. The activity of this enzyme has been studied in different plant species subjected to ozone treatment. These studies support a strong positive correlation between ozone exposure, ADC activity, and polyamine contents of the plants. High ADC activity and putrescine levels are characteristic responses of the Bel B tolerant variety of tobacco to ozone exposure [77]. In barley leaves, the application of difluoromethyl arginine, a specific inhibitor of ADC, extended the visible injuries resulting from a subsequent ozone fumigation [84]. Moreover, root-applied polyamines increased the foliar levels of polyamines in tobacco Bel W3, thereby protecting the leaves of this sensitive line from ozone damage [85].

Hydroxycinnamic acids conjugates of polyamines also have been shown to increase after ozone exposure [77]. In general, elevated levels of polyamines correlate with oxidant stress resistance [86] probably because they can act as free radicals scavengers [87]. A model for the inhibition of senescence by polyamines has been proposed in which polyamines bind to membranes preventing lipid peroxidation by quenching free radicals that catalyze this process. Free radicals also are needed for the ACO activity, and this could be the reason why polyamines inhibit ethylene biosynthesis [74]. The same model could also apply for protection against ozone-induced damage by polyamines. The scavenging effects of polyamines has been shown not to be due to the amine group itself but to the conjugated phenolic hydroxy group, since polyamine conjugates, but not the free polyamines, are effective scavengers for ROIs [85].

Pathogen-Related Proteins

Close similarities between ozone- and pathogen-induced reactions in plants have been stressed in several reviews [36,88,89]. The relationship between these two processes became evident when mutants screened for their susceptibility to fungal pathogens turned out also to be ozone sensitive [90]. Moreover, ozone treatments habitually lead to changes in plant susceptibility to pathogenic attack [11].

Plant responses to biotic stress caused by a wide range of pathogens is currently becoming one of the leading research fields in plant molecular biology [46]. Plant-pathogen interactions may be divided into compatible and incompatible reactions depending on if pathogen invasion takes place or not, respectively. Plant defense mechanisms against pathogens are mediated by ligand-receptor interactions (also named gene-for-gene) between *Avr* (the pathogen avirulence gene) and *R* (the plant resistance gene) resulting in the locally induced hypersensitive response that leads to localized plant cell death and thereby to the isolation of the pathogen at the necrotic site. This interaction stimulates further responses, including the signal that triggers the systemic acquired response (SAR), a whole-plant and wide-range resistance developed by the plant after being attacked by pathogens.

The local and controlled production of ROIs by the cell is one of the main components in the plant response against pathogens. Fungal and bacterial elicitors trigger a biphasic ROI production. Phase I is a very rapid response (within minutes) and not always correlated with plant disease resistance. Phase II is produced many hours later and correlates with the degree of resistance of the plant to the pathogen [16,17].

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

Pathogen-related proteins (PRs) are a group of polypeptides induced in plant hosts by pathogens which share some biochemical characteristics, such as low molecular weight, stability at low pH, and resistance to degradation by proteases. PRs are classified in five functional groups containing both acidic extracellular and basic vacuolar members. For example, some are β-1,3-glucanases and chitinases, enzymes that degrade the cell wall of fungal pathogens, and others are proteinase inhibitors or proteases degrading the pathogen proteins [91]. β-1,3-Glucanases and other hydrolases could be also involved in the recycling of monomers from polysaccharides of necrotic areas, thereby salvaging useful products [92]. In any case, as a result of the coordinate expression of PRs, the plant becomes more resistant to pathogenic attacks [93].

PRs induction both at the postranscriptional and postranslational levels have been demonstrated in several instances after ozone treatment [92,94,95]. Furthermore, PRs genes have been isolated in a differential screening in ozone-treated against control parsley plants [37].

Phenolic Compounds and Cell Wall Constituents

Many potentially protective phenylpropanoid compounds, including flavonoids, furanocoumarins, and lignin, play a role in plant defence responses. These compounds are synthetized under different environmental stress conditions such as wounding, pathogenic attack, UV light, and ozone exposure [96].

The first regulatory enzyme in this pathway is the phenylalanine-ammonium lyase (PAL) that converts phenylalanine in cinnamic acid initiating the phenylpropanoid secondary metabolism. Several branched pathways, leading to different families of compounds, emerge after the PAL-catalyzed first step (Fig. 4).

Rapid and transient increases in PAL activity due to transcriptional regulation of the PAL genes have been described in plants exposed to ozone [47]. There are several isoforms of PAL and only some of them are induced by stress. The PAL induction patterns by ozone, plant pathogens, or wounding are extremely similar, which is evidence of a remarkable parallelism among these responses [88].

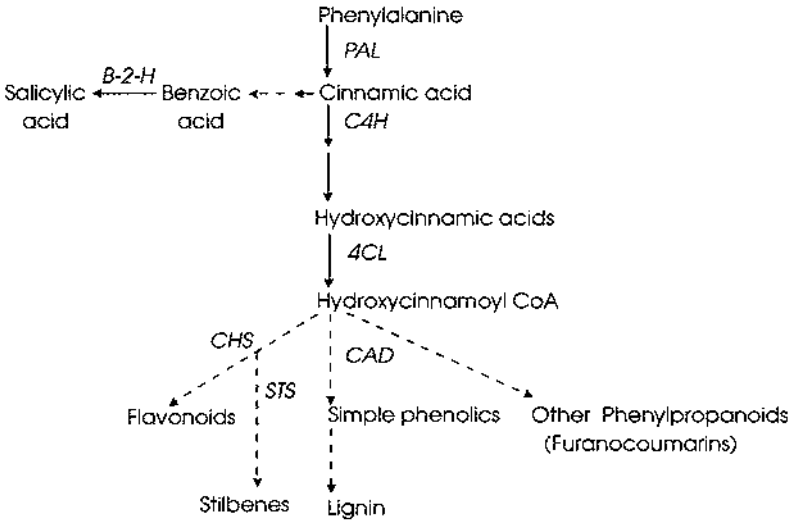

FIGURE 4 Schematic phenylpropanoid metabolism in plants. Indicated regulatory enzymes are phenylalanine ammonium lyase (PAL), benzoate-2-hydrolase (B-2-H), p-coumarate: CoA ligase (4CL), chalcone synthase (CHS), stilbene synthase (STS), and cinnamyl alcohol dehydrogenase (CAD).

Salicylic acid is a cinnamic acid–derived signaling compound that accumulates in response to several stresses, including ozone treatment [97]. Salicylic acid is plausibly implicated in the ozone-signaling pathway (see section on Salicylic Acid below).

Lignin and suberin are complex polymers formed by the oxidative combination of simple phenolics, which are usually conjugated with sugars and organic acids [98]. These reactions are particularly important in woody tissues. However, in response to stress conditions, lignin-like products can be formed in other tissues as part of the general defense strategy of plants. Cinnamyl alcohol dehydrogenase (CAD) is the key regulatory enzyme in lignin biosynthesis and its activity also has been shown to increase through transcriptional activation following ozone treatment [99,100].

Flavonoids are synthesized via chalcone synthase (CHS), a branching enzyme in the pathway. Some of these compounds absorb UV light–protecting cells against UVB damage by avoiding DNA dimerization and breakage [96]. Accumulations of flavonoids seem to be required for normal pollen development, and their induction by stress may also serve to prevent pathogenic infection. Increases in CHS activity after ozone exposure also have been reported [101,102].

Stilbenes are phytoalexins related to flavonoids. They branch out of the common pathway through the regulatory enzyme stilbene synthase (STS), which is strongly induced by pathogens [103]. Primary needles of 6-week-old pines exposed to ozone increase several hundred- to thousandfold the activity of the STS in a dose-dependent manner; therefore being useful as an ozone marker [102].

Flavonoids and furanocoumarins, which usually accumulate in response to UV light and pathogens respectively, are both induced by ozone treatment in parsley. This result suggests that ozone could produce a cross induction of the UV- and pathogen-defense responses [37,47].

Other Ozone-Induced Gene Products

New molecular approaches are leading to identification of genes induced by ozone. Sharma and Davis [104] have isolated a novel ozone-induced cDNA (AtOZ1) of unknown function in *Arabidopsis* by the technique of mRNA differential display [105]. Eckey-Kaltenbach et al. [37] have isolated a cDNA corresponding to a heat-shock protein (HSP) through a differential screening. Although the involvement of HSP in oxidative stress defense is well known in yeasts [106,107], this is the first time that these proteins have been described to participate in oxidative responses in plants. Transition metal metabolism also has been implicated in defense reactions against oxidative stress in other organisms [107]. In this regard, a transcript for a cytosolic copper transport protein, which may be implicated in delivering copper to the secretory compartiments, has been found to increase following ozone treatment in *Arabidopsis* (H. Mira and L. Peñarrubia, personal communication). Further examples of transcripts induced by ozone exposure are an enzyme for the biosynthesis of terpenes [108], a thiol protease and protease inhibitors [109], and polyubiquitin, which suggest the involvement of the ubiquitin system in ozone-damaged protein degradation [108].

MOLECULAR BIOLOGY OF OZONE PERCEPTION AND SIGNAL TRANSDUCTION MECHANISMS

Contrary to other initiation events in plant transduction processes, the ozone response apparently does not begin with the recognition of the effector molecule by a receptor. No ozone receptor has been reported to date, and it is not unreasonable to postulate that this receptor simply does not exist. After all, plant ozone stress is a very recent phenomenon, and it is likely that the components of the ozone response have been sorted out from preexisting responses to other stresses activated through coincident steps of chemical damage. This conjecture is supported by the fact that every reported ozone-induced gene (see Table 1) has been shown also to be affected by other stresses or natural senescence. For example, the expression of a heat shock (sHSP) and two PR proteins is induced by ozone, but only sHSP is activated by heat shock [37]. This fact suggests that ozone can activate

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

different signal transduction pathways, with one of them merging with paths of the heat-shock response perhaps through interaction with some heat-shock transcription factors, as has been shown to happen in other eukaryotic organisms during oxidative stress [107,110].

Signaling Molecules

Also with regard to the signaling cascade, no specific molecules have been described in the case of the response to ozone which probably means that common cellular intermediate signals could mediate this response. This fact would explain the rather inespecific nature of the ozone response and the cross induction with other stresses. A wide variety of chemical signals that are known to participate in other processes also have been implicated in the ozone transduction pathway. However, since some molecules could act as a chemical signal only within an extremely narrow range of concentration and under particular circumstances, quantitative, spatial, developmental, and species-specific aspects must be taken into account before assuming their role in a process. Among these potential signal molecules are the following.

Reactive Oxygen Intermediates

During pathogenic attacks, ROIs are produced at primary infection sites, and they act as early diffusible signals leading to the activation of detoxification systems in distant cells [16,111].

$O_2^{-\bullet}$ has been shown to be the signaling molecule that induces plant defense genes in the mutant *lsd1* which mimic disease lesions [112]. However, owing to its longer life and higher permeability across membranes, H_2O_2 has been proposed as the best candidate for signaling among ROIs. Indeed, H_2O_2 is involved in the signal transduction pathway of the hypersensitive response [113]. Moreover, H_2O_2 has been implicated in limiting the spread of cell death by induction of cell-protectant genes in surrounding cells [114,115]. GST transcripts increase in response to a narrow range of H_2O_2 [114]. In addition, H_2O_2 inhibits the growth of diverse microbial pathogens [116] and also contributes to plant cell wall strengthening through peroxidase-mediated cross linking of Pro-rich structural proteins [117,118].

Overproduction of H_2O_2 in tobacco transgenic plants by expression in the apoplast of an H_2O_2-generating glucose oxidase has been shown to increase the resistance to pathogenic attacks by activation of host defense mechanisms [116,119]. Besides, H_2O_2 increases benzoic acid-2 hydroxylase enzyme activity [120], which is required for the salicylic acid biosynthesis (see Fig. 4) associated with the systemic acquired response. However, exogenous application of H_2O_2 did not induced PAL or CHS gene expression [114].

Baker et al. [46] have suggested a parallelism between the mammalian immune and the plant pathogenic responses with regard to the function of ROIs. In the mammalian immune response, ROIs induce the expresion of genes through the activation of the redox-regulated transcription factors NF-κB and AP-1 [121]. Different ROIs are able to activate NF-κB, whereas $O_2^{-\bullet}$-producing agents are not [122]. Antioxidants also have different effects on the activation of these transcription factors [123]. AP-1 activation is involved in the UV response pathway, which is highly conserved from yeast to mammals [124]. Curiously, proteinase inhibitors I and II from potato tubers have been shown to block UV-induced AP-1 activation in mammals probably through inhibition of the signaling mechanism that mediates UV-induced carcinogenic cell transformation [125]. The DNA-binding domain of AP-1 have cysteine residues that only bind to its target *cis* DNA element when they are reduced by the nuclear redox factor Ref-1 [126,127]. An *Arabidopsis* homologue of Ref-1 has been described in plants [128].

ROIs, produced in the apoplast of ozone exposed plants, may be either detoxified by the extracellular radical scavengers or they can react with plasma membrane components initiating the production of intracellular signals. Similar to pathogenic attack responses, a biphasic production of ROIs have been detected in the apoplast of tobacco plants exposed to ozone [36]. Endogenously produced ROIs, most likely generated through secondary alterations of energy transduction components in the chloroplasts and mitochondria, could further contribute to the diversification of responses, especially to the numerous changes described in the chloroplasts.

Jasmonates

Jasmonic acid and its methyl ester, methyl jasmonate, are oxidation products of the linolenic acid from the plasma membrane via the octadecanoic pathway [129]. The role of jasmonates as signal transduction intermediates have been well characterized during induction of proteinase inhibitors in tobacco and tomato after UV irradiation and wounding [129a]. These compounds have been demonstrated to play a critical role in promoting transcription of several wound- and senescence-related genes [130], although both jasmonate-dependent and jasmonate-independent responses have been described during wound-induced signal transduction [131].

Jasmonates could also be involved in plant senescence, since their exogenous application to leaves decreases the expression of some photosynthetic genes causing chlorosis [132]. In contrast, high levels of jasmonates have been described in young and reproductive tissues. In order to conciliate both findings, Creeman and Mullet [129] have suggested that the role of jasmonates could be related to inhibition of the photosynthetic apparatus, thereby avoiding premature accumulation in young organs and helping chloroplast dissassembly during senescence.

Jasmonates could also play a role in the ozone response. It has been suggested that ozone-induced ROIs could mediate lipid peroxidation and induction of the lipoxygenase activity that releases jasmonic acid from linolenic acid [133]. Moreover, methyl jasmonate and its precursors participate in the gene induction of flavonoid glycosides by ozone [47] and mediate the induction of PAL mRNA accumulation by H_2O_2 [134].

Ethylene

Ethylene has been widely associated with both natural and stress-induced senescence. Recent studies with transgenic plants, where ethylene biosynthesis have been blocked, suggested that senescence is initiated by an age-dependent developmental program which is ethylene independent. However, ethylene influence senescence timing as a way to respond to environmental conditions [135].

Ethylene signal transduction has been deciphered in recent years, and it is becoming one of the best-known plant hormone transduction pathways. Genes involved in the ethylene response have been identified in *Arabidopsis*. The ethylene receptors [136,137] show homology with two-component sensor-regulator bacterial proteins and resemble a hybrid protein sensor-regulator kinase responsible for signaling hyperosmotic stress in yeast. Dowstream in the ethylene signaling pathway is CTR1 [138], a negative regulator which encodes a Raf-1–like protein kinase homologous to those involved in multiple signaling cascades of eukaryotic cells. The participation of other genes in ethylene signal transduction has been recently reviewed [139–141].

Ethylene induction is one of the first events detected in plants after ozone treatments, correlating with ulterior visible injury and decline of the photosynthetic apparatus [34]. Owing to the similarities shown between ozone damage and the plant/pathogen–mediated hypersensitive response, a role as an abiotic elicitor has been proposed for ozone [79,89]. Together with other damage-related factors, ethylene is thought to play a role in the development of symptoms controlling or promoting the spread of cell death.

Since both ethylene and jasmonates are probably involved in ozone transduction, they might perhaps interfere with each other. For example, methyl jasmonate is known to stimulate ethylene production in fruits mainly through enhancement of the activity of the ACC oxidase [142]. Ethylene and jasmonates have been shown also to cooperate in the signaling pathway following wounding in tomato, rendering complicated patterns of gene expression which may differ between species [131,143].

Salicylic Acid

Salicylic acid is required to induce systemic acquired resistance (SAR) and PR gene expression [144,145]. However, it remains unclear if salicylate is or is not the long-distance systemic signal for SAR induction. The role of salicylic acid in the plant defense is complex and may differ from species to species. Elevated levels of salicylic acid can also inhibit jasmonic acid and ethylene

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

biosynthesis interfering with the signaling pathways of these molecules during wound-induced responses [143,146,147].

Salicylic acid stimulates ROIs production owing in part to the direct inhibition of the catalase activity of a salicylic acid–binding protein [148,149], and ROIs in turn activate salicylic acid biosynthesis, acting as a positive effector of the benzoate-2-hydroxylase. Recent data have suggested a model for the role of the oxidative burst and/or the salicylic acid in the hypersensitive and SAR responses [150]. In this model, pathogen-induced oxidative burst (phase I) leads to rapid activation of the phenylpropanoid pathway, thereby promoting salicylic acid synthesis. Pathogen-induced phase II of the oxidative burst means a persistant rise in H_2O_2 by the recognition of an incompatible pathogen. The sustained activation of salicylic acid synthesis, together with other factors, would potentiate the ROIs production in phase II leading to cell death (in the hypersensitive response) and to systemic acquired resistance [150].

Exposure to ozone or UV light trigger salicylic acid biosynthesis in tobacco probably through chemical release of the precursor, benzoic acid, from its conjugated forms [97]. Both glycosylated and free forms of salicylic acid accumulate rapidly after ozone treatment. Free salicylic acid induction is transient, reaching a maximum after 6 h of ozone treatment in correlation with the activation of plant defense mechanisms, as measured by PAL and GST-1 mRNA accumulation [151]. This fact suggests that ozone activates the hypersensitive response and the SAR through signaling pathways that involve salicylic acid.

Plants engineered to be deficient in salicylic acid, through the expression of a bacterial salicylate hydrolase (nahG), did not produce a normal systemic acquired resistance response [152]. Moreover, transformed plants also are affected in their response to ozone, being more susceptible than control plants, developing necrotic lesions and becoming slightly chlorotic. This response was more pronounced in aged plants; probably due to the fact that the activation of the antioxidant response depends partly on salicylic acid accumulation. The study of these plants by Sharma et al. [151] allows us to dissect the different signaling routes in the ozone response and has led to the description of three different gene expression behaviors:

- Genes whose mRNA induction by ozone was abolished in transgenic plants (e.g., PR1) indicating that their induction is salicylic acid dependent.
- Ozone-induced genes which also accumulate in these plants (e.g., PAL). This indicates that there is also a salicylate-independent pathway in the ozone response.
- Genes that accumulate habitually under ozone treatment but their expression is attenuated in these plants (e.g., GST1), indicating that they are under control of at least two independent regulatory pathways.

Genetic Studies

Genetic approaches are providing insights for understanding the role of salicylic acid in defense responses (for a recent review, see Ref. 153).

Nonexpresser of PR genes (*npr*1) mutants are defective in the SAR response expression at a step downstream of salicylic acid. When these mutants are treated with ozone, accumulation of PAL mRNA is unaffected, whereas PR1 transcripts are detected at very low levels [151]. This result shows that NPR1 is necessary in the signal transduction for PR1 expression. However, GST1 transcripts remained at almost the same level than in wild-type plants, suggesting that the salicylic acid–dependent component in the regulation of GST1 does not require NPR1. Ozone-induced disease resistance also is disrupted by the *npr*1 mutation. This mutation appears not to interfere with the hypersensitive response [154] indicating that ozone-induced resistance is mediated basically by the SAR pathway [151]. Moreover, *npr*1 plants were not more sensitive to ozone damage suggesting that the antioxidant response does not require NPR1, a protein containing ankyrin repeats [155], which probably mediate protein-protein interactions. NPR1 shares similarity at the gene sequence level with the mammalian IκB, an inhibitor of NF-κB, that regulates the cytosolic localization of

this transcription factor. This similarity suggests that NPR1 could act as a transcriptional regulator of PR gene expression [46].

Mutants with spontaneous hypersensitive response lesions in the absence of pathogenic infection have been described in several plant species indicating that the hypersensitive response is under genetic control [156]. The *Arabidopsis* mutants *lsd1* (lesions simulating disease) constitutively express PR proteins and produce salicylic acid [157]. LSD1 encodes a zinc finger protein that participates as a negative regulator in the transcription of death-response genes [158].

Cis Elements

Conserved regulatory protein-binding nucleotide sequences in the promoters of several stress genes [159,160] are probably responsible for the coordinate induction by converging signaling pathways. The study of *cis*-acting regions in the promoters of ozone-induced genes is providing some information about these interactions. Recently, the stilbene synthase promoter from grapevine fused to the glucuronidase reporter gene has been analyzed in transgenic tobacco plants [161]. Glucuronidase activity after ozone treatment was distributed all over the leaf in small spots, mainly in palisade and parenchymal cells. Analysis of the promoter revealed an elicitor-responsive element (ERE). Interestingly, deletion analysis demonstrated that regions responsible for its inducibility by pathogens and ozone are located in different, nonoverlapping zones of the promoter. Moreover, the fact that the ERE element is included inside the ozone-responsible area of the promoter appears to indicate that the ozone effects on gene regulation are related to elicitation [161].

CONCLUSIONS

Although a relatively recent environmental problem, ozone is already causing important agricultural losses, while short-term predictions regarding a desirable attenuation of the pollution levels in industrialized countries are pessimistic [162]. In this context, sustainable agriculture would require to address seriously the problem of ozone damage to plants, the molecular details of which are recently beginning to emerge thanks to the wealth of data supplied by the molecular biology approach. Some of the main conclusions of these studies are summarized in the following scenario (Fig. 5).

Ozone enters the leaf through the stomata and, once in the apoplast, it may react with the cell wall and membrane components. As a result of some of these reactions, ROIs, singlet oxygen, and other free radicals are produced. These species have three possible destinies. First, they can be detoxified by the antioxidant compounds present in the apoplast. Second, they can diffuse (especially H_2O_2) inside the cell. Third, they may further react with membrane components generating a variety of products that can act as intra- or extracellular signals. These putative signals could be detected by nuclear sensors leading to the biosynthesis of ethylene and salicylate which would mediate further responses.

Intracellular ozone-induced signals, other than those acting on the nucleus, could be responsible for changes in the chloroplast membranes that have been described in ozone-exposed cells. Alterations in energy transducing membranes or electron carriers of chloroplasts and mitochondria may potentially lead to enhanced ROI production that in turn results in further damage to these molecules. This positive-feedback chain, or ''vicious circle,'' of ROIs in these organelles has to be quenched by antioxidative systems, or else it has been proposed as the mechanism responsible for accelerated senescence. The enhanced production of ROIs may contribute to the global increase in the oxidative conditions inside the cell and trigger a senescence program responsible for downregulation of chloroplastic gene expression. Ethylene could also participate in the timing of stress-induced senescence. Probably all three plant cell genomes (nuclear, mitochondrial, and chloroplastic) possess redox sensor mechanisms to detect the rise of oxidants. Under these circumstances, cross-talk between the nucleus and the organelles appears to be critical to integrate the global antioxidative response. Transcriptional and posttranscriptional mechanisms of nuclear control over the chloroplast

Marcel Dekker, Inc.

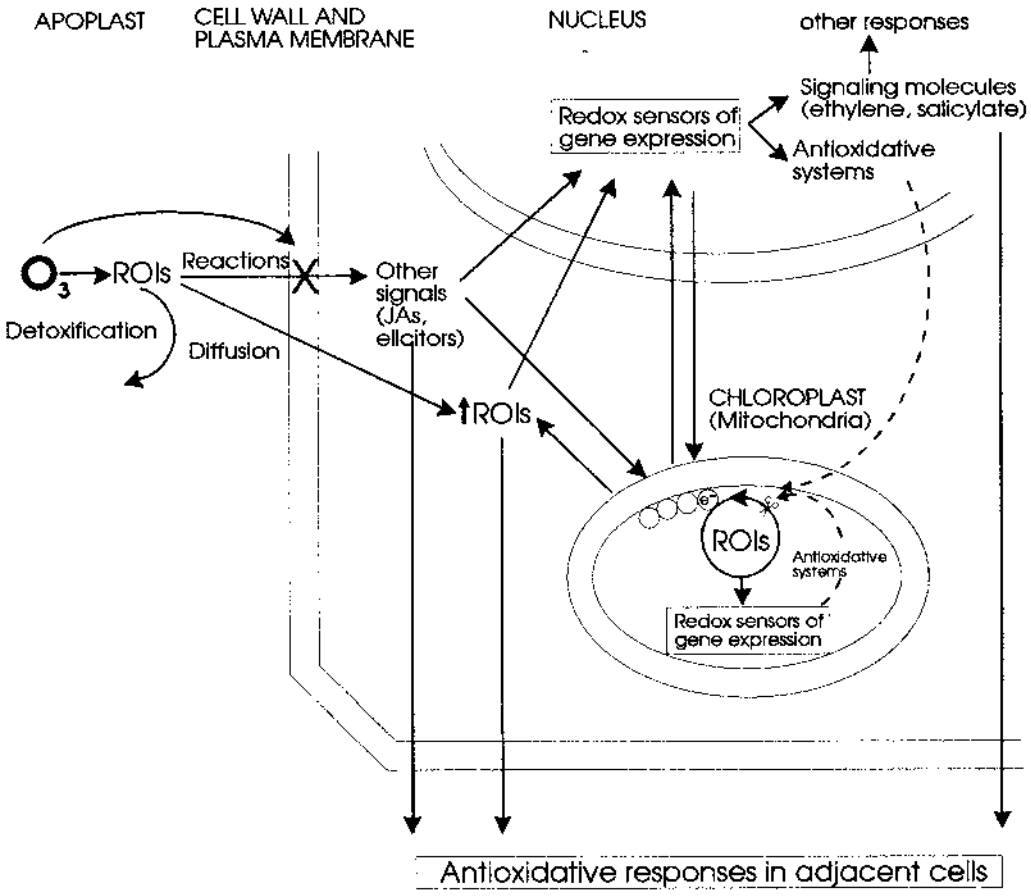

FIGURE 5 A model of the signaling mechanisms whereby ozone exposure induces cellular responses and modulates gene expression. Perception of intracellular conditions and cross-talk among the different plant cell genetic systems is central to this model. Postulated signaling molecules are ROIs, ethylene, salicylate, jasmonates (JAs), and chloroplast-targeted nuclear effectors.

protein expression have been shown to act under different environmental conditions [163–165]. Jasmonates could additionally (or alternatively) mediate nuclear-directed chloroplastic alterations in the gene expression during ozone exposure, since these compounds have been proposed to inhibit the chloroplastic functions inducing senescence.

Depending on the intensity of the stress caused by ozone, adaptative (under low-level long-term exposures) or necrotic (under acute treatments) responses can take place. These qualitatively different behaviors could result from a threshold phenomenon. Antioxidative defenses, both nuclear and chloroplastic, would act controlling the levels of ROIs up to the point where they become overwhelmed. Below this permissible level, intracellular conditions would be compatible with cell survival and the response would be adaptative. However, if the critical threshold is exceeded, uncontrolled ROI production will probably lead to irreversible oxidative injury, and the damaged cells may initiate a death program that would produce a necrotic lesion. Meanwhile, the surrounding cells would receive diffusing signals that activate their defenses against oxidative stress.

The diversity in the responses to ozone could depend on multiple interacting factors, for example, the ozone dose and time of exposure, plant species characteristics, and developmental stage, and simultaneous presence of other stressing factors. Taken together, these factors could modulate the response through the variety of signals, interactions, and cross-talks mediating the ozone response. Currently, a clear picture of these interactions at the molecular level is lacking, probably because several important pieces of the complex signal transduction pathway are still missing. New approaches, such as the study of the ozone response in specific mutants or transgenic plants, are helping to solve questions about the role of single signal molecules in the whole transduction pathway. Besides, further work is needed to investigate the plausible involvement in the ozone response of other habitual signaling components, such as G proteins, calcium, protein kinases (MAPKs), and phosphatases, since these components have been shown to participate in closely related plant signal transduction processes, such as plant-pathogen interactions [166–170].

Genetic Factors Affecting Abiotic Stress Tolerance in Crop Plants

ARUN KUMAR JOSHI
Institute of Agricultural Sciences, Banaras Hindu University
Varanasi, India

INTRODUCTION

Plant growth and development is a result of the interplay between the genetically governed potential of the plant and the plant environment in which it grows [1,2]. Therefore, a plant's peaceful way of living is often disturbed by a number of environmental factors among which abiotic factors are of crucial importance. The earth's surface, which is 70% saltwater and 30% land [3], possesses only half of its land area free from extremes of water and temperature, and to soil erosions and difficult geography. The other half, which is used for agricultural production, also faces various abiotic stress problems that are considered to be the main source of yield reductions all over the world [4]. These abiotic stresses are either stable or fluctuating in nature. Stable stresses are those due to abnormal pH or metal toxicity. Unstable or fluctuating stresses include abnormal levels of water (drought/flooding), temperature (cold/hot), and other factors such as pollutants.

Abiotic stresses are characterized by the occurrence of more than one stress at the same time or throughout the growing cycle even though one stress may dominate [5]. Since the whole biotic world, directly or indirectly, is dependent on plants for survival, any disturbance to plants gets reflected in their own disturbance. This is of greater reality for humans and their agriculture, and it is even greater in the present situation where all our natural resources are shrinking except the number of mouths to feed. Therefore, providing relief to crop plants from abiotic stresses is providing relief to ourselves. Relief from abiotic stresses is possible either by changing/avoiding the environment or changing the genotype of the plant itself. Genetic manipulation of crop plants, to make them ready for abiotic stress areas, now seems possible with our increased knowledge about the genetic factors affecting abiotic stress tolerance. However, in some cases, it is difficult to differentiate between the genetics of the traits associated with stress and the tolerance of the stress itself. Breeding for abiotic tolerance may be direct (selection pressure under stress) or indirect (selection pressure under a stress-free environment) [3]. The recent, advent of molecular tools, especially molecular markers, has revolutionized the genetic analysis of crop plants and provided not only

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

geneticists but also physiologists, agronomists, and breeders with valuable new tools to identify traits of importance in improving resistance to abiotic stresses [6].

DROUGHT TOLERANCE

Crops all over the world are exposed to chronic or sporadic periods of drought [4], a multidimensional stress affecting plants at various levels of organization [7]. Drought stress affects yield by reducing both sink and source. It can be a result of stress affecting either one directly or their interaction with one another [7]. Before seeing the face of the sun or facing the external world, the living plant (the dormant embryo) within the seed is highly tolerant to desiccation but loses its tolerance on germination and emergence. Plants survive under drought through avoidance or postponement of dehydration or tolerance [8–12]. The ability of a crop to grow satisfactorily in areas subjected to water deficits has been termed drought resistance [8]. Plants tolerate drought stress through various morphological, biochemical, and molecular adjustments at the whole-plant level.

Morphophysiological Traits: Genetic Basis

Although there are no traits that confer global drought tolerance [13], numerous constitutive traits carry a large impact on crop performance under drought stress [7]. According to Wilson [14], traits associated with water-use efficiency act through their effect on (a) timing of crop development, (b) efficiency of root to harvest water, (c) effective transpiration control by the shoots and the relationship of transpiration and photosynthesis, and (d) the ability of plants to endure stress. Any trait that reduces transpiration or increases photosynthesis will increase water-use efficiency. Ludlow and Muchow [15] have reviewed important traits in crops for success in water-limited environments. Although several traits join to fight drought, the genetics of some of the traits useful under drought conditions is given below:

Earliness

Rapid plant development and early maturation requires less water thus works through avoidance [8–12,15]. There is genetic variation for earliness both across and within species [12,16,17]. For example, in wheat, there is much genetic variation in flowering time and maturity [18]. The *Rht* genes in wheat possibly possesses the pleiotropic effect on earliness [18]. In maize, a strong quantitative trait locus (QTL) for flowering date and anthesis to silking interval was identified on the same chromosome as the genes for yield under drought [19].

Roots

An extensive root system is desirable for efficient water extraction in different crops [12,20–22]. Genetic variation in root characteristics do exists in crop plants [20,23–28]. Many root characteristics have been shown to be under genetic control and are quantitatively inherited. But in rice, the difference in the depth of rooting is controlled by only a few genes [29,30]. There is genetic variation for root hydrolic conductance in wheat, and this is heritable [31]. Genetic variability for root size was found in sorghum [32], wheat [33], rice [34], soybean [25], and oat [35]. The density of root-hairs also shows considerable genetic variability (200 cm^2 in trees to 2500 cm^2 in cereals), but little is known about the intraspecific variability and genetics of this trait [36]. Root traits (root length, root number, root-tip thickness, and root/shoot weight ratio) in rice have been found to posseses moderate heritability and are under the control of both additive and dominance gene effects [29,30,34]. The predominance of additive gene action for maximum root length and number has been reported in rice [37]. Some of these traits also showed heterosis in several crop plants [7,38,39].

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

Stomatal Conductance

Reduced stomal conductance through various characters such as stomatal frequency, length, and behavior [15] increases, water-use efficiency. Genetic variation has been reported for various stomatal characters [40–42], and they seem to be highly heritable [40,43].

Epicuticular Wax

The waxy layer covering the plant parts, for example, the glaucous characteristic in wheat and the bloomed trait in sorghum, improve water-use efficiency. Genetic variation has been reported for the bloomed trait in sorghum [44,45] and glaucousness in wheat [46]. Variation for cuticular wax also has been reported in other crops; for example, oat [47], rice [48], and barley [49]. The genetics of epicuticular wax has been investigated in several crop species; the presence of waxy bloom was found to be controlled by a single dominant gene [36]. Heritability for bloomed trait of sorghum was low [45].

Osmotic Adjustment

Osmotic adjustment (OA) reduces the rate of leaf senescence (stay green trait), because it increases both avoidance and tolerance of dehydration. Genetic variation for this trait has been found in wheat (*ms* gene) [50–55], sorghum [56–59], millet [60], cotton [61], rice [62], and pigeon pea [63]. OA is simply inherited and only one or few genes are involved in wheat [50,55,64] and soybean [65]. In rice, the *indica* cultivars tend to be more dehydration tolerant than *japonica* cultivars [62]. A gene for OA was located in chromosome 7A of wheat [64]. On the basis of homeology between a small segment of chromosome 7 of wheat and chromosome 8 of rice [66,67], it has been suggested that there might be association between the OA gene of wheat and rice.

Transpiration Efficiency

The transpirational efficiency of C_4 plants is greater than of C_3 plants [68,69]. Genetic variation for transpiration efficiency has been reported in wheat, barley, cotton, peanut, and sunflower [31,70]. Its inheritance is complex [15] but heritability is high [70,71]. High heritability has been noted in crested wheat grass [72], peanut [73], and wheat [74–76] and moderate in cowpea [77]. It has been reported that transpiration efficiency may be under the control of few genes in tomato [75].

Several other traits such as, for example, the mobilization of preanthesis assimilates, leaf movements, epidermal conductance, developmental plasticity, and leaf area maintenance, also are important for drought tolerance [15]. Genetic variation for some of these traits also has been reported, for example, for mobilization of preanthesis assimilates [78,79] and leaf area maintenance [80,81]. Richards and Passioura [82] found an intraspecific variability in bread wheat for xylem vessel diameter which possess high heritability. Leaf rolling showed genetic variation in sorghum [83,84] and rice [10,84]. Genetic variation for epidermal conductance has been observed in rice [85,86], sorghum [87,88], and soybean [89]. Low lethal water status also exhibits genetic variation in sorghum [87,89], wheat [90], pigeon pea [91], and cotton [92].

Genetics

The genetics of drought resistance can be partly understood through the inheritance of traits responsible for drought avoidance or postponement or tolerance as described above. However, the situation is complex, as single genes that substantially change water-use efficiency are difficult to find and generally it involves many genes and many interactions [12]. Tolerance to drought is rare in the vegetative parts of plants, whereas angiospermous seeds and pollen are able to survive extreme dehydration [93]. Genes responsive to drought, desiccation, high osmoticum, or wilting have been identified in tomato [94], *Craterostigma plantagineum* [95], maize [96], barley [96], rice [97], *Arabidopsis* [98], tobacco [99], soybean [100], and cotton [101].

To understand the genetic mechanism of osmotic adjustment and dehydration tolerance in rice, a recombinant inbred (F_7) population was mapped with 127 restriction fragment length polymorphism (RFLP) markers; one major locus was found to be associated with osmotic adjustment in rice [62]. This locus may be homeologous with a single recessive gene previously identified for the same trait in wheat; the putative osmotic adjustment locus and two of five quantitative trait loci (QTLs) associated with dehydration tolerance were close to chromosome regions associated with root morphology [62].

The location of genes having a major effect on drought-induced abscisic acid (ABA) accumulation in wheat was determined by using molecular markers, a set of single chromosome substitution lines, and populations derived from a cross between high-ABA–producing and low-ABA–producing genotypes [102]. A similar drought test with detached and partially dehydrated leaves confirmed the location of gene(s) regulating ABA accumulation in the long arm of chromosome 5A [102]. MAPMAKER QTL showed the most likely position for the ABA quantitative trait locus to be is between the loci *Xpsr575* and *Xpsr426*, about 8 cm from *Xpsr* 426; other QTLs for ABA accumulation may be present on chromosome 3BS and 6AL [102]. It was reported that xylem ABA (not root ABA) was associated with stomatal conductance and root characteristics; genes for yield under drought and ABA were located on different chromosomes in maize and, therefore, were unlikely to be related [19].

A QTLs for response to drought has been reported in different crops such as maize [19,103–107], sorghum [108,109], rice [110,111], wheat [102,112], and barley [113]. There is clear evidence now that all the major cereal species have extensive linkage blocks where gene order is conserved [114], which probably represents fragments of a hypothetical ancestral cereal ''chromosome'' [6].

Gene Expression

Water deficit is one of the most common abiotic stresses that effects the growth and development of plants through alterations in metabolism and gene expression [115]. Genetic information to withstand drought is present in plants in stress genes, but these genes are expressed only in particular developmental stages [116]. The molecular studies of dehydration stress are mainly based on (a) desiccation tolerance of the maturing embryo [117] and resurrection plants (angiosperms that are able to survive dehydration and revive upon hydration) [95,118], (b) *Arabidopsis thaliana* [119–121], and (c) other crops such as, for example, tomato, pea, wheat, and barley [122]. Genes regulated by drought stress can be divided in to three groups [122]: genes encoding polypeptides of unknown function, genes encoding *Lea* proteins and related polypeptides, and genes encoding polypeptides of known function.

DNA sequence analysis of osmotic stress–inducible cDNAs indicate that genes responsible for drought [6,19,62,102–113] encode a variety of proteins [123]. Many of the proteins encoded by these cDNAs have been classified into various groups; namely, LEA (late-embryogenesis abundant) [101], RAB (responsive to ABA) [124], or dehydrin [96] proteins. LEA proteins and dehydrins are classified on the basis of their characteristic amino acid motifs, whereas RAB proteins are classified based on expression in response to ABA [123]. The LEA proteins, first identified during seed maturation and desiccation, express in water-stressed vegetative tissues in almost all plants [123]. They are supposed to protect the dehydrating cells by a variety of mechanisms, including renaturation of unfolded proteins, sequestration of ions, and stabilization of native protein structure [123]. Recently, it has been demonstrated that the accumulation of barley HVA1 protein, a group of three LEA proteins, in transgenic rice confers increased tolerance to water deficit as well as to salt stress [125].

Genes have also been isolated from the resurrection plant, *Craterostigma plantagineum*, which can recover completely from complete dryness with in 24 hs of contact with water [126,127]. Many of the desiccation-induced genes share sequence homology with LEA genes [126,128]. The early responsive to dehydration stress (ERDS) genes in comparison with ABA-responsive genes are preferentially responsive to the dehydration stress [129].

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

The dynamics of water transport in plants is influenced by water channel proteins in plants [130,131] which are related to the superfamily of membrane intrinsic proteins (MIPs) first characterized in *Escherichia coli*. The function of different MIP channels vary [132,133]. Several MIP-related proteins have been identified in plants. A member of this family, *Trg* 31 (in pea), was initially identified when gene expression was induced in partially dehydrated leaves [134]. Another dehydration-inducible gene was isolated from *A. thaliana* [135]. NOD 26, the first plant MIP protein to be characterized [136], is abundant in the prebacteroid membrane root nodules. MIP-like tonoplast intrinsic proteins (TIPs) and their corresponding genes have been identified [137]. Water deficit results in diminished growth of young leaves. In soybean, water-stressed plants show increased expression of genes encoding the vegetative storage proteins *(Vsp)* [138]. But the same does not occur in the mature leaves even though they possess the potential to express *Vsp* when leaves are wounded [139].

Breeding

Despite many decades of research, drought continues to be a major challenge to agricultural scientists probably because of the difficult nature of the target environment [140,141] and the interaction of drought with other abiotic as well as biotic stresses [142]. This is supported by the observation that, in water-limited environments, the yield of the biomass of current cultivars is about the same as cultivars from over a century ago [143]. However, the wonderous display of plant adaptations to dry habitats points to the fact that a substantial genetic variation for drought tolerance exists and this may be used for plant breeding [144].

The problem of breeding crops for drought environments is not due to the want of enough genetic variation but probably lies in the elusive design of the ideal plant, the ideotype [145], which has been in attention [146,147] for both normal and stress conditions [7]. The demands of genes depend on the type of ideotype required for the water-stress area. Since a large number of traits take part in the plant-stress response, the task is not easy in practical terms.

The water status of a plant is a function of uptake (by roots) and loss (via stomata and cuticle) of water; therefore breeding strategies may broadly focus on either of these two parameters [148]. So far, the breeding strategies for drought areas have been suggested to depend on (a) selecting genotypes with improved yield in water-stress environments [139]; (b) identifying and selecting traits that contribute to drought avoidance, drought tolerance, or water-use efficiency [15]; and (c) even selecting under nonstress environments and then trying in stress areas [144,149]. Without plant selection under water-deficient conditions, traits beneficial under water stress may be missed [12]. However, in favorable environments, there is less error and thus high yield potential expressed in favorable environments can also have a spinoff in less favorable environments [144]. In Australia, where wheat is grown in a water-limited environment, 95% of the current cultivars can be traced to the CIMMYT germplasm where breeding is done under highly favorable environments [144].

There are few reports of the transfer of alien DNA into crop species specifically to improve drought responses [6], but an extensive introgression program is in progress to transfer useful traits from *Festuca* into *Lolium* [150–152]. In some of the introgression lines with *F. arundinacea* in *L. multiflorum* × *F. arundinacea* crosses, drought resistance was equivalent to the *Festuca* donor [151]. This single chromosome addition lines of *F. arundinace* onto *L. multiflorum* also showed improved drought resistance [6]. Hence, this work looks promising for the future to improve the drought responses of other graminaceous crops [6]. The introgression of the drought-tolerant machanism present in wild species in cultivated plants is in progress in several laboratories [153,154]. Another strategy for the genetic improvement of plants under drought has been to identify gene(s) of desiccation tolerance, for example, in desert plants or wild species [155,156], and transfer them to agronomic crops [157]. Transgenic rice plants having tolerance to water deficit and osmotic stress have been reported [158]. However, this effort is not expected to be of much significance, and the mechanisms of desiccation tolerance at the plant level are believed to be quite efficient [107].

The QTL mapping techniques are a hope for the future with regard to improved abiotic stress

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

tolerance and drought stress in particular [6]. The locations of QTL are now easy to compare across species, as demonstrated through the comparison of the QTLs of root characters in maize and rice [103,110]. Marker-assisted selection, using Random Amplified Polymorphic DNA (RAPD), improved the yield performance in common bean in stress conditions [159]. Although molecular genetics might prove to be important, the identification of stress-responsive genes or even their cloning and insertions seems to be beyond practical application unless their function and value within the ideotype can be demonstrated [7].

SUBMERGENCE TOLERANCE

Tolerance to waterlogging or submergence tolerance is associated with crops grown in high-rainfall areas of the world. Most of the knowledge regarding submergence tolerance is on account of the studies on rice crops, 16% of whose total world area is affected by this problem [160]. Limited gas diffusion in water is considered to be the principal cause for the adverse effects of submergence [161]. Therefore, tolerance to flooding is associated with the ability to cope with the problems associated with submergence, such as, for example, anaerobiosis, lower carbon assimilation due to less CO_2 and radiation [162,163], and high ethylene levels. This is partly achieved by avoidance—through maintenance of growth processes leading to elongation of plants to maintain their foliage above water [164].

Morphophysiological Traits: Genetic Basis

Several morphophysiological traits have been reported to be associated with submergence tolerance [165]. Setter et al. [165] listed 17 morphophysiological traits as part of the mechanism explaining submergence tolerance in rice. These traits were classified into presubmergence, submergence, and postsubmergence traits. Among these, the three important traits are (a) carbohydrate concentration, (b) alcoholic fermentation, and (c) elongation of the stem. The favorable effects of high carbohydrate concentration [166–170] and high alcoholic fermentation [171–175] are well documented. Stem elongation does favor avoidance but, on the other hand, there is a strong negative correlation between elongation growth and percentage of survival of seedlings during submergence [176,177], because elongation growth competes for energy and carbohydrates required for maintenance processes for survival [165]. The elongation mechanism is effective only when the water level remains high for a considerable period, as in deep-water rice cultures. It is not desirable under flash-flood conditions, because when the water recedes, the plants tend to lodge [178].

Genetics

The existence of varietal differences for submergence tolerance has been reported by several workers in rice [179–182]. Mohanty et al. [183] reported that submergence tolerance in rice was dominant over suceptibility and that both major and minor genes were involved in the inheritance. A 10×10 half-diallel analysis [184] showed a significant additive and nonadditive gene action for submergence tolerance, but additive effects were more important. Tolerance was dominant over nontolerance, and the average dominance was within the range of incomplete dominance; Wr/Vr graphic analysis also suggested the involvement of both major and minor genes [184].

In an earlier study [185], it was reported that at least three submergence-tolerant genes are present in the four most tolerant of rice varieties; namely, FR13A, Thavalu, Kurkardppan, and Goda Heenati. Analysis of F_2 and backcross generations of the above four rice varieties and two susceptible (IR 42 and Nona Bokra) lines indicated the presence of a single dominant gene for submergence tolerance [165]. It was also found that the first three tolerant lines possessed the same gene for submergence but was different in the cultivar Goda Heenati. This finding was supported by the bimodal distribution of rice lines for submergence in Thailand [186], but it was contradicted by the normal distribution noted in the Phillipines [186]. The finding of the three most tolerant rice lines

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

having the same gene for submergence tolerance suggested that a common factor related to tolerance of limited gas diffusion (e.g., one of the enzymes of alcoholic fermentation) may be responsible for genotypic differences in the submergence tolerance of rice [165]. It also suggests that a gene for a transcription factor is involved in the expression of a multiple gene cascade that confers submergence tolerance [165].

Gene Expression

Gene expression for anaerobic (submergence) stress is better known than other abiotic stresses [165,187,188]. The knowledge of gene expression during anaerobisis is due to the finding in maize that alcohol dehydrogenase (ADH) activity increases owing to flooding [189–191]. ADH activity which allows maize to survive in flooding reflects a simultaneous expression of two unlinked genes, *Adh1* and *Adh2* [192]. The *Adh1* and *Adh2* cloned cDNA families have been identified and analyzed extensively [193,194]. The regions of *Adh1* and *Adh2* genes upstream from the site of transcription initiation show homology with respect to an 11-bp homologus region that includes a TATA box and three other segments 8 bp in size [195]. The other important enzyme is pyruvate decarboxylase (PDC) [196], which is governed by three *Pdc* genes in rice [197].

During anaerobiosis, a shift in protein synthesis was reported [195] where it was found that there is repression of preexisting protein synthesis followed by de novo synthesis of a new set of proteins. This has been reported in several crops; for instance, soybean [198], maize [195,199], rice [200], sorghum, barley, pea, and carrot [165]. The shift in protein synthesis is quite fast with a transition period of few hours. The polypeptides (33 kd) formed during this transition period are referred as transition polypeptides (TPs). Another group of 20 polypeptides (anaerobic polypeptides; ANPs) also is induced after a 90-min gap which includes isozymes of alcohol dehydrogenase [201], glucose-6-phosphate isomerase [202], fructose-1, 6-diphosphate adolase [203], and sucrose synthetase [165]. In rice, the two *Adh* genes [204] and three *Pdc* genes have been cloned and characterized [197,205,206]. Genes of these two enzymes are now being used for over- and underexpression studies in rice [165] by using the coding regions of *Adh* and *Pdc* genes through two types of promoters: constitute (CaMV35S and Act1) [207] and inducible (6 XARE) [208].

Submergence tolerance being a complex character, it is likely that the putative single gene for submergence tolerance either (a) encodes a transcription factor (*trans*-acting factor) (i.e., a protein or RNA which binds to specific regulatory DNA sequences [209]) or (b) affects the signal transduction pathway (i.e., the number of steps after the submergence treatment by which the plant activates the set of genes required for survival [210]). Around a dozen major genes known to be induced under anaerobic condition in maize [211,212] and rice [213,214] possess a similar sequence in their promoters [215] and therefore suggests the involvement of a common transcription factor [165].

Breeding

Breeding for submergence tolerance has been an important objective for rice breeders. Systemic screening at International Rice Research Institute (IRRI), the Philippines, has resulted in the identification of flood-resistant rice cultivars such as FR13A, FR43B from India and Kurkaruppan and Goda Heenati from Sri Lanka [184]. Another submergence-tolerant elite line of IRRI, IR 49830 (-7-1-2-2) whose ancestry includes FR13A, IR42, and IR48 [216], has been reported to have a four to five times higher yield than FR13A [165]. Shuttle breeding programs between IRRI and the national agricultural research institutes of several countries now provide promising advance lines as well as segregating populations for use in their target environments [165]. However, the success achieved in submergence tolerance all over the world is far below our need and expectations. A probable reason for the absence of the significant introduction of improved submergence-tolerant rice cultivars during the last two decades has been the confusion between genuine submergence tolerance and shoot elongation [217]. Another factor for the above might be intolerance to other common stresses like phosphorus and zinc deficiency and presubmergence drought [218]. Despite

a limited knowledge in the physiological and molecular basis of submergence stress, the association of submergence tolerance in traditional tolerant genotypes with poor agronomic traits direct us to harness the tools of molecular biology to rebuild rice plants for better fitness [165].

HIGH-TEMPERATURE TOLERANCE

Heat stress, especially during reproductive development, causes severe yield reductions in different crops. It is an important problem in tropical and subtropical environments and is believed to increase in the future because of global warming [219]. In dry land areas, heat stress may occur in association with radiation and drought stress [220]. Plant responses to heat stress are diverse, but photosynthesis is considered to be the most heat-prone plant process [221–224]. Photosynthesis and respiration are more sensitive to heat stress in cool-season species such as wheat than in warm-season plants [223]. The thermal stability of warm-season species is associated with the properties of the photosynthetic system, including key enzymes and the thylakoid membrane, with the thylakoid membrane being more heat sensitive than the cell membrane [223]. Other reports [225–227] suggest that high temperature retards the conversion of sucrose to starch in developing grains (e.g., in wheat). Thus, any of a number of important metabolic functions may be disrupted because of heat stress, but a cell membrane system that remains functional during heat stress appears to be central to the adaptations of plants to high temperature [228]. Understanding the molecular and physiological bases of heat tolerance in higher plants has proved difficult owing to its complexity [229,230].

Genetic Basis

Knowledge regarding traits conferring high temperature tolerance and their genetics is essential for the creation of genotypes capable of giving high yields under high-temperature environments worldwide [231]. However, no single trait can be said to be directly responsible for heat-stress tolerance, although several traits have been found to be associated with this mechanism. Therefore, high-temperature tolerance is characterized by measuring whole-plant productivity traits (e.g., yield traits) or by utilizing bioassays in different crops [231]. Different traits utilized in such studies are, for example, flower bud abortion and a reduction in pod fill in common bean [232]; electrolyte leakage [233,234], membrane thermostability [235], a reduction of 2,3,5 triphenyl tetrazolium chloride [231,236–239] and chlorophyll fluorescence in wheat [240]; electrolyte leakage in soybean [241–243] and common bean [243]; and heat-shock proteins in sorghum [244,245], cotton [246], wheat [237,247], and maize [248,249]. Most of these traits are measures of the effect of the heat stress rather than the cause of heat-stress tolerance. Therefore, the genetics of traits causing heat-stress tolerance and the heat tolerance itself is difficult to be seperate. Hence, all traits are discussed below to understand the genetics of heat-stress tolerance.

Substantial genotypic variation for heat tolerance was found in groundnut, soybean, pigeon pea, and chickpea and they were ranked from heat tolerant to heat sensitive in the same order [250]. Quantitative inheritance with a large environmental effect was reported for heat tolerance at pod and seed set in snap bean [251]. In another study, a single dominant gene in one snap bean accession and two genes with epistatic effect in another were reported [252]. In a study involving two resistant and two susceptible genotypes of common bean (*Phaseolus vulgaris*) crossed in all possible combinations, including reciprocals, quantitative inheritance was noted for heat tolerance [232]. Additive effects were significant for two heat-tolerance traits (flower bud formation and pod filling) in common bean. Cytoplasmic effects, including the interaction of cytoplasmic and nuclear genes, were also recorded [232]. In cowpea, tolerance to the inhibition of flower bud development under high temperature and a long day was due to a recessive gene [253], whereas tolerance during pollen formation was under the control of a single dominant gene [254]. In tomato (*Lycopersicon esculentum*), it was reported that heat tolerance during fruit set was conferred by a few partially dominant genes, but narrow sense heritability was very low (8%) owing to large environmental effects [255].

Genetic effects on membrane thermostability in wheat in 90 F_2-derived lines of heat-tolerant

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

and heat-susceptible lines showed that heat tolerance is not simply inherited [235]. Genetic differences in membrane thermostability were noted in soybean (*Glysine max* L. merr.) [241,256]. Hybrids of heat-tolerant and heat-susceptible soybean genotypes were found to be intermediate but closer to the tolerant parent in tolerance; the number of genes involved could not be estimated [241].

Marsh et al. [243] examined the inheritance of membrane stability in common bean and found that heat tolerance was under the control of few genes. They also found low additive effects along with epistasis. In a diallel including the reciprocal of six wheat genotypes, significant general combining ability effects and maternal effects were noted [240]. On the basis of the relation of the heat-stress effect and the reduction of 2,3,5 triphenyl tetrazolium chloride, which produces a red formazen, significant differences in acquired high-temperature tolerance were reported in wheat [239]. Using 20 F_1 progenies produced through a complete 5×5 diallel mating design of tolerant and susceptible genotypes showed that only the general combining ability effect was highly significant, accounting for 67% of total genetic variation [231].

There is extensive evidence of both qualitative and quantitative intraspecific genetic variability for low molecular weight (LMW) heat-shock proteins (HSPs) in crops; for example, sorghum [244,245], cotton [246], wheat [237,247], and maize [248,249]. Very few reports are available regarding HSP gene transmission in plants. Additive inheritance for some HSPs has been reported in barley where the presence of hybrid-specific HSPs indicated the activation of genes that were suppressed in one parent [257]. Both additive and nonadditive inheritance were demonstrated in the F_1 hybrids of maize [248]. Intraspecific qualitative polymorphism in LMW synthesis is extremely rare [258], and quantitative variation in HSP synthesis may determine relative thermal tolerance levels [259]. A genetic analysis of HSPs in maize, HSP synthesis revealed both qualitative and quantitative polymorphism implicative of the differences in HSP structural genes and regulatory factors [260]. The F_1 hybrid HSP profile indicated that the synthesis of all parental HSPs conformed to dominant inheritance patterns, including complete dominance, overdominance, and codominance; there was evidence for unlinked loci of four different HSP gene pairs, but data for three other HSP gene pairs were inconclusive [260].

Gene Expression

Heat stress is known to induce HSPs, which [261] are known to be associated with acquired thermal tolerance in many species, including bacteria [262], mamalian fibroplasts [263], and higher plants such as, for example, soybean [264,265], wheat [237], cotton [266], and maize [249]. In plants, a heat shock of 8–10° C above normal growing temperature induces the synthesis of both high (65–110 kDa) and low (15–27 kDa) molecular HSPs, with the LMW proteins being the most prevalent [267,268]. A subset of the LMW group, 15–18 kDa, is unique to higher plants [195].

The LMW HSPs are a complex group, with as many as 30 members being present in soybean [269]. The induction of LMW HSPs has been well documented [270], and their number is known in some monocot species [268]. Detection of low and high molecular weight HSPs synthesized in seedlings and flag leaves in flowering plants suggest that HSPs are synthesized before leaf temperatures reach levels that are considered injurious to growth and development [271].

HSPs are among the fastest known gene expressions in plants [272]. The heat shock response may be the accumulation of damaged proteins [273]. This is supported by the fact that small-protein ubiquitin, which has a role in the ATP-dependent breakdown of abnormal proteins [274], is itself an HSP [275].

Limited information is available about the structural relationships among the HSP genes and the molecular regulation of their transcription and translation to protein [248,260,276]. On the basis of nucleotide and amino acid similarities and protein localization, there are four families of structural LMW HSP genes known in plants [277]; one each encoding plastid localization and endomembrane proteins and two that encode cytoplasmic proteins (classes I and II). The HSPs of 17–18 kDa comprise classes I and II. There are several class II gene sequences [278,279] as well as class I cDNA HSPs [280].

Breeding

Increasing productivity under heat-stress conditions requires the development of heat-tolerant genotypes in all crops. Improvement of heat-stress tolerance can contribute to sustainability and provides a way to extend the area under cultivation [250]. Limited progress has been made with regard to breeding heat-tolerant genotypes probably because yield losses due to heat are more subtle than biotic stresses [281]. The two most important hurdles are the absence of substantial information on the genetic diversity for heat-tolerance traits and effective screening techniques [282]. Both in vivo and in vitro methods are used for screening but in vitro methods are advantageous in that they are plant conserving, and this feature is important in plant breeding for heat tolerance [250].

The level of tolerance to high temperature varies among genotypes [240,283,284] suggesting that the trait can be improved [240]. The indication of larger additive genetic variation with regard to some traits believed to be associated with heat stress also indicates that gains from selection for improved heat tolerance should be possible. Breeding for heat tolerance in cowpea has involved a pedigree breeding approach with selection beginning in the F_2 generation [285] to incorporate major recessive genes conferring heat tolerance during early floral bud and seed coat development [286]. It has been suggested that to overcome difficulties caused by environmentally induced variation, incorporating a heat-tolerance pod set into other genetic backgrounds will require family selection in advanced generations to ensure that the trait is fixed [254].

Recurrent selection has been suggested to accumulate genes favoring high-temperature tolerance based on chlorophyll fluorescence measurements in wheat [240]. One of the most popular wheat varieties of India, HUW234, which currently occupies more than 3 million hectares of area, possesses the unique feature of both avoidance and tolerance of heat stress of the north eastern plains zone of the country. Its early maturity, profuse tillering, high grain number per spike, and fast ripening provides it with a clear superiority over other varieties under late to very late sown conditions when the hot winds of early summer cause serious yield losses.

COLD TOLERANCE

Low temperature, especially in the northern region of the temperate climatic zone, presents substantial obstacles to the survival of plants throughout the winter [287] and is one of the most severe stresses that limits crop growth and productivity [288]. Reductions in grain yield are incurred not only as a direct result of winter damage but also as a result of limiting the areas where such crops can be sown [289]. Although low-temperature stresses are usually of two types, chilling at above 0° temperature and freezing at subzero temperature [290], the winter may expose young seedlings to many kinds of stresses (as in wheat) such as, for example, a direct frost effect, cold winds, snow cover, intense freezing and glaciation of the soil, and frost lifting in the spring. In grasses and wheat, there are two different mechanisms of tolerance to ice encasement: rapid (wheat) and slower (grasses) glycolysis [287]. Following cold acclimation, a number of forage species show a high tolerance to the extremely cold condition of ice encasement [291] even greater than that of winter wheat [287]. In grasses, Berings hairgrass has recently been shown to have an extremely high tolerance to anoxia [292], a property that is common to many arctic plants [287]. The physiological and biological processes which lead to cold tolerance or the adaptation of plants to low temperature are extremely complex [293].

Morphophysiological Traits: Genetic Basis

Like other abiotic stresses, tolerance to low temperature also is due to the joint action of several traits of plants. Significant correlations were established between cold hardiness and days to head [294] and growth habit [295–297] in wheat. In general, spring wheat lines are less hardy than winter

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

lines and the spring growth habit is dominant over the winter growth habit. The winter growth habit of wheat is possibly inherited by a *Vrn* (vernalization requirement) gene [297]. Chahalan and Law [298] found no evidence of a genetic linkage between cold hardiness and the vernalization requirement in wheat even though chromosomes in homeologus group 5 were implicated in the control of both of these characters. Studies in grass species (e.g., clover) also do not show correlation between a single trait and cold tolerance [299–301]. Photoperiodism, an important trait for the adaptability in cold climate, is governed by genes present in the group 2 chromosome of wheat [302]. At least three genes, *Ppd1, Ppd2*, and *Ppd3*, governing photoperiodism are known in chromosomes 2D, 2B, and 2A respectively [303]. Low temperature has been found to enhance anthocynanin synthesis in plants, such as sorghum, cabbage, maize, Arabidopsis, apple, roses, and petunia [304].

Genetics

Winter hardiness is a genetically programmed integrated process [305,306]. The genetics of winter hardiness was studied as early as 1912 when Nilsson-Ehle [307] of Sweden investigated winter hardiness in wheat, and on the basis of the appearance of transgressive segregants in a cross of two cultivars intermediate in winter hardiness, he reported that it is a quantitative trait under the control of a polygenic system [307]. Since then no general opinion has arisen on the issue. The trait has been reported to be recessive [308], intermediate [309,310], dominant [308], or overdominant [308,311]. It has been reported that winter hardiness is under the control of dominant genes in mild cold, whereas under severe cold, it is governed by recessive genes [296,312–315]. Winter hardiness behaved as a recessive factor as early as 1923 in a cross made by Schafer [316].

A majority of studies indicate a polygenic control of cold tolerance [295,312,317–321]. The quantitative nature of winter hardiness also is supported by the absence of a drastic improvement in the winter hardiness of different crops [322–324], the appearance of transgressive segregants [299], and a complex of factors influencing winter hardiness [325]. However, all the genes do not work together and different genes affect tolerance at different levels of stress [313]. There is evidence from studies showing that winter hardiness genes may act as dominant or recessive depending on the type of environment [296,305,312,326,327]. In wheat, 11 chromosomes carry genes for cold tolerance with chromosome number 5 being the most important [328]. Some studies have implicated 15 of 21 chromosomes pairs of wheat to be associated with cold tolerance [315] with chromosomes 5A [298,329] and 7A, 4D, and 5D [315,330] being most commonly mentioned. In barley, a major QTL was found associated with chromosome 7 [331,332]. In *Solanum* spp., the nonacclimated freezing tolerance and acclimation capacity were found to be separate heritable traits controlled by few genes [333]. In rye (*Secale cereale*), cold hardiness is controlled by genes with mainly additive effects [334].

The genetics of frost tolerance, studied in winter wheat by using complete diallel [313,335, 336], showed that frost tolerance is controlled by an additive-dominance system [314,315,337]. Several studies [305,336,338,339] have shown that frost tolerance is a complex character controlled by at least 10 of the 21 pairs of chromosomes [305]; chromosomes 5A and 5D have been implicated most frequently and they appear to carry major genes [336]. The gene for frost resistance (*Fr1*) was located on the long arm of chromosome 5A [336,340], and there might be close genetic linkage between *Vrn1* and *Fr1* [341]. Studies done so far indicate the presence of four major genes for vernalization requirement: *Vrn1, Vrn2, Vrn3* [342,343], and *Vrn4* [344]. Another gene, *Vrn5*, also was reported [345].

Cold tolerance is under the control of both additive and nonadditive gene effects in chickpea [346] and pea [347,348]. Genetic interactions also play an important role in cold tolerance [346]. Three additive genes or linkage groups are reported to control winter hardiness in pea [349]. The expression of low-temperature tolerance has been found to be under the control of the same genetic factors in the sporophyte and gametophyte of potato [350–352]. High heritability estimates for cold hardiness have been reported in wheat [297,315,337], barley [353,354], and oats [355].

Gene Expression

The molecular mechanism which regulates cold tolerance is not sufficiently well known [292]. In 1970 [306], Weisner suggested that cold acclimation might involve changes in gene expression. Since then, however, more and more information has been reported in this field [293,356–359]. The realization that cold acclimation requires altered expression of tolerance-related genes not seen under nonacclimating conditions has the basis for isolation and characterization of cold-induced genes [293]. Several studies have demonstrated that plants synthesize a new set of proteins when exposed to a cooler environment [324]. The existence of partially different mRNA populations in nonacclimated and acclimated plants has allowed the isolation of cDNAs corresponding to acclimation-specific mRNAs by differential screening, as in alfalfa [358,360], *Arabidopsis* [361], and barley [290,362–363]. The temporal pattern of low-temperature (LT)–induced gene activation varies between different plant species ranging from few hours (*A. thaliana*) [119,364–366] to several days [358,367,368].

The LT responsive genes are transcriptionally regulated through sequence-specific transcription factors that bind to their target sequence on the corresponding promoters [290]. LT-induced genes contain certain sequence elements that resemble ABA-responsive [369] and drought-responsive elements [370]. Homologous regions are also present in the promoters of LT-induced genes: *cor15a* [371], *rab18, kin1, kin2* [369], *lti29*, and *cor47* [290].

Identification of an mRNA group which only functions during the cold effect and codes proteins found only in frost-resistant wheat varieties [359] suggests a positive correlation between the quantity of proteins synthesized during the cold effect and the frost resistance of the varieties [293]. Some mRNAs decline during exposure to low temperature, as in *Brassica* [372], rice [373], and spinach [324].

Cold-induced rRNA synthesis in wheat takes place in seedlings as the result of low temperature during the first few days of cold treatment [374,375], and the cold-induced rRNA synthesis is closely correlated to the rRNA cistron number [375]. Quantitative and qualitative changes have been noted in the rRNA maturation processes owing to low temperature in a weak frost-resistant line of wheat as a consequence of which there is an increase in the last precursors (1.4 and 0.9 MDa) of the two stable cytoplasmic rRNAs [293].

Freezing tolerance includes tolerance to freeze-induced dehydration [324,376]. This is further substantiated by the fact that several of the LT-induced proteins are similar to proteins induced in response to water stress (dehydrins) [101,377]. Certain proteins having a putatative protein-stabilizing function (*Bip, Hsp70, Hsp90*) have been identified among LT-induced proteins [378,379]. Cryoprotective polypeptides capable of protecting the plant thylakoid membrane in vitro against the freeze-thaw cycle also has been reported in cabbage and spinach [380,381]. A structural similarity of the gene product of *kin1* from *A. thaliana* with an antifreeze protein of winter flounder [361] led to the speculation of the presence of an antifreeze protein, which was later contradicted [382]. However, there are reports of the presence of an antifreeze protein in winter rye [383,384].

In *A. thaliana* leaves, pigment accumulation in response to low temperature results from the activation of phenylalanine ammonia-lyase (*pal*) and chalcone synthase (*chs*) gene transcription in a light-dependent manner [385]. It was suggested that light dependency is a general feature of cold-induced gene expression. However, in *Petunis corolas*, cold activation of *chs* expression was not light dependent [304]. The effect on *chs* expression was not always correlated with that on anthocyanin content suggesting a posttranslational effect [304]. Earlier, Christie et al. [386] suggested that the effect of temperature is associated with transcription, transcript stability, translation, and enzyme activity. Low temperatures do not simply create conditions that facilitate the developmental activation of *chs* expression; they act as a separate inducing signal [304,386]. The transduction of a low-temperature signal (2–5° C) for the activation of a cold-acclimation–specific (*cas*) gene also has been studied that probably does not belong to the *chs* group [304].

The transcripts of enzymes of the fermentation pathway, alcohol dehydrogenase (ADH) and

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

pyruvate decarboxylase (PDC), have been found to increase as a result of hypoxic acclimation in wheat [174] and maize [387]. However, more tolerant forage grasses, timothy (*Phleum pratense*) and Berings hairgrass (*Deschampsia berengensis*), show lesser activity of ADH and PDC [287].

Desication often accompanies cold acclimation and freezing stress [324]; therefore, at the molecular level, genes induced by water stress and ABA also are induced by cold stress in barley, rice, and spinach [373]. In contrast, genes induced by cold temperature can respond to water stress and ABA [315,361,363]. Homology between HSPs and cold-induced proteins has been reported in potato [363].

Breeding

Conventional breeding has been utilized by breeders worldwide to enhance cold tolerance in different crops. It has been suggested that, in chickpea, selection would be more effective if dominance and epistatic effects were reduced after a few generations of selfing [346]. Sutka [336] suggested three ways to improve genetic variation for frost tolerance in wheat: interspecific crossing, chromosome manipulation, and the induction of somaclonal variation. Wild species related to cultivated wheat, for instance, *Aegilops cylindrica, Agropyron glaucum* (intermedium), and *Agropyron elongatum*, are extremely promising sources of increased genetic variation [336] for cold tolerance. Disomic additions of *Agropyron glaucum* were able to survive freezing to a temperature as low as $-18°$ C. A somaclone of wheat was significantly better than control for cold tolerance, and thus it is of practical importance [388].

In vitro selection through anther culture has been suggested as a useful tool for breeding low-temperature tolerance in crops [350–352] on the ground that there is genetic overlap between the sporophyte and the gametophyte [389]. Gametophytic selection for low-temperature tolerance has been succesfully demonstrated in tomato [390], maize [391–393], and potato [394].

Despite great progress in understanding the molecular basis for plant cold acclimation, the complexity of the system hampers the genetic engineering of plants having freezing tolerance [290]. Among the possible approaches to enhance cold tolerance in plants, the ways that hold promise are [290] (a) increasing the freezing resistance of the plant plasma membrane by increasing the amount of phospolipid [394,395], as shown successfully in tobacco [396,397]; (b) metabolic alterations alleviating the detrimental effects of desiccation stress (e.g., osmotic adjustment through osmoprotectants) [290]; (c) exploiting cryoprotective and antifreeze proteins (e.g., fish antifreeze proteins [398]); and (d) manipulation of signal pathways leading to the expression of tolerance genes.

SALINITY RESISTANCE

Soil salinity is a major agricultural problem, particularly in irrigated agriculture. Around 10% of the world's arable land is affected by salinity [399,400]. One third of the land in Australia is salt affected [401], whereas in India and Pakistan, such areas constitute around 5% of their total cultivable land. In irrigated areas, the percentage of salt-affected land is much higher. In the United States, 23%, of the irrigated land is under salt effect [400]. With as much as half of the world's existing irrigation systems under the influence of secondary salinization, alkalization, and waterlogging [402], the coexistence of irrigation and salinization threatens the current agricultural productivity [403]. Despite the importance of salt-affected areas in world agriculture, too little progress has been made in improving the salt tolerance of crops [400,403]. The problem is expected to increase in the future and an intregrated approach seems to be the only answer.

Morphophysiological Traits: Genetic Basis

Traits associated with salt tolerance have been investigated by several workers [399,400,404–408], but exact traits are still to be identified [399]. The differential response of plants to salt stress at

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

different growth stages has added further problems in this area. In wheat and sorghum, salt tolerance is associated with seed size, with larger seeds having greater tolerance [409,410]. Seedling survival in saline solution also is an indicator of the salt tolerance of crops and has been studied in *Medicago* [411,412], forage crops [413], and potato [414]. The results showed that characters underlying short-term tolerance may contribute to long-term tolerance but did not themselves confer long-term tolerance [415].

Two broad physiological mechanisms by which plants respond to salt stress [408] are (a) inclusion and the use of inorganic ions as osmotica to maintain a favorable water balance (halophytic response) and (b) partial exclusion of ions and the synthesis of organic solutes for osmotic adjustment (glycolytic response) [416,417]. Salt tolerance is associated with an increased capacity of ion regulation through compartmentation and the transport of toxic ions, osmotic adjustment, and the maintenance of membrane integrity [418]. Most of the crops respond to salt stress by excluding ions from the shoot, and genetic variation exists for the threshold level at which the exclusion mechanism fails [408]. Physiological and genetic factors that contribute to the growth of glycophytes at a very high salt concentration are related to survival more than yield potential and hence are of little interest to growers except those engaged in subsistence agriculture [419]. Low sodium transport has been suggested as an important heritable trait for salt tolerance in rice [420–421]. Chlorine ion exclusion was responsible for the genetic difference for salt tolerance in soybean [422] and was found to be a heritable character in white clover (*Trifolium repens*) and lucern (*Medicago sativa*) [406]. Under salt stress, a tolerant tomato genotype accumulated significantly less Na^+ and Cl^- and more Ca^{2+} than the leaves of a sensitive genotype [408]. Generation mean analysis indicated that, under salt stress, both absolute and relative growth and the Na^+ and Ca^{2+} accumulation in the leaf were genetically controlled with additivity being the major genetic component [408]; a moderate estimate of narrow sense heritability (0.49 ± 0.09) was obtained for shoot dry weight under salt-stress treatment [423]. Potassium ion selectivity was identified to be a principal adaptive mechanism to salt stress in legumes and cereals [424,425].

Genetics

The degree to which different plants can tolerate high concentrations of salt in their rooting medium is under genetic control [411,426–430]. The genetics of salt tolerance has been investigated in several crops and results so far indicate monogenic to polygenic control. Salt tolerance was recorded as a heritable trait in *Agropyron intermedium* [431] and barley [432]. In sorghum, the genetic variation for osmotic adjustment was studied in 10 inbred lines and variation was noted to be due to more than a single gene and both general and specific combining ability effects were found to be significant [433]. Greater tolerance of wild sunflower, *H. paradoxus*, is due to a single dominant gene, Sa_1, but a modifier may also be present [434]. Salt tolerance in wheat grass showed that tolerance behaves in additive fashion [435]. In tomato, stage-specific polygenic control was suggested to control salt tolerance [436–438]. In another study, generation mean analysis showed that additive gene action was the predominant component for salt tolerance in tomato; narrow sense heritability was estimated to be moderately high [439]. Six marker loci in tomato have shown an association with QTLs involved in yield under salinity [440].

The *GPert* (''Golden Promise'' erectoides) mutation, produced by gamma-ray irradiation in barley variety Maythorpe in the late 1950s, which is allelic to *ari-e* mutants (short awned, *brevi-aristatum*), has a significant effect on salt tolerance [441]. *GPert* performs similar to other *ari-e* mutants (*ari-e*. 1, *ari-e*. 119, *ari-e*. 156, and *ari-e*. 228) and possesses a relatively low shoot Na^+ content and a higher salt-tolerance index [442] in comparison with nonmutants. These mutants show greater tolerance than *denso* (*sdw*) or *ert-k*^{32} dwarfing mutants [441,442]. The *GPert* mutation is modified by the genetic background [443,444] and also is associated with drought-tolerance characters [442].

In saline environments, bread wheat, *Triticum aestivum* (genomes AABBDD), accumulates less Na^+ and more K^+ on expanding and young leaves than durum wheat, *T. turgidum* (genomes

AABB) [444]. Chromosome 4D accounts for 50–60% of the difference between bread wheat and durum wheat for this trait [425,445]. Dvorak and Gorham [425] recombined chromosome 4D with durum wheat chromosome 4B by using the *phlc* mutant of durum wheat and found that K^+/Na^+ discrimination is controlled by a single locus on the long arm of chromosome 4D, which was designated *Kna1*. The *Kna1* locus was mapped on a short region in the 4DL arm and was completely linked to *Xwg199, Xabc305, Xbcd402, Xpsr567*, and *Xpsr375* [444]. The 5J chromosome of *Agropyron junceum* carries a major dominant gene(s) conferring tolerance to salt [446]. In barley, genes with positive effects for salt tolerance were located on chromosomes 4H and 5H of *H. vulgare* and $1H^{ch}$, $4H^{ch}$, and $5H^{ch}$ of *H. chilense* [447].

Gene Expression

Adaptation of plants to a saline environment must be due to some salt-related changes in the pattern of gene(s) expression [408]. More than 100 genes were estimated to be expressed when subjected to salt stress [449]. There are several reports of alterations in protein accumulation due to salinity [405,448,449]. One of the most characterized genes associated with salt tolerance is the gene encoding a 26-kDa protein called osmotin, which is responsive to several environmental and hormonal signals, including osmotic and pathogenic stress [450–454]. Osmotin gene expression and protein accumulation were elicited in the vegetative tissues of tomato in response to short- or long-term exposure to NaCl as well as after severe water loss [455]. This gene also is stimulated by ABA [124,454]. Although NaCl can induce the osmotin gene through changes in the ABA levels, this signal also can regulate osmotin mRNA accumulation by ABA-independent signal transduction pathways, as suggested for the *Em* gene in rice [456] and other ABA-inducible mRNAs from wheat [457] and rapeseed [458]. *Cis*-deletion analysis of the osmotin promoter indicated that the induction by NaCl, ABA, and ethylene is associated with the same region of the promoter [459]. Many molecular responses to salt stress in the common ice plant (*Mesembryanthemum crystallinum*) are elicited primarily by the transcriptional induction of specific genes [460,461].

Breeding

Like all other stresses, breeding of tolerant cultivars is crucial to fight the ill effects caused by high-salt concentration. Breeding for salt tolerance has been proposed to the extent of possible crop production in seawater [462,463]. Of various ways to tackle the salinity problem, exploitation of the genetic mechanism is the most important strategy. Deliberate exploitation of the genetic mechanism is mainly possible through (a) direct use of halophytes [464–466] or choosing salt-tolerant crops according to the problem; (b) introgression of tolerant genes from salt-tolerant genotypes (related or distant) [403]; and (c) use of nonconventional approaches such as tissue culture and molecular biology.

Despite having knowledge about a long list of halophytes and their economic potential as fodder, fuel [403,464,465], and oilseed [466], their direct use as an economic crop is still in its dormancy. Among these, jojoba (though not too salt tolerant) is a suitable crop for such areas [400]. On the basis of our knowledge about the sensitivity of crop plants to high-salt concentration, appropriate crops can be grown according to the intensity of the salt concentration in the soil. Cultivated crop plants can be classified into tolerant, intermediate, and sensitive types. Shanon [400] has presented an elaborate review on the genetic variability of domesticated crop plants to salt stress. Barly is one of the most salt-tolerant crops; other tolerant crops are, for example, sugar beet, cotton, canola (*Brassica* spp.), asparagus, red beet, zucchini squash, date palm, pomegranate, grape, wheat grass, and bermuda grass. Crop plants having intermediate tolerance are, for example, sorghum, sunflower, saffflower, sugarcane, potato, alfalfa, faba bean, almond, plum, orange, grapefruit, peanut, chrysanthemum, carnation; the salt-sensitive group includes, for example, rice, corn, wheat, legumes, linseed, cowpea, lentil, chickpea, citrus, avocado, stone fruits, apricot, peach, blackberry, strawberry, aster, poinsettia, gladiolus, azalea, gardenia, gerbera, amarylis, and African violet. Introgression of

salinity tolerance has been attempted from related genera and species in some crops, such as wheat and tomato, but without success because of the absence of correct information about the exact kind of traits, their genetics [467,468], and the difficulties in recovering the traits of agronomic value.

However, intervarietal crossing has yielded successful salt-tolerant genotypes in some crops. For example, few salt-tolerant wheat varieties (KRL 1–4, Raj 3077, WH 157, JOB 66) have been developed in India during the past few years and are being successfully grown in salt-affected areas. Based on the problems associated with the breeding of salt-tolerant genotypes in crops, it has been suggested that it is better to select for yield rather than salt tolerance [448,469]. Rosielle and Hamblin [470] also suggested that selection for productivity will increase yields in both stress and nonstress environments. However, this strategy may not work in all agroeconomic environments, for instance, in a waterlogged condition where salt-tolerant rice is the only alternative [403]. Therefore, the use of physiological parameters might prove to be a useful component of breeding through pyrimiding component physiological traits, at least in sensitive species [403]. According to Flowers and Yeo [403], salt-tolerant genotypes can be developed through a crossing program which maximizes recombination followed by single-seed descent and selection for resistance along with agronomic characters. Among novel ways of enhancing the salt tolerance of crops, the important ones proposed are the use of undifferentiated cells in tissue culture and gene manipulation through molecular biology. Although difficulties are still present in both methods, some success has been obtained in crops such as alfalfa [471], bent grass [472], potato [473], and citrus [474,475].

ACID SOIL TOLERANCE

Similar to other abnormal environments, a low pH of soil also retards plant growth and development, thereby causing yield reductions. Soil acidity is a function of H^+ activity in the soil solution [476] and shows both chronological and spatial (horizontal and vertical) variation [477]. Acid soils are phytotoxic owing to a complex of nutritional disorders which includes both deficiency (Ca, Mg, Mo) and excess (Al, Mn, H) availability of different nutrients [478,479]. In this complex situation, the most damaging is the Al toxicity [480], which causes a number of disorders and may also influence the water-stress tolerance of crops [477,481]. Manganese toxicity, which is not as important as Al toxicity, also has received attention during recent years [482,483].

Acid soils are scattered worldwide in patches with the greater proportion being in tropical regions. Hence, this is of concern to a vast population of growers. The increased awareness about the soil acidity problem and the consequent yield reductions have attracted researchers to unravel the mechanism of resistance against the acid pH of soils [477,482,484–486]. Aluminium toxicity, being most crucial, has received the most attention in our attempt to understand the tolerance to soil acidity.

The mechanisms involved in Al tolerance are complex and could differ among species [487]. Plants tolerate Al toxicity in two ways: (a) Al exclusion from plant tissues, especially the symplastic portion of root meristems (e.g., by chelation of Al by organic acids), and (b) internal Al detoxification by converting Al into a harmless form [477,487]. In contrast to Al, Mn tolerance seems to be largely based on an internal mechanism only. The probable reasons for this are the role of Mn as an essential element and the biological and chemical similarities between Mn and Mg [477].

Morphophysiological Traits: Genetic Basis

There is a strong correlation between the soil acidity and the root growth of plants [487–489]. Inheritance of root length under acid soils in wheat showed polygenic control with a wide range of the degree of dominance [488]. In rice, the relative root length under acidic pH showed both additive and dominance effects with a preponderance of the additive effect; the trait was partially dominant with high heritability, and one group of genes was detected [489]. In soybean, along with

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

thicker roots, increased seed weight also was found as an associated response with selection for seedling tolerance to acidity [487,490]. For Mn, a common gene system in both the root and shoot of wheat has been suggested [491].

Among physiological mechanisms countering a low pH effect, exudation of organic acids by plant roots is the most acceptable mechanism of external tolerance to Al toxicity [492]. Al tolerance also is reported to be associated with a greater efficiency of phosphate uptake [480,493] and cation exchange capacity [494]. Although there are indications of variation for these traits [492–494], the genetics of these traits has not been elucidated.

Genetics

Substantial genetic variation for tolerance to acid soil has been reported in different crops, such as, for example, wheat [477,495–498], rice [499], maize [500–502], and soybean [487]. Genetic studies on acid tolerance in crops indicate both qualitative and quantitative inheritance. Monogenic control was reported in wheat [495,496,503–505] and maize [500,501]. Two dominant genes have been shown to be responsible for Al tolerance in wheat variety Atlas 66 [506], whereas several genes were found in relatively the less tolerant line Chinese Spring [477]. Resistance to Al toxicity may be different at the seedling and adult plant stages [477].

Quantitative inheritance for tolerance in acid soils is reported in wheat [488,507,508], rice [489], maize [509–513], and soybean [487]. Al tolerance was dominant over sensitivity, but, at the same time, it showed a greater role of the additive gene effect [488,507]. Allelic variation for genes controlling Al tolerance has been noted in wheat [514], barley [515], and maize [500]. A change in the direction of dominance with a change in Al toxicity has been reported in wheat [488,506,516] and barley [515], which might be due to the differential expression of tolerant genes at varying levels of Al concentrations. In rice, both GCA and SCA were important for Al toxicity [489], but GCA was more prevalent. Reciprocal effects were also noticed [489]. Similarly, in maize, both additive and doimant genetic variations were reported for yield under acid soils [509–513].

In wheat, hexaploid (AABBDD) wheat is more tolerant than the tetraploid or diploid variety. The tolerance of the D genome is maximum followed by A and B genomes, respectively. The R genome of rye (*Secale cereale*) possesses even greater tolerance than the D genome of wheat. The Un genome of wheat (*T. ventricosum*) also possesses acid soil tolerance. Although the genes associated with Al tolerance are present in all the three genomes of wheat, the most important locations are 2DL and 4DL [517–519]. In rye, Al-tolerance genes are located on chromosomes 3R, 4R, and 6R [518], but when transferred to wheat, they show reduced tolerance probably due to their suppression by the unknown genes of wheat [518].

A wide genetic variation for Mn tolerance also has been recorded in wheat [482,520] with the suggestion that only few genes are involved in the Mn tolerance [482]. It has been suggested that the inheritance of tolerance to Al and Mn is independent and different genes may be involved [491,521–523], but there might be genes for the coregulation of their inheritance [477].

Gene Expression

The ability of plants to tolerance soil acidity is associated with a syndrome of cellular and molecular activities. A large number of genes take part in the whole operation by synthesizing different proteins. The idea that plants develop Al tolerance through the synthesis of proteins capable of inactivating Al [524] has now grown to a near reality with the identification of several proteins showing increased synthesis in response to Al [525–528]. A protein called RMP51 (51 kDa) has been reported to occur in the roots of an Al-tolerant cultivar of wheat; this protein has shown insensitivity to Mn, Cu, and heat stress, but is induced by Cd also [529]. However, none of the known proteins can be said to be the product of a gene conferring Al tolerance [477].

Breeding

In view of the increasing food demand and the shrinking of land resources, the need for the genetic improvement of crops for their tolerance to acid soils is beyond question. This might be a case of necessity rather than economics, although it might prove useful in the long run.

It is true that genetic tolerance does not correct the problem of soil acidity and only postpones the need to take corrective action [477], but a judicious crop cultivation may have a beneficial effect on the soil in a variety of ways. Tolerance to acid soils varies from crop to crop and genotype to genotype. For example, rye is more tolerant than common wheat and common wheat is more tolerant than barley. In wheat, a number of Al-tolerant genotypes have been identified; for example, Atlas 66. Genotypes of Brazilian origin show a high tolerance to Al toxicity [477].

Breeding for acid soil tolerance has gained momentum with the development of reliable screening techniques. Both laboratory and field screening methods are used. The most common screening medium for Al and Mn tolerance is solution culture, which is a nondestructive measurement of tolerance. During screening, the tolerance is generally measured based on the damage to the root/shoot [530] and the degree of severity following exposure to Al [507].

The presence of dominance for acid soil tolerance has enabled breeders to use the backcross method of breeding for improving acid soil tolerance. A successful example is the transfer of a major gene for Al tolerance from the Carazinho variety of wheat to the Egret variety [531] in Australia. It has been suggested that early generation selection may be beneficial in breeding for Al tolerance in rice, and a pedigree method may also be used [489]. Recurrent selection also has been suggested as an alternative method to exploit the additive gene action related to Al tolerance in wheat [515,532] and maize [510,511,533]. In the CIMMYT breeding program, which utilizes the shuttle breeding program, selection for acid tolerance is generally done following the evaluation of the genotypes for yield and quality [534].

Interspecific hybridization also is a possible way of improving acid soil tolerance in crops. For example, tetraploid hybrids of *T. aestivum* × *T. ventricosum* [535] were developed for meeting the same objective. Although under investigation [528,529,536], molecular biology has still to play a role in breeding for tolerance to acid soils.

CONCLUSIONS

Increasing pressure on our natural resources, including land, is being realized by everyone. As our land area cannot be increased, the only hope of extending cultivable area is through greater utilization of the so-called ''unfit areas'' which suffer from various stress problems. A large portion of this area suffers from severe abiotic stresses. However, this does not mean that abiotic stresses do not occur in other areas. In fact, abiotic stresses are prevalent in almost all cultivable lands, although in variable intensities and durations. It is common to see our crops suffering from or fighting with abiotic stresses such as abnormal levels of water, temperature, and soil pH. When our crop plants suffer, we also suffer directly or indirectly.

Abiotic stresses despite so vivid and important for crop production, tolerance mechanisms are not fully understood and efforts to enhance tolerance of crop varieties are still far from satisfactory. Of the various reasons for this slow progress, the absence of clearcut traits conferring tolerance and the complexity caused by the simultaneous occurrence of more than one stress in variable intensities and durations are the most important ones. However, the efforts of various researchers have succeeded in correlating some morphophysiological traits with concerned stresses along with the genetic mechanism involved. Molecular genetics also is contributing in a slow but sure manner to expand our knowledge in this direction. Several varieties have been released in different countries for meeting the challenge posed by abiotic stresses. Even manmade crops like ''Triticale'' have been created to occupy marginal lands with high-stress pressure. Although abiotic stresses can be tackled better by an intregated approach, genetic manipulation should remain as the main strategy.

When we are thinking of settling planets other than earth, our hopes are alive to design plants sturdier than ever before.

Response of Green Beans (*Phaseolus vulgaris* L.) to Salt Stress

Mohammad Pessarakli
University of Arizona
Tucson, Arizona

INTRODUCTION

The gradual progress of desertification due to the detrimental effects of natural stress factors such as low precipitation, long-term drought, heat, and erosion coupled with improper human activities as a result of overgrazing, the overutilization of land, and the application of insufficient management decisions and improper agricultural practices, urbanization, and industrial activities has left extensive arable lands at the potential risk of conversion to unusable soils. These problems are more severe in arid and semiarid regions where the soils already encounter salinity and sodicity problems and are more vulnerable to stress conditions.

The accumulation of high soluble salts in a soil can significantly decrease the value and productivity of agricultural lands. Salt and water stress have been recognized as major agricultural problems, especially in arid and semiarid regions. Retardation of crop yield by salinization also has been known for a long time. Since the early 1900s, various investigations of the effects of salts on plant growth have been undertaken covering a range of aspects from the plant response to the salinity to salt behavior in soils [1–26]. Physiological studies have revealed that the major effects of salinity on plant growth retardation are osmotic and specific ion effects [10,16,18–21,24,26–40]. Furthermore, the reduced nutrient uptake by plants grown in saline environments has been observed in several species of plants [5,14,16,18,20,24,33,35,41–50]. Differences in salt tolerance among plant species also have been long recognized [21,28,35,39,51–82]. Although the agricultural scientists started studying the salinity tolerance of plants almost 50 years ago in the early 1950s (see Refs. 51–53 and the references cited therein), there is still a great deal of interest in working on this subject (for the recent work on this subject, see Refs. 39 and 80–85). According to Qadir et al. [83], cultivation of salt-tolerant grasses in a saline or saline-sodic soil may mobilize the native lime ($CaCO_3$) in these soils through root action. This may substitute the chemical approach for reclamation of such soils. Recently, Apte and Thomas [84] reported that the simultaneous application of a

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

halotolerant nitrogen-fixing cyanobacteria during crop growth seems to be an attractive possibility for the reclamation and improvement of saline soils, especially since it also can supplement the nitrogen requirement of the corp. Also, De Villiers et al. [85] in recently assessing salinity tolerance of different plant species found that the perennials seemed to be better suited for rehabilitation purposes under saline soil conditions. However, the role that salt tolerance plays in causing differences in the growth and development, nutrient uptake, and metabolism between various plants, among plant species, and at different stages of growth is still a major concern among investigators, and it is not yet fully understood. The discovery of the physiological basis of salt tolerance in crops and the use of this knowledge to obtain more tolerant cultivars by modern plant breeding procedures should result in substantial increases in world food production.

The effect of salt stress on nutrient element utilization and nutrition as well as metabolism in plants has been studied for various plants using different methods. The results are still inconclusive. However, the change in nutrient metabolism induced by excessive salt is commonly accepted among scientists as one of the most important factors responsible for abnormal plant metabolism and reduced growth. Bernstein et al. [86] found that despite the decrease in total N uptake the leaf N concentration of some grain and vegetable crops increased with increasing salinity at all N fertilization levels. Increased in the N concentration of corn (*Zea mays L.*) and cotton (*Gossypium hirsutum* L.), plants under salinity stress was reported by Khalil et al. [41]. The uptake and metabolism of $^{15}NH_4^+$ and $^{15}NO_3^-$ in red kidney beans (*Phaseolus vulgaris* L.) was adversely affected by both salt and water stress at −0.4 MPa (−4 bar) osmotic potential [42,43,87]. Reduced ^{15}N uptake and metabolism as well as impaired protein synthesis under stress conditions by various crops also have been reported by several other investigators; Helal and Mengel [88] (barley, *Hordeum vulgare* L.); Pessarakli and Tucker [45] and Al-Rawahy et al. [49,50] (tomato, *Lycopersicon esculentum* Mill.); Pessarakli and Tucker [46] (eggplant, *Solanum melongena* L.); Pessarakli et al. [47] (corn); Pessarakli [48] and Pessarakli et al. [89,90] (green beans, *Phaseolus vulgaris* L.). However, Pessarakli and Tucker [44,91] found that ^{15}N uptake and protein synthesis by cotton plants increased under low levels (−0.4 Mpa, −4 bar, osmotic potential) of NaCl salinity. Increased total N concentration of plants grown in saline substrate was also reported by Bernstein and Pearson [4].

To explain these different results, a dilution or concentration effect (depending on the relative severity of salt stress on growth or nutrient, i.e., N uptake) was reported as a cause of the fluctuations in N content or concentration in plants [42,44–46,48].

Among the various environmental stress factors, salinity appears to have been given more attention than any other factors both in the past and at present. This is clearly seen from the continuous investigations and the voluminous reports that are continuously being generated on this subject. Hundreds of publications dealing with plant and crop stress caused by salinity are annually added to the literature on this subject [1–35,38–129]. For some recent reports during the 1990s, see elsewhere [22–26,39,40,48–50,80–85,92,93,95,96,102–129].

Despite the voluminous publications dealing with the effects of salt stress on plant growth and nutrient (i.e., N) nutrition, the literature concerning this issue on green beans is scarce. The reports of Gauch and Wadleigh [3], Balasubramanian and Sinha [13], Bhivare and Nimbalkar [14], Csizinsky [16], Coons and Pratt [19], Wignarajah [23], Frota and Tucker [42], Saad [43], Hoffman et al. [64], Maliwal and Paliwal [65], Harbir-Singh et al. [70], Salim and Pitman [72], Ashraf and Rasul [73], Alislail and Bartels [92], and Velagaleti et al. [93] deal primarily with the effects of salinity on the growth and/or chemical composition of other types of beans and are not concerned with green beans. Among the cited references in this chapter, in addition to the author's own research work, only that of Bernstein and Pearson [4] reported the influence of exchangeable sodium ions on the yield and chemical composition of green beans. However, their work was not concerned with N (labeled or nonlabeled) uptake and metabolism by the reported plant species. Thus, green beans were selected to be covered in this chapter primarily because they are classified as salt-sensitive plants [94]. Also, the effects of salinity on the growth and nutrient uptake and utilization by these plants have not been studied and documented sufficiently. In addition, these salt-sensitive plant species were selected for discussion in this chapter to compile information regarding the re-

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

sponses of different plant species which are discussed by different authors in this book. This information is being compiled in a volume to assist the readers in comparing all these various salt-tolerant plant types under the stressful environmental conditions.

Thus, this chapter is concerned with responses in terms of growth, nitrogen (total and ^{15}N) uptake, protein synthesis, and water absorption by three cultivars of green beans (Tender Improved, Slim Green, and Kentucky Wonder) at the vegetative stage of growth under normal and NaCl stress conditions with the following objectives.

1. To compare the growth of these cultivars by evaluating their dry matter yield under normal and NaCl-stress conditions
2. To compare total N and ^{15}N uptake and distribution in plant roots and shoots by these cultivars as affected by salinity
3. To evaluate protein synthesis by these plant species under normal and salt-stress conditions
4. To study the water absorption by these cultivars as influenced by NaCl stress

FACTORS EVALUATED REGARDING THE RESPONSES OF GREEN BEANS TO SALT STRESS

Dry Matter Production

The effects of NaCl salinity on dry matter production of the three cultivars of green beans have been examined in several studies [48,89,90,95]. All these studies reported that the NaCl stress significantly reduced total dry matter yield for all three cultivars, but Tender Improved was the least severely affected at all salinity levels (Table 1; data from Ref. 89). The degree of reduction in dry matter yield increased with the increasing salt-stress level and over time. Other investigators also have

TABLE 1 Dry Matter Yield of Three Green Bean Cultivars Under Various NaCl-Stress Levels at Different Harvest Times

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

reported reductions in dry matter production and decreased in yields of other bean cultivars [4,16,19,42,43,48] and a number of other crops [6,12,15,17,25,44,47,49,50,58,86,87,91,97,107,108, 113,117,129].

Under NaCl stress, shoot and root growth were substantially lower for the Slim Green and Kentucky Wonder cultivars as compared with the Tender Improved cultivar [48,89,90,95]. This phenomenon indicates the presence of significant interaction effects between salinity and cultivars. Roots appear to be affected less than shoots by salt stress for all cultivars.

The dry matter production and growth period were linearly correlated (r^2 values ranged from 0.89 to 0.99 for different treatments) [48]. For all cultivars, the dry-matter yield increased as the growth period progressed [48,89,90,95].

Total N Uptake by Plants

According to Pessarakli [48] and Pessarakli et al. [89,90], the total N uptake by green bean plants was significantly decreased with increasing salinity of the nutrient solutions for all cultivars at all three harvests. The results of Pessarakli's study [48] is presented here (Table 2). The Slim Green cultivar contained substantially lower total N than the other two cultivars at each harvest for all corresponding treatments except for the control shoots at the third harvest. The uptake values were markedly lower at the first harvest for this cultivar indicating a slower initial N uptake and a slower early growth rate for the Slim Green cultivar. For all cultivars, shoots contained substantially more

total N than roots [48,89,90], probably due to the larger dry weights of shoots than roots (larger sink size).

The reduction in total N uptake was similar to the reduction pattern for total dry matter yield by plants under NaCl stress. The similar reduction pattern for total N uptake and dry matter yield indicates that the major portion of the absorbed N was incorporated into protein and contributed to plant growth and development. As N uptake decreased, dry matter yield also decreased under the NaCl-stress condition. This is supported by reports of several investigators [3,11,43,47,87,88,91,96], which indicated that the changes in N metabolism caused by salinity stress is one of the most important factors responsible for abnormal plant metabolism, reduced growth, and decreased crop yield.

Total N Concentration in Plant Tissues

All three studies conducted by Pessarakli [48] and Pessarakli et al. [89,90] reported that total N concentrations in all three cultivars generally were lower in plants subjected to salinity, especially at the highest NaCl stress levels as compared with controls. Table 3 indicates this finding. However, for a salt-tolerant cotton plant, the N concentration was significantly higher in NaCl-stressed plants even at a higher level of salinity (−0.8 Mpa, −8 bar, osmotic potential as observed by Pessarakli and Tucker [44]. An increase in N concentrations of corn and cotton plants under salt-stress conditions was also reported by Khalil et al. [41]. Therefore, differences in N concentrations of these

different crops (cotton as compared with green beans) under salt stress are probably due to differences in their salt tolerance. At each stress level, the total N concentration of the Tender Improved cultivar generally tended to be lower than those of the other cultivars [48,89,90]. This is probably due to a dilution effect, since the Tender Improved cultivar produced significantly higher dry matter than the other cultivars at each stress level for each harvest. The total N concentration of the roots was generally higher than that of the shoots at each harvest for each cultivar for any corresponding treatment except for the control Tender Improved plants [48].

Nitrogen-15 Uptake by Plants and Distribution of ^{15}N in Plant Shoots and Roots

The results of several studies [48,89,90] on different cultivars of green beans showed that the total ^{15}N uptake by plants was decreased with increasing salinity of nutrient solutions at all three harvests for all three cultivars. The ^{15}N results of an experiment completed by Pessarakli [48] is presented here in Table 4. The reduction in the ^{15}N uptake followed the same reduction patterns as total N and dry-matter yield under stress conditions. This is an indication that the absorbed ^{15}N was incorporated into protein and contributed to plant growth and development as reflected in dry matter production. The Slim Green cultivar absorbed the least amount of ^{15}N under NaCl stress conditions. The absorbed ^{15}N values were higher for the Kentucky Wonder cultivar and generally highest for the Tender Improved cultivar under stress conditions. However, the Tender Improved cultivar contained significantly lower ^{15}N in both shoots and roots at the third harvest under normal (nonsaline) condi-

tions as compared with the other two cultivars [48]. Substantial differences between the ^{15}N uptake by cultivars at each salinity level (Table 4) implies a significant interaction effect between salinity and cultivars at each harvest for each plant part. Significant decreases in the ^{15}N uptake by these plants under high salinity level is in agreement with experimental data obtained with red kidney beans [42,43], cotton [44], barley [88], tomato [45,49,50], and eggplant [46]. However, the low level of NaCl salinity (−0.4 MPa, −4 bar, osmotic potential) in cotton slightly enhanced the ^{15}N uptake [44]. This phenomenon is probably due to the difference in the salt tolerance of these different plant types (cotton as compared with green beans).

The nitrogen-15 contents of green bean shoots were reported [48] as being of higher magnitudes than those in roots for all three cultivars at all salinity levels (see Table 4). These differences are considered to be due to the larger dry weights of shoots than those of roots for all cultivars (larger sink size). The shoot/root ratios of the ^{15}N content tended to increase with time and decrease with increasing salinity for all cultivars except for the Kentucky Wonder cultivar at the third harvest with −0.25 MPa (−2.5 bar) stress. This may have been due to the retarded translocation of ^{15}N from roots to shoots caused by salt stress and the accumulation of ^{15}N in shoots as the growth period progressed. This effect also can be clearly seen by comparing the ^{15}N concentration values between shoots and roots (Table 5; data from Ref. 48). The concentration of ^{15}N in both shoots and roots increased as the growth period progressed and decreased as the salinity level increased for all cultivars. This pattern was similar to the shoot/root ratios of the ^{15}N content of plants. The ^{15}N concentration in roots was far greater than that in shoots for all cultivars. This higher concentration of ^{15}N in roots can be explained, in part, as the absorption of NH_4^+ onto the root surface or infusion of

ammonium and nitrate ions into the root apparent free space, as suggested by Pessarakli and Tucker [44–46] and Pessarakli [48].

Nitrogen-15 Uptake Rates

The ^{15}N-uptake rate, expressed as milligrams of ^{15}N absorbed per kilogram of dry matter produced by plants per day, is presented in Table 6 (data from Ref. 48). At each salinity level, ^{15}N uptake rates peaked at the earliest harvest and decreased as the growth period progressed for both the shoots and roots for each cultivar. This finding indicates that the younger plants absorbed ^{15}N at a faster rate than the older ones regardless of the stress level. Nevertheless, ^{15}N-uptake rates significantly decreased under NaCl stress as compared with the controls at each harvest for all cultivars in both plant parts except for the roots of the Tender Improved cultivar at the second and third harvest. At the earliest harvest, Slim Green shoots, had a substantially lower ^{15}N-uptake rate than the other two cultivars under normal conditions.

Protein Synthesis by Plants

The crude protein contents of both shoots and roots of the three green bean cultivars were markedly lower under stress conditions as compared with the controls (Table 7; data from Ref. 89). Under stress conditions, the Tender Improved cultivar produced significantly more protein than the other two varieties. Protein synthesis in shoots was substantially higher than that in roots for all the three

cultivars. This significant difference appears to be due to the higher dry matter production of shoots than roots for any treatment for any of the three cultivars. Pessarakli et al. [90] used two sources of N (ammonium and nitrate) for evaluating protein synthesis in green beans and found that, under normal (nonsaline) conditions, the nitrate-treated plants synthesized appreciably more protein than the ammonium-treated ones at each harvest for all three cultivars. This phenomenon was more noticeable in roots than in shoots for each cultivar. However, except for the Tender Improved cultivar at the first harvest, the crude protein content of plants was substantially lower under stress as compared with the controls for either source of N. Among the three cultivars, salt stress had the most severe effect on protein synthesis in the Slim Green for both NH_4-N and NO_3-N sources of N.

The impaired protein synthesis under stress conditions by other bean cultivars such as red kidney beans [43,87] and other types of plants such as barley [88], cotton [91], alfalfa (*Medicago sativa* L. [96], peas [98], wheat (*Triticum aestivum*) L. [99], tobacco (*Nicotiana tobaccum* L.) [100], and corn [130] have been reported previously by many investigators. In these studies, either the decreased amino acid incorporation into protein or the reduction in polyribosome levels due to the salt stress was reported as the reason for the depressed protein synthesis by plants. This may be a reason for the reduction in protein synthesis in green beans.

Water Uptake by Plants

For all three cultivars of green beans, the total water uptake decreased with increasing salinity (Table 8; data from Ref. 48), and the decrease patterns were similar to those of dry matter production [48]. The Tender Improved cultivar absorbed more water than the Kentucky Wonder and Slim Green cultivars under NaCl-stress conditions. However, under normal condition, the Kentucky Wonder cultivar absorbed significantly more water than the other two cultivars at the second and the third harvests [48]. The absorbed water values for the Slim Green cultivar were the lowest among the three cultivars at each harvest for any corresponding treatment. The reduction in water uptake by

other plants or other bean cultivars due to salt stress has been reported by many investigators [9,15,25,42–47,101,102], who generally agreed that plant root permeability (expressed as the hydraulic conductivity of the root system) decreased significantly under salt-stress conditions. This may explain the reduction in the water-uptake rate and may contribute to a similar reduction in nutrient absorption resulting in retarded plant growth and decreased dry matter production under salt-stress conditions.

Water-Use Efficiency of Plants

Water-use efficiency, expressed as milliters of water absorbed per gram of dry matter produced by plants is presented in Table 8 (data from Ref. 48). These data indicate that all three cultivars tended to use water more efficiently at the earliest harvest than at later harvests either under normal or stress conditions. This appears to be due to the faster rate of growth and higher dry matter production rate (gram of dry matter produced per day, which can be calculated from the dry matter data; see Table 1) at the earliest harvest than at the later harvests (a dilution effect). Nevertheless, all cultivars at each harvest (except for the Slim Green and Kentucky Wonder cultivars at the first harvest) used substantially less water for each unit of dry matter produced under stress conditions as compared with the controls. At each harvest for any corresponding treatment (except control plants at the first harvest), the Tender Improved cultivar used substantially less water for each unit of dry matter produced (used water more efficiently) than the other two cultivars.

SUMMARY AND CONCLUSIONS

The effects of NaCl stress on dry matter production, total N, ^{15}N, crude protein, and water uptake by three green bean cultivars have been discussed in this chapter.

The total dry matter production was greater for the Tender Improved cultivar than for the Kentucky Wonder and Slim Green cultivars for any corresponding treatment at each harvest. For all three cultivars, the total dry weight decreased significantly with the increasing salinity level. The reduction in dry weight due to NaCl stress was less for the Tender Improved cultivar than for the other two cultivars. Total N and ^{15}N uptake by all three cultivars substantially decreased under NaCl-stress conditions. The nitrogen-15 concentration and shoot/root ratios of ^{15}N decreased with increasing salinity. The nitrogen-15 concentrations of shoots were less than those of roots for all plants. Sodium chloride stress severely reduced the crude protein content of plant parts for all three cultivars at all three harvests. However, the Tender Improved cultivar appears to be less affected by salinity than the other two varieties. The shoots of all plants contained substantially higher total crude protein than the roots for all treatments. This appears to be due to the higher biomass of the shoots than of the roots for any corresponding treatment. Nevertheless, the shoots were more severely affected than the roots by salinity when salinized plants were compared with the controls for each plant part. Sodium chloride stress severely decreased the crude protein content of all three cultivars at each harvest for both sources of ^{15}N. However, the Tender Improved cultivar appeared to be the least and the Slim Green the most severely affected by salinity among the three varieties.

Under normal (nonsaline) conditions, green beans appear to absorb and utilize more NO_3-N than NH_4-N into protein synthesis. In contrast, under salt stress, NO_3-N seems more severely affected than NH_4-N for being incorporated into protein. Furthermore, any level of salt stress will likely cause a drastic reduction in the protein content and N metabolism in the salt-sensitive bean plants.

For all cultivars, water uptake also was substantially decreased under stress conditions, particularly at the highest level of stress. Among the three cultivars, the Tender Improved variety was the least and the Slim Green variety the most severely affected by salinity in all aspects of stress. This is an indication of the difference in the salt tolerance of these cultivars. Therefore, among the three cultivars discussed here, the Tender Improved cultivar of green beans appears to be the most suitable for growing under field conditions. Furthermore, since there are numerous cultivars of green beans, additional testing of their response under saline conditions could detect a wider range of tolerance and susceptibility to soil salinity. This will enable researchers to select the most salt-tolerant cultivars to be recommended to the growers.

Salt and Drought Stress Effects on Metabolic Regulation in Maize

HANS-WERNER KOYRO
Justus-Liebig Universität Giessen
Giessen, Germany

BERNHARD HUCHZERMEYER
Hannover College of Veterinary Medicine
Hannover, Germany

INTRODUCTION

Salinity may occur naturally or can be induced by agriculture. In any case, it is an environmental stress that limits the growth and development of salt-sensitive plants [1]. Worldwide about 33% of the irrigated land is affected by salinity, and more land is not being irrigated because of salinity than there is new land made available by means of advanced irrigation procedures [2,3]. Even when the proper technology of saltwater irrigation is applied, salt is accumulated in the soils, which often impairs the growth of crop plants of low-salt tolerance. Salt tolerance is relatively low in most crop species. Therefore, not only selection and breeding for salt tolerance are important issues for traditional agricultural production in arid and semiarid regions, they may also offer the potential for utilizing the unlimited resource of seawater for irrigation [3]. Epstein et al. [4] showed that grain yields of up to 1 t/ha can be reached when undiluted seawater, supplemented with nitrate and phosphate, is used for irrigation. The interests in the economic feasibility of halophyte utilization also increased during the last decade, and in several projects halophytes were cultivated for greenification, fodder or vegetables [5–8]. Breeding of salt-tolerant glycophytes and evaluating the economic feasibility of halophytes are both promising attempts to reduce the destruction of ancient agarian societies.

Salinity Effects on Plant Physiology

The breeding of salt-tolerant crops depends on the knowledge of the physiological responses to salt stress. There are three major constraints for plant growth on saline substrates: water deficit, ion excess, and nutrient imbalance. Salt exclusion minimizes ion toxicity but accelerates water deficit, whereas absorption facilitates osmotic adjustment but also can lead to toxicity and nutritional imbal-

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

ance [1,9,10]. Moreover, as will be pointed out below, salinity can affect the regulation of metabolic pathways, because metabolites active as regulatory ligands may become sequestered to the vacuoles. It is often not possible to distinguish the relative contribution of these constraints to growth inhibition at the whole-plant level. There also may be differences between plant tissues and stages of plant development. The long-term exposure of a plant to salinity may result mainly in ion toxicity in the older leaves or leaf parts and in water deficit and shortage of carbohydrates in the younger leaves or in the meristematic zone.

Most studies on the effcts of salt stress on plants focused on the growth and development of leaf tissues [11,12], but some data on the salt effects on the root system are available as well [13]. The root is the fist plant organ to become exposed to soil salinity, and in many instances it plays a crucial role in the exclusion of salt from the leaves [14]. Moreover, the response of the root apical zone to salt stress is critical to furhter growth and development of the root system.

A high selectivity during the ion uptake and transport are prerequisites for the adaptation of plants to saline habitats [15]. It helps to diminish a nutritional imbalance. However, there is no significant difference between the content of the major nutrients in halophytes and in glycophytes [16]. The specificities for the uptake of K^+, Mg^{2+}, and Ca^{2+} are neither in halophytes nor in glycophytes sufficient to hinder a dilution of these ions at the tissue level. A second prerequisite is the homeostasis of the ions in the metabolically active compartments. The salt-induced changes of ion relations can be tolerated because Na^+ and Cl^- concentrations are relatively low in the cytoplasm [17]. Simultaneously, the K^+, Mg^{2+}, and Ca^{2+} concentrations decrease mainly in the vacuoles and stabilize the homeostasis of these ions in the cytoplasm. A compartmentation of Na^+ and Cl^- into the vacuoles is essential to avoid flooding of the cytoplasm. The accumulation of high concentrations of essential ions in the leaf tissues during periods of low salinity can be one mechanism to enhance NaCl tolerance.

It was shown that the halophytes *Beta vulgaris spp. maritima* and *Laguncularia racemosa* have a special inter- and intracellular K^+, Ca^{2+}, and Mg^{2+} buffer in plants grown without NaCl. It helps the salt-treated plants to grow under salinity and to exclude Na^+ from the plants without significant ion deficiency. The sea beet, for example, has crystal cells with high Ca^{2+} concentrations in the spongy parenchyma and high Mg^{2+} concentrations in the photosynthetically active cells. K^+ is uniformly distributed in all tissues. *Laguncularia* also has crystal cells with high Ca^{2+} concentrations, but the Ca^{2+} concentrations too are high in all other spongy parenchymal cells [10,18]. The highest Mg^{2+} concentrations can be measured in the vacuoles of the epidermal cells, and the K^+ concentrations are high in all leaf tissues but in the spongy parenchyma. The distribution of these elements among different cell layers enables the plant to store them and reduces the deficiency if uptake is hindered because of salinity. Further investigations will have to show if similar buffers exist in maize and if they are effective only for a short period of time or if they enhance the NaCl tolerance in general.

It may be generally assumed that plants have an encoded capability for stress perception, signaling, and response. Biochemical studies have revealed similarities in processes induced by salt stress that lead to the accumulation of metabolites, such as (a) nitrogen-containing compounds like proline, other amino acids, quarternary amino compounds, and polyamines, and (b) hydroxyl compounds like sucrose, polyols, and oligosaccharides. More recent results indicate that the gene pattern activated in response to salt stress is common to most plant families. Learning about the biochemical and molecular mechanisms by which plants tolerate environmental stress is necessary for genetic engineering approaches to improve crop performance under stress. We will discuss these phenomena taking salt stress on maize as an example.

Metabolites accumulated on salt stress seem to function in three ways: (a) They act as osmolytes, faciliating the retention of water in the cytoplasm and allowing sodium sequestration to the vacuole or apoplast. (b) Protection of cellular structures might be accomplished through interactions with membranes, protein complexes, or enzymes. Their function may involve scavenging active oxygen. Compatible solutes are strong water structure formers [19]. Thus, according to the preferential exclusion model [19–21], such molecules will be preferentially solubilized in the bulk water

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

of the cell rather than in the hydration shell of proteins or other labile macromolecules. They may then contract with small, highly charged molecules, which preferentially solubilize in the water of the hydration sphere where they may interact electrostatically with the macromolecule causing damaging effects at high concentration. (c) There is a growing body of evidence that plants are capable of sensing photosynthesate concentrations. Sensing sugar concentrations appears to control gene expression and by this cell differentiation is regulated [22–26].

Whereas the accumulation of compatible solutes contributes to the maintainance of cell growth under conditions of increased ion concentration, many organisms also have developed efficient methods to keep the ion concentrations in the cytoplasm at low levels. In bacteria, Na^+/H^+ antiporters provide both a mechanism for pH homeostasis and the primary mechanism for Na^+ extrusion [27]. In plants, antiporters have been observed on both the plasma membrane and the tonoplast, which in principle are capable of evacuating the cytoplasm. Increased antiporter activity on the tonoplast has been observed by treatment or adaptation to salt [28,29]. The plasma membrane and tonoplast antiporters appear to be organized differently at the molecular level and may both be composed of multiple subunits. These characteristics may complicate the ability to modify such activities.

In the past, many studies of abiotic stress tolerance have monitored the physiological status of stressed plant compared with unstresed controls. Mechanisms have been deduced from such descriptions. But, until recently, these studies have not included molecular and genetic analyses of stress-tolerance principles. Knowledge from physiological measurements has led to a few studies on the biochemical mechanisms underlying tolerance to salt stress. Our growing understanding of the biochemical mechanisms involved in stress tolerance makes it possible to search for specific genes.

Adaptation of Plants to Saline Habitats

The salt resistance of vascular plant tissues depends on the mechanisms of salt tolerance [30,31]. Salt regulation comprises avoidance of intake, elimination, and dilution. On the other hand, salt tolerance is defined as the property of the protoplasm to cope with high salt concentrations via compartmentation [17]. Adaptation by salt exclusion requires mechanisms for the avoidance of an internal water deficit [3]. In terrestrial halophytes, salt tolerance is based mainly on the inclusion of salts in the leaves and their utilization for turgor maintainance and for the replacement of K^+ by Na^+ in various metabolic functions [10,18]. Exclusion also can be an important factor to high salt tolerance, but adverse effects on water balance and reduced growth rates are the consequences [32,33]. Most crop species such as *Zea mays* are glycophytes and show an inverse relationship between salt uptake and salt tolerance [1]. However, there are large differences in sodium exclusion ability between different cultivars of maize [34]. Even when Na^+ and Cl^- concentrations remain relatively low in the shoot, growth is inhibited [3]. The application of excessive NaCl or Na_2SO_4 concentrations showed that Na and not Cl is the most toxic ion in maize under salinity stress [35]. There was a stronger negative correlation between the Na^+ concentration in the third leaf with the survival of 26 maize cultivars [36,37]. Cultivars with lower Na^+ concentrations in the shoot were more salt tolerant. Additionally, growth depression seems to be not a result of ion deficiency (Mg^{2+}, K^+, Ca^{2+}) but of an impaired osmoregulation [3] (H.-W. Koyro et al., in preparation). The calcium status in salt-treated root tissues has been found to be an adequate measure, being a prerequisite for the maintenance of a high K^+/Na^+ selectivity [38–40]. The K^+/Na^+–uptake ratio increases in the presence of Ca^{2+} in maize. There too was an increase of the Mg^{2+} concentrations in the leaves after salt treatment (H.-W. Koyro et al., in preparation).

Mechanisms inhibiting excessive Na^+ transport to the shoots of plants grown in saline substrate operate mainly in the cortex cells, in the endodermis, in the innermost layer of the cells of the cortex, and in the xylem parenchymal cells of the root. The Casparian band constitutes an effective barrier against passive solute movement into the stele. In most plant species, suberin lamellae are found in the exodermis, hypodermis, and endodermis [41]. The free space accessible for passive flux of saline solutions represents only 5% in maize [42]. However, it has been shown that the

rhizodermal cells play a central role in ion uptake and are the predominant location of P-ATPases [43,44]. NaCl salinity enhances the V- and P-ATPase activities in roots of the salt-sensitive and Na^+-excluding *Sorghum* much more than in roots of the Na^+ includer *Spartina* [45]. In the same study, a correlation was shown between increases of Intra Membraneous Particle (IMP) frequencies on rhizodermal membranes (tonoplast and plasmalemma) and ATPase activities.

In maize cultivars, the differences of the sodium exclusion seem to be related to differences of passive Na^+ permeability of the root cell membranes [34]. The ability to maintain K^+ homeostasis and low Na^+ concentrations in the cytoplasm of these cells seems to be the crucial factor of the degree of salt tolerance [46]. The partitioning of the remaining Na^+ and Cl^- between old and young leaves and vegetative and reproductive organs and among distinct cell types within the leaf blade are of crucial importance and are characteristic for salt-tolerant species [11,19] (H.-W. Koyro et al., in preparation). A steep gradient between young and old leaves by restricting the import into young leaves, inflorescences, and seeds has been shown for a more salt-tolerant maize cultivar [36]. High K^+ and low Na^+ concentrations are achieved by low xylem transport rates of both ions and a high supply of K^+ through the phloem of mature leaves [47]. This system depends on the K^+ storage capacity of the mature leaves and the restricted Na^+ import via the shoot. The collapse of this way of regulation leads to a nearly spontaneous and distinct decrease of the K^+/Na^+ ratio in leaf tissues (H.-W. Koyro et al., in preparation).

In salt-excluding species like maize, growth in a saline substrate with a relatively low water potential requires an increase in the synthesis of organic solutes such as sugars and amino acids or a high selectivity at the uptake of K^+, Mg^{2+}, and Ca^{2+}. The osmotic adjustment of salt-excluding plants has a distinct influence on the energy balance. It is much more economical in terms of energy for a plant to accumulate NaCl than to synthesize sugars for osmoregulation [48,49]. Growth depression is a logical consequence, because, in terms of energy demand, exclusion of NaCl is most energetically costly. It has been shown that salt stress can lead to an increase of the water-use efficiency in maize and the change from a C_3 plant type to a C_4 plant type [50]. As will be discussed below, both factors can extend the degree of salt tolerance.

SPECIAL FEATURES OF MAIZE PHYSIOLOGY

Leaf Development

The characteristic strap shape of monocot leaves is generated through polarized patterns of cell division and expansion that maintain cells in files [51]. It was originally thought that the majority of divisions in monocot leaves take place at a basal intercalary meristem [52]. More recent data have shown that cell divisions in maize occur in a different manner during two phases of leaf development: During the first phase, divisions occur throughout the leaf and become restricted to the base of the leaf only after initiation of the ligule at the leaf blade/leaf sheath boundary during the second phase of leaf development [53]. Despite the apparent age mosaicism, cellular differentiation tends to occur in a basipetal direction [54,55].

A clonal analysis of the bundle sheath and mesophyllic cells in maize leaves has shown that the mesophyllic cells in the middle layer of the leaf (these are cells having no epidermal contact) are more closely related to the bundle sheath than to other mesophyllic cells [56]. Since all mesophyllic cells are functionally equivalent, this information suggests that photosynthetic cell type differentiation is position dependent and not lineage dependent. In C_4 monocots and dicots, the vascular system obviously provides the framework around which photosynthetic bundle sheath and mesophyllic cells are arranged in a radial pattern referred to as ''Kranz anatomy'' [57–59].

Bundle sheath and mesophyllic cells are distinguished by a number of morphological features [57,59]. The most obvious ones are: Bundle sheath cells have thick cell walls and numerous large starch-containing plastids. Mesophyllic cells have thin cell walls and smaller, randomly distributed chloroplasts that do not accumulate starch during the daytime. Unlike bundle sheath cells, mesophyllic cells are never in contact with the vascular tissue. In maize, the chloroplasts of bundle sheath

and mesophyllic cells are morphologically similar early in development (both have been found to contain grana stacks) [60,61]. Subsequent maturation of bundle sheath cell choroplasts results in the granaless bundle sheath chloroplasts found in the mature leaf and described in most textbooks. We will refer to leaf maturation in the following sections and discuss the salt-stress effects on both morphology and enzyme pattern. The bundle sheath cells of NADP-ME (malic enzyme specific for $NADP^+$)–type grasses, such as maize, most often contain granaless chloroplasts in a centrifugal location and include a suberized lamella.

Division of Labor Among Mesophyll and Bundle Sheath Cells

Photosynthesis by C_3 plants suffers from the low affinity of ribulose-1,5-bisphosphate caboxylase oxigenase (Rubisco) toward atmospheric CO_2 and limitation by photorespiration. The major function of the C_4 pathway is to overcome the limitation by low CO_2 concentration, which results in significant increases in photrespiration. The C_4 photosynthesis pathway serves as a CO_2 pump to concentrate CO_2 at the site of Rubisco and thus supresses its oxygenase activity and the associated photorespiration [62].

As shown in Figure 1, the C_4 photosynthesis pathway eliminates photorespiration by splitting photosynthetic reactions between two morphologically distinct cell types: the bundle sheath and the mesophyll. Rubisco is physically separated from atmospheric oxygen by its compartmentalization in the internally localized bundle sheath cells. This scheme is advantageous in hot, dry conditions but can be energetically wasteful. Some studies have suggested that certain C_4 plants function as C_3 plants under conditions when the use of the C_3 pathway is energetically favorable [63,64].

C_4 function depends on the morphological and functional differentiation of bundle sheath and mesophyllic cells and on the spatial regulation of photosynthetic gene expression. It is generally accepted that the mesophyllic cells contain all of the phosphoenolpyruvate carboxylase (PEPC) in the leaf and that the bundle sheath cells contain all of the Rubisco and most of the enzymes of the Calvin cycle. The carboxylation of PEP thus occurs in the mesophyllic cells, with the formation of oxaloacetate (oxac) and malate (mal) or aspartate (asp). In a subsequent reaction sequence, this C_4 compound is transferred to the bundle sheath cells where it is decarboxylated to form pyruvate (pyr). Pyruvate is transferred back to the mesophyll and becomes phosphorylated inside the mesophyllic choloplasts to form PEP again. As shown in Figure 1, the effect of this C_4 cycle is the transfer of CO_2 from the mesophyll to the bundle sheath at the expense of two ATPs per molecule of CO_2 transferred. In the final reaction sequence, CO_2 is fixed inside the bundle sheath chloroplasts in the reaction sequence of the Calvin cycle.

C_4 plants have been classified in three subgroups based on the different enzymes which decarboxylate C_4 acids in the bundle sheath: (a) the NAD^+-malic enzyme, (b) the PEP carboxykinase, and (c) the $NADP^+$-malic enzyme. Plants of the NAD^+-malic enzyme and PEP carboxykinase types tend to form aspartate, whereas plants of the $NADP^+$-malic enzyme type tend to form malate. The extent of this different behavior depends on external factors such as the nitrogen nutrition of the plants. Malate can carry reducing equivalents from the mesophyll to the bundle sheath. If aspartate is transferred, the plants need to have photosystem (PS) II active in the bundle sheath to generate the reductant required for CO_2 assimilation. The disadvantage of this situation is that O_2 from the water-splitting system will compete with CO_2 sites on the Rubisco.

$NADP^+$-malic enzyme–type plants possess chloroplasts which lack grana stacks inside the bundle sheath. The bundle sheath and mesophyllic cells of maize leaves have different metabolic functions. The initial steps of CO_2 assimilation in the C_4 cycle are spatially separated from the Benson-Calvin cycle [65–67]. The maize mesophyllic cell contains chloroplasts with both PSI and PSII. In contrast, the bundle sheath chloroplasts are deficient in PSII and exhibit very little net O_2 evolution [65]. Hence, the bundle sheath chloroplasts are restricted in their capacity for noncyclic electron flow and NADPH formation. Therefore, there is a net NADPH deficit in the bundle sheath cells, and a large proportion of the assimilated carbon, in the form of 3-phosphoglycerate, has to

Marcel Dekker, Inc.

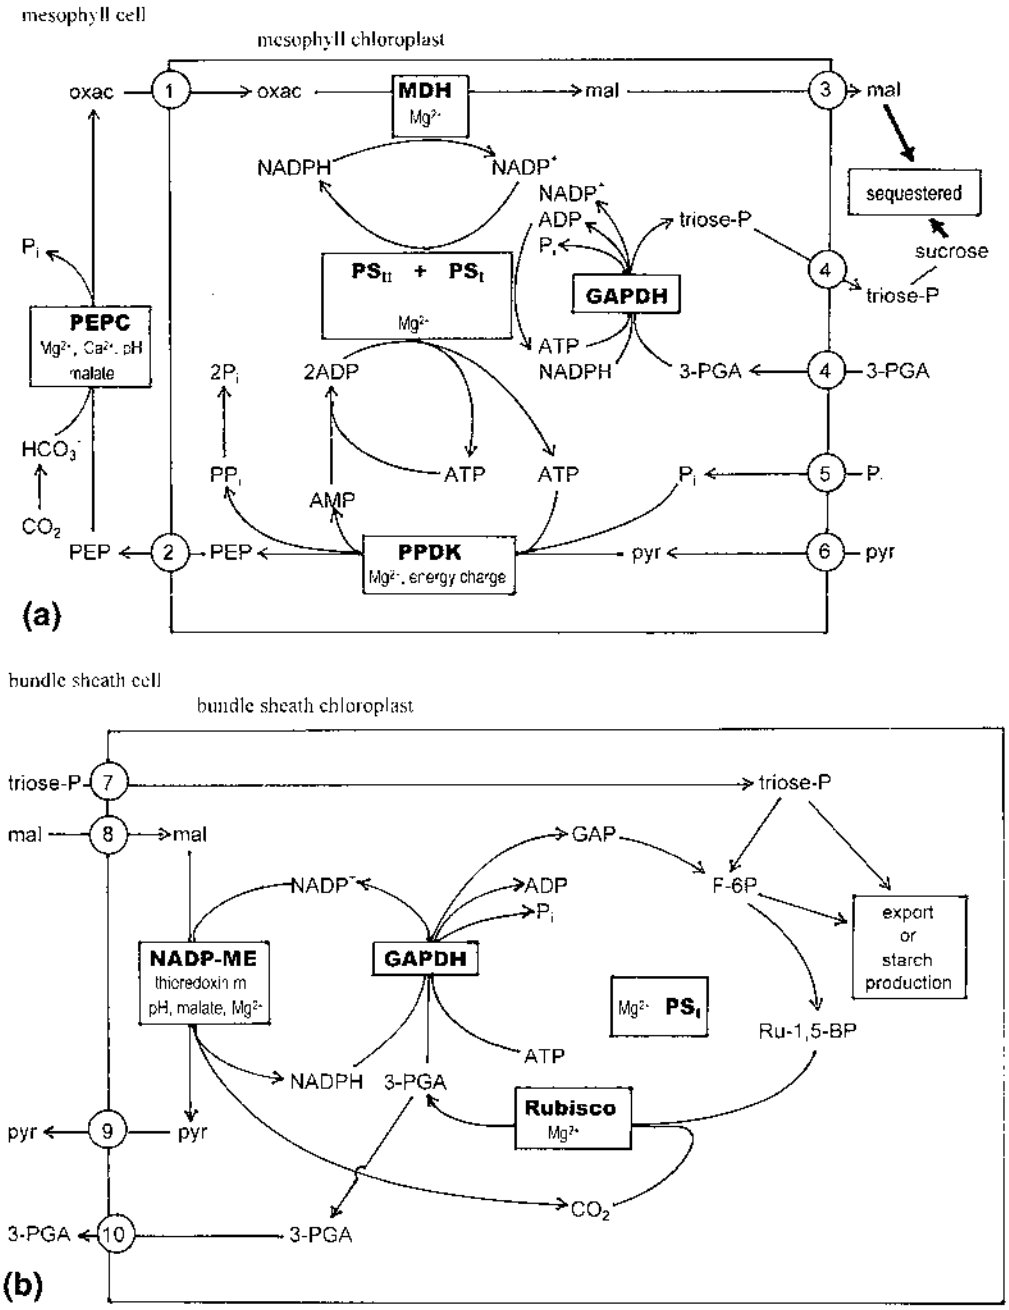

FIGURE 1 Pathways of CO_2 assimilation in maize leaves. Photosynthetic reactions are split between mesophyll (1a) and bundle sheath cells (1b). Effectors are called regulating enzyme activities essential for the operation of the total system. A prerequisit for the functioning of the C_4 cycle is an exchange of intermediates between both cell types. Membrane transport is brought about by translocators at a rate equal to the rate of CO_2 assimilation: (1) The oxalo-

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

travel to the mesophyllic cells for reduction to triose phosphate, which is then returned to the bundle sheath [65]. The operation of C_4 photosynthesis requires that the intermediates malate (aspartate), glycerate-3-phosphate, and triosephosphates) move between bundle sheath and mesophyllic cells at rates equal to those of CO_2 assimilation. Owing to this, C_4 plants have different transport properties compared with C_3 plants. It may be mentioned here that malate may become sequestered inside the vacuole as a primary response to salt stress (see Fig. 1). This reaction interferes with the redox status of cells active in photosynthesis, and will reduce the rate of CO_2 fixation. Moreover, other essential reactions, nitrate reduction, for instance, too may be affected. As a consequence of this distribution of assimilate, sucrose synthesis from triose phosphate is restricted to the mesophyllic cells, whereas starch synthesis is predominant in the bundle sheath [68,69]. Similarly, the alternate respiratory pathway and the enzymes of nitrogen assimilation are differentially partitioned between the two cell types [68,70,71]. Since NADPH in the bundle sheath cells is in short supply, the question arises as to whether other NADPH-requiring reactions also are limited to the mesophyllic cells and are depleted in the bundle sheath tissues.

PHYSIOLOGICAL DESCRIPTION OF SALT STRESS EFFECTS ON MAIZE

General Observations

Much of the physiological research into salinity has concentrated on three topics: (a) water relations, (b) photosynthesis, and (c) the accumulation of a particular metabolite, assuming that one or more of these processes would limit growth in saline conditions. Most of these studies have been descriptive and have established patterns of responses in many crop species. One approach toward understanding the mechanisms of salt tolerance at the whole plant level is to follow the series of events that exposure to salinity initiates. Such time studies do not prove causal relations, but they can eliminate some possibilities. For example, if leaf expansion slows before photosynthesis does, then the decrease in photosynthesis cannot be causing the decrease in leaf expansion.

Salinity stress is composed of the osmotic and ionic components, both of which could potentially affect plant performance. Shoot growth is usually more affected than root growth [1]. Even though Na^+ and Cl^- are not the dominant ions in all saline soils, almost all research on salinity is done using NaCl as the stress agent [72–74]. The water-stress effect observed after NaCl treatment also can be induced by the addition of the nonpenetrating osmolyte polyethylene glycol (PEG) to the root medium [75]. These investigators conclude that hardening of leaf cell walls is a primary event in the chain of growth-regulatory responses to PEG-induced water deficits in maize.

The discovery of carrier proteins specific for water is an important step toward understanding the mechanism by which plants adopt to water stress [76]. Water channels facilitate the flux of water along an existing osmolarity gradient. Expression of tonoplast and plasma membrane aquaporin transcripts, some of which are water-stress inducible, is correlated with cell elongation [77].

---

acetate translocator shows an extremely low affinity to malate and thus allows oxaloacetate uptake in the presence of malate. (2) The PEP translocator catalyses the export of PEP in exchange for P_i. (3)(8) The dicarboxylate translocator predominantly is active in transporting malate. (4)(10) The triosephosphate-phosphate translocator is transporting in exchange dihydroxyaceton phosphate, glycerinaldehyde-3-phosphate, and phosphate. (5) This means that phosphate may enter the chloroplasts via two different translocators: [2,4]. (6) The pyruvate translocator is active in the light-dependent uptake of pyruvate into the mesophyll chloroplasts. It is under discussion whether it operates in the bundle sheath chloroplasts in a different way [9]. As indicated, photosynthetate may become sequestered on salinization.

Ion uptake and compartmentation are crucial not only for normal growth but also for growth under dry and saline conditions, because both stresses lead to a disturbance of ion homeostasis. Key components for homeostasis under salinity stress are Na^+/H^+ antiporters. Physiological studies have observed Na^+ excretion in the root system and vacuolar deposition of Na^+ in leaves. The results argue for the existence of a Na^+/H^+ antiporter activity that removes Na^+ from the cytosol, but until now no plant Na^+/H^+ antiporter protein has been purified. Despite the lack of progress in isolating a plant Na^+/H^+ antiporter, a putative antiporter has been isolated from yeast [78]. The finding that overexpression of a Na^+/H^+ antiporter in yeast increases Na^+ tolerance indicates that pH regulation is not disturbed. This implies that endogenous H^+ATPases and H^+PPases can sufficiently supply protons to drive Na^+ efflux. Overexpression of Na^+/H^+ antiporters solely in the root epidermis might make transgenic plants better Na^+ excluders.

Increases in the concentrations of solutes that contribute substantially to the osmotic pressure are often measured on the assumption that their accumulation improves growth. As pointed out by Munns [79], there is no clear evidence to support this. In a more recent paper, Munns [80] states that salts taken up by the plant do not directly control plant growth by affecting turgor, photosynthesis, or the activity of any one enzyme. Rather the build-up of salt in old leaves hastens their death, and the loss of these leaves affects the supply of assimilates and hormones to the growing regions and thereby affects growth. This statement may be kept in mind when analyzing the information summarized below.

Does Turgor Affect Growth Rate?

It appears to be widely accepted that turgor regulates stomatal conductance and cell expansion and hence plant growth in soils of low water potential. But, at a higher time resolution, some data prove that there are transient effects of a change in the leaf turgor on leaf expansion. On a time scale of days and weeks, the turgor of salt-affected plants is not always reduced. Turgor is sometimes lower in expanded leaves of salt-affected plants than controls [81], but often turgor is similar to or higher than controls [82–85].

A reduction of turgor was thought to be a factor limiting leaf elongation when plants were osmotically stressed (see Refs. 86 and 87 and references therein). This concept has been challenged by several other groups [81,86,88–93]. In an excellent study on the elongating regions of soybean stem [92], turgor was estimated by four different techniques using psychometers, a pressure chamber, and a pressure probe. All methods were comparable and indicated that water stress did not inhibit the turgor pressure in the growing zone of soybean stems.

In grasses, where the growing zone of the leaf is tightly enclosed by other leaves and not exposed to the atmosphere, the turgor pressure has been estimated from measurements with a pressure probe [81], psychrometers [89–91], and the Chardakov technique [86,90]. In each of these cases, the turgor was not reduced by osmotic stress once leaves had recovered to steady-state elongation rates even though these rates were below that of the control.

The turgor of leaves of salt-sensitive plant varieties is usually higher than their salt-tolerant relatives [80]. This is presumably because salt sensitivity is usually associated with poor exclusion of salt by roots, and salt concentrations are higher in leaves of sensitive genotypes than in tolerant ones. With two genotypes of wheat differing in salt tolerance, the more sensitive one, with the higher turgor, had a greater reduction in stomatal conductance than the tolerant one [89]. Such observations suggest that something other than turgor is controlling stomatal conductance.

Thiel et al. [81] and Yeo et al. [94], using a pressure probe, found no detectable change in the turgor of elongating leaf cells of plants growing in saline solution. Using a different experimental approach, data have been collected for plants in soil or nonionic solution of low water potential with the same outcome: Turgor in elongating tissues is either not affected by water deficit [93,95,96], or when it is, there is no correlation between the local elongation rate and the turgor of the cells [97,98]. The same lack of effect of turgor was shown for plants growing in a drying soil [99].

These results imply that turgor does not control growth, and that measurements of leaf water relations and osmotic adjustment have little value in predicting or explaining the growth rates of

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

salt-affected plants. Of course, turgor is essential for growth. Without turgor, there would be no extending force acting on the cell wall, and it could not expand. But the rate of cell wall expansion is controlled by the rheological properties of the cell wall; described by Green et al. [100] as ''wall-softening'' and ''strain-hardening'' processes, and not directly by turgor. A molecular explanation for these processes is given by Passioura and Fry [101].

There is consensus in the literature indicating that turgor does not limit the growth of osmotically stressed maize regardless of the method used to estimate turgor [11,12]. Measurements of apparent turgor indicated that, initially, there was a reduction of the apparent turgor, but after 4 h, when leaf elongation reached new, but reduced steady-state rates, the apparent turgor returned to control values.

Salt Effects on Ca^{2+} Functioning

Calcium has been recognized as a transducer of hormonal and environmental signals to the responsive elements of cell metabolism [102,103]. Changes in cytosolic Ca^{2+} activity trigger the chain of events that result in tuning a phosphorylation process on and off, thus ultimately affecting a large number of biochemical reactions [103,104]. The hypothesis of Ca^{2+} being the primary physiological transducer of environmental stress effects has been advanced for chilling injury [105], Al^{3+} toxicity [106,107], and salt stress [108–110]. Therefore, it appears that disturbance of the cell Ca^{2+} homeostasis may be the primary response to a variety of environmental stresses. As such, it may precede the hormonally mediated decline in both the growth rate and the rate of acquisition of all resources as common features of plants growing in suboptimal environment [111].

Cell wall loosening (breaking of calcium load-bearing bonds) as a consequence of acidification is a prerequisite for increased wall extensibility, and therefore cell elongation [112]. It has been shown that salinity does not reduce the activity of H^+-ATPases in the plasma membrane [113,114], and that the zone of acidification close to the root tip is similar in both salt-stressed and control roots [114].

Salinity severely affects Ca^{2+} uptake and transport, so that shoots frequently show symptoms of Ca^{2+} deficiency [73,115–119], especially in salt-sensitive genotypes [120,121]. Increased salinity reduces the amount of Ca^{2+} bound to endomembranes in *Zea mays* protoplasts [109].

Supplemental Ca^{2+} alleviates deleterious salt effects probably through mitigating the toxic effect of Na^+ ions rather than the osmotic effects associated with salt stress [122]. Therefore, the ratio Ca^{2+}/Na^+ in the rooting medium (or the Ca^{2+}/Na^+ activities) appears as the more reliable indicator for salt stress than the Na^+ concentration alone [123,124].

No apparent change in permeability of the plasma membrane after exposing *Zea mays* root protoplasts to 100 mM NaCl for up to 1 h was observed [109]. Such a result places more importance on the direct effect of Na on both the plasma membrane and endomembrane Ca^{2+} transport systems.

In intact root-hairs as well as root protoplasts of *Zea mays*, other monovalent cations may also inhibit Ca^{2+} binding to the plasma membrane [125]. The order of inhibition, $Li > Cs \gg Rb > Na > K$, precludes any inference about possible specific ionic effects in connection to the ion radius (with and without hydration shell) and/or specific ion charge. Therefore, the observed effect on Ca^{2+} displacement from the plasma membrane by monovalent cations [108,125,126] may be due to the nonspecific effects of the increased ionic strength of the external solution on both Ca^{2+} activity in the apoplasmic space and electrical properties of the plasma membrane.

Direct Toxic Effects of Salts on Meristematic Tissues

Much of the scientific attention has focused on the limitations caused by ion toxicity [1,9,87,127]. This factor is important for sure, but removal of the long-term limitation to plant growth by the development of plants capable of ion exclusion or compartmentation will not alleviate the water-stress component. Thus, long-term growth will still be limited by this primary response. Therefore, it also is important to study the mechanisms by which salinity inhibits growth in the short term.

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

Na^+ Exclusion and Na^+ Sequestering in Leaf Tissues

Bernstein and colleagues have shown, in early experiments, that cultivars with low rates of salt accumulation in leaves yielded best in saline soils. Grafting experiments showed that salt accumulation in leaves was controlled by roots [128]. No difference in Na^+ efflux but higher Na^+ influx was noted in salt-sensitive genotypes of *Zea mays* compared with the salt-tolerant ones; sodium uptake was greater in seedlings than in plants at later stages of growth [34]. Sodium ions that entered the cytoplasm may be sequestered into the vacuole. The Na^+/H^+ antiport activity in tonoplast vesicles that is being fueled by the pH difference across the tonoplast (lower pH in the vacuole) appears to be responsible for Na^+ accumulation in the vacuole. Stellar parenchyma cells of the roots and mesocotyl accumulate Na^+, thus reducing its load to the *Zea mays* leaf cells via the xylem transport [129]. Hajibagheri et al. [38] showed that, in 26 salt-stressed maize cultivars, shoot Na^+ concentration and plant survival were negatively correlated. Other experiments did not support the hypothesis that Na^+ is toxic to maize. A simple positive correlation between Na^+ exclusion and salt tolerance was not observed by Lessani and Marschner [130].

The data of two greenhouse experiments with 100 mM NaCl and 50 mM Na-sulfate revealed significantly greater Na^+ exclusion from the shoots of cultivar Pioneer 3906 than from Across 8023. These findings show that the Pioneer cultivar is a strong Na^+ excluder, which has also been demonstrated by Maas et al. [131] and Schubert and Läuchli [132]. Besides effective Na^+ exclusion at the root surface of cultivar Pioneer as a result of the relatively low passive sodium permeability of the epidermal and cortex plasmalemma [34], the lower Na^+ and higher K^+ concentrations observed by Fortmeier and Schubert [37] in the shoot tissue of the Pioneer cultivar compared with the Across cultivar indicate that there is efficient Na^+ exclusion from the xylem by parenchymal cells, where a K^+/Na^+ exchange may be responsible for the control of Na translocation to the shoot [14,133].

The results of an investigation presented by Fortmeier and Schubert [37] suggests that the leaf sheath is important for salt tolerance as a result of sequestering of Na^+. The Na^+ concentration of the leaf sheaths were almost two times higher than those of the leaf blades. This was true for both cultivars, but the level of Na^+ was much higher in the Across cultivar than in Pioneer one, which indicates the storage capacity of Na^+ in the roots of cultivar. Across is lower than that of cultivar Pioneer.

Turgor Maintainance and Photosynthesate Sequestering

On salt stress, the reduction of growth is greater than the decrease in photosynthesis, and the reduction of shoot growth is much greater than the reduction of root growth [134]. It is broadly acceptable that the total carbon usage can be partitioned to growth, maintenance, transport, and storage. Analysis of this partitioning is by no means trivial. The best-resolved effects of salinity are those on the maintenance costs of the shoots. As would be expected, the maintenance respiration of rapidly growing plants is generally much higher than that of more slowly growing, environmentally less-responsive species. Salinity-induced changes also are greater. This probably reflects, in part, the additional costs of transport associated with salt exclusion. Increased maintenance costs, however, cannot explain all loss of growth. Increases in carbohydrate accumulation with salinity are already known. Although this use does not result in loss of carbon from the plant, it may well remove it from the pool available for immediate metabolism, growth, or regulation.

Growing tissues of plants respond to external salinity by rapid adjustment of internal osmotic potentials and thus maintain the water potential gradient required for turgor maintenance [90]. Moreover, cell micropressure probe measurements and indirect bulk estimates of turgor in elongating stem or leaf tissues of maize [11,12] consistently revealed the absence of any long-term (hours to days) salinity effects on turgor. Thus, longer term effects on growth might be regulated by induced reductions in the mechanical extensibility characteristics of the growing tissues (''wall hardening'') [100,101]. Estimates of turgor pressure, yield threshold, and hydraulic conductivity of growing

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

maize leaf tissues indicated that they were not greatly affected by long-term salinization, and that, by default, changes in wall extensibility were responsible for growth inhibition [135]. Two other reports indicated that wall extensibility in pea stems and maize leaves were altered by salinity [136,137]. They found that growth-inhibitory effects of salinization for 5 h were primarily related to reductions in the wall extensibility coefficient. However, Cramer and Bowman [11,12,137] detected significant changes in the wall extensibility coefficient only after 24 h of salinization, and they related the earlier inhibition of growth to changes in yield threshold pressure and effective turgor.

Osmotic adjustment, the lowering of osmotic potential by the net increase in intracellular solutes, is recognized as an adaptive mechanism to water stress in many crops and is considered to be a major component of drought-tolerance mechanisms. Osmotic adjustment is one aspect of a highly complex and integrated system of adaptation to water deficits. The degree of osmotic adjustment depends on the rate of the decrease in the leaf water potential [138]. The compounds involved in osmotic adjustment are principally soluble sugars, K^+, organic acids, Cl^-, and free amino acids [139].

It is clear from numerous similar studies of water and salt relations, however, that turgor maintainance alone does not assure continued leaf expansion [87,93]. It may be that photosynthetic capacity is insufficient to provide the carbon both for wall synthesis and for ''turgor-driven cell expansion.'' Or it may be that some higher level controls operate to limit expansion in spite of the available potential. Munns and Termaat [87], for example, argued that shoot growth was not limited by the lack of substrate. Instead the existing carbohydrates were metabolically unavailable for wall synthesis, and they supported the hypothesis that the controlling message originated in the roots. This interpretation is supported by Cramer and Schmidt [140], who reported that maize leaf elongation is limited by the reduction of effective turgor, and that cell wall extensibility is unaffected by salinity.

The difference in the long-term growth response of the two cultivars under salt conditions indicates that Na^+ exclusion is positively correlated with salt tolerance in maize. A comparison of the growth responses and ionic concentrations of the plants between the two experiments with Na-chloride and Na-sulfate indicates that Na^+ is the most toxic ion in maize under salinity. In the 100-mM NaCl treatment, Cl^- concentrations in the shoot of the Across cultivar were not significantly higher than those of the Pioneer variety [35]. Furthermore, in the 50-mM Na-sulfate treatment, the Cl^- concentrations in the shoots and roots did not differ between the two cultivars. Cultivar Across 8023 showed the same toxic symptoms in the NaCl and the Na-sulfate treatments, with higher Na^+ concentrations in the shoot. The root and shoot growth of cultivar Across with 50 mM Na-sulfate was decreased to a greater extent than that of the Pioneer cultivar in the NaCl experiment.

The response of the leaf elongation rate to water deficit has most often been analyzed by considering the behavior of plants subjected to both the soil water potential and the low evaporation demand. In this case, at least a large part of the control of the leaf elongation rate is linked to a message originating from the roots and traveling to the shoots. This was demonstrated using experimental designs where the leaf water potential was maintained high and constant by pressurizing [141] or splitting the root system [142] while soil water was progressively depleted. Abscisic acid (ABA) could play a major role in this message [143,144], and it has recently been shown to induce mRNA populations in intact plants [143], with some of them being associated with inhibition of the elongation of the maize mesocotyl at low soil water potential [144].

On the basis of these data Ben Haj Salah and Tardieu [145] conclude that ABA signaling alone cannot account for the changes in the leaf elongation rate of droughted plants. The time course of the leaf elongation rate markedly diverged from that of changes in the ABA concentration in the xylem in droughted plants subjected to varying evaporation demands and diverged from that of the ABA fluxes in ABA-fed plants. The daytime and nighttime effects of soil water deficits also clearly differed in time and space in spite of nearly constant ABA concentrations inside the xylem. It is suggested [145] that the effect of water deficit on the leaf elongation rate should be analyzed as the superposition of two effects—one linked to the soil water status and probably involving ABA signaling and the other linked to the transpiration rate or the leaf water status and involving local events in the leaf. A hydraulic signal is the most likely possibility to account for this second effect.

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

Instant Effects of Changes in Salinization

Some reports indicate that the salinity-related inhibition of leaf elongation may be extremely fast (observed after only 1 min following addition of salt to the root medium) [94] and independent of the roots [11,12]. This apparent controversy places a great significance to the research that would identify a primary response to salinity. Yeo et al. [94] argued that the water supply to the roots is the only factor that can be preceived, transmitted, and translated into a stoppage of leaf growth that was detected after only 1 min.

The short-term response (up to a few days) of plants to salinity appears to be different from the long-term response. According to Munns and Termaat [87], short-term responses of shoot growth to salinity may not be limited by water deficit, ion toxicity, or carbohydrate supply. Nevertheless, growth is still inhibited. However, the short-term response was not correlated with Na^+ exclusion, a result which was also obtained by Schubert and Läuchli [132] and Cramer et al. [146]. In this first phase, water stress rather than ion toxicity affects plant growth [80]. When salinity is applied to the root medium of maize plants, leaf elongation is inhibited immediately [147], but it recovers to a new steady-state rate which is below that of the control. In contrast to the observations of Fortmeier and Schubert [37] and results obtained by Schubert and Läuchli [132], Cramer [147] found that the short-term effects of 75 mM NaCl, with or without supplemental Ca^{2+} (10 mM), on the kinetics of leaf elongation of maize cultivars Pioneer abd DeKalb (a Na^+ includer) were different. After 24 h salinization, cultivar DeKalb appeared to be more salt sensitive and responsive to supplement Ca than the Pioneer cultivar.

Neumann [135] has found a rapid and reversible modification of the extension capacity of the cell walls in elongating maize leaf tissues responding to root addition and removal of NaCl. The long-term inhibition of the cell wall extension capacity was reversed within 20 min of salt withdrawal from the root medium. The rapid reversal of the inhibition of the wall extensibility and leaf growth after salt removal from the root medium of long-term salinized plants suggested that neither the deficiencies in growth essential mineral nutrients nor the toxic effects of NaCl on the plasma membrane viability were directly involved in the inhibition of leaf growth. Rapid metabolically regulated changes in the physical properties of growing cell walls, caused by osmotic and other effects, appear to be a factor regulating maize leaf growth responses to root salinization.

Calculations

Leaf elongation is a function of the rate of cell production and expansion. Cell expansion is dependent on water uptake and the rheological properties of the cell wall. According to Boyer [148], expansion can be described by equation (1):

$$v^{-1} * dv * dv^{-1} = \mathrm{mL} * (m + L)^{-1} * (y_0 - y_s - Y) \quad (1)$$

where v, t, m, L, y_o, y_s, and Y are the volume of the cell, time, cell wall extensibility, hydraulic conductivity, xylem water potential, cell osmotic potential, and yield threshold, respectively. Although cell expansion is three dimensional, it can be adequately described in one dimension as well [149].

When the rates of cell expansion are plotted as a function of $(y_o - y_s)$, the plot is theoretically linear with the x intercept equal to Y and the slope equal to the yielding coefficient $\mathrm{mL}/(m + L)$ [66]. If hydraulic conductivity is not limiting, then equation (1) can be reduced to:

$$v^{-1} * dv * dv^{-1} = m * (y_p - Y) \quad (2)$$

where y_p is the cell turgor. The slope of equation (1) simplifies to m in the equation (2) [148].

Experimentally, the cell expansion rates may be modified by lowering the osmotic potential around the cells or roots, which changes cell turgor [86,100]. Okamoto et al. [150] took a different approach and modified the shoot elongation rates by excising the roots and hydraulically increasing

the xylem pressure to increase elongation. Their technique has the advantage of increasing the force for cell expansion three dimensionally, but it has the disadvantage that the plant must be excised, which may eliminate regulatory factors from the root or add regulatory factors due to wounding. Estimates of Y have been presented for water-stressed plants [86,100,149,151,152]. In maize leaves, Y increased with water stress from approximately 0.37 to 0.44 MPa [86], and it was the single factor regulating the short-term steady-state LER of water-stressed maize.

The yielding coefficient, mL/(m + L), was unaffected by salinity in experiments with maize, and it therefore was not a limitation to the RER [11,12]. Moreover, these investigators found that *m* is not affected by salinity. This result is in good agreement with earlier work using the Instron technique on the leaves of barley [153] and bean [154]. Likewise, the data presented by Cramer and Bowman [11,12] suggest that, in maize, *L* was not affected by salinity, because both the yielding coefficient and *m* were unaffected by salinity. This conclusion is supported by data indicating that *L* of the roots does not appear to limit the LER of salt-stressed maize [12]. Furthermore, *L* did not limit the leaf growth of salt-stressed barley [93,155].

Summary of Physiological Description of Salt Stress Effects on Maize

Maize (*Zea mays* L.), a C_4 plant of tropical origin, is one of the most important crops for animal and human food and agroindustrial purposes worldwide [156,157]. An understanding of the factors that determine the sensitivity of maize are particularly important, since stress tolerance remains a major selection criterion in current maize-breeding programs. The complexity of stress syndromes, however, requires that many different techniques be utilized. Faster progress could certainly be made if groups of investigators with complementary expertise work together.

Maize is classified as a salt-sensitive crop plant [158]. The response of maize to salinity varies depending on the stage of development [131,159,160]. Vegetative growth appears to be more sensitive to salinity, whereas plants are much less affected at later stages [161]. The vegetative growth of maize is severely impaired even at rather low salt concentrations [131]. Maize excludes sodium, in contrast to the more salt-tolerant barley, which has Na^+-including abilities [162], but there are large differences in the sodium exclusion ability between different cultivars of maize [34].

Munns [80] has proposed a biphasic model of the growth response to salinity. According to this model, growth is first reduced by a decrease in the soil water potential. This phase of growth reduction is a water-stress effect and may be regulated by inhibitory signals from the roots. One such signal may be ABA as it increases in the xylem sap of plants in saline soil [163,164]. The water-stress effect observed after NaCl treatment can also be induced by the addition of the nonpenetrating osmolyte PEG to the root medium [75].

Schubert and Läuchli [132] showed that there was no positive correlation between sodium exclusion and salt tolerance in maize in a short-term experiment of 17 days. The more recent data of Cramer et al. [146] are in aggreement with this result. The investigators found that the salt tolerance of maize was not associated with sodium exclusion. In this first phase, water stress rather than ion toxicity affects plant growth [80], and genotypes differing in salt tolerance respond identically in this first phase [80]. Therefore, it can be concluded that the growth response of maize within the first 2 weeks of salinity is primarily affected by osmotic factors. When salinity is applied to the root medium of maize plants, leaf elongation is inhibited immediately [147], but it recovers to a new steady-state rate which is below that of the control. In contrast to the observations of Fortmeier and Schubert [37] and results obtained by Schubert and Läuchli [132], Cramer [147] found that the short-term effects of 75 mM NaCl, with or without supplemental 10 mM Ca^{2+}, on the kinetics of the leaf elongation of maize cultivars Pioneer and DeKalb (a Na^+ includer) were different. After 24 h of salinization, cultivar DeKalb appeared to be more salt-sensitive and responsive to supplemental Ca^{2+} than cultivar Pioneer.

In the second phase, the concentration of toxic ions increases rapidly, especially in old leaves, which die as a result of the fast increase of the salt concentration in the cell wall or the cytoplasm

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

when vacuoles can no longer sequester incoming salts. In this second phase, genotypes which vary in salt tolerance may respond differently as a result of their different abilities to exclude toxic ions or to sequester them in the vacuoles [80].

Fortmeier and Schubert [37] argued that the difference in the long-term growth response of two maize cultivars under salt conditions indicates that Na^+ exclusion is positively correlated with salt tolerance. A comparison of the growth responses and ionic concentrations of the plants between experiments with NaCl and Na_2SO_4, respectively, indicates that Na^+ is the most toxic ion in maize under salinity.

BIOCHEMICAL ASPECTS OF SALT-STRESS EFFECTS ON MAIZE

Primary Effects of Salinity on Photosynthesis and Respiration

It has been pointed out by many investigators that growth is limited by the rate of photosynthesis. This view is based on the frequent observation that photosynthesis in salt-affected plants is reduced. However, the growth is affected before photosynthesis, as has been clearly demonstrated by Yeo et al. [94]. Further, long-term studies have found that growth declines more than photosynthesis [82,165,166]. So, salinity affects carbon assimilation per plant via a smaller leaf area rather than a reduced rate of photosynthesis [23]. A special situation occurs after prolonged periods of exposure to salinity. Then, levels of reserve carbohydrates can become low. The leaf area of such plants is probably quite low because of salt injury. So it is not surprising that high CO_2 improves the growth of plants for long periods under salinity [167].

When measuring the relative growth rates and the net assimilation rates of maize cultivars in water-stress treatment and controls at 20 days after treatment [138], it was found that the relative growth rate and the net assimilation rate decreased under stress. The results indicate substantial adaptation to water stress via osmotic adjustment and turgor maintenance. Sugar and K^+ were the major osmotic contributors in maize. Sugar concentration during drought treatment was almost twice that of controls at both 10 and 20 days. K^+ concentration increased at 10 days after withholding water, but a considerable difference was not seen at 20 days. Ca^{2+}, Mg^{2+}, and Na^+ concentrations increased slightly and phosphate decreased during stress treatment at both 10 and 20 days. K^+ was the major osmotic contributor in well-watered controls, whereas sugar became the major contributor with increasing water deficits [138]. These results suggest that sugar plays a major role in decreasing the osmotic potential under water-deficit conditions in maize. Under low leaf water potential conditions, stomata respond by closing, with a consequent reduction in transpiration as well as assimilation [168], leaf rolling occurs in minimizing evapotranspirational water loss [169] during water deficits. Cultivars with the ability to maintain turgor are capable of maintaining physiological processes at low leaf water status and are tolerant to drought.

Another aspect of discussions has been that decreases in growth with salinity may be due to increased respiration rates resulting from higher energy requirement [170,171]. We will refer to this point when discussing the salinity effects on ATPase activity, and we explain that this idea is not in accordance with in vivo observations with salt tolerant plants.

Inhibiting the Metabolism of Unidentified but Essential Metabolites by Salinity

Several investigators have discussed the fact that the uptake of salt might directly affect the production of a metabolite essential for cell growth. But it is unlikely that salt would be toxic in meristems: The salt concentrations in shoot apices [172–175] is not high enough to affect metabolism. It is

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

unlikely that salt in rapidly expanding tissues would be toxic to enzymes. The expanding vacuoles would readily accommodate the salt and would prevent their build-up in the cytosol or the cell wall. It is more likely that salt reaches toxic levels first in mature leaves. As soon as roots encounter salinity, salts start to build-up in leaves. These salts are preferentially sequestered in vacuoles, and there is much evidence to suggest that the compartmentation of salts in the vacuoles is an important feature of salt tolerance [176]. The sodium concentration in the cytosol and chloroplasts is kept at a level of 100–150 mM by sodium uptake into the vacuoles until its concentration becomes so high that the net uptake by the vacuole becomes zero [134]. If the leaf is still transpiring when the vacuole is ''full,'' incoming salts must then build-up in the cytoplasm or the cell wall. Thus, the cell dies of salt poisoning or dehydration depending on whether salts build-up in the cytoplasm or cell wall. In either case, death of the cell would occur within a few days of the vacuole ceasing to take up incoming salt. The rise of the salt concentration would occur so rapidly that it is likely to affect all enzymes almost simultaneously.

There are some enzymes that are more sensitive to salt than others [177], but the salt concentration in the cytoplasm could increase by 10 mmol per hour, so there would be at most a day's difference between the most sensitive and the most tolerant enzyme being poisoned by salt [80]. But, within the context of this chapter, we should be interested in tolerable salt concentrations rather than poisonous ones. Therefore, we will focus on salinity affecting or regulating metabolic pathways, taking as an example experimental data on some key enzymes.

H^+-ATPases

In the context of active transport, V-type and P-type H^+-ATPases have to be distinguished, being predominantly active in the tonoplast and plasmalemma membranes, respectively. This can be done easily by applying the phosphomolybdate method and by the sequential inhibition of the different ATPase types [178–180]. Whereas V-type ATPases exclusively catalyze the ATP-driven export of protons, the different P-type ATPases can transport other cations as well. It has been found that ATPases vary their apparent K_m for ATP with the size of the membrane potential and the ion transport rate. At low transport rates, K_m may be as low as 1–2 μM ATP, whereas K_m values of 50–100 μM have been measured at high transport rates brought about in the presence of the K^+-ionophore valinomycin (U. Homeyer and B. Huchzermeyer, unpublished results). Anyway, these affinities towards ATP are very high. ATPases efficiently can reduce the phosphorylation potential, when their activities become enhanced in response to salt stress.

The plasmalemma H^+-ATPase links ATP hydrolysis to the extrusion of protons from the cytoplasm to the apoplast [181]. This provides the driving force for solute transport at this membrane. A characteristic property of the H^+-ATPase is the stimulation of its activity by K^+ [182]. Owing to the complex kinetic profile observed for maize plasmalemma preparations, it was proposed that the H^+-ATPase might conduct a H^+/K^+ exchange that would contribute to K^+ uptake into the maize cells [182]. This transport mechanism was thought to be of special importance when external K^+ concentrations are low compared with other ions. But, in a more recent paper, Briskin and Gawienowski [183] showed that the H^+-ATPase provides the driving force for cellular K^+ uptake by secondary mechanisms such as K^+ channels or H^+/K^+ exchange systems. The plasma membrane H^+-ATPase does not directly mediate ATP-mediated K^+ transport.

As the plasma membrane H^+-ATPase provides the potential for the transport of Na^+ and Cl^- between the apoplast and symplast, the activity of this pump must be critical to the energy-dependent transport required for ionic homeostasis in saline environments. In the fully expanded leaves of *Atriplex nummularia*, Niu et al. [184] found that H^+-ATPase mRNA levels were induced specifically by NaCl. mRNA accumulated in the bundle sheath cells, but not in the gland cells, implicating xylem unloading into the bundle sheath cells as a crucial control process for ionic homeostasis when the shoot is responding to NaCl stress. Salt-induced plasma membrane H^+-ATPase gene expression, which is assumed to be a basis for at least part of higher H^+ transport activity, occurs during stress

adaptation but not after the new adaptive state has been achieved. When ionic gradients have been established, altered membrane permeability restricting the Na^+ influx may be the primary basis for ionic homeostasis [185].

The capacity to alter the membrane permeability may be another criterion to differentiate halophytes and plants do not tolerate salts. Plants lacking this ability permanently depend on the energy-consuming active salt transport processes. In contrast to these experiments with a halophyte, we did not find a distinct NaCl-induced H^+-ATPase activity in maize leaves at a first glance. We rather recognized that photosynthetic active leaves died as soon as the cytosolic NaCl concentration started to increase. But, meanwhile, some NaCl stimulation of the H^+-ATPase activities in fully developed leaves could be detected: After 1 day of salinization, there was a transient increase of P-ATPase in the leaves in salinized plants compared with the leaves of the control plants. After a salinization period of about 30 days, V-ATPase increased until it suddenly collapsed at a time when all other enzyme activities became reduced. This latter point probably indicates the moment when salt concentrations build-up in the cytosol and the leaf cells start to die. Owing to variations in the growth rate of different plant cultures, it is difficult exactly to reproduce, in terms of days, these results and define the periods of enhanced ATPase activities (H. Klenke, unpublished results).

In maize roots, most of the V-ATPase activity is located in the stelar parenchyma, with only very low activity in the cortex. Growth of the roots in 100 mM NaCl brought about a marked increase in V-ATPase activity of the cortex, with only a small effect on the stele suggesting that expression in the cortex is under environmental control. The promoter region of a V-ATPase gene for the catalytic subunit of carrot has been sequenced and shown to be active in enhancing gene expression. Interestingly, an ABA box identified as sufficient to confer responsiveness to this hormone is present. In experiments with tobacco cells, it has been shown that ABA increases V-ATPase gene expression [186].

These experimental results match our data on NaCl sequestering in maize on salinization. Isolated enzymes appeared to be more sensitive to NaCl than photosynthetic $^{14}CO_2$ incorporation into sugar compounds. But, owing to our experimental technique, we measured the total NaCl concentration in the cell sap rather than inside the cytosol or chloroplasts. The easiest explanation of the discrepancies observed in our experiments is to assume that most of the NaCl was sequestered to the vacuole and toxic effects on enzymes involved in photosynthesis became manifest no earlier than the enhanced NaCl concentrations appeared in other cell compartments (H. Klenke, unpublished results). Vacuolar compartmentation of Na^+ and Cl^- is an essential mechanism for salt tolerance, since it results in lower cytosolic ion levels and faciliates osmotic adjustment, as already discussed above [134].

Development of C_4-Type Metabolism in Maize

The control of photosynthetic gene expression in plants is often complex, with regulation occurring at many levels and in response to numerous developmental, metabolic, or environmental signals. For Rubisco, the principal photosynthetic enzyme present in the chloroplasts of all higher plants, alterations in the expression of chloroplastic genes encoding the large subunit and nuclear genes encoding the small subunit can be mediated by (a) light [187,188,189], (b) developmental processes [190], or (c) photosynthetic metabolism [191–194]. Therefore, varied Rubisco concentrations under salinity are difficult to allocate to direct or indirect effects (via salt interfering with enzymes active in metabolism). In many cases, the control of Rubisco gene expression has been shown to be due to the control at the level of transcription [190,195], although examples of regulation occurring at posttranscriptional levels, such as RNA turnover, transport, processing, or regulation of translation, have been documented [190,196,197].

In C_4 plant species, genes encoding Rubisco and other photosynthetic enzymes have acquired additional or modified forms of regulation [67]. C_4 development appears to require many independent modifications to already existing C_3-type expression patterns for numerous photosynthetic genes, and these added levels of regulation may involve both transcriptional and posttranscriptional

control mechanisms [67,198–200]. Steady-state levels of C_4 enzymes and their mRNAs increase severalfold if dark-grown plants are illuminated [201–204]. This is an increase from the low levels that are developmentally induced even in darkness.

Early in leaf development, maize shows a ground state with Rubisco in all photosynthetic cells. This ground state is modified to give the more specialized C_4-type gene-expression pattern. The first step in this modification appears to be the repression of the Rubisco expression in the mesophyllic cells. This repression requires light and is only effective in the mesophyllic cells in proximity to a vein [205–208]. The low levels of Rubisco found in dark-grown maize seedlings represent accumulation in both the bundle sheath and mesophyllic cells [202,207]. If dark-grown plants are illuminated, the Rubisco accumulation is restricted to the bundle sheath cells and mesophyll-localized Rubisco is turned over more efficiently in the leaf blade than in the leaf sheath. This suggests that illumination is an essential component of the positional information that represses Rubisco in the mesophyllic cells of C_4 plants. Run-off experiments with nuclei from separated cell types suggest that this repression occurs posttranscriptionally, because Rubisco small subunit transcripts appear to be initiated in both cell types in maize [198]. The possibility of cross contamination of cell types in such experiments makes it impossible to rule out a role for transcriptional regulation.

The light dependence of the bundle sheath–specific and mesophyllic cell–specific gene expression has been further examined in situ [207]: Maize husk leaves with widely spaced veins were allowed to develop under various levels of illumination. In low light, Rubisco accumulates in the mesophyllic and bundle sheath cells and C_4 enzymes are absent. In high light, cell-specific C_4 enzymes accumulate principally in cells close to veins. This observation is consistent with measurements of photosynthetic enzyme levels in maize plants grown under high and low levels of illumination [209–211]. These results suggested that development in low-light levels favored the accumulation of the C_3 enzyme Rubisco, whereas higher light levels resulted in greater levels of both Rubisco and the C_4 fixation enzyme PEPC. This C_3/C_4 shift is accompanied by a new spatial pattern of gene expression. Compared with those in leaves grown in low light, mesophyllic cells of high-light–grown leaves have higher levels of pyruvate, phosphate dikinase (PPDK) and PEPC but lower levels of Rubisco and NADP-ME than the bundle sheath cells [212]. With respect to the above-mentioned observation that the Rubisco gene expression is controlled by photosynthetic metabolism, it may be argued that the C_3/C_4 shift is under the control of metabolite levels conditioned by the neighboring vein. The shift from the C_3-like to C_4-type Rubisco gene expression occurs in the basipetal direction, so that bundle sheath cell–specific expression of Rubisco was observed initially at the apex of young leaves and progressed rapidly downward to the leaf base. We will refer to these observations when discussing the salt-stress effects on enzyme patterns in developing maize leaves.

Key Enzymes of C_4 Metabolism in Maize

The enzymes addressed here may be easily localized in Figure 1, which shows the pathways of carbon metabolism within mature mesophyllic and bundle sheath cells, respectively. Moreover, in parts a and b of Figure 1, as well as in Table 1, possible salinity effects are indicated. Applying low salt concentrations, none of these enzymes will become inactivated or even denaturated, but salt stress will interfere with the regulation of the catalytic activities of these enzymes.

Phosphoenolpyruvate Carboxylase

Catalysis: Phosphoenolpyruvate carboxylase (PEPC, EC 4.1.1.31) in higher plants is a cytosolic, oligomeric, highly regulated enzyme [213,214]. It catalyzes the β-carboxylation of phosphoenol pyruvate in the presence of hydrogencarbonate and divalent metal cations to yield oxaloacetate and orthophosphate.

$$\text{Oxaloacetate} + \text{ATP} <=> \text{Phosohoenol Pyruvate} + \text{ADP} + CO_2$$

TABLE 1 Key Enzymes of C_4 Metabolism in Maize

Enzyme	Essential elements for catalysis and regulatory lignads	Other effectors	Salinity effects
PEPC	Mg^{2+} essential for catalysis Strictly alkaline pH optimum, stimulated by Ca^{2+} Allosteric effects: Positive: glucose-6-P, triose-P Negative: L-malate, aspartate	Phosphorylation potential affects catalytic activity via its effect on protein kinase activating the enzyme.	Direct effects via salt interfering with Mg^{2+} and Ca^{2+} uptake Indirect effects by reducing phosphorylation potential due to enhanced ATPase activity
NADP-MDH	Light activation via thioredoxin m	High $NADP^+$/NADPH ratios result in reduced catalytic activity via $NADP^+$ competition for electrons with thioredoxin m	Sequestering of reducible substrates oxaloacetate, 3-PGA, malate will affect the $NADP^+$/NADPH ratio
NADP-ME	Mg^{2+}, pH, and malate concentration directly affect substrate binding to the catalytic site Allosteric effects: Positive: CoA, fructose-1,6-bis-P Negative: Cl^-, NO_3^-, HCO_3^-		Direct effects via impaired ion uptake Indirect effects via sequestering of effectors as well as effects brought about by ATPase and translocator-mediated pH shift
PPDK	Mg^{2+} promotes PET/pyr exchange in the catalytic site K^+, NH_4^+ stimulate catalytic activity ADP inhibits enzyme activity; oxalate prevents from ADP-inhibition. Inhibited by proteinphosphorylation; activated by light dependent dephosphorylation	Mg^{2+} essential for forming the catalytic active tetramer Sugar, polyols, and pyruvate protect the tetramer form dissociation	Direct effects via salt interfering with ion uptake Rate of enzyme inactivation depends on ATP/AMP and pyr/PEP ratios: minimal variations in phosphorylation potential bring about massive effects on catalytic activity

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

Therefore, it is obvious that this enzyme is involved intimately in the dicarboxylic acid metabolism in plants. In addition to its cardinal role in the initial fixation of carbonate during C_4-type photosynthesis, PEPC functions in several anaplerotical metabolic pathways, such as C-N partitioning in C_3 leaves [213]. Moreover, PEPC isoforms have been identified in various plant tissues playing specialized roles; PEPC of guard cells is only one such example [215].

In the presence of hydrogencarbonate, phosphoenolpyruvate can undergo hydrolysis to form pyruvate. Under in vivo conditions, that is, in the presence of Mg^{2+}, this hydrolysis contributes less than 5% to the total reaction flux, but it becomes more important in the presence of other cations, with a yield of 50% being found in the presence of Ni^{2+} [216]. Thus, salt cations competing for uptake with Mg^{2+} may interfere with the apparent carboxylation yield. Recent studies on the catalytic mechanism indicated that there is a strict synergism in substrate binding to the active site of the enzyme: Mg^{2+} binds first, and this binding is at equilibrium, phosphoenolpyruvate binds second, and hydrogencarbonate binds third. Moreover, all three substrate components have to be present inside the catalytic site before the reaction starts [217].

From stereochemical studies, it may be concluded that during catalysis phosphate is transferred first to form a carboxyphosphate. In a subsequent intermediate state, an enzyme base depronates the carboxyl group of the carboxyphosphate, which decomposes to form enzyme-bound CO_2 and P_i. In this state CO_2 is located above the plane of the enolate within bonding distance of the carbon-3. In this state, the divalent metal cation plays a crucial role. Obviously, metals other than Mg^{2+} lower the reactivity of the enolate. The result is a loss of CO_2 in the presence of other divalent metal cations [216].

Regulation: PEPC and sucrosephosphate synthase are well-known examples of plant enzymes in vivo regulated by enzyme phosphorylation [218,219]. Moreover, it is well documented that various isoforms of plant PEPC are subjected to allosteric regulation by both positive (glucose-6-phosphate and triose phosphates) and negative (L-malate, aspartate) effectors, and that the affinity of these effectors is strictly dependent on the pH value. (See Table 1 for a summary.) For instance, the K_i for L-malate of the C_4 PEPC from *Sorghum* is decreased 25-fold when measured at pH 7.3 compared with the one determined at pH 8.0 [220]. Indirect effects on PEPC activity of salinization may be expected when these effectors become sequestered to the vacuoles during the first phase of the salt-stress response. These modulators of PEPC activity may be imported from the bundle sheath. This feature provides a means of communication between the Calvin cycle and the C_4 cycle.

It has been shown that the C_4-PEPC is reversibly light activated in vivo by a phosphorylation of a serine residue at the 110-kDa subunit's N-terminus that directly or indirectly depends on photosynthesis. This activation mechanism is modulated by the incident photosynthetic photon flux density above a minimum threshold of about 300 μmol m^{-2} s^{-1}. In maize, Ser-8 and Ser-15 are the two candidates that might become phosphorylated [221–223]. Phosphorylation of PEPC not only results in the activation of its catalytic activity but also fine tuning by allosteric regulation becomes changed: A reduced sensitivity toward L-malate inhibition (K_i is sevenfold increased) and a higher affinity of the allosteric sites toward glucose-6-phosphate (K_a becomes fivefold decreased) have been observed [220,224].

It has been concluded from available experimental data that PEPC phosphorylation is brought about by a Ca^{2+}-independent 30- to 39-kDa kinase that is light-dark regulated in C_4 plants in vivo [225]. It is generally accepted that the light-induced C_4 transduction cascade is initiated in the illuminated chloroplasts by photosynthesis. From in situ experiments, it may be concluded that increases in the pH and Ca^{2+} concentration within the cytosol of the mesophyllic cells function as regulatory elements. On the other hand, it is still a matter of discussion whether 3-phosphoglycerate, generated in the Calvin cycle of bundle sheath chloroplasts, functions as a messenger as well. In addition to the above-mentioned allosteric effects, there is strong evidence for a regulation of cytosolic protein synthesis under the control of another protein kinase [226,227]. This reaction cascade tuning PEPC catalytic activity is summarized in Table 1.

The maize PEPC enzyme family posseses at least five nuclear genes; the C_4-PEPC is unique and is located near the centromer of chromosome 9 [228,229]. The C_4-PEPC gene is expressed in

photosynthetic tissues during greening via a phytochrome-mediated response [230]. Gene expression is not correlated to the Kranz leaf anatomy, because, in maize, it also occurs in inner leaf tissues and tassels [231]. In maize, it has been found that cytokinins upregulate the transcriptional activity of the C_4-PEPC gene [232]. In the facultative Crassulacean acid metabolism (CAM) plant *Mesembryanthemum crystallinum* (ice plant), the transcription of the CAM-PEPC gene is induced by ABA, which is produced under salt stress [233,234]. It has been shown that salt stress in *M. crystallinum* causes three protein factors (PCAT-1, -2, and -3) to bind to AT-rich regions of the Ppcl promotor [235]. Similar promoter sequences have been found in *Sorghum* as well [236]. But, up to now, no clear results concerning salt-stress–induced regulatory mechanisms in maize are available. Nevertheless, the above-sumarized direct effects of divalent cations on the catalysis and regulation as well as the regulatory effects of metabolites seem to suggest salinity effects on PEPC.

Malate Dehydrogenase Specific for NADP$^+$

The malate dehydrogenase specific for $NADP^+$ (NADP-MDH, EC 1.1.1.82) was originally found by Hatch and Slack [237] in plant leaves. It catalyzes the reversible reduction of oxaloacetate in the presence of NADPH to form malate and $NADP^+$.

$$\text{Malate} + NADP^+ <=> \text{Oxaloacetate} + NADPH$$

The enzyme is predominantly located in mesophyllic chloroplasts. The C_4 acid is transported to the bundle sheath cells. It was shown that the active enzyme, but not the enzyme in its inactive disulfide form, is irreversibly inactivated by the thiol-reacting reagent N-ethylmaleimide. In accordance with its physiological function, the production of C_4 acid, the affinity toward malate is low as compared with the other substrates. Ashton and Hatch [238] published the following data: $K_{m/NADP} = 45\ \mu M$, $K_{m/NADP} = 50\ \mu M$, $K_{m/malate} = 24$ mM, and $K_{m/oxaloacetate} = 18\ \mu M$.

The catalytic activity of NADP-MDH (malate dehydrogenase specific for $NADP^+$) is rapidly and reversibly inactivated when leaves are darkened. The same observation can be made with isolated mesophyllic chloroplasts from maize [239]. Light activation can be inhibited by 3-(3,4-Dichlorophenyl-1,1-dimethylurea (DCMU), and thiol reagents like DTT are essential to keep the catalytic activity in leaf extracts [239,240]. Thioredoxin *m* has been shown to be involved in the light-dependent activation of NADP-MDH [241–245]. The degree of activation of NADP-MDH varies with light intensity, and it has been concluded that high catalytic activity depends on the conditions of the rapid ferredoxin-mediated reduction of thioredoxin *m* [246]. This interpretation is supported by the finding of Leegood and Walker [247] that adding oxaloacetate or 3-Phosphoglycerate (3-PGA) reduced the level of activation of NADP-MDH possibly via $NADP^+$ production by the reduction of these substrates. The enhanced $NADP^+$ concentration inside the mesophyllic chloroplasts results in a decrease of the steady-state level of reduced ferredoxin and hence reduced thioredoxin.

Such correlations are important for the understanding of salt-stress–induced variations of enzyme activity as well. Experiments with maize leaves [248–250] indicate that the level of NADP-MDH activity under physiological conditions depends on the source to sink ratio of photosynthesates: Reducible substrates (oxaloacetate and 3-PGA) produced by CO_2 fixation result in an increased $NADP^+$ level and a decrease of the ferredoxin (thioredoxin *m*) redox state and the degree of NADP-MDH activation. Finally, it has to be kept in mind that low O_2 concentrations inside the mesophyllic chloroplast will decrease the rate of direct oxidation of thioredoxin *m*, and this would favor an increase in the activation state of NADP-MDH [246].

NADP$^+$-Malic Enzyme

The $NADP^+$-malic enzyme (NADP-ME, EC 1.1.1.40) catalyzes the oxidative decarboxylation of malate to form pyruvate and CO_2 inside the bundle sheath chloroplasts. Pyruvate subsequently is transported back to the mesophyll. The decarboxylation is paralleled by a reduction of $NADP^+$, thus providing NADPH for the Calvin cycle.

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

$$\text{Malate} + \text{NADP}^+ <=> \text{Pyruvate} + \text{NADPH} + \text{CO}_2$$

NADP-ME is sensitive to malate, pH, and Mg^{2+} in a manner indicating that it probably is largely inactive in the dark. It is activated by coenzyme A and fructose-1,6-bisphoshate, which increases its activity 4- and 16-fold, respectively. Chloride and nitrate are inhibitory ligands; high levels of bicarbonate give some inhibition [251]. In summary, it may be speculated that there are both direct and indirect effects of salinity on the catalytic activity of this enzyme.

Pyruvate, Phosphate Dikinase

Pyruvate, phosphate dikinase (PPDK, EC 2.7.9.1) catalyzes the reversible phosphorylation of pyruvate to form phosphoenol pyruvate (PEP) [252–254]:

$$\text{Pyruvate} + \text{ATP} + \text{P}_\text{i} <=> \text{PEP} + \text{AMP} + \text{PP}_\text{i} + 2\ \text{H}^+$$

In C_4 plants, the operation to form PEP inside the mesophyllic chloroplasts is favored by the presence of very high levels of adenylate kinase and pyrophosphate activities [255]. The fact that the PPDK activity is lowest among the C_4 cycle enzymes and close to the observed rates of photosynthesis in C_4 leaf tissues suggests that this enzyme might catalyze the rate-limiting step of C_4 photosynthesis [246,255–257]. This view is supported by the fact that the activity is subject to many regulatory controls. PPDK from maize has been purified by Sugiyama [258]. The enzyme has a molecular weight of 387 kDa and represents a tetramer of its 94-kDa subunit. The enzyme is inactivated in the absence of Mg^{2+} and dithiol compounds like DTT. Inactivation in the absence of Mg^{2+} results in the dissociation of the active tetramer to an inactive dimer.

The isolated enzyme from maize can be protected from dissociation not only by the addition of Mg^{2+} but also by high concentrations of sugars, polyols, and pyruvate [246]. This Mg^{2+} dependency suggests that the PPDK activity may be reduced if external salts compete with Mg^{2+} for uptake. Andrews and Hatch [252] proposed a two-step mechanism for catalysis:

$$\text{Step 1: PPDK} + \text{ATP} + \text{P}_\text{i} <=> \text{PPDK-P} + \text{AMP} + \text{PP}_\text{i}$$
$$\text{Step 2: PPDK-P} + \text{Pyruvate} \Leftrightarrow \text{PPDK} + \text{PEP}$$

They observed that the PEP/pyruvate exchange required Mg^{2+} but not other substrates, and the AMP-ATP exchange was very strongly affected by varying both P_i or PP_i concentrations. The requirement for Mg^{2+} in excess of ATP under in vitro conditions could not be overcome by the addition of other divalent cations like Mn^{2+} or Ca^{2+}. Moreover, the activity of the maize enzyme can be stimulated by both ammonium ions and K^+ but not by Na^+ [246].

In vivo PPDK activity declines in the dark and is rapidly reactivated on illumination of maize leaves. For activation of phosphate, Mg^{2+} and a reducing agent (DTT under in vitro conditions) are required. But it was clearly shown by several investigators that the thioredoxin system is not involved in PPDK activation [246]. A protein factor, PDRP (a dimer consisting of two identical 45-kDa subunits) exclusively located in the mesophyllic chloroplasts is involved in ATP as well as in ADP-dependent inactivation and light-dependent activation of the PPDK catalytic activity [259].

ADP-dependent inactivation is inhibited by oxalate. On the other hand, oxalate as well as pyruvate are inhibitors of catalysis [260,261]. The transfer of the β-phosphate from ADP phosphorylating a PPDK threonine residue is one possibility to inhibit the catalytic activity. In the presence of ATP, a histidine residue of the catalytic site becomes phosphorylated, and this phosphorylation also results in an inhibition of the enzyme. During light-dependent reactivation, the phosphate is transferred on orthophosphate to form pyrophosphate. This reaction can be inhibited in vitro by the addition of AMP, ADP, or PP_i.

It has been clearly shown that the rate of ADP-mediated PPDK inactivation depends on the phosphorylation status of the enzyme. This status is controlled by the ATP/AMP and pyruvate/PEP ratios inside the mesophyllic chloroplasts. Activation of catalytic activity is brought about by a high-energy charge resulting in a high ATP/ADP ratio in the chloroplast. Relatively small changes in

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

the level of the energy charge result in dramatic changes in the relative activity of the PPDK population. These observations imply that salt stress might affect the PPDK activity not only via competition among cations but also by variations of the energy status and the metabolite concentrations inside the mesophyllic cells. Such variations will be brought about by increased ATPase activities under salinity.

Photorespiration and Nitrogen Metabolism

Labeling studies with $^{14}CO_2$ and $^{18}O_2$ have indicated that glycine and serine are synthesized in C_4 plants particularly under conditions of high O_2 or low CO_2 [262–265]. Using isolated bundle sheath strands, Farineau et al. [264] demonstrated the incorporation of $^{14}CO_2$ into glycine and serine in maize at low bicarbonate concentrations. The addition of α-hydroxypyridinemethanesulphonic acid, an inhibitor of glycollate oxidase, resulted in both a reduced ^{14}C-labeling of glycine and serine and an increased labeling of glycollate. In a similar experiment, isoniazid, an inhibitor of glycine decarboxylase, increased the labeling of glycine and decreased that of serine. These data suggest that, even in C_4 plants, there can be an appreciable metabolism of carbon through the photorespiratory pathway under some conditions. It must be assumed that the majority of the CO_2 evolved during photorespiration in C_4 plants is immediately reassimilated by Rubisco and is not lost from the bundle sheath cells [266].

A major source of cytosolic NADH for the reduction of nitrate is a malate/oxaloacetate shuttle that operates in green leaves between the chloroplasts and the cytosol. In the leaves of C_4 plants, photorespiration is restricted to bundle sheath cells, whereas nitrate assimilation is found in the mesophyll [267]. If the pyruvate dehydrogenase complex (PDC), located in the mesophyllic cells, were sensitive to ammonia produced by photorespiration, the spacial separation in the mesophyll and bundle sheath, respectively, would result in a protection of the PDC. The advantage of the C_4 morphology would thus be twofold: Photorespiration is reduced relative to its contribution in C_3 photosynthesis and the ammonia production by photorespiration and nitrate reduction are spacially separated in C_4 plant leaves [268].

The actual separation of reductive steps in the bundle sheath and mesophyllic cells of C_4 plants would contribute to reduce photorespiration in the bundle sheath cells and enhance the potential NADH supply derived from the malate shuttles in the mesophyllic cells. In mesophyllic cells, the NADPH produced in the chloroplasts can be used to reduce oxaloacetate or the 3-phosphoglycerate imported from the bundle sheath. The reduction products from either reaction would then be available to generate NADH in the cytosol, which in turn is available for nitrate reduction. Thus, the compartmentation of metabolism in C_4 plants is designed for the maximal supply of NADH to the cytosol.

Nitrate reductase has been shown to be light activated via ATP and Mg^{2+}-dependent protein phosphorylation [269]. Any treatment that affects the levels of cytosolic ATP or Mg^{2+} concentrations can inhibit the light-mediated activation of the enzyme. Moreover, salts competing with Mg^{2+} for uptake into the cytosol or affecting the malate/oxaloacetate status of the cell will interfere with the nitrate reduction and affect growth.

Biosynthesis of Compatible Solutes

Glycinebetaine is synthesized by many halophytes and is thought to play an important role in the salt tolerance of these species as a compatible osmotic solute [270]. In higher plants, glycinebetaine is synthesized from choline in a two-step, chloroplast-localized pathway [270]. Whereas homozygous glycinebetaine-accumulating maize plants exhibit less severe growth inhibition than near isogenic glycinebetaine-deficient plants under salinity stress, the high glycinebetaine accumulation in maize appears to be associated with a 5% grain yield penalty under well-irrigated field conditions [271]. Glycinebetaine is a known growth stimulant of certain pathogenic fungi; thus, it is plausible that glycinebetaine accumulation in maize confers susceptibility to stalk pathogens.

In leaves of maize, starch is usually exclusively located in the bundle sheath chloroplasts. However, on continuous illumination with high-light intensity, enzymes necessary for starch synthesis appear in the mesophyllic chloroplasts and starch synthesis takes place there as well [272]. The major portions of sucrosephosphate synthase, fructose-6-phosphate kinase, and fructose-2,6-bisphosphate are present in the mesophyll. In line with this observation, sucrose synthesis occurs predominantly in the mesophyll and sucrose has to be transported through the bundle sheath cells to the phloem [272].

The accumulation of carbohydrates in source leaves leads to the inhibition of photosynthesis and the concomitant decrease in Rubisco protein, some Calvin cycle enzymes, and chlorophyll. Jang and Sheen [24] used a maize protoplast transient expression system to monitor the effects of a variety of sugars and metabolic intermediates on the promoter activity of genes encoding photosynthetic enzymes. Glucose and other substrates of hexokinase, but not the phosphorylated products, acted as repression signals. Therefore, hexokinase was proposed to mediate the sugar-sensing control of metabolic pathways. Potential intermediary steps in signaling have been implied for protein phosphorylation/dephosphorylation and Ca^{2+}/calmodulin [25,26]. These data suggest that building high concentrations of photosynthesate to compensate for the external osmotic potential of salts not only sequesters sugars from metabolism in maize but also the decreases the expression of C_3 and C_4 cycle enzymes.

Summary of Salinity Effects on Maize Photosynthesate Metabolism

From the above discussion, it becomes obvious that salinity affects metabolism mainly at two levels: gene expression and enzyme catalysis. Moreover, it appears to us that there are only a few key reactions responsible for bringing about a cascade of secondary responses. In this context, it is interesting to note that enzyme patterns and chloroplastic morphology are not strictly coupled, and that metabolic pathways may become varied. Preiss et al. [50] could show, for example, that malate may become an additional substrate to acetate to form fatty acids, when in the chloroplasts of young maize plants, the C_4 pathway becomes dominant over the C_3 pathway.

Recent discussions of the salinity effects on maize metabolism are based on the results published by Aoyagi and Bassham [273] and Crespo et al. [274]: Pulse-chase–labeling and enzymic studies indicated that maize leaves begin to express C_4 enzymes during several stages of their differentiation. Full C_4 photosynthesis is probably missing in the base section of young maize seedlings and appears later in the middle and top section of the leaves [273]. In a study of 1- to 5-week old *Zea mays* plants, different activities of PEPC and Rubisco have been found in the lower and upper leaves. The data have been interpreted as indicating the existence of C_3 and C_4 pathways in the same plant [274].

In leaves of graminaceous plants, cell divisions occur primarily in the basal meristem, with older cells being displaced by younger cells below them. This process results in a positional gradient of cell ages with younger, less-differentiated cells at the base and older, more-differentiated cells toward the tip of each leaf. This developmental gradient has been used by several investigators to examine the aspects of leaf development in maize [23,275–277]. Although small quantities of PEPC mRNA are detectable in the basal region of the leaf, a significant mRNA accumulation is coincident with that of the polypeptide at 4–6 cm from the leaf base [278]. The strict correlation between PEPC mRNA and its protein concentrations suggests that regulation of the genes encoding this enzyme may be primarily transcriptional [278].

A recent study [23] has investigated whether salinity interferes with the induction of the C_4 type enzyme patterns in maize. Twenty-one days after germination, one half of a well-watered maize population was stressed with an additional 50 mM NaCl in the nutrient, and development and enzyme patterns were watched during the following 3 weeks. In order to monitor the development of C_4-type metabolism in the fourth leaf, it was portioned into five sections (tip to base) and PEPC, NADP-MDH, and GAP-DH activities isolated from these portions were measured day by day. The central

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

results of the experiment can be summarized as follows: (a) Salinity reduces leaf growth (increase of fresh weight) and leads to an increase of extractable enzyme activity. (b) The enzyme pattern in the leaf tip section at the beginning of salinization (day 21 after germination) already represented the C_4 type and did not vary during the rest of the experiment. (c) All five leaf sections of the control plants showed the same C_4-type enzyme pattern 4 weeks after germination indicating that the fourth leaf was differentiated at this time. The salt-stressed plants, on the other hand, did not finish differentiation during the course of the experiment. (d) Most interesting is the result that the activities of the C_4 pathway enzymes PEPC and NADP-MDH remain strictly coupled, although these enzymes are localized in the mesophyllic and bundle sheath cells, respectively.

In analogy to the above-discussed variation of Rubisco activities in the mesophyllic and bundle sheath cells during the initiation of the C_4 metabolism in young leaves, a ground state of the enzyme pattern with glycerinealdehydephosphate dehydrogenase (GAPDH) present in the mesophyll and bundle sheath may be assumed. As enzyme activities have been measured after extraction from the leaf sections, increasing enzyme activities in the extracts have to be attributed to a newly synthesized enzyme protein. It is a generally accepted observation that the induction of the C_4 enzyme pattern needs high light intensity. Taken together with the observation that photosynthesates are capable of regulating the expression of genes and hexokinase may function as a sensory element [22–26], it may be concluded that the primary metabolites of CO_2 fixation are active in C_4 gene activation as soon as their concentrations in the cytosol reach a threshold value. Consequently, it may be concluded that C_3-C_4 pathway maturation will be affected under salt stress, because photosynthesate becomes sequestered inside the vacuoles in response to salinity. Such an interpretation would suggest that salt affects the differentiation of the pathway of CO_2 fixation by reducing the concentration of photosynthesate. The most probable way to bring about such a reduction is by sequestering photosynthesates inside the vacuole as a response to a salt-stress signal transmitted from the maize root system.

Water Stress and Alfalfa Production

MICHAEL J. OTTMAN
University of Arizona
Tucson, Arizona

ALFALFA ADAPTATION

Alfalfa (*Medicago sativa* L.), or lucerne as it is sometimes called, is a perennial herbaceous plant with superior forage quality. It is the most important forage crop in the world and was the first forage crop to be domesticated [1]. Alfalfa is a legume, and it is able to fix nitrogen from the air through a symbiotic relationship with *Rhizobium* bacteria. It has a tap root that can reach 11 m or more that allows it to escape drought [2]. Alfalfa becomes dormant during periods of drought and will resume growth once water becomes available. Alfalfa can be feed as hay, green chop, silage, cubes, pellets, or grazed.

Alfalfa originated in areas with hot, dry summers in the Near East (Iran) and Central Asia [1]. Alfalfa spread long before recorded history and is found on every continent [1]. Alfalfa may have been disseminated as early as 7000 BC from Mesopotamia through trade with other regions [3]. It has become adapted to many areas throughout the world since its original spread from its center of origin thousands of years ago. Alfalfa is best adapted to the temperate zones throughout the world and prefers slightly alkaline, well-drained soil. Most of the world's alfalfa production is centered in the United States, Argentina, southern Europe, and parts of the former Soviet Union [4]. It can survive in extremely cold areas, but other forage crops are better adapted in these regions. Alfalfa is not usually grown in the tropics because of problems with disease, weeds, and stand life and of poor curing conditions. Stands do not last more than 2–3 years in many regions of the southern United States owing to factors other than acid soils or drought stress [5]. The highest alfalfa yields are obtained in warm, arid areas where production is possible nearly year round.

Alfalfa growing regions have been classified according to temperature, latitude, and precipitation [6–8]. Water stress may occur in both humid and arid regions. Water stress in humid regions may occur as a result of inadequate soil moisture at the start of the season or untimely rainfall or drought during the season. These episodes of water stress in humid regions may occur frequently, but they are not common or severe enough to warrant the expense of an irrigation system. Water stress rather than direct temperature effects is responsible for decreased mid season growth that occurs in many alfalfa production regions of North America [9]. Water stress can occur in arid regions even with irrigation. The irrigation system, for example, may not be engineered to meet

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

peak water demands by the crop during the hottest part of the year. Sometimes irrigation systems fail because of mechanical breakdowns, problems with the uniformity of water distribution, or the unreliability of the water-delivery system to the farms. In addition, during peak water-use periods, other crops on a farm may also require water and have priority over the water originally designated for alfalfa. Whether in humid or arid regions, water stress commonly limits alfalfa production.

ALFALFA WATER REQUIREMENTS

Water use is driven by solar radiation, temperature, wind speed, and crop canopy development [10]. Seasonal water use also is affected by the number of cuttings or the length of the growing season and cultural factors that enable the crop to reach its yield potential. Seasonal evapotranspiration in alfalfa can range from 407 mm in Geneva, NY [10], to 1887 mm near Phoenix, AZ [11]. Maximum daily water use can be near 0 on rainy days to 9–15 mm d^{-1} in Saudi Arabia [12]. The highest consumptive use is obtained when the days are longgst in June and July in most areas. The consumptive use during other months is less, being almost in proportion to day length. The monthly consumptive use curve for alfalfa is bell shaped with a peak in June and July and ''tails'' at the beginning and end of the growing season [11]. An example of seasonal water use for alfalfa compared with other crops near Phoenix, AZ, is 1887 mm for alfalfa, 1046 mm for cotton, 993 mm for oranges, 902 mm for wheat, and 216 mm for lettuce [11]. Alfalfa has high seasonal water use compared with other crops, since it is a perennial crop with a long growing season.

Forage yield and root mass are related to evapotranspiration. Evapotranspiration and forage yield are linearly related in alfalfa [13–15] and other crops. The relationship between evapotranspiration and grain yield, however, is often curvilinear owing to a higher proportion of vegetative growth compared with grain at higher evapotranspiration levels [16,17]. After water stress is relieved, growth greater than normal has been observed [18]. However, compensatory growth is sometimes due to an increased leaf growth and not stem length or dry matter, which may actually be reduced [19]. The relationship between evapotranspiration and root mass is curvilinear [20]. In the case of water stress, however, root growth can be affected positively or negatively. Salter et al. [21] measured a decrease in root weight but an increase in root fibrousness as water stress increased. Root growth may be increased by limited water stress under low evapotranspirational demand but the opposite may occur under high evaporative demand [22].

Water-use efficiency (WUE), or the ratio of crop production to evapotranspiration, has been reported in alfalfa to decrease with water stress [23,24]; increase with water stress [25], especially if evaporative demand is low [24]; or not be affected by water stress [26]. The relationship between water-use efficiency and water stress is inconsistent possibly due to the type of water stress or factors other than water stress affecting yield. Water-use efficiency for alfalfa varies considerably and examples of reported values are 1.0 kg m^{-3} in the Imperial Valley of California [26]; 1.0–3.0 kg m^{-3} in Minnesota [27], 1.2 kg m^{-3} composited from Las Cruces, NM, Reno, NV, North Dakota, and Nebraska [28]; 1.2–2.3 kg m^{-3} in North Dakota [29], and 2.3 kg m^{-3} in the San Joaquin Valley of California [15]. In Israel, a seasonal decline in WUE was reported from 2.8 kg m^{-3} between April and early June to 1.0 kg m^{-3} in August [30]. The seasonal decline in WUE reported in hot areas has been attributed to high nighttime temperatures that reduce forage yield [31]. Reported values of WUE for alfalfa compared with other crops are 1.2 kg m^{-3} (alfalfa), 1.8 kg m^{-3} (wheat and cotton), 2.9 kg m^{-3} (corn), and 3.3 kg m^{-3} (grain sorghum) [32].

If we assume that alfalfa has a water-use efficiency of 1–3 kg m^{-3}, then 100–33 mm of water, respectively, will be consumed in evapotranspiration to produce 1 t ha^{-1} of alfalfa. In low rainfall areas, more irrigation water needs to be applied than is actually consumed by the crop owing to the nonuniformity of application and losses from evaporation, runoff, and deep percolation. Nevertheless, water-application efficiency, or ratio of evapotranspiration to applied water, is usually high for alfalfa, since it is a deep-rooted crop [33,34]. Water-application efficiencies reported for Arizona crops are 75% for alfalfa, 76% for cotton, 62% for wheat, 31% for lettuce, and 22% for oranges

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

[34]. Water-application efficiencies vary depending on the type of irrigation system and how well it is managed. The amount of irrigation water applied and yield are linearly related in alfalfa [28,29,35] similar to consumptive use and yield, but the relationship becomes curvilinear at high levels of water application. If more irrigation water is applied than the plant can use, additional increases in yield will not be obtained. Alfalfa can extract water from depths of 11 m [2], but the effective rooting zone for water extraction has been reported to be 2.4 m for irrigated alfalfa [11,36]. The actual effective rooting zone can vary, of course, depending on soil characteristics, irrigation practices, amount and distribution of rainfall, and depth of the water table. A water-uptake pattern of 46–26–18–10% over depth increments of 0.6 m has been reported [37]. The water-uptake pattern can differ depending on the amount of water available in various soil layers and other factors.

ALFALFA RESPONSE TO WATER STRESS

The water status of plants is usually described by the water potential. The water potential is the sum of the osmotic, pressure, matric, and gravitational potentials [38]. The osmotic potential is related to the solute concentration, the pressure potential is the pressure or turgor exerted against the cell wall, the matric potential is capillary or adsorptive forces, and the gravitational potential is the component attributed to gravity. The matric and gravitational potentials are usually small and can be ignored. The plant maintains turgor as the water potential decreases by increasing the solute concentration. Turgor pressure maintenance allows stomates to remain open, photosynthesis to continue, and growth to be uninterrupted. Alfalfa yields usually decline once the plant water potential falls below -1.0 to -1.5 MPa [15,39–41]. The plant will close its stomates under water stress in an attempt to maintain turgor. Stomatal closure prevents CO_2 from entering the plant and affects carbon fixation, photosynthesis, and growth.

Stomatal closure causes the canopy temperature to increase. Stomatal closure due to water stress elevated the leaf temperature by 8.5°C in the study of Carter and Sheaffer [41]. The crop water stress index (CWSI) uses this change in the leaf or canopy temperature to assess the water status in alfalfa and other crops. The CWSI normalizes the differences between the air and canopy temperature using the vapor pressure deficit (VPD). Water stress decreases the difference between the canopy and air temperature [24]. Yield is linearly related to the CWSI in alfalfa but quality is not predicted adequately [42]. The canopy temperature and the related CWSI values can differ based on dormancy class [43]. Temperature stress days (TSD) [44] and the difference between canopy and air temperature [45] have been used as indicators of water stress, but the CWSI is superior, since it accounts for environmental differences. The canopy temperature and associated parameters such as evapotranspiration, leaf conductance, and leaf water potential usually cycle diurnally under high moisture conditions but the leaf conductance and the water potential may remain low throughout the day if the water stress is severe [41,46].

The first outward signs of water stress in alfalfa is the blue-green or gray-green appearance of the plant and wilting and cupping of leaves. Cupping is related to a decline in the plant water potential [47] and to an ambient vapor pressure deficit [48]. The stems become shorter and thicken and fewer are produced. Water stress causes leaf cells to become smaller, which reduces water loss under arid conditions [49]. In cool climates, plants selected for larger leaves are expected to have a greater water-use efficiency under water stress than plants with smaller leaves owing to a higher growth rate and reduced transpiration rate [23]. However, when stomates are closed, small leaves reduce the increase in leaf temperature above air temperature [50]. Plants subjected to water stress have lower cell wall, neutral sugar, and glucose concentrations [51]. Water stress decreases the leaf chlorophyll concentration [52]. Water stress increases the epicuticular wax production but the wax production was not found to decrease cuticular transpiration [53]. Alfalfa exhibits heliotropism, adjusting its leaf surface perpendicular to the sun (diaheliotropism) early and late in the day and adjusting its leaf surface to avoid the sun (paraheliotropism) at midday [48]. Paraheliotropism is assumed to be a stress-avoidance mechanism, but no clear relationship has been shown between

paraheliotropism and the xylem water potential [48]. However, Moran et al. [54] showed that water stress diminished diurnal tracking of the sun by alfalfa leaves and the canopy assumed a more vertical profile compared with well-watered plots.

Certain biochemical changes occur because of water stress. Water stress results in an increase in the total amino acid concentration in the phloem of alfalfa, especially of proline [55]. Asparagine accounts for up to 70% of the amino acid content in the phloem sap of alfalfa but does not vary with water stress [55]. The ability to metabolize oxidants may be an important adaptation to water stress [56]. The maintenance of leaf cytokinins also is important during drought, and mycorrhizal symbiosis may play a role in this process [57]. Abscisic acid appears to mediate adaptive responses in plants to a variety of stresses including water deficit. Yeast and animals use kinase to mediate stress signals, and the kinase pathway mediates drought in alfalfa independent of abscisic acid [58]. A family of genes exist in alfalfa that encode a group of proteins that are inducible by abscisic acid and environmental stresses [59].

Photosynthesis, respiration, and nitrogen fixation are decreased by water stress. The net photosynthesis usually declines with water stress owing to closing of stomates or nonstomatal factors. Nonstomatal factors have been shown to be of equal or major importance compared with stomatal factors [60,61]. Nonstomatal factors responsible for a decrease in the net photosynthesis from water stress include decreased light-saturated photosynthetic activity, apparent quantum yield, electron transport rate, intercellular response to CO_2, and RuBP carboxylase activity [61]. Alfalfa plants suffering from water stress increase the partitioning of photoassimilates to the roots [19]. Respiration decreases under severe water stress in alfalfa [62] or, in other forage species, if water stress causes stomatal closure [63,64]. Water stress decreases symbiotic nitrogen fixation in alfalfa [14,62,65]. Nitrogenase activity and nodule number and size is reduced by water stress [66,67]. Nodules may resume activity when water stress is relieved or may be shed under severe water stress [68]. Symbiotic nitrogen fixation requires 1–2 days to recover once water stress is relieved [69]. Mychorrhizal symbiosis may play a role during drought by maintaining the leaf cytokinin levels [57].

Alfalfa quality is usually increased by water stress, since stem growth is slowed [40] resulting in an increased leaf to stem ratio [14,70]. In some studies, however, quality components were not consistently affected by water stress [14,27]. The effect of water stress on alfalfa quality depends on the timing and severity of the stress. If water stress is severe enough to cause leaves to shed, then quality can decrease. Stress at the bud or flower stage after the stem has extended also can decrease forage quality owing to a reduction in the leaf to stem ratio from leaf loss and a deterioration of leaf quality [71]. A forage quality increase due to water stress is accounted for mainly by the slowing of growth and a delay in maturity [70]. Water stress also can increase the quality of forage by decreasing the cell wall concentration [51,70] but not necessarily the cell wall degradability [51]. Water deficit can increase in vitro digestible dry matter and crude protein [70,72] and increase concentrations of Ca, Mg, Zn, K, and P in the entire plant [72,73].

Alfalfa may adapt to water stress through avoidance or tolerance mechanisms. Increased root mass and depth of rooting are examples of dehydration avoidance [21,30,49]. A small root system may restrict water loss and delay the onset of drought. Mild dehydration tolerance is related to the accumulation of osmotically active substances such as proline and sucrose [50,74,75]. Osmotic adjustment maintains turgor and is related to tolerance of low water potential [76], may enhance water uptake by maintaining root extension [50], and delay the time to reach the lethal leaf water content [77]. Sucrose and proline not only serve as osmoticants but also as protectants of membranes and proteins during dehydration [78–80]. In more extreme cases of water stress, the tolerance of protoplasmic dehydration is necessary for the plant to survive [81].

PRODUCTION FACTORS

Many factors related to alfalfa production affect water stress directly or indirectly. Deep ripping increases root development and the water infiltration rate [82]. The addition of manure before plant-

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

ing can increase soil porosity and water penetration [83]. Firming of the seedbed may be necessary if soil moisture is limiting for better seed/soil contact and stand establishment [84]. If soil moisture conditions are not favorable, deeper seeding is recommended than if moisture conditions are optimum [84]. Companion crops seeded with alfalfa help control wind and water erosion and suppress weeds but compete with alfalfa for water as well as light and nutrients. Placing a band of phosphorus fertilizer near the seed at planting time is advantageous on low-fertility soils when dry periods follow seeding [85,86]. Increased water availability increases top growth and uptake of all major and secondary nutrients [87]. Water stress decreases the yield benefit of P and K fertilization [88,89], and P fertilization increases water-use efficiency [88]. The addition of lime to acid subsoils has been observed to increase root penetration [90,91] and performance under water stress should improve. Soil ammendments such as gypsum or sulfur increase water infiltration in sodic soils and thereby decrease susceptibility to water stress. Harvest schedules are usually dictated by soil moisture conditions, especially in irrigated areas. Cutting too early when the soil is wet can compact the soil, which could result in water infiltration and water-stress problems later. Cutting too late may result in yield and quality losses from water stress, and inadequate soil moisture for regrowth while the hay is drying in the field before irrigation water can be applied.

Water stress usually lessens the expression of alfalfa diseases that are associated with excessive soil moisture. For example, fewer symptoms of verticillium wilt (*Verticillium albo-atrum* Reinke et Berth) were observed under drought stress than nonstressed conditions, and verticillium wilt altered the leaf potential [92] and reduced the stomatal conductance under drought [93]. Low soil moisture reduced the effects of the stem nematode (*Ditylenchus dipsaci* [Kühn] Filipjev) and fusarium wilt (*Fusarium oxysporum* f. sp. *medicaginis*) [94]. Phytophthora root rot (*Phytophthora megasperma* [Drechs] f. sp. *medicaginis* Kuan & Erwin [Pmm]) is associated with excess soil moisture, and relieving saturated soil conditions can help control the disease. Scald is a physiological disease caused by flooding during periods of high temperatures that can be managed by avoiding standing water.

Water stress adversely affects insects such as potato leafhopper (*Empoasca fabae* Harris) and silverleaf whitefly (*Bemecia argentifolia*). Potato leafhoppers tend to probe fewer cells and cause less injury if the alfalfa plant is water stressed [95]. Under water stress, potato leafhopper population declined by half, the development period of the nymphs increased, and adult survivorship, fecundity, and oviposition rates decreased with water stress [96,97]. Silverleaf sweetpotato whitefly damage was less on water-stressed compared with well-watered alfalfa, presumably because the insect preferred the more succulent growth of the well-watered plants [98].

Excess soil moisture and loss of the alfalfa stand can lead to weed infestation. Certain weeds can survive saturated soil conditions in contrast to alfalfa. Alfalfa can usually survive when soil moisture is low, whereas many weeds desiccate. In fact, summer irrigation termination was commonly practiced as a weed-control measure in the southwestern United States until the early 1960s when effective herbicides were introduced.

SUBOPTIMAL IRRIGATION STRATEGIES

Suboptimal irrigation strategies for alfalfa include deficit irrigation and irrigation termination. Deficit irrigation involves applying less irrigation water than the crop actually needs by altering the amount or frequency of the irrigation. The irrigation amount can be altered with sprinkler irrigation systems by applying a certain percentage of the crop evapotranspiration requirement. Yield decreases in direct proportion to the difference between the amount of water applied and the amount of water required for maximum yield in a particular environment [15]. Irrigation frequency can be altered by applying fewer irrigations. Irrigating once per cutting resulted in 87% of the yield of irrigating twice per cutting in the study of Frate et al. [99]. Water-application efficiency, or the ratio of evapotranspiration to applied water, often increases with deficit irrigation, since irrigations are applied to relatively dry soils and less water is potentially lost to deep percolation and surface runoff.

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

Irrigation termination usually involves not irrigating alfalfa for one or several cuttings. Irrigation termination has the advantage of not incurring production costs but the disadvantage of potential residual effects on yield even after irrigations are resumed. Some of the earliest research on alfalfa irrigation termination was conducted at Mesa, AZ, by Schonhorst et al. [100]. In this study, stands were actually enhanced if alfalfa irrigation was terminated during the summer for two cuttings and yields recovered when irrigations resumed. Schneiter [101] conducted a similar study in Tucson, AZ, and found that alfalfa stands and subsequent yields were not damaged by withholding irrigation water during the summer. Alfalfa yields recovered in the second cutting after irrigations were resumed in an irrigation termination study in the San Joaquin Valley of California that included a July/August irrigation skip and an irrigation termination from July to the following season [99]. Irrigation termination lasting two cutting cycles during the summer had no long-term effect on the alfalfa yield in Cyprus, but the yields were reduced by 20% the first harvest after irrigations were resumed [102]. Drought stress that lasted 2 and 8 months did not affect alfalfa growth the following winter and early spring in Israel [30]. In a study conducted in the Imperial Valley of California, alfalfa stands were not affected by irrigation termination the first and second years presumably owing to the reliance on subsoil moisture during the termination period but were severely reduced the third year [98]. Hay yields generally rebounded by the second cutting after irrigations were resumed except during the third year where modest yield reductions were noted. Irrigation termination treatments resulted in soil salt build-up and increased weed pressure. Ottman et al. [103] conducted irrigation cutoff studies at Maricopa and Yuma, AZ. At Maricopa, alfalfa yields following the summer termination treatment were not affected the first year, but, in the second year, were 67% of the control the first cutting after irrigations were resumed and 85% of the control the second and similar thereafter. The summer, fall, and winter termination strategy resulted in reduced alfalfa yields for most cuttings even after irrigations were resumed. On an alfalfa stand at the Yuma location, summer irrigation termination (July through October) resulted in severe stand loss (33% of the control) and permanent productivity damage. Winter irrigation termination (November through February) had no effect on the alfalfa stand and reduced yield 41% during the termination period. Stand loss occurs when the crown moisture content drops below 40%, according to Wissuwa et al. [104], and can be used as a guideline of when to reirrigate alfalfa to avoid permanent damage. Whether crown desiccation is a cause or effect of stand loss that can occur during irrigation termination is not known. A decrease in root nonstructural carbohydrates has been correlated with stand loss during irrigation termination in one study [105] but no correlation was found in another study [103]. Irrigation cutoff strategies have resulted in greater applied water-use efficiency or more forage produced per unit of water applied [99,100,103]. However, applied water-use efficiencies also have been decreased by irrigation cutoff strategies if yields after irrigations are resumed are permanently damaged [98,103].

Alfalfa is a deep-rooted crop that can deplete subsoil moisture. The classic work of Kiesselbach et al. [2] demonstrated the importance of subsoil moisture to depths up to 10 m for alfalfa production. If shallow water tables are present, surface irrigation can be reduced [106]. The success of suboptimal irrigation strategies may depend on the availability of subsoil moisture to maintain the crop during periods of water stress.

Salinity Tolerance in Turfgrasses

KENNETH B. MARCUM
University of Arizona
Tucson, Arizona

INTRODUCTION

The importance of turfgrass has increased rapidly in the last several decades. In 1993, the annual expenditure for maintaining turfgrass in the United States, including labor but excluding capital expenses, was approximately $45 billion [1]. This was double the amount reported in 1985. And turfgrass maintenance expenditures in the United States are projected to be $90 billion by the year 2000 [2].

The need for salt-tolerant turfgrasses is ever increasing. Growth of the turfgrass industry, accompanied by rapid urban population growth, has put enormous pressures on limited freshwater supplies. Many state and local governments have reacted by placing restrictions on the use of potable water for irrigating turfgrasses. This is particularly evident in a number of western states, where current laws now *require* the use of saline secondary water sources (such as effluent) for irrigation of golf courses and other large turf facilities [3,4]. In coastal states, where urbanization also has been particularly rapid, overpumping, and resultant salt water intrusion of coastal wells used for irrigating turf facilities has widely occurred [5,6]. Finally, in northern areas, the use of salt for deicing roads has resulted in soil salinization along roadsides planted to turfgrass [7].

DEFINING SALINITY TOLERANCE IN TURFGRASSES

Although substantial differences in salinity tolerance exist among turfgrasses [8–10], many environmental, edaphic, and plant factors also interact with salinity level to influence plant salinity tolerance [11–14]. Salinity tolerance often differs with the stage of plant development (e.g., seedling, juvenile, mature) [15]. Climatically, temperature, relative humidity, and air pollution can influence the plant response to salinity [11]. For example, most plants are more sensitive to salinity under hot, dry conditions than under cool, humid ones, probably due to increased evapotranspirational demand, favoring increased salt uptake [16]. Air pollution increases the apparent salt tolerance in oxidant-sensitive crops [11]. Edaphic factors also influence the plant response to salinity [12,13]. Soil water content changes have a direct effect on rootzone salinity. Indeed, soil salinity varies with time and depth, increasing as the soil dries between irrigations, and also as depth increases, with salt

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

concentrations approximately that of the irrigation water near the soil surface, to many times higher at the bottom of the rootzone [11,17]. In most saline situations, sodicity problems can occur, as the primary ion in most saline soils is sodium. In finer textured soils, this can result in anaerobic conditions in the rootzone, which can have a more profound effect on plant growth than the salinity itself [13,17]. To minimize the effects of variable edaphic and climatic conditions on plant responses to salinity, some researchers have utilized solution or hydroponic culture under controlled environmental conditions (growth chambers, greenhouses) in plant salt-tolerance research.

Owing to interacting factors discussed above, the ''absolute'' salinity tolerance level of a particular genotype or cultivar cannot be determined [11,12]. For example, the salt tolerance of Bermudagrass cv. Tifway, indicated as the level of salinity required to reduce the shoot dry weight by 50% was reported as 33 dS m^{-1} [18], 27 dS m^{-1} [19], 18.6 dS m^{-1} [20], and 12 dS m^{-1} [21]. The use of different criteria to measure salinity tolerance further complicates comparisons. For example, shoot weight [15], shoot weight reduction relative to nonsalinized plants [22], root weight or length [23,24], shoot/leaf length [25,26], shoot visual injury [27], plant survival [28], and seed germination [29] have all been used as measures of salinity tolerance in turfgrasses. Finally, the units used in measuring salinity often vary from study to study. Units of measurement frequently used include salts on a weight basis (parts per million total dissolved solids [TDS ppm], total dissolved solids in milligrams per liter [TDS mg L^{-1}], total dissolved solids in milliequivalents per liter [TDS meq L^{-1}]), or on a conductivity basis (millimhos per centimeter [mmhos cm^{-1}], decisiemens per meter [dS m^{-1}]). Wherever possible, I have standardized units to dS m^{-1} to facilitate comparison of studies.

Even with these limitations, the relative (to one another) salinity tolerance of turfgrasses can be estimated within studies and between studies having at least one entry in common. This chapter presents the results of existing turfgrass salt tolerance studies and attempts comparisons, where possible, to derive relative salinity tolerances of currently used turfgrasses and also of alternative, proposed turfgrasses. Cultivar studies also are reviewed, and salt-tolerant cultivars within species are presented. The C_3 (cool-season) turfgrasses are presented first, followed by C_4 (warm-season) turfgrasses. See Table 1 at the end of this chapter for a summary of the estimated relative salinity tolerance of turfgrass species.

RELATIVE SALINITY TOLERANCE OF C_3 (COOL-SEASON) TURFGRASSES

Alkaligrasses (*Puccinellia* spp.)

Alkaligrasses are found inhabiting saline and alkaline sites throughout the cooler portions of North America [30]. These low-growing, perennial bunchgrasses were first considered for use as turfgrass in Illinois [31] and Colorado [32] when alkaligrasses were found along roadsides where deicing salts had eliminated other grasses. Fults [33] listed three *Puccinellia* spp. as being the most valuable for turf: weeping alkaligrass (*Puccinellia distans* [L.] Parl.), Nuttall alkaligrass (*P. airoides* [Nutt.] Wats and Coult.), and Lemmon alkali grass (*P. lemmoni* [Vasey] Scribn.). Alkaligrasses are mainly suited for low-maintenance turf, and they have been used successfully along roadsides and on some residential and athletic grounds [9].

Alkaligrasses are by far the most salt-tolerant cool-season grasses having turflike growth characteristics. Weeping alkaligrass has been reported surviving in soils with EC_e (salinity, in electrical conductance, of soil-saturated paste extract) over 46 dS m^{-1} [32]. The U.S. Salinity Laboratory [17] listed Nuttall alkaligrass as having high salt tolerance (EC_e 12–18 dS m^{-1}), being more salt tolerant than bermudagrass (*Cynodon dactylon* L.) but less salt tolerant than saltgrass (*Distichlis spicata* var. *stricta* (Torr.) Beetle; *D. spicata* var. *spicata* (L.) Greene). Harivandi et al. [34] found a weeping alkaligrass accession to be more salt tolerant than an accession of Lemmon alkaligrass in terms of leaf yellowing and survival. Lunt et al. [35] reported weeping alkaligrass survived relatively well

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

in sand culture when irrigated with EC_{iw} (salinity, in electrical conductance, of irrigation water) 32 dS m^{-1} over a 4-month period, suffering less injury than creeping bentgrass (*Agrostis palustris* Huds.), tall fescue (*Festuca arundinacea* Schreb.), colonial bentgrass (*Agrostis tenuis* Sibth.), and Kentucky bluegrass (*Poa pratensis* L.). Hughes et al. [15] reported forage yields of a weeping alkaligrass accession were reduced 33% over a 5-month period when irrigated with EC_{iw} 32 dS m^{-1} (NaCl) in a greenhouse pot trial. In contrast, perennial ryegrass (*Lolium perenne* L.) was reduced 44% and Kentucky bluegrass 47%. Ahti et al. [28] reported weeping alkaligrass cv. Fults to be more salt tolerant than other fine fescues (*Festuca* spp.) or Kentucky bluegrass cultivars tested, continuing to exhibit healthy vigorous growth with essentially no leaf injury following 80 days of exposure to EC_e 32 dS m^{-1}. Root elongation of Fults weeping alkaligrass seedlings was inhibited to a lesser extent than seedlings of perennial ryegrass, creeping bentgrass, or red fescue (*Festuca rubra* L.) when exposed to 25 dS m^{-1} NaCl [36]. In a greenhouse pot trial irrigated with salinized (final levels not given) water for 5 weeks, Nuttall alkaligrass suffered no leaf chlorosis, whereas weeping and Lemmon alkaligrasses suffered slight leaf chlorosis. Other turfgrasses, including perennial ryegrass, creeping bentgrass, tall fescue, red fescue, and Kentucky bluegrass suffered higher degrees of leaf firing [27].

Percentage of germination after a 15-day expousre to 75% seawater (EC_{iw} 28.5 dS m^{-1}) was greater for Lemmon and weeping alkaligrasses than for Dawson creeping red fescues, perennial ryegrass cv. Pennfine, creeping bentgrass cv. Seaside, and Kentucky bluegrass cv. Merion [37].

Bentgrasses (*Agrostis* spp.)

Creeping Bentgrass (*Agrostis palustris* Huds.; *A. stolonifera* L.)

Creeping bentgrass is considered to be relatively salt tolerant by most investigators, being classified as tolerant of soil EC_e from 8 to 16 dS m^{-1} [10,13,38,39] or 6 to 10 dS m^{-1} [8]. Hannon and Bradshaw [40] reported natural ecotypes of creeping bentgrass to be slightly more salt tolerant than red fescue ecotypes. In a pot experiment irrigated with equimolar concentrations of NaCl and $CaCl_2$ over a 5-month period [35], creeping bentgrass cv. Seaside was more tolerant than tall fescue, colonial bentgrass, and Kentucky bluegrass. The Seaside cultivar survived EC_{iw} 31 dS m^{-1}, with a 50% reduced growth rate occurring at EC_{iw} 18 dS m^{-1}. Greub et al. [27] found salinity tolerance of Seaside to be greater than the perennial ryegrasses, rough bluegrass, and Kentucky bluegrasses tested. Grasses were irrigated with 2.6 M NaCl for 5 weeks, and salinity tolerance determined as the percentage leaf firing.

There appears to be a good deal of variability in the salinity tolerance among genotypes of creeping bentgrass. Substantial variation in salinity tolerance has been reported among natural populations (ecotypes) of creeping bentgrass, with seaside selections being more salt tolerant than inland selections [24,40–42]. Younger et al. [43] reported differences in the salinity tolerance among seven creeping bentgrass cultivars grown in solution cultures up to EC_{iw} 26 dS m^{-1}. Salinities resulting in 50% relative shoot growth reduction ranged from EC_{iw} 9 to 26 dS m^{-1}. The salinity tolerance decreased in the order Seaside, Arlington, Pennlu, Old Orchard, Congressional, Cohansey, and Penncross cultivars. No other creeping bentgrass turfgrass cultivar salinity trial has been published to date.

Colonial Bentgrass (*Agrostis tenuis Sibth.*), Velvet Bentgrass (*A. canina* L.), and Redtop (*A. alba* L.)

Very little salinity work has been done on these bentgrass species. Colonial bentgrass has been rated as having poor salinity tolerance, tolerating EC_e less than 4 dS m^{-1} [10,13,39] or EC_e less than 3 dS m^{-1} [8]. In a greenhouse experiment in which pots were irrigated with saline water until death, a tall fescue accession survived longer than Astoria colonial bentgrass [44].

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

Salinity tolerance of velvet bentgrass has not been ranked, but, in a greenhouse pot study, colonial bentgrass cv. Bardot and velvet bentgrass cv. Novobent were compared with three creeping red fescue and two perennial ryegrass cultivars [45]. The bentgrasses were the least salt tolerant.

In a germination experiment using salinized agar [5], salt levels required to reduce germination by 50% decreased in the order redtop cv. Streaker (16,000 ppm $\approx$ 25 dS m^{-1}), creeping bentgrass cv. Seaside (23 dS m^{-1}), velvet bentgrass cv. Kingston, colonial bentgrass cv. Exeter (23 dS m^{-1}), colonial bentgrass cv. Highland (22 dS m^{-1}), creeping bentgrass cv. Penncross (21 dS m^{-1}), creeping bentgrass cv. Pennlinks (20 dS m^{-1}), and creeping bentgrass cv. Penneagle (18 dS m^{-1}).

Bluegrasses (*Poa* spp.)

Kentucky Bluegrass (*Poa pratensis* L.)

A number of salinity studies have been done on Kentucky bluegrass in the United States, reflecting its wide use among cool-season turfgrasses. Kentucky bluegrass has been ranked as having poor salinity tolerance, tolerating EC_e less than 4 dS m^{-1} [10,13,38,39,46] or EC_e less than 3 dS m^{-1} [8]. Lunt et al. [35] reported a Kentucky bluegrass accession to survive an EC_{iw} of only 8 dS m^{-1}, whereas creeping bentgrass cv. Seaside and tall fescue cv. Alta survived an EC_{iw} of 19 and 13 dS m^{-1}, respectively. Butler et al. [9] reported that Kentucky bluegrass will not grow well in soils with an EC_e greater than 4 dS m^{-1}. Horst and Taylor [26] reported the growth of Kentucky bluegrass cultivars, on average, was reduced 50% at EC_{iw} of 11 dS m^{-1}.

There does not appear to be an extensive range of salinity tolerance differences among the Kentucky bluegrass cultivars studied. Six Kentucky bluegrass cultivars had greater shoot weight reductions and more shoot tissue injury than two cultivars of perennial ryegrass and a creeping bentgrass exposed to 4.5 Mg NaCl ha^{-1} $week^{-1}$ over a 3-week period [27] (actual concentrations of irrigation water were not given). Although there were no differences in the shoot dry matter yield, the shoot salt injury was significantly less for Nugget than other Kentucky bluegrass cultivars (Fylking, Park, Pennstar, Newport, and Merion). Nugget, Ram I, and Baron Kentucky bluegrasses suffered less shoot visual injury than Adelphi when irrigated with EC_{iw} of 15 dS m^{-1} over a 2-month period [47]. In a greenhouse pot experiment, 23 Kentucky bluegrass cultivars were subirrigated with EC_{iw} of 14 dS m^{-1} for a period of 97 days [28]. Appearance (percentage live leaf tissue) decreased in the order Nugget, K1-148, Bristol, and Parade. Subsequent statistical groups were Sydsport, Windsor, Cheri, Victa, Touchdown, A-34, Fylking, Newport, and Rugby followed by Park, South Dakota Certified, Aquila, Majestic, Baron, and Bonnieblue followed by Pennstar, Adelphi, Merion, and Vantage. Ahti et al. [28] reported that there was not a very wide range of salinity tolerance among Kentucky bluegrass cultivars compared with other turfgrasses studied. Torello and Spokas [48] tested 37 Kentucky bluegrass cultivars by spraying NaCl at increasing weekly concentrations onto field plots. At the end of 9 weeks, cultivar differences in turf quality (composite of color and shoot density) were small. Majestic, Princeton, and Galaxy had the highest turf quality, whereas Haga, Plush, and Victa had the lowest ratings. These two cultivar groupings were significantly different from each other, but both groupings were statistically similar to the remaining 31 tested cultivars. In a subsequent experiment, Torello and Symington [49] measured the leaf and root length of seedlings of five Kentucky bluegrass cultivars grown in nutrient agar medium containing up to 1% NaCl. Variables consistently showed Adelphi and Ram 1 to be more salt tolerant than Nassau, Bensun, and Baron. Fylking performed better than Merion Kentucky bluegrass in field plots having an average EC_e of 11.4 dS m^{-1} [50]. The seedling leaf blade growth of 44 Kentucky bluegrass cultivars was tested under a range of salinity from 7500 to 15,000 ppm (EC_e 25 dS m^{-1}) of a NaCl/$CaCl_2$ mix [26]. Cultivars having the greatest leaf blade growth included Arista, Nugget, Delta, Prato, Baron, Park, S-21, Pennstar, Fylking, Windsor, Victa, Birka, Banff, Cheri, and Oregon Common.

In comparing cultivar salt tolerance ratings in the above studies, there are conflicting trends, perhaps due to a narrow range of salt tolerance within this species. Only Nugget was consistently in the top group in the four studies in which it appeared. In contrast, Fylking was in the top statistical

group in two studies, but, in two others, it had only intermediate salt tolerance. In two studies, Park was ranked fairly low in salt tolerance, but it was in the top group in the Horst and Taylor [26] study. Also, in some studies, Adelphi and Baron ranked as being salt tolerant, whereas they ranked as being salt sensitive in others. Merion consistently ranked as being salt sensitive in the three studies in which it was included.

Reiten et al. [51] reported germination of Kentucky bluegrass cv. SD Common to be completely inhibited by 0.6% NaCl (EC_{iw} 11 dS m^{-1}). Forty-four Kentucky bluegrass cultivars were tested for percentage of germination under a range of salinities from 7500 to 15,000 ppm (EC_e 25 dS m^{-1}) [26]. There was a continuous decrease in the percentage of germination from 100 to 4%, with Delta, Park, Prato, Warrens 113, and Nugget having the highest percentage of germination.

Rough Bluegrass (*Poa trivialis* L.)

In a greenhouse pot experiment in which grasses were exposed to 4.5 Mg NaCl ha^{-1} $week^{-1}$ over a 3-week period, a rough bluegrass accession suffered more shoot injury than creeping bentgrass cv. Seaside, was equal in the salt tolerance to perennial ryegrass cv. Common and three Kentucky bluegrass cultivars (Pennstar, Nugget, and Park), and was more salt tolerant than Kentucky bluegrass cultivars Fylking, Newport, and Merion [27].

Fescues (*Festuca* spp.)

Creeping Red Fescues (*F. rubra* L.)

Probably more salinity studies have been done on creeping red fescues than any other turfgrass, particularly in Europe and Canada, owing to their widespread use in cooler climates. There are two types of creeping red fescues: a strong creeping type with 56 chromosomes (*F. rubra* L. ssp. *rubra*) and a slender creeping type with 42 chromosomes (*F. rubra* L. ssp. *trichophylla* Gaud. or ssp. *litoralis* [Meyer] Auguir) [52]. However, most salinity research does not distinguish these two types (accessions are listed simply as ''red fescue'' or *Festuca rubra* L.).

There appears to be a broad range of salinity tolerance within creeping red fescues. Creeping red fescue is generally rated as having poor salt tolerance, tolerating an EC_e less than 4 dS m^{-1} [10,13,38,39] or an EC_e 3–6 dS m^{-1} [8]. However, Butler et al. [46] rated red fescue as having medium salt tolerance, tolerating EC_e of 8–12 dS m^{-1}. Salt-tolerant naturally occurring coastal populations of creeping red fescue have been described [53,54]. Michelmann [55] reported accessions of strong and slender creeping red fescue to have greater salinity tolerance than perennial ryegrass and velvet and colonial bentgrasses. Greub et al. [27] reported Ruby red fescue to be intermediate among cool-season grasses in salt tolerance: equivalent to perennial ryegrass cultivars (Common, NK-200), less tolerant than tall fescues (Alta, K-31) and creeping bentgrass cv. Seaside, but more tolerant than a rough bluegrass and redtop accession. However, Gibeault et al. [50] reported red fescue to have poor salt tolerance (equivalent to colonial bentgrass but less than Kentucky bluegrass and perennial ryegrass) when grown in field plots having EC_e averaging 11 dS m^{-1}. Shildrick [56] stated that slender creeping fescue cultivars (such as Dawson and Oasis) are generally more salt tolerant then strong creeping red fescues (such as Ruby and Bargena). Humphreys [57] found a salt-marsh ecotype of creeping red fescue to be much more salt tolerant than the tolerant slender creeping red fescue cultivars Dawson and Oasis. Potted grasses were sprayed with a 16% w/v NaCl spray over a period of 4 weeks. Humphreys [57] stated that differences among creeping red fescue cultivars are in fact more closely related to the point of origin than to the subspecies. Leaf number, leaf length, root number, and root length were measured in seedlings exposed to up to 170 mM NaCl for 30 days [49]. All measured parameters indicated creeping red fescue cv. Dawson above even Fults weeping alkaligrass, followed by creeping red fescue cv. Checker, and then 5 Kentucky bluegrass cultivars. In contrast, Fults weeping alkaligrass was reported as being the most salt tolerant in a study comparing a number of cool-season grasses [28]. Potted grasses were irrigated with water containing 1.25% NaCl (EC_{iw} 21 dS m^{-1}) for 90 days, with salt tolerance

measured as the percentage of leaf firing. Salt-tolerance ratings were as follows: Fults weeping alkaligrass > creeping red fescues > Kentucky bluegrasses > Chewings fescue > hard fescue = sheep fescue. Among creeping red fescues, Dawson and Golfrood were more tolerant than other cultivars. The salt tolerance of seven slender creeping red fescue cultivars was determined by measuring the root length of seedlings growing hydroponically in up to 250 mM NaCl (EC_{iw} 25 dS m^{-1}) [58]. Oasis, Hawk, Polar, Merlin, and Dawson were more tolerant than S59 and Jupiter. Saltol, a creeping red fescue collected from a saline tidal marsh on the St. Lawrence River, was more salt tolerant than Biljart, Carlawn, Highlight, Ottawa 1 creeping red fescues, Baron, Bristol, Merion, Nugget, Touchdown Kentucky bluegrasses, and Manhattan, Norlea, NK-200, Pennfine, Yorktown perennial rye grasses [59]. Potted grasses were sprayed five times with 4% road salt (85% NaCl) solution and visually rated for salt injury. Comparing all studies, it appears that Dawson, Oasis, and Saltol have superior salinity tolerance to other creeping red fescue cultivars. It appears that the red fescues merit better than the rating of poor salt tolerance given by some investigators.

Germination of slender creeping red fescue cv. Dawson was superior to Kentucky bluegrass cv. Merion and creeping bentgrass cv. Seaside and equivalent to perennial ryegrass cv. Pennfine and alkaligrass [37]. Grasses were germinated in Petri dishes containing 75% seawater (EC_{iw} 28 dS m^{-1}). Relative percentage of germination was compared among 16 creeping red fescue cultivars following 7 weeks' exposure to 260 mM NaCl (25 dS m^{-1}) [60]. Polar had the highest % germination, followed by Dawson, and then Koket and Novorubra, Erika, Famosa, Jamestown, and Reptans.

Chewings Fescue (*F. rubra* L. ssp. *commutata* Gaud.)

Chewings fescue has been ranked as being moderately salt sensitive, tolerating only EC_e 3 to 6 dS m^{-1} [8]. Torello and Symington [49] ranked Chewings fescue as being less salt tolerant than creeping red fescues. In a greenhouse pot experiment, Greub and Drolsom [44] reported a Chewings fescue accession to have poor salt tolerance, being equivalent to Kentucky bluegrass cv. Merion and colonial bentgrass cv. Astoria but less tolerant than Nuttall alkaligrass, tall fescues cv. Alta and K-31, and creeping red fescue cv. Ruby. An inland population of Chewings fescue was less salt tolerant than a maritime one [61]. Yield reduction occurred at 100 mM NaCl (EC_{iw} 11 dS m^{-1}) for the inland population but not until 200 mM (EC_{iw} 21 dS m^{-1}) for the maritime population. Chewings fescue cv. Highlight was found to be less salt tolerant than seven slender creeping red fescue cultivars in a seedling root growth trial [58].

Hard Fescue (*F. longifolia* Thuill.)

Hard fescue has been ranked as being moderately sensitive to salinity, tolerating only EC_e 3–6 dS m^{-1} [8]. In a study in which pots were subirrigated with 1.25% NaCl (EC_{iw} 32 dS m^{-1}) for 80 days, hard fescues cv. Scaldis, Centurion, and Durar had poorer salt tolerance than creeping red fescue cultivars; measured as visual leaf firing [28].

Meadow Fescue (*F. elatior* L.)

Meadow fescue has been ranked as having poor salt tolerance, tolerating EC_e less than 4 dS m^{-1} [10,13,39,46]. In a greenhouse study, a meadow fescue accession was less salt tolerant than four tall fescue cultivars (K-31, Falcon, Rebel, Houndog). Pots were subirrigated with 0.8% NaCl (EC_{iw} 14 dS m^{-1}) and visually rated for salt injury over a 2-month period [47].

Sheep Fescue (*F. ovina* L.)

Sheep fescue has not been ranked for salinity tolerance. Sheep fescue cultivars Firmaula and Barok were equivalent in salt tolerance to hard fescues, being less salt tolerant than creeping red fescues [28].

Tall Fescue (*F. arundinaceae* Schreb.)

Tall fescue has been rated as medium in salinity tolerance, tolerating EC_e 4–8 dS m^{-1} [10,13,39] or EC_e 6–10 dS m^{-1} [8,38,46]. Lunt et al. [35] reported salinity tolerance to decrease in the order

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

alkaligrass, creeping bentgrass cv. Seaside, tall fescue cv. Alta, Kentucky bluegrass, and colonial bentgrass cv. Highland. Alta shoot growth was reduced 50% at 160 meq L^{-1} (EC_{iw} 14 dS m^{-1}). Pots were irrigated with a 50/50 mix of NaCl and $CaCl_2$ over a period of 5 months. In a greenhouse experiment in which pots were irrigated with EC_{iw} 16 dS m^{-1}, salt tolerance decreased in the order tall fescue cv. K-31, Kentucky bluegrass cv Nugget, buffalograss, blue grama, and Kentucky bluegrass cv. Alelphi [47]. Greub and Drolsom [44] reported tall fescue cv. Alta and K-31 to be even more salt tolerant than Nuttalls alkaligrass as well as creeping red fescue cv. Ruby, Kentucky bluegrass cv. Merion, and colonial bentgrass cv. Astoria. In contrast, Greub et al. [27] reported Nuttall alkaligrass to be more salt tolerant than tall fescue cv. Alta and K-31, whereas Lemmon alkaligrass was equivalent to the tall fescues. More sensitive grasses were creeping bentgrass cv. Seaside, followed by creeping red fescue cv. Ruby and perennial ryegrasses cv. Common and NK-200, followed by redtop, and finally rough bluegrass. Horst and Beadle [25] determined germination rates and seedling growth of 16 tall fescue cultivars exposed to up to 15,000 ppm of 50/50 NaCl and $CaCl_2$ (EC_{iw} 25 dS m^{-1}). After 3 weeks' exposure to 25 dS m^{-1}, cultivars with the highest seedling fresh weight included four Belt series, Houndog, Alta, Gallway, and Kenwell. The germination rate was somewhat associated with growth with the top group including the four Belt series, Houndog, Kenmont, Gallway, T-5, and K-31. Comparing the limited information available, Alta would be ranked as being salt tolerant among tall fescue cultivars.

Ryegrasses (*Lolium* spp.)

Perennial Ryegrass (*Lolium perenne* L.)

Perennial ryegrass is typically ranked as having medium salinity tolerance, tolerating EC_e of 4–8 dS m^{-1} [10,13,38] or 6–10 dS m^{-1} [8]. In a field trial with soil EC_e averaging 11.4 dS m^{-1}, perennial ryegrass cultivars maintained better quality than red fescue, Kentucky bluegrass, and colonial bentgrass cultivars [50]. Although statistical comparisons were not given, the shoot dry matter yield of perennial ryegrass cv. Common and NK-200 was reduced less than in six Kentucky bluegrass cultivars, a rough bluegrass, a creeping bentgrass, and two tall fescue cultivars [27]. In contrast, Michelmann [55] reported perennial ryegrass to be less salt tolerant than red fescue but more salt tolerant than velvet or colonial bentgrasses.

The shoot dry weight, as a percentage of control plants, was not different among the perennial ryegrass cultivars tested (Vic. Cert., Tasdale, Barlata, and Linn) [29]. Grasses were exposed to 300 mM NaCl for 2 weeks (EC_{iw} 30 dS m^{-1}).

Dudeck and Peacock [62] germinated six perennial ryegrass cultivars in Petri dishes containing salinized (10,000 ppm seawater) agar. Total germination was greater for Pennant, Citation II, and Palmer than for Horizon, Derby, and Fiesta, whereas the germination rate was the highest for Pennant.

Annual Ryegrass (*Lolium multiflorum* Lam.)

Marcar [29] reported an accession of annual ryegrass to be less salt tolerant than perennial ryegrass Vic. Cert., with 50% shoot growth reductions occurring at 100 and 150 mM NaCl, respectively (EC_{iw} 10.5 and 15.5 dS m^{-1}). However, the effect on germination was reversed, with 50% germination occurring at 330 mM NaCl for annual ryegrass and at 250 mM NaCl for perennial ryegrass (32 and 29 dS m^{-1}).

RELATIVE SALINITY TOLERANCE OF C_4 (WARM-SEASON) TURFGRASSES

Bahiagrass (*Paspalum notatum* L. Flugg.)

Harivandi et al. [8] ranked bahiagrass as being moderately sensitive to salinity, tolerating EC_{iw} of 3-6 dS m^{-1}. However, In a pot study, shoot growth of bahiagrass cv. Pensacola was reduced by an EC_{iw} of only 0.4 dS m^{-1} and did not survive an EC_{iw} higher than 0.8 dS m^{-1} (EC_e 2.5 dS m^{-1}) over

the 255-day trial [63]. Dudeck and Peacock [22] reported bahiagrass cv. Argentine to be less salt sensitive than other warm-season turfgrasses, with 50% shoot yield occurring at EC_{iw} of 9.3 dS m^{-1}. Grasses were grown hydroponically and exposed to salinity increments of up to 42.6 dS m^{-1} for 6 months. The same investigators [64] reported germination of bahiagrasses cv. Argentine and Pensacola were more affected by synthetic sea salt ranging from 0 to 5800 mg L^{-1} (0–≈11 dS m^{-1}) than were other warm-season turfgrasses.

Bermudagrasses (*Cynodon* spp. Rich.)

Bermudagrasses widely used for turfgrass consist of two species. Common Bermudagrass (*Cynodon dactylon* L.), being cosmopolitan in distribution, is one of the world's worst weeds [65]. It also is the most widely used warm-season turfgrass. Interspecific hybrids of *Cynodon dactylon* and *C. transvaalensis* Burt-Davy (African Bermudagrass), often called ''hybrid'' Bermudagrasses, are typically sterile triploid, fine-textured grasses used for golf courses and other high-value areas. These have been produced in turfgrass-breeding programs. There also are some occurrences of natural crosses of *C. dactylon* and *C. transvaalensis*, commonly known as *C.* x *magennisii* [66]. As these types are typically referred to, and grouped together as Bermudagrass in the literature, I have avoided subsectioning this genus.

Bermudagrasses are invariably ranked as having excellent salinity tolerance, tolerating EC_e 8–16 dS m^{-1} [10,13,38,39], >10 dS m^{-1} [8], 12–18 dS m^{-1} [17], or 16–18 dS m^{-1} [46]. The shoot growth of bermudagrass cv. Santa Ana was reduced 50% relative to control plants when exposed to 160 meq L^{-1} of a 50/50 mix of NaCl and $CaCl_2$ (EC_{iw} 16 dS m^{-1}) for 6 weeks [67]. Pasternak et al. [68] reported bermudagrass cv. Suwannee to be more salt tolerant than seashore paspalum in a field experiment irrigated with EC_{iw} of up to 14 dS m^{-1}. There seems to be a good deal of variability in salt tolerance in the bermudagrasses. An ecotype collected from an alkaline soil in India had much greater salinity tolerance than one from a normal soil [69]. The shoot dry matter yield of the alkaline soil ecotype was not reduced over an 8-week period by EC_{iw} of 12 dS m^{-1}. Two common bermudagrass selections collected from the windward coast of Oahu, Hawaii, were more salt tolerant than Tifgreen [70]. Other bermudagrasses (Sunturf, Tifdwarf, and FB-137) were intermediate in salinity tolerance. Dudeck and Peacock [18,22] compared bermudagrasses cv. Tifway and Tifway II with other warm-season turfgrasses. Grasses were exposed to saline hydroponic solutions for 6 months and shoot dry weights compared with control plants. Tifway was more salt tolerant than Tifway II, with a 50% shoot growth reduction occurring at 33 and 24 dS m^{-1}, respectively. Smith et al. [21] compared Tifway with Tifway II in solution culture. Tifway was slightly more salt tolerant than Tifway II, with 50% shoot growth reductions occurring at EC_{iw} 12 and 11 dS m^{-1}, respectively. Eight bermudagrasses were grown in hydroponics for 10 weeks at EC_{iw} up to 32.5 dS m^{-1} [20]. The range of salinity tolerance among cultivars was relatively narrow, with 50% reductions in the shoot growth ranging from EC_{iw} 17.4 to 22.5 dS m^{-1}. Salinity tolerance decreased in the order Tifdwarf, Tifgreen, FB-137, Tifway, Tiflawn, Everglades, Common, and Ormond. Francois [71] compared three bermudagrass cultivars in sand culture and exposed to EC_e up to 35 dS m^{-1} for 10 months. Tolerance decreased in the order Tifton 86, Tifway II, and Tifton 10, with a 50% shoot growth reduction ranging from EC_{iw} 31 to 24 dS m^{-1}.

Using the existing studies to rank bermudagrass cultivars is problematic owing to the variability among studies. A common bermudagrass selection was ranked as being relatively tolerant in one study [70] but as sensitive in another [20]. This is probably a result of the highly heterozygous character of common bermudagrass, having a large range of ecotypes [21]. Tifway has been ranked as being more tolerant than Tifway II in the two studies in which they were compared [21,22]. However, Tifdwarf was ranked as being tolerant in one study [20] but intermediate in another [70]. Similarly, Tifgreen was ranked as being tolerant [20] and sensitive [70] among cultivars studied.

Germination of Common bermudagrass was not affected by salinity from 0 to 5800 mg L^{-1} ($EC_{iw} \approx 10$ dS m^{-1}) synthetic sea salt [64].

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

Buffalograss (*Buchloë dactyloides* (Nutt.) Englem.)

Buffalograss has been classified as being moderately tolerant to salinity (EC_e 6–10 dS m^{-1}) [8]. A salinity level resulting in 50% shoot growth reduction of four cultivars (Sharp Improved, Texoka, Topgun, and Plains) was reported to be EC_{iw} 15 dS m^{-1} [72]. Grasses were evaluated after 40 days of exposure. buffalograss cv. Prairie was less salt tolerant than zoysiagrass cv. Meyer and bermudagrass cv. Arizona Common [73] and also less tolerant than tall fescue cv. K-31 but more tolerant than Nugget and Kentucky bluegrass cv. Adelphi [47]. Wu and Lin [74] found substantial differences in germination and seedling survival among diploid and polyploid buffalograss clones, but overall they ranked buffalograss as being moderately sensitive to salinity, with 50% shoot dry weight reductions occurring at 8–10 dS m^{-1}. In a subsequent study, the Wu and Lin [75] found no significant differences in salt tolerance at the seedling stage among nine buffalograsses of different ploidy levels, although the germination rate was different among genotypes, being substantially inhibited at EC_{iw} 5 dS m^{-1}). Germination of two buffalograss clones was invariably better than Kentucky bluegrass cv. SD Common, with the upper limit for germination being at 2.8% NaCl ($EC_{iw} > 40$ dS m^{-1}) [51].

Carpetgrass (*Axonopus* Beauv.)

Two species of carpetgrasses have been used to a limited extent for turfgrass: common carpetgrass (*A. affinis* Chase) and tropical carpetgrass (*A. Compressus* [Swartz.] Beauv.) [39]. Carpetgrass has been classified as having poor salt tolerance [39]. A germination test revealed a common carpetgrass accession to be more sensitive to salinity than bermudagrass cv. Common but less sensitive than bahiagrasses cv. Argentine and Pensacola [64].

Centipedegrass (*Eremochloa ophiuroides* [Munro] Hack.)

Centipedegrass is invariably classified as having poor salt tolerance, tolerating $EC_e < 4$ dS m^{-1} [10,13,38,39], or <3 dS m^{-1} [8]. Centipedegrass has been the least salt-tolerant warm-season turfgrass in several studies. Centipedegrass cv. Common and bahiagrass cv. Argentine were equivalent in salinity tolerance, with a 50% reduction of shoot growth occurring at 9 dS m^{-1} [18,22]. St. Augustinegrass, bermudagrass, seashore paspalum, and zoysiagrass were more salt tolerant. In another study, centipedegrass cv. Common was least tolerant among warm-season turfgrasses, with a 50% shoot yield reduction occurring at EC_{iw} 6 dS m^{-1} [19].

St. Augustinegrass (*Stenotaphrum secundatum* [Walt.] Kuntze)

St. Augustinegrass has been ranked as being tolerant to salinity, tolerating EC_e 8–16 dS m^{-1} [10,13,38,39] or >10 dS m^{-1} [8]. A Hawaiian selection [19] and St. Augustinegrasses cv. Floratine [70] were reported to be equally salt tolerant to seashore paspalum and more tolerant than several bermudagrasses, Japanese lawngrass cv. Korean Common, and centipedegrass in solution culture. A 50% shoot dry weight reduction occurred at 40 dS m^{-1} for the Hawaiian selection [19]. St. Augustinegrasses cv. Seville and Floratam were more tolerant than Tifway and Tifway II in solution culture, with a 50% shoot dry weight occurring at 30, 19, 12, and 11 dS m^{-1}, respectively [21]. In contrast, Dudeck and Peacock [22] reported Floratam to be less salt tolerant than hybrid zoysiagrasses cv. Emerald, seashore paspalum cv. FSP-1, and bermudagrass cv. Tifway but more tolerant than centipedegrass and bahiagrass. A 50% shoot reduction occurred at 22 dS m^{-1} for Floratam. Meyer et al. [76] reported the shoot and root growth of St. Augustinegrass cv. Seville to be less affected by salinity than Floratam in solution culture containing up to 34 dS m^{-1}. Dudeck et al. [77] compared four St. Augustinegrass cultivars in solution culture. Seville was more salt tolerant than Floratine, Floratam, and Floralawn, with a 50% shoot dry weight reduction occurring at 28

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

and 23 dS m^{-1}, respectively. In comparing studies for cultivar salinity tolerance, Seville was invariably found to be more tolerant than other cultivars in three studies.

Seashore Paspalum (*Paspalum vaginatum* Swartz)

Seashore paspalum has been ranked as the most salt-tolerant warm-season turfgrass, tolerating $EC_e > 16$ dS m^{-1} [13,38]. Seashore paspalum cv. Futurf has been reported to exist in soils with EC_e 40–45 dS m^{-1} [78], although it is more generally accepted that seashore paspalum can withstand up to EC_e 22 dS m^{-1} [79]. Major [80] reported both Fults weeping alkaligrass and Futurf seashore paspalum survived $EC_e > 50$ dS m^{-1} in greenhouse pot culture. Marcum and Murdoch [19] reported a Hawaiian selection of seashore paspalum to have a 50% shoot dry weight reduction at 40 dS m^{-1} in greenhouse solution culture, being equal in tolerance to St. Augustinegrass and Manilagrass but more tolerant than bermudagrass, Japanese lawngrass, and centipedegrass. In contrast, a seashore paspalum accession was reported to be less salt tolerant than bermudagrass cv. Suwannee in field plots [68]. Differences in salinity tolerance among seashore paspalum genotypes has been noted. Dudeck and Peacock [22] compared two Florida seashore paspalum genotypes (FSP-1 and FSP-3) to other warm-season turfgrasses in solution culture. The Emerald zoysiagrass hybrid was found to be the most tolerant, followed by FSP-3, then bermudagrass cv. Tifway and FSP-1, then bermudagrass cv. Tifway II and St. Augustinegrass cv. Floralawn, and finally centipedegrass cv. Common and bahiagrass cv. Argentine. Dudeck and Peacock [81] compared four seashore paspalum cultivars in solution culture. FSP-1 was the most tolerant, with a 50% shoot growth reduction at EC_e 28.6 dS m^{-1}, followed by Futurf and FSP-2, and finally Adalayd (EC_e 18.4 dS m^{-1}). Not enough studies have been done to make salt-tolerance comparisons among seashore paspalum cultivars possible.

Zoysiagrasses (*Zoysia* spp.)

Zoysiagrass used as turf grass consists of several species: Japanese lawngrass (*Zoysia japonica* Steud.), Manilagrass (*Zoysia matrella* [L.] Merr.), and Mascarenegrass (*Zoysia tenuifolia* Willd. ex Trin.), as well as the interspecific hybrid cultivar Emerald (*Z. japonica x Z. tenuifolia*). Other zoysiagrass species (*Z. sinica* Hamce, *Z. macrostachya* Franch. and Sav., *Z. koreana*) are either being considered for use as turfgrass or are being used as turfgrass in Asia [82]. General salt-tolerance rankings which compare turfgrass genera have traditionally not made this species distinction, although recent studies have revealed large differences among species. Zoysiagrass in general has been ranked as being salt tolerant compared with other turfgrasses, tolerating EC_e 8–16 dS m^{-1} [10,13,38,39] or 6–10 dS m^{-1} [8]. Japanese lawngrass cv. Meyer was reported to be equivalent in salt tolerance to bermudagrass cv. Arizona Common but more tolerant than buffalograss cv. Prairie and grama grasses [73]. Dudeck and Peacock [22] reported Emerald hybrid zoysiagrass to be more salt tolerant than any other warm-season turfgrass in the study, having a 50% shoot dry weight reduction at 37 dS m^{-1}. In decreasing order of salt tolerance: Emerald > FSP-3 seashore paspalum = Tifway bermudagrass > FSP-1 seashore paspalum > bermudagrass cv. Tifway II = Floralawn St. Augustinegrass > Common centipedegrass = Argentine bahiagrass. FC13521 Manilagrass was more salt tolerant than Korean Common Japanese lawngrass in solution culture, with 50% shoot dry weight reductions at 40 and 12 dS m^{-1}, respectively [19]. An accession of *Z. koreana* was reported to be the most salt tolerant, followed by an accession of *Z. sinica* and *Z. matrella*, and finally an accession of *Z. japonica* [83]. Fifty-nine zoysiagrass genotypes were compared for salt tolerance in solution culture [84]. Zoysiagrass species decreased in salt tolerance in the order *tenuifolia, matrella, japonica x tenuifolia, sinica, macrostachya*, and *japonica*. Diamond Manilagrass was the most salt tolerant among 17 cultivars tested, being superior to EI Toro, Belair, Meyer, Korean Common Japanese lawngrass, and Emerald zoysiagrass hybrid.

Alternative C_4 Grasses

Several warm-season grasses having turf-type characteristics are known for their exceptional tolerance to salinity or drought stress. These are saltgrass (*Distichlis spicata* var. *stricta* [Torr.] Beetle;

D. spicata var. *spicata* [L.] Greene), *Sporobolus virginicus* (L.) Kunth, curly mesquite (*Hilaria belangeri* [Steud.] Nash), and gramagrasses (Bouteloua spp. Lag.) [9,15,32,85]. Although generally thought to be too coarse in texture for use as turfgrass, these grasses can be mowed and are currently used as ground covers in marginal areas.

The USDA Salinity Laboratory [17] ranked salt-tolerant (tolerating EC_e 12–18 dS m^{-1}) grasses in order of decreasing salt tolerance: saltgrass, Nuttall alkaligrass, and bermudagrass. In a solution culture experiment [73], saltgrass was more salt tolerant than Common bermudagrass,

TABLE 1 Estimated Relative Salinity Tolerance of Turfgrasses

C_3 (cool season) turfgrasses	Salinity tolerance[a] (dS m^{-1})	C_4 (warm season) turfgrasses
	40+	Saltgrass
		Sporobolus virginicus
Nuttall alkaligrass	30	Seashore paspalum
Weeping alkaligrass		Mascarenegrass
Fults		Manilagrass
Lemmon alkaligrass		Diamond
	22	St. Augustinegrass
		Seville
	18	Hybrid zoysiagrass
		Emerald
		Bermudagrass
		Tifway
	15	Japanese lawngrass
		El Toro, Palisades
Creeping bentgrass	12	
Seaside, Mariner		
Tall fescue		
Alta, K-31		
Creeping red fescue	10	
Dawson, 'Oasis' (slender),		
Ruby (strong)		
Perennial ryegrass	8	Buffalograss
Manhattan		Gramagrasses
Redtop		
Rough bluegrass	4	Centipedegrass
Kentucky bluegrass		Carpetgrass

Meadow fescue		
Annual ryegrass		
Annual bluegrass	3	Bahiagrass
Colonial bentgrass		
Velvet bentgrass		

[a] Relative salinity tolerance is an estimate (based on literature) of the salinity (EC_e in dS m^{-1}) at which the grass can acceptably grow or the point at which shoot growth is reduced by approximately 50%.

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

Meyer zoysiagrass, sideoats and black gramagrasses, and Prairie buffalograss. Saltgrass continued to grow in solutions containing 50 dS m^{-1}, equivalent to full-strength seawater. Saltgrass was found to be more salt tolerant than seashore paspalum or bermudagrass in field plot experiments [68]. The shoot growth of *Sporobolus virginicus* was stimulated under moderate salinity, peaking at 15 dS m^{-1}. The shoot growth continued at a lower rate even at 45 dS m^{-1}, whereas root growth increased, relative to control, to the highest salinity level (45 dS m^{-1}) [86]. *Sporobolus virginicus* continued to grow without injury after 4 months' exposure to full-strength seawater (45 dS m^{-1}) [87]. Kinbacher et al. [47] reported blue gramagrass to be salt sensitive, being equivalent in tolerance to Kentucky bluegrass. Research has shown that saltgrass, alkali sacaton, and *Sporobolus virginicus* continue to grow well in full-strength seawater (>45 dS m^{-1}), and, thus they can be considered to be true halophytes.

OVERALL SALT-TOLERANCE RANKING OF TURFGRASSES

There is considerable difficulty in precisely ranking the salinity tolerance of turfgrasses because of factors discussed at the beginning of this Chapter. These include the different methods of quantifying the relative salt tolerance used in the reviewed studies (i.e., relative shoot dry weight reduction, percentage of leaf burning, root growth changes, germination) and the difference in environmental conditions under which studies were done, such as temperature, light, and soil differences (or lack of soil, as in solution culture experiments), all of which are known to interact with relative salinity tolerance measurements. Also the units used to quantify salinity levels differed among studies. Hence, there was a good deal of variability in the results among studies, often resulting in contradictory cultivar rankings within species, but sometimes even resulting in contradictory species rankings. Even more affected by these factors are estimates of actual salinity tolerance levels in terms of salinity (dS m^{-1}). I have attempted to summarize the current literature concerning turfgrass salt tolerance into a table (Table 1) ranking turfgrass species relative to one another. If information regarding cultivar differences is available, salt-tolerant cultivars are listed immediately below each turfgrass.

Jake F. Weltzin
University of Notre Dame
Notre Dame, Indiana

INTRODUCTION

Humans have been interested in factors that constrain the distribution of plants at least since Aristotle considered this concept over 23 centuries ago. This early interest has been sustained to the present, and it is reflected in contemporary definitions of ecology (e.g., see Ref. 1): the analysis of interactions that determine distribution and abundance of organisms. Further, physiological ecology and response to stress have been the central foci of ecological investigations since the inception of ecology as a formal discipline (e.g., see Refs. 2 and 3 and citations therein). Nonetheless, a significant gap divides physiological ecology from population ecology. Although physiological ecology provides a solid foundation for the post hoc interpretation of ecological patterns, a mechanistic link between physiological ecology and population ecology has yet to be fully explored. The inability to integrate physiological ecology and population ecology belies extensive literature in both disciplines.

Grime [4] defined stress as, ''the external constraints which limit the rate of dry-matter production of all or part of the vegetation.'' This definition was refined by Welden and Slauson [5] to exclude biotic interactions: ''abiotic stress is an external condition, apart from the activities of other organisms, that induces strain in an organism.'' We adopt this more precise definition in order to exclude interference. Inter- and intraspecific competition are important processes that constrain the structure and function of vegetation systems [6]; however, they are beyond the scope of this chapter.

Whereas the term *stress* refers to an external condition or process acting on a plant, *strain* refers to the internal physiochemical changes within that plant in response to a stress. Thus, strains mediate the response of plants to stresses. Strain may be assessed in several ways (e.g., by measuring

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

growth rate, photosynthetic rate, or tissue water potential). Although strains refer to suboptimal physiological states (relative to a sometimes only theoretical optimal state), they are not always expressed at the whole plant level, and they may not reduce fitness or affect population dynamics [5].

Stresses on wildland plants considered in this chapter include water, temperature, nutrient stress, defoliation, and climatic variation. Although defoliation and climatic variation are often considered as disturbances, or ''mechanisms which limit the plant biomass by causing its partial or total destruction'' [4], we discuss them herein as stresses important to the structure and function of wildland plant systems.

Stress indirectly affects the structure and function of all naturally occurring communities and ecosystems. Adaptation to various kinds and intensities of stress (e.g., drought, frost, defoliation) is requisite to the survival of wildland plants. Understanding how wildland plants respond to stress provides important insights into patterns and processes in communities and ecosystems. Nonetheless, stress per se does not exist at levels of organization higher than the individual plant. Communities and ecosystems are not organismal entities but rather comprise variously interacting species that often cease to coexist when the environment changes (e.g., see Refs. 7–9). The responses of communities and ecosystems to the environment are most appropriately viewed as a product of the responses of individual organisms to their environment. As such, the terms *health, integrity*, and *degradation* are inappropriate descriptors of ecosystems [10–12] and will not be used herein.

This chapter provides an overview of the importance of stress in wildland ecosystems. We review the major sources of stress in these systems and discuss the relevance of stress to ecosystem structure and function. Finally, we review recent attempts to link physiological response to ecosystem processes.

INTEGRATION OF STRESS RESPONSES: THE PLANT AS A BALANCED SYSTEM

The mechanistic, or bottom-up, approach in ecology represents one important strategy for understanding current vegetation patterns and predicting vegetation responses to changing conditions. Within this context, responses of populations, communities, and ecosystems to environmental stress are best understood at the level of the whole plant. By impairing the function of individual plants, stress has important implications for groups of plants (e.g., populations, communities). Different species, and even individuals within a species, display different levels of tolerance to various stresses. These differences form the basis for competitive exclusion or coexistence of individuals and species in environments where conditions are sometimes limiting to plant growth. Growth and survival of an individual plant may be constrained by any of several stress factors, and the existence or importance of these factors may depend on the abundance of neighboring plants. These factors operate independently or in combination, and they frequently interact with one another, so that stress ultimately constrains the distribution and abundance of plant individuals. As such, these constraints on distribution and abundance of plants exert primary control over ecosystem structure and, sometimes, ecosystem function. Stress responses of individual plants, therefore, play a central role in our understanding of the dynamics of natural ecosystems.

A plant functions as a balanced system with respect to resource acquisition and use. If natural selection has molded plant function to maximize growth or fitness under stressful conditions, then plants should allocate internal resources (C, N, P) in such a way that source and sink activities are kept in equilibrium. Allocation to different resource-acquiring structures in response to stress, therefore, should occur so that growth is equally limited by all resources [13] and internal resource pool sizes remain constant [14]. In economic terms, investment in a particular function (e.g., soil nutrient uptake, photosynthetic capacity, defense) should cease if the return in terms of growth or fitness is lower than the investment or lower than returns from alternative investments [13,15]. For example, under light limitation, plants will invest proportionately greater amounts of nitrogen to light-harvesting chlorophyll and less to the enzyme Rubisco such that photosynthesis per unit nitrogen allocated to leaves is maximized. Magnitudes of stress response, therefore, may be interpreted as the degree to which the balance of plant functions and internal resource limitations deviate from the optimum

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

achievable by a particular genotype or species. This balancing act should be directly related to the impact of stress on growth or fitness. Consequently, across habitats differing in resource availability or stress conditions, populations frequently evolve genetically fixed allocation and growth responses that match the overall limitations of the environment [16].

The concept of optimal allocation or functional equilibrium has fostered numerous theories about the mechanistic basis for community and ecosystem dynamics [17–19] and provides a framework for managing ecosystem functions [19] and for elucidating scaleable ecosystem processes [20]. It is not clear, however, at what temporal or spatial scale one should interpret allocation shifts or physiological acclimation to stressful conditions. Plants can respond almost instantaneously to fluctuations in resource supply or to conditions which reduce the efficiency of particular organs. Stomatal conductance and leaf photosynthetic capacity respond rapidly to changes in light levels [21] or humidity [22], but allocation shifts at the level of the whole plant occur over longer periods. Plants that differ in life span or growth rate employ different strategies for balancing resource demands of different functions and have different patterns of allocation in response to stress or changes in resource supply. Short-lived herbaceous plants or plants from resource-rich environments tend to shed and redeploy new resource-acquiring organs (leaves, roots) in response to changes in the resource supply. Long-lived perennial plants or plants adapted to resource-poor environments often rely on physiological acclimation of existing organs rather than redeployment [16]. In both instances, it is assumed that the return is maximized from allocation investments (redeployment or acclimation) and that physiological and fitness trade-offs or costs accompany the different strategies.

Current patterns of allocation in response to stress, however, may have evolved under selective pressures no longer present within a plant's environment. Consequently, not all responses may be the optimum achievable for keeping the plant as a balanced system. The evolution of plastic responses to stress (as opposed to genetically fixed responses among populations or species) may depend on the spatial and temporal dynamics of the stress as well as other life history or genetic constraints [23–25]. Constraints on the adaptive response to stress, in fact, may determine the rate or pattern of vegetation responses to global change [26,27].

The appropriate resource for evaluating the cost and return from allocation in response to stress is assumed to be carbon or mass, but other plant nutrients (N and P) can be allocated in a manner independent of mass [28]. Furthermore, the cost of acquiring and processing these nutrients, in terms of grams of glucose [29], may be difficult to assess [30–32]. Even the level at which one assesses the cost of growth or reproduction may have a bearing on how we interpret optimal allocation responses. Physiologically based measures of cost are often preferred over measures based on fitness because of the difficulty in estimating the contribution of reproduction to future generations in long-lived plants.

Because allocation to different functions involves trade-offs between costs and returns, the response of plants to stress and the role of these responses at population, community, and ecosystem levels depend on how plants have evolved to manage functional trade-offs within a given environment. The role of plant life forms, adaptive strategies, and functional types in community and ecosystem processes is determined by these allocation trade-offs at the whole plant level. Here we review examples of plant functional trade-offs associated with temperature, water, nutrient, and defoliation stress in wildlands and describe how these trade-offs influence processes and dynamics at the ecosystem level.

Temperature Stress

Temperature affects many aspects of plant growth and development and has a primary influence on the distribution of plant species [33–35]. Plants in natural environments frequently experience temperatures or conditions that cause tissue temperature to be suboptimum for growth or photosynthesis [36]. All tissues and life stages of the plant can be affected by temperature. Temperature stress affects processes at different organizational levels, including gene expression [37], enzyme function [38], membrane integrity and function [39], cell division [40,41], photosynthesis [42,43], respiration [44–46], phloem translocation [47], root and shoot allocation [48], and reproductive

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

development [43,48,49]. It is beyond the scope of this chapter to address in any detail the physiological responses of wild plants to temperature or any other single environmental condition at all of these organizational levels. Comprehensive reviews of temperature effects on wild plants are provided by Berry and Bjorkman [50], Berry and Raison [36], and Long and Woodward [51].

In general, temperature stress can affect the efficiency of resource capture and use by plants and may be an important selective pressure shaping patterns of allocation to different plant parts or functions. Adaptation to temperature stress can involve modifications in the energy balance characteristics of leaves and canopies to maintain favorable tissue temperatures or physiological stability across the range or extremes in temperature conditions. C_4 photosynthesis represents a major biochemical and anatomical adaptation that enhances photosynthetic efficiency at high temperature [52] and has ramifications for species and vegetation distribution along altitudinal and latitudinal gradients [53,54]. Many studies have observed photosynthetic acclimation or stability to changing temperature conditions [43,55], as well as ecotypic variation for photosynthetic function across habitats that differ in growing season temperature [56]. Unfortunately, few studies have addressed the physiological or fitness costs associated with photosynthetic acclimation or tolerance to broad ranges of temperature.

Modifications in leaf orientation or morphology (e.g., wilting under high heat loads or vertically oriented leaves) that decouple tissue and ambient temperatures can have positive physiological and/or fitness consequences [57–59]. The production of reflective hairs or waxes on leaf surfaces may serve a similar function [60,61], but like fixed patterns of leaf orientation, the development of a reflective epidermis can have physiological and demographical costs. Allocation to reflective leaf hairs in the desert shrub *Encelia farinosa* increases through the growing season and differs among populations along an aridity gradient in the arid southwestern United States. Reflective leaf hairs are costly in terms of the energy required for their production and they reduce the amount of radiation absorbed for photosynthesis [60]. It is not surprising that when water is available to *Encelia* plants, either in spring or as an intrinsic part of the habitat, transpirational cooling rather than radiation reflectance becomes the dominant mechanism by which plants decouple leaf and air temperature [60,62]. Although it is widely known that sensible versus latent heat loss varies across aridity gradients, the implications of plant level trade-offs between reflectance and transpiration for ecosystem level evapotranspiration, energy exchange, and productivity seem apparent but have not been fully explored.

The ability of plants to meet their nutrient and water demands for photosynthesis, growth, and reproduction is linked to the root responses to soil temperature [63,64]. Water and nutrient acquisition and transport from the roots to shoots can be impacted by temperature in several ways. First, the roots themselves are sensitive to temperature. Across the natural range of most plant species or over the course of the season, soil temperature varies greatly. Unfortunately, few studies have addressed the impact of these temperature variations on root function in wild plants. The roots of plants from warm climates, however, express a greater tolerance to high temperatures than do the roots of plants from cooler environments [36]. Root growth, demography, and respiration are apparently strongly affected by the soil temperature under natural conditions [63,65] and may determine patterns of belowground resource uptake in many situations. High surface soil temperature may be one factor contributing to the inability of certain shrub and tree species to utilize summer rains in southern Utah [66,67] potentially limiting the productivity and distribution of temperature-sensitive species.

Low soil temperature in the spring may limit root growth and contribute to water stress and low water transport efficiency in forest trees even when the soil is relatively moist [68]. Additionally, the hydraulic conductivity of the xylem is influenced by frost and by temperature-dependent variations in the viscosity of liquid water [69,70]. Susceptibility to frost cavitation increases with the vessel size [71,72] and constrains seasonal leaf phenology in a number of species [73]. Because vessel size is inversely related to conducting efficiency, a trade-off between hydraulic conducting capacity of stems and susceptibility to damage by frost is unavoidable. Susceptibility to frost cavitation is an important yet relatively unexplored mechanism that may limit species function and distribution near the margin of their range [72,74,75].

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

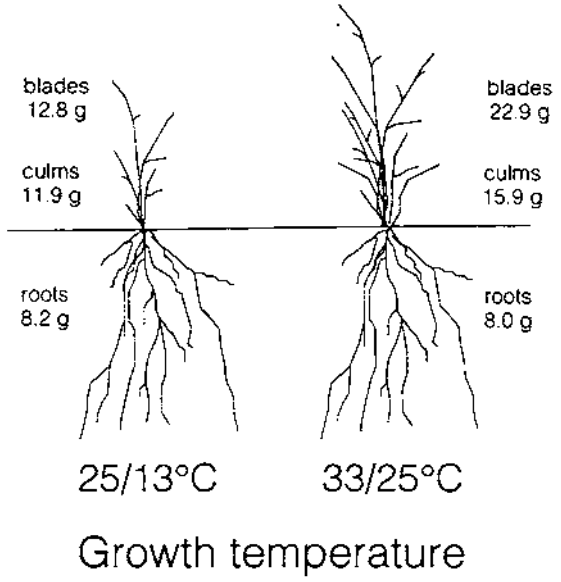

FIGURE 1 Biomass of root, culm, and leaf blades of the invasive C_4 grass *Pennisetum setaceum* (Fountain grass) grown for 56 days at high and low temperatures in a growth chamber environment. (Redrawn from Ref. 43.)

Biomass accumulation in above- and belowground organs is strongly affected by temperature. In general, ecotypes of plant species from colder climates allocate proportionally more mass to roots than to shoots compared with ecotypes from warmer regions. This allocation response may have evolved to offset the demand for limiting soil nutrients in colder climates [76–79]. Plasticity also is observed when plants are grown experimentally at different temperatures. Williams and Black [43] found that the C_4 grass *Pennisetum setaceum* maintained proportionally greater mass in roots than in shoots when grown at 25/13°C (day/night) temperature conditions than when grown at 33/25°C (Fig. 1). Apparently, shoot growth was inhibited exclusively by different temperature conditions for this warm-season grass. Greater dry mass accumulation in roots for plants grown in colder temperature conditions may be due to slower fine root turnover and death [80] coupled with a greater impact of the low temperature on shoot expansion and growth [81]. However, patterns observed for plant biomass allocation responses to experimental temperature stress at the population level are not seen in broad comparisons at the community level across natural gradients [81]. High belowground dry matter accumulation, therefore, may not be an essential trait for survival in cold climates.

Water Stress

Water stress is a dominant feature of most wildland ecosystems, and the importance of water balance on community structure is widely recognized (e.g., see Refs. 82–86). Nearly all wildland areas are characterized by periodic drought, and plants possess an impressive array of adaptations for surviving these periods.

Water loss from leaves to the atmosphere is an unavoidable consequence of CO_2 exchange in terrestrial plants. Consequently, water is often the single most limiting factor to plant growth and ecosystem productivity in arid and semiarid regions [87] and has a primary influence on the distribution of species and vegetation. Plants have evolved a variety of morphological and physiological features that allow them to complete their life cycles and persist in water-limited environments.

Reviews on plant physiological responses to drought stress from different perspectives are provided by Turner [88], Schulze [22], Tyree and Sperry [69], and Passioura [89].

Water stress has been cited as the ultimate constraint on plant distribution. For example, Merriam [90] invoked water stress as the primary factor influencing the distribution of dominant plants in the mountains of the southwestern United States. Merriam's descriptions of life-zones along altitudinal gradients have been supported by contemporary research bolstered by sophisticated analytical tools unavailable to Merriam (e.g., see Refs. 91 and 92). This extensive body of work on plant water relations indicates that species respond differently to water stress, and this differential response explains why plants are ''sorted'' along elevational gradients.

At spatial scales of a few meters or smaller, water stress may be mediated by the presence of neighboring plants. These neighbors may exacerbate water stress by interfering with water uptake or they may alleviate water stress by ameliorating the microclimate. Negative effects on plant survival have been attributed to interference in most wildland ecosystems (e.g., see Ref. 6 and references therein). The presumed mechanism for this interaction is that one individual preempts the use of the resource (water) more quickly or more efficiently than other individuals. Positive effects (facilitation) have been attributed to amelioration of the microclimate in arid and semiarid sites (e.g., see Refs. 93–95) and hydraulic lift (nocturnal transport of soil water from deep to shallow layers) [96]. Alternatively (and possibly concomitantly), shade provided by the canopy of one individual reduces the evaporative demand and, hence, water stress on individuals beneath the canopy.

Much work has been conducted on the cellular and molecular components of drought response (e.g., osmotic adjustment, compatible solutes, membrane structure and function), but physiological ecologists have tended to focus on the patterns and processes of water stress at the leaf, root, and whole-plant levels, particularly focusing on the impacts on plant gas exchange and growth. Adaptations to water stress at the whole-plant level involve trade-offs among different organs and functions of the plant. At the leaf level, minimizing transpirational water loss by stomatal closure under drought conditions reduces net CO_2 uptake but increases instantaneous water-use efficiency [97] while allowing the plant to avoid low shoot water potentials. Debate continues, however, on the exact control mechanism for stomatal closure—root abscisic acid (ABA) signals or feedforward or feedback responses at the leaf [98–101]—and what measure of humidity is sensed by plants in drying air [102–104]. Because both soil and atmospheric drought influence transpiration rates and stomata in similar ways, it is difficult to distinguish their effects at the whole-plant level, especially along complex climatic gradients typical of natural vegetation. Despite these unresolved issues, it is clear that plants have evolved numerous responses to water stress that maximize fitness in arid and semiarid environments.

Rooting profiles of plants illustrate obvious trade-offs between different solutions to coping with limited water in dry environments. Deeply rooted perennial species such as mesquite (*Prosopis* spp.) overcome periods of little or no rainfall during the growing season by using groundwater or water stored deep in the soil from prior rains. Construction and maintenance of an extensive root system, however, is energetically costly. Alternatively, shallow-rooted perennial plants are very effective at capturing moisture from growing season precipitation (e.g., summer monsoonal rains), but they can potentially experience wide fluctuations in soil moisture availability that can limit gas exchange to periods when rainfall is high. Consequently, seasonal patterns of water use, drought stress, and productivity vary widely between deep- and shallow-rooted plants even within the same habitat [105]. Diverse rooting profiles may limit competitive interactions among perennial plants in arid and semiarid ecosystems and may be one explanation for species coexistence [82,106,107].

Generalizations about soil resource partitioning and coexistence of different plant life forms should incorporate explicit consideration of plant life history. For example, mature *Quercus emoryi* Torr. (Emory oak) trees and perennial bunchgrasses within temperate savannas of the southwestern United States obtain water from relatively deep and shallow depths in the soil profile, respectively (Fig. 2) [108]. Such soil moisture resource partitioning may facilitate the coexistence of these life forms. However, grasses and 1- and 2-year-old *Q. emoryi* seedlings obtained water from similar depths in the soil profile, which suggests that soil moisture partitioning between *Q. emoryi* and

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

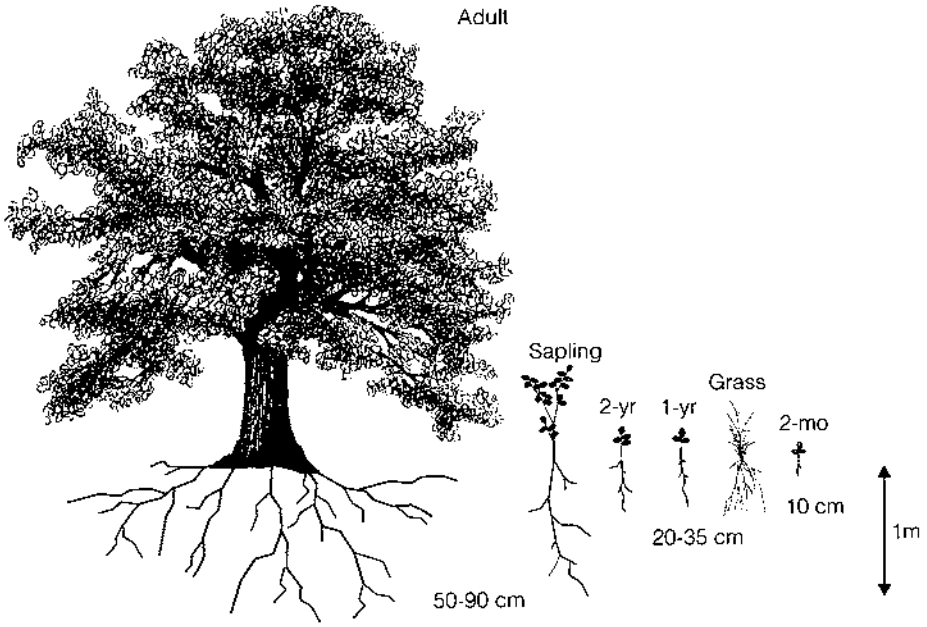

FIGURE 2 Acquisition of soil moisture from different depths in the soil profile for *Q. emoryi* (Emory oak) at different phenological stages, and coexisting grasses, in a temperate savanna of the southwestern United States [108]. Both life forms, and all phenological stages of *Q. emoryi*, utilize soil moisture derived from summer precipitation in September. Adult and sapling *Q. emoryi*, trees obtain soil moisture from 50–90 cm, 2-year-old and 1-year-old *Q. emoryi* and coexisting bunchgrasses access soil depths of 20–35 cm and 2-month-old *Q. emoryi* utilize water from the top 10 cm of the soil profile.

coexisting grasses does not occur for at least 2 years after seedling germination. Further, very young tree seedlings (about 2 months old) use water from shallower depths in the soil profile than grasses, which may facilitate germination and early establishment of *Q. emoryi*. Thus, soil resource partitioning occurs at some, but not all, developmental stages of woody plant development, with potential implications for woody plant population dynamics.

The hydraulic architecture of plants plays a critical role in determining species response to drought conditions regardless of where in the soil profile plants may be taking up water. Water flow from roots to leaves conforms to Darcy's law where the volume flow rate is a function of the plant hydraulic conductance (inverse of resistance) and the pressure drop from the root to the leaf resulting from evaporation at leaf surfaces. Conductance to flow along the soil-plant-atmosphere continuum has been the subject of much investigation, particularly in light of how plants may have evolved to optimize water usage for maximum production or fitness in arid regions. Hydraulic conductivity of the soil and root-soil contact are potentially important in limiting water flux to roots in drying soil [109,110]. Hydraulic conductivity of the root-to-leaf pathway represents an additional constraint on transpiration and is impacted by water stress in several ways. The xylem can be impaired by air embolisms that cause cavitation during periods of drought or high transpiration. The xylem water potential necessary to induce this cavitation varies widely among plants [111] and has been shown to correlate with the lowest xylem water potentials normally experienced under natural conditions [71]. Plants tend to control stomata such that the xylem water potential does not fall below cavitation-inducing pressures [112,113]. As soil moisture or humidity declines, either transpiration is reduced

or leaf-specific hydraulic conductivity is increased. In this way, plants balance the demand for transpirational water loss and carbon uptake by leaves with allocation to root absorption or stem-conducting tissue [68,114]. There is only a modest negative relationship or trade-off between the hydraulic conductivity and the susceptibility to drought cavitation for the wildland species that have been examined to date [115]. This may be because susceptibility to cavitation is more a function of vessel and tracheid pit anatomy than conduit size [116].

Preferential allocation to roots is a common response to water-stress conditions in wild plants [32,117]. Theoretically, plants should allocate energy to the growth and maintenance of the roots in a patch of moist soil if the physiological cost of this allocation is lower than the energy gained via photosynthesis from uptake of that moisture [13]. Unfortunately, there are very few data to validate this hypothesis for wildland species. Nobel et al. [63,118] found that the roots of succulent species in the Sonoran Desert have very low combined construction and maintenance costs. These succulents employ the crassulacean acid metabolism (CAM) photosynthetic pathway and are known to have relatively high water-use efficiency. The combination of high water-use efficiency and low root growth and maintenance costs likely contributes to the success of CAM succulents in very arid environments (root efficiency is maximized). Rapid, but low-efficiency, exploitation of water by roots may be favored under some circumstances such as intensely competitive environments or when belowground water resources are not limiting [64].

In addition to the impacts at the cellular, leaf, or whole-plant level, water stress may have important direct effects on ecosystem processes. For example, water stress at the leaf level may influence the stand level or regional transpiration fluxes. Of importance is the degree to which stomatal behavior controls transpiration from whole trees and stands [119] and the influence of stand structure and composition on canopy level transpiration [120]. Stomatal behavior and the development of a boundary layer may differ among patches of vegetation dominated by different species [121], thereby influencing the rates or patterns of transpiration and energy exchange on larger scales [99,119].

Nutrient Stress

Soil nutrient stress is a common feature in most wildland ecosystems [122]. Competitive interactions among plants, plant distribution at local and regional scales, and ecosystem productivity are strongly influenced by soil nutrient availability. Even in arid and semiarid regions where water imposes the primary constraint on plant growth and productivity, nutrient limitation can be a dominant feature of the environment experienced by plants. Numerous studies have shown greatest growth enhancement when soil mineral nutrients (particularly nitrogen) and water are experimentally added together in arid and semiarid ecosystems [123–125].

Soil-derived nutrients are allocated internally in a manner consistent with resource optimization theory. The plant internal nitrogen and carbon pools regulate efficient allocation under changing environmental conditions and resource demands by the plant [32]. Experimental additions of soil nutrients tend to shift allocation of biomass away from roots towards the shoots bringing internal carbon and nutrient reserves to a balance that is most favorable for maximum growth [13]. Plants adapted to nutrient-poor conditions tend to have inherently low relative growth and leaf turnover rates, use the limiting nutrient very efficiently by reabsorption from senescing tissues, and respond only modestly to experimental nutrient amendments [17,122,126]. Plants from nutrient-rich sites, in contrast, often have high relative growth rates and leaf turnover rates, and they are not effective at remobilizing nutrients to new growth or recovering nutrients from senescing tissues, but respond greatly in terms of growth to nutrient amendment. In general, evergreen perennials and sclerophyllous shrubs tend to dominate nutrient-poor sites, and deciduous or herbaceous plants tend to dominate nutrient-rich sites [17,122].

The degree to which preferential allocation occurs to above- or belowground plant components may depend on plant growth form. For example, evergreen Emory oak seedlings (*Quercus emoryi*)

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

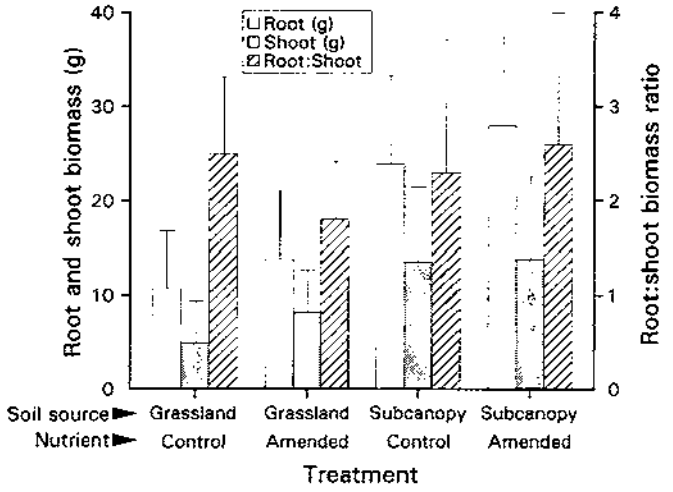

FIGURE 3 Root and shoot biomass (g) and root:shoot biomass ratios for 10-month-old *Q. emoryi* (Emory oak) seedlings grown in a greenhouse in Tucson, Arizona (J. F. Weltzin et al. unpublished data). Seedlings were grown within 1-m columns filled with soil collected from the subcanopy of *Q. emoryi* and in adjacent treeless grassland; soils received either a full nutrient amendment (equivalent to 12.0, 10.6, and 10.0 g m^{-2} yr^{-1} N, P, and K, respectively) or no nutrient amendment (control) ($n = 5$). Nutrient and nutrient $\times$ soil source interactions were not significant ($P > .23$) for any parameter. Vertical lines represent 1 standard deviation.

characteristic of southwestern savannas were grown in soils collected from beneath mature conspecifics and from adjacent treeless grassland [127]. Seedlings in each soil received either a full nutrient amendment or no nutrient amendment. Contrary to expectations, seedlings in the amended grassland soils (that had relatively low nutrient contents) did not exhibit preferential allocation to shoots (Fig. 3). Similarly, *Q. emoryi* grown from acorns in the field along a gradient of annual water inputs from 359 mm yr^{-1} to 846 mm yr^{-1} exhibited no reallocation response to watering treatments [128]. These results contrast with the observations of the growth response of deciduous *Q. douglasii* seedlings to resource manipulations in California (e.g., see Refs. 129 and 130). However, intrinsically low potential growth rates of evergreen plants such as *Q. emoryi* may constrain their ability to respond to resource additions [17,126]. In addition, resources other than those experimentally added may limit plant growth [131]. Further, biomass allocation in drought-adapted species such as *Q. emoryi* may be relatively insensitive to variations in soil resource availability, particularly soil moisture [132,133], or may be ontogenetically constrained [134].

The dynamics of vegetation are strongly influenced by soil nutrient conditions. Early ideas on primary succession implied a linkage to soil organic matter and nutrient accumulation fostered by colonizing plants [135]. The more subtle spatial and temporal dynamics of vegetation also are clearly linked to the effect that plants have on soil nutrient dynamics. Species adapted to conditions of low soil nutrient supply produce leaf litter that is low in nitrogen concentration and chemically protected from herbivores. These traits tend to reduce rates of decomposition and mineralization in the soil and reinforce low levels of nutrient supply to plants [126]. Dominant plants need only affect the mineralization dynamics of a small fraction of the total soil nutrient pool (labile nutrients found in surface soil) to have large impacts on overall ecosystem nutrient and vegetation dynamics. For example, Wedin and Tilman [136] found that Eurasian C_3 grasses produced

higher quality litter that released nitrogen at higher rates in soil than did C_4 perennial grasses in Minnesota old fields. These differences in litter quality were enough to alter soil nitrogen mineralization rates.

Although plants possessing the C_4 photosynthetic pathway require less nitrogen for photosynthetic metabolism on a per unit leaf basis than do C_3 plants, the ecological advantage in nutrient-poor soils is not always realized by C_4 plants. Sage and Pearcy [137] found that *Chenopodium album*, a C_3 herb, was more productive at low nitrogen supply rates than was the C_4 herb *Amaranthus retrofexus*. Fertilization experiments in Minnesota prairie ecosystems, however, caused alien C_3 grasses to become community dominants [138] in place of native C_4 perennial grasses. The outcome of competition and the community composition changes following disruption or changes in the nutrient supply, furthermore, may depend on other plant resources and their temporal or spatial distribution. For instance, Ehleringer et al. [139] predict that C_4 invasive species like *Salsola* will become dominant in native desert shrub ecosystems on the Colorado Plateau region in North America following disturbance of the nitrogen-fixing cryptobiotic soil crusts and increases in the intensity of the summer monsoon system predicted by global circulation models [140]. The soil crusts are responsible for up to 80% of the nitrogen inputs to these systems and are very sensitive to surface disturbance [141]. Summer season precipitation increases are important for the predicted outcomes, since C_4 species in this ecosystem maintain greater growth and photosynthetic rates in the hot summer season and utilize greater amounts of monsoon precipitation than do the native C_3 shrub species.

Defoliation Stress

All wildland plants experience defoliation (i.e., loss of aboveground tissue), and perennial plants usually experience repeated bouts of defoliation during their lives. Herbivores and fire are primary sources of defoliation of wildland plants. Similar to other sources of stress in plants, defoliation influences physiology, growth, and survival and ultimately may influence distribution of individual plants.

Considerable research has documented the responses of wildland plants to various seasons and intensities of defoliation, and this research has been summarized by several investigators (e.g., see Refs. 142–145). However, the physiological bases for predicting the plant response to defoliation are not known for most wildland species. Rather, most knowledge about defoliation has been derived from case studies of individual plants or plant assemblages. The vast literature on defoliation has been used to invoke many physiologically based hypotheses for plant responses; tests of these hypotheses are becoming more common in concert with technological advances.

Plant responses to defoliation are strongly dependent on the morphological and physiological features of plants. Relationships between these factors enable us cautiously to provide a few generalizations about the plant response to defoliation, as described below.

In general, the morphological trait that confers maximum resistance to defoliation involves the location of the primary growing points (e.g., meristems). Protection of these tissues by soil or plant tissue such as bark or dense leaves minimizes the risk of defoliation-induced mortality. Thus, rhizomatous grasses and woody angiosperms which are capable of resprouting from belowground tissues usually tolerate fires and high intensities of herbivory. In contrast, stoloniferous grasses (e.g., *Bouteloua eriopoda* [Torr.] Torr.) and woody plants with unprotected aboveground buds (e.g., most conifers) are susceptible to mortality induced by herbivory or fire. However, species with unprotected buds may possess characteristics that enable rapid recolonization of burned or grazed areas (e.g., serotinous fruits, recalcitrant seeds), which indicates that no single trait can reliably predict the plant response to defoliation.

The response to defoliation is closely related to the availability of water. In fact, plants may be particularly susceptible to defoliation-induced mortality during periods of limited water availability regardless of the plant phenology or the intensity of defoliation [146]. Both above- and belowground growth are reduced by defoliation [147–151] and reductions are especially pronounced when soil

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

moisture is limited [146], presumably because reductions in the root growth constrain water uptake from the soil. Reductions in the root growth also may affect nutrient uptake.

Plant phenology influences the response to defoliation. For example, herbaceous plants are particularly susceptible to defoliation during the period of late vegetative and early floral growth [148,152,153]. Seedlings of the arborescent legume *Prosopis glandulosa* Torr. (honey mesquite) become increasingly intolerant of repetitive top removal with increasing age at initial defoliation (Fig. 4). Retention of functional cotyledons that otherwise abscise within about 20–40 days of shoot emergence may enable seedlings to tolerate defoliation early in their life cycle [154] (cf. Refs. 155 and 156). Similarly, delayed senescence and stimulated photosynthesis of leaves remaining on partially defoliated plants have been reported for various plant growth forms [157]. Plant functions are relatively unaffected by defoliation during the period after seed formation and before initiation of spring growth [146,158,159], presumably because plant physiology is largely restricted to maintenance activities rather than growth or reproduction.

Characteristics that influence the plant response to defoliation, depending on species and sites, include canopy architecture, rooting habit, carbohydrate status, growth form, and inherent growth rate among others [160,161]. For example, large bunchgrass plants with fine leaves tend to be more susceptible to fire than small, coarse-leaved plants, because abundant litter which accumulates in the crowns of the former plants burns longer and more completely than the litter in the latter plants; the associated heat load on meristematic tissue apparently causes high mortality [162].

Fires and herbivores may produce dissimilar effects on plants. Fires usually remove more biomass than herbivores during a specific temporal period, which produces several distinct local differences between these two types of defoliation. Unlike herbivores, fires increase solar insolation at the soil surface, increase soil temperature, and volatilize more nutrients. These differences in the physical environment are responsible for many of the differences in the biological response between fire and herbivory.

There also is considerable variability in the plant response within these broad categories of defoliation. For example, defoliation by invertebrates may be quite dissimilar to defoliation by vertebrates; similar caveats pertain to generalist herbivores versus specialist herbivores and different intensities of fire among other factors. In addition to the variability associated with differences

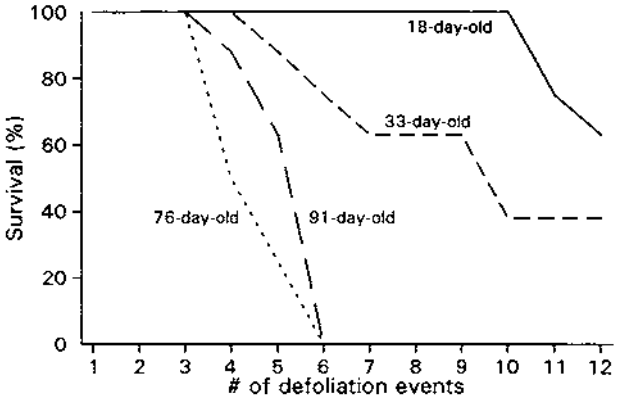

FIGURE 4 Survival of *Prosopis glandulosa* (honey mesquite) initially defoliated above the cotyledonary node at 18, 33, 76, and 91 days after shoot emergence and defoliated thereafter at 2-week intervals (n = 8). Seedlings were grown from seed in commercial potting soil in a controlled environment chamber. Soil water content was maintained near field capacity, and water soluble fertilizer was applied twice monthly. (Adapted from Ref. 154 and J. F. Weltzin, unpublished data.)

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

between and within these sources of defoliation, additional variability arises from comparisons across taxa and environments. The responses of individual plants are highly variable and are dependent on environmental conditions before, during, and after defoliation events [163]. Therefore, the response of individual plants may deviate from the generalizations described in this section [146,154,161].

Several investigators (reviewed in Refs. 164–166) have suggested that herbivory increases total productivity, reproductive output, or fitness of some plant species. Empirical evidence for ''overcompensation'' by grazed plants is generally weak, and responses have been poorly linked to physiological mechanisms. Nonetheless, the phenomenon has been at least partially documented for a few systems [167].

STRESS IN THE FACE OF GLOBAL ENVIRONMENTAL CHANGE

The concepts and examples described in the previous sections indicate that much is known about the response of individual plants to various agents of stress. In some cases, the responses of plant assemblages can be explained on the basis of individual plant responses. It also is evident that stress factors interact with one another. Given the anticipated rapid and substantial changes in atmospheric composition, considerable knowledge about the response of individual plants to stress must be re-evaluated in light of these changes. Current knowledge may help predict the responses to some future changes but may be deficient for other predictions. However, the functional equilibrium or optimal allocation concept of the plant response to stress provides the theoretical framework for predicting responses to changing environmental conditions and resource limitations of the future [32]. Since shifts in the allocation at the whole-plant level determine the rates of resource use or processing by the plant, it may be feasible to at least generate crude predictions of the vegetation responses to future conditions. A mechanistic approach is preferable here, because we have few good analogues or environmental gradients that may provide the information needed to predict the responses to future conditions.

Atmospheric concentrations of carbon dioxide have been rising since the beginning of the 19th century and are predicted to reach about 700 ppm by the middle to end of the 21st century [168]. Increases in CO_2 levels are predicted to have both direct (e.g., reduction of stomatal conductance) and indirect (e.g., alteration of surface temperatures or precipitation regimens) effects on vegetation [169]. The response of plants to elevated CO_2 has been documented for a great number of species and growth and life forms [170]. Increases in CO_2 typically benefit plants with C_3 photosynthetic metabolism by decreasing photorespiration and by increasing net CO_2 assimilation, quantum yield, temperature optima for photosynthesis, and water- and nutrient-use efficiency (see reviews in Refs. 171–178). Furthermore, tolerance of C_3 plants to heat, drought, salinity, and other stresses is improved by elevated CO_2. As such, C_3 plants exposed to elevated carbon dioxide levels generally exhibit increases in net photosynthesis and above-and belowground biomass production. For example, a recent comprehensive literature survey of 250 C_3 species grown individually under conditions of elevated CO_2 reported a 47% increase in dry matter accumulation [170].

In contrast, plants with C_4 photosynthetic metabolism have been regarded as being relatively unresponsive to elevated CO_2, or responses have been inconsistent [170,174,175,179]. However, recent research with C_4 species suggests that they may also benefit from rising CO_2 levels [180–183]. In their review of literature, Poorter et al. [170] found a statistically significant 10% increase in the net biomass accumulation for C_4 plants grown singly under elevated CO_2 concentration. Positive responses of C_4 species to elevated CO_2 levels have been attributed to small but consistent increases in photosynthesis [184], increases in water-use efficiency (WUE) caused by reductions in stomatal conductance [181,185], or interactive effects of leaf water potential and photosynthesis [180].

However, the actual response of plants to CO_2 enrichment varies among species and photosyn-

thetic pathway types and depends on other biotic and abiotic environmental conditions such as soil fertility and moisture, species characteristics, or competitive environments [179,186–188]. For example, based on the response of C_3 and C_4 plants grown separately, a priori one might predict that elevated CO_2 would favor C_3 plants over coexisting C_4 plants (see Refs. 175 and 189, but see Ref. 190). However, studies of the effects of CO_2 enrichment on plants grown together have produced a variety of outcomes. In a recent review of the effects of elevated CO_2 levels on C_3 and C_4 plants grown together, Reynolds [179] concluded that when environmental factors are not limiting, C_3 species typically increase performance relative to C_4 species. Conversely, when competitive interactions are strong or soil fertility is high, CO_2 increases may favor species that are superior competitors for light regardless of their photosynthetic pathway (e.g., see Refs. 185, 188, 191, and 192).

Regardless, it is often hypothesized that shifts in the competitive abilities of C_3 and C_4 plants that experience increased atmospheric CO_2 concentration or other indirect effects of climate change may result in changes in their relative abundance or spatial distribution [173,193–196]. For example, it has been hypothesized that increases in CO_2 may enhance the growth and establishment of C_3 shrubs in C_4-dominated grasslands of the southwestern United States [175,186,189,197]. Increases in the WUE and fine root biomass of C_3 woody plants under elevated CO_2 (e.g., see Refs. 186, 198, and 199) suggests that these plants may be able to expand their distribution into ecosystems where water is otherwise a limiting factor [194]. A simple WUE model developed by Idso and Quinn [200] suggested that a doubling of atmospheric CO_2 levels would cause oak woodlands dominated by *Q. emoryi* Torr. in the southwestern United States to shift downslope and displace extensive regions of semidesert grassland. The indirect effects of CO_2 enrichment on soil water availability include increased WUE for most species, with ramifications for species currently limited by dry conditions [83].

LINKING PHYSIOLOGICAL AND ECOSYSTEM PROCESSES

Linking stress responses of individual plants with ecosystem processes (i.e., scaling up) represents a major challenge, and it is a primary focus of contemporary research. The goal of this exercise is to develop methods for extending very limited ground measurements of ecosystem function (CO_2 uptake, evapotranspiration, energy exchange) to large areas (region, globe) and predict ecosystem functional responses to future climatic and human land-use conditions [201].

Individual responses to any number of future environmental changes (elevated CO_2, precipitation redistribution, climate warming) can be interpreted within the theoretical framework of optimal allocation. Furthermore, interactions at the community level, either positive or negative, that impact local resource availability or that affect essential plant functions, likewise can be viewed within this context [32]. These interactions, however, are complicated and may limit our ability to use simple bottom-up approaches to predict the responses of vegetation to global changes.

Field [20] argues that if plants have evolved a limited set of optimal responses to resource limitations and stress, then nitrogen distribution and allocation within plants will be good predictors of plant carbon gain capacity and can be scaled to the ecosystem level. The whole canopy photosynthetic capacity, therefore, could be sensed remotely for the purposes of global assessment of carbon fluxes. Essential to this approach is a consistent scaleable relationship between maximum photosynthetic rate and nitrogen concentration of photosynthetic tissues and the spectral qualities of the leaf canopy. In this sense, one could view the plant canopy as a ''superleaf'' that has predictable characteristics under different resource supply rates.

The variety of solutions that plants have evolved to meet the demands of environmental stress and resource limitation in natural environments is exemplified by the diversity of plant life forms, phenologies, and physiological systems. Limitations to scaling the plant ecophysiological processes to the ecosystem are due to the complexity of resource-use patterns displayed by plant species and life forms and the patterns of micrometeorological fluxes and feedbacks in natural ecosystems

[202,203]. A complicated but widely applicable approach to scaling plant responses to the ecosystem level involves classifying plant species into functional groups and assessing the abundance of these groups across the landscape. The plant functional type (PFT) concept has emerged as a useful way to organize plant species with similar responses to and impacts on ecosystem processes into manageable and meaningful categories. Useful traits for a PFT classification would include the characteristics of the plant form and function that influence the rates and processes of transpiration, energy exchange, nutrient cycling, and migration into new habitat [201]. Depending on the spatial scale of interest, the traits could be very specific or very general such that modeling and prediction are practical and explanatory. PFT description of dominant plant species should recognize species-environment responses and potentially account for habitat conditions. This is similar to the ''norm of reaction'' concept that is useful for interpreting the ecological and evolutionary responses of genotypes, populations, and species [204] to environmental heterogeneity but are applied here to changes in species' functional roles at the ecosystem level.

The PFT concept explicitly recognizes that the relationship between species diversity and ecosystem function is tenuous. Identification of functionally different groups for specific ecosystems is necessary to generate meaningful predictions about the effects of species removals on ecosystem properties [205]. To make PFT classifications robust, experiments must be carefully executed to minimize confounding factors between diversity and other factors that may influence ecosystem function. Thus, results from the few experimental investigations to date, which indicate that increased diversity of plant functional types increases ecosystem productivity and stability [135,206–210], may not apply to other systems. Research being conducted on the Jornada Experimental Range in southern New Mexico, wherein species diversity and PFT diversity are being experimentally manipulated by selective removals, should shed additional light on the interactive effects on this issue (L. Huenekke and W. Schlesinger, unpublished data).

CONCLUSIONS

Stress is a phenomenon that occurs at the scale of individual plants but that has important manifestations at the ecosystem level via the effects on organismic interactions and fluxes of energy and materials. Because plants function as a balanced system, stress will have somewhat predictable effects on allocation patterns and resource use that potentially can be scaled to higher levels. Consequently, predictions of the stress effects at the ecosystem level will necessarily be improved with the development of robust physiological models. Although optimal physiological responses to stress are difficult to model and measure, and are not expected in every situation, the concept provides a useful starting point for predicting vegetation responses to altered resource distributions brought about by anthropogenic or natural perturbations. Recent research has focused on empirical descriptions of the plant response to elevated CO_2 levels and illustrates the complex nature of responses of plant assemblages. A clearer understanding of processes that link physiological stress responses with population, community, and ecosystem processes will greatly enhance our ability to predict the structure and function of wildland ecosystems into the next century.

INTRODUCTION

Saline soils are of worldwide occurrence, but their incidence is more severe in arid and semiarid regions. Higher evapotranspiration than precipitation in these areas aggravates the situation further. The capillary rise, often of bad-quality water, brings salts to the surface from the deeper horizons, which are not leached down and out of the root zone. In the presence of a shallow water table, the process of salinization of soil surface is further accelerated.

In spite of our efforts to counter the menace of salinity, it remains a major threat to agriculture. It is affecting yields on large areas and is creeping into fertile lands at an alarming pace. In most of the developing countries, the ever-increasing population and soil degradation at a rate higher than reclamation make the problem of saline soils even worse. These lands, which are abundant, are not generally suited for most of the field crops. The solution lies in leaching the excess salts out of the rootzone and subsequent drainage. Sinking of tube wells and the installation of tile drains may help, but this is a costly proposition.

The persisting demand for conventional agricultural production will continuously recharge the groundwater and subsequent discharge will make the reversal of the situation unlikely at least in the near future. Being a long term problem, soil salinity requires suitable land utilization choices to be made. One option may be the planting of trees and shrubs, many of which can withstand much higher salinities than most of the conventional agricultural crops [1].

The following sections highlight some of the candidate species for salinity and relevant soil

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

problems, like sodicity and waterlogging. The species mentioned here are only meant for illustrative purposes, and the list is not exhaustive. Many more and possibly even better ones for a particular condition may exist. There also is a need to conduct more experiments to match the suitability of species for the conditions of a site. Efforts to introduce *Leucaena leucocephala* in the Sahel, for instance, did not bring desirable results, because the pH there was much lower (6.0 or below) than required (above 6.5) for most of the varieties. A proper approach would be to assess the detailed physicochemical properties of the site and make recommendations accordingly. An alkaline soil may, for instance, allow better growth of *Casuarina equisetifolia*, *Acacia auriculiformis*, *Phoenix dactylifera*, and *Tamarix* spp. *Pinus* and *Bambusa* spp. do better under acidic pH, *A. raddiana* and *Acacia senegal* grow well in loose, light, and sandy soil, and *A. nilotica* and *Bauhinia reticulata* prefer heavy, clayey soils that may become waterlogged during the rainy season [2].

TREES ON FARMS

The importance of trees needs no emphasis, and their products and by-products are too many to cite here. There is no denying the fact that there is no farm, big or small, without trees. Trees are known to conserve soil and water supplies, check erosion and runoff, enrich the soil, and reduce the hardships of rural life. They not only provide shelter for workers during the hot sunny days, but in many cases supply the much needed fuel, complement fodder requirements, and provide cash return through sale of their wood.

In areas of high wind velocity, trees may be useful for windbreaks and shelter belts. The effectiveness of shelter belts in reducing wind erosion has been demonstrated in many parts of the world. When used as windbreak, one often hears of root competition and other undesirable effects of trees (e.g., shade, allelopathy), but the yield gains of the protected crop often outweigh the losses if any. Root competition is of major concern, because it shares the nutrients and water with the crops. This can be avoided by digging a trench between the tree row and the field to check the access of tree roots.

It is, however, also worth mentioning here that the resources of a small farmer are limited. The farmer has to meet the requirements of his or her family and livestock from the farm. It necessitates the maximum use of the land at the farmer's disposal. Consequently, he or she is a mixed system farmer, who is interested in immediate gains and cannot afford to invest in ventures with a sizeable time gap between investment and return. Growing trees is a proposition which requires a waiting period. The introduction of fast-growing multipurpose tree species has reduced this time gap to some extent [3]. These species may meet several needs, and the overall returns may be comparable with other farming systems, but growing annual crops will still be more attractive. However, through education and by providing proper incentives, a farmer can be convinced to accept other profitable proposals.

The practice of the block plantation of *Acacia nilotica* (known locally as ''hurries''), which has been in vogue in the Sindh Province of Pakistan since the 1850s, is a case of the adoption of tree planting for improving marginal lands, including salt-affected ones. In this system of planting, seed of *A. nilotica* is scattered over the marginal plot which, after the initial soaking dose, receives only the run-off from adjoining fields. The seedlings grow among a crop for the first season, after which very close trees are removed for wider spacing, but the stand is still so thick that the canopies intermingle. The stems are thin, straight poles and after 5–6 years can be sold at a profit. The root biomass and the leaf fall enriches the soil for normal cultivation. Thus, the farmer not only gets a monetary benefit with a minimum input but also ends up with a much improved piece of land.

CHARACTERIZATION OF SALT-AFFECTED SOILS

Saline soils are characterized by an EC_e (electrical conductivity of the soil saturation extract) greater than 4 mS/cm, pH below 8.5, and an ESP (exchangeable sodium percentage) less than 15. These

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

soils generally contain neutral soluble salts comprising chlorides and sulfates of sodium, calcium, and magnesium and they possess good physical condition and permeability owing to the flocculating effect of neutral salts. Sodic/saline-sodic soils, on the other hand, have a high pH and exchangeable sodium. They have greatly impaired physical and chemical conditions owing to the deflocculating effect of sodium on soil resulting in, for example, surface crusting, compaction of subsoil, reduced infiltration rate, and poor hydraulic conductivity. A more precise classification of salt-affected soils is given:

Salinity		Sodicity	
ECe (mS/cm)	Class	ESP	Class
<4	Nonsaline	<15	Nonsodic
4–8	Slightly saline	15–25	Slightly sodic
8–15	Moderately slaine	25–35	Moderately sodic
>15	Highly saline	>35	Highly sodic

EXTENT OF SALT-AFFECTED LANDS

Of the approximately 13 billion ha total land areas on earth, about 1 billion ha are affected by salinity/sodicity [4,5] (Table 1). This does not include the former Soviet Union (about 2.22 billion ha), for which data are not available. According to another report [6], saline/sodic soils cover about 26% of the world's cultivated land. Incidentally, most of the developing and underdeveloped countries of south and Southeast Asia, Africa, and South America lying in arid/semiarid regions, are the worst affected by this threat.

India, for instance, has about 7 million ha of saline/sodic lands [7], whereas the neighboring Pakistan, with a much smaller land area, has about 4.2 million ha of such lands in the Indus Basin only [8]. The whole country may have as much as 6–7 million ha [9], resulting in a national economic loss of about 32 million US$ annually [10]. In these countries, waterlogging is the main cause of the upward flux of salts, which is due to the intensive and continuous use of surface irrigation and has altered the hydrological balance of the affected areas.

TABLE 1 Worldwide Occurrence of Saline/Sodic Soils in Million Hectares

	Total area	Affected
North America	2137.80	17.72
South America	1753.47	129.16
Africa	2963.63	80.54
Australia	788.66	357.33
Europe	472.96	50.80
South Asia	678.02	84.83
North and Central Asia	1103.01	211.69
Southeast Asia	897.62	19.98
Former USSR	2227.00	N.A.
Total	13022.17	952.05

Source: Refs. 4 and 5.

270 Madison Avenue, New York, New York 10016

Adding to the problem is a more serious and perpetual loss of water through seepage from canals and watercourses. Waterlogging, even for short periods and with nonsaline water, may have adverse effects on plant growth. Stagnant water, even if nonsaline, reduces the growth of most flood-tolerant species (e.g., *Taxodium distichum*) [11].

TREES ON WATERLOGGED SOILS

Tolerance to waterlogging has not been studied systematically in the field because it is very difficult to maintain uniform waterlogging during extended periods. The information available has been derived from observations recorded from natural habitats (i.e., swamps, seasonally waterlogged areas). Modifications like the development of aerenchyma in roots and the proliferation of roots which run laterally near the ground surface help in flooding tolerance. The former helps in relieving anoxia, and the surface roots start functioning normally as soon as the water recedes from the surface, but the deeper roots are still inundated [12]. van der Moezel et al.[13] reported that *Casuarina obesa* and *C. glauca* developed aerenchyma in the roots and, consequently, they grow better than *C. cristata*, *C. cunnighamiana* and *C. equisetifolia*. Data derived from other reports suggest that *Eucalyptus camaldulensis* may tolerate long-term flooding [14]. Other waterlogging-tolerant species include *Melaleuca* spp., *Eucalyptus tereticornis*, *E. robusta, Salix* spp., *Syzygium cuminii*, *Terminalia arjuna*, and *Albizia procera* [15].

Unfortunately, vast areas of saline lands have a shallow water table or they get inundated during the rainy parts of the year. In saline waterlogged soils, the effects are compounded, and it has been observed that plants which can withstand fairly high salinities do not grow well or even fail to survive if salinity is combined with waterlogging. This makes the choice of species difficult for such conditions.

Many *Eucalyptus*, *Casuarina*, and *Acacia* species exhibit high salt tolerance, but they will not tolerate waterlogged conditions associated with salinity, whereas some *Acacia* spp. (e.g., *nilotica*, *stenophylla*) are fairly tolerant of the combination of waterlogging with low to moderate salinity [16–18].

TREES IN SODIC SOILS

Sodic soils are characterized by poor physical conditions, nutritional imbalance, and ion toxicity. Sodicity tolerance has generally been characterized by ESP: sensitive species are affected at ESP of about 10, moderately tolerant at 20–25 and highly tolerant at >25 [15]. Some tree species having fairly high sodicity tolerance are *E. tereticornis*, *E. camaldulensis*, *Prosopis juliflora*, *A. nilotica*, *A. auriculiformis*, *Zizyphus* spp. [19], *A. modesta*, *A. stenophylla*, *P. chilensis*, *P. siliquestrum*, *P. alba*, and *C. obesa* [20].

SALINITY AND PLANT GROWTH

Plants exposed to saline condition face various stresses, which may be (a) reduced availability of water due to the low osmotic potential of the external medium compared with that of the cell sap (also sometimes termed *physiological drought*); (b) specific ionic effects, especially those of Na and Cl; and (c) nutritional, enzymatic, hormonal, and other disturbances due to combined effects of (a) and (b).

Plants which are capable of withstanding the harmful effects of these stresses do so, for example, through controlled transpiration (i.e., reduction in uptake of harmful ions), the production of organic osmoregulants (e.g., proline, glycinebetaine), the selective uptake of K in preference to Na (avoidance), succulence (i.e., dilution of harmful ions), the excretion through salt glands, salt hair,

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

and the shedding of salt-loaded leaves (reducing salt load) [21]. Such plants consequently complete their life cycle better than those which succumb to the above pressures.

Glycophytes, the class of plants to which all of field crops belong, have only limited tolerance to salinity. Halophytes, the salt-loving plants, on the other hand, can grow in fairly high salinities, and they may even require certain salt concentrations for optimum growth [22]. The potential use of most of the halophytes has, however, yet to be explored, although these plants have a wealth of very useful species having food, industrial, medicinal, land conservation, and esthetic values [23–25].

SALINITY AND TREES

Gainful utilization of the salt-affected lands would be possible through the use of salt-tolerant glycophytes or suitable halophytes; the former have a low threshold level of salt tolerance [26] and the later have low utility. Trees may prove an attractive alternative, as the threshold of many species for stress tolerance is higher than most field crops. If it is a multipurpose tree, then the owner gets a good return of desirable products from an area where nothing worthwhile grew before. The microenvironment, root action, and leaf fall, for example, may gradually improve the soil condition and allow growth of less stress-tolerant species after the land has been under trees over a period of time.

A number of fruit trees are known to be appreciably salt tolerant. These include, among others, date palm (*Phoenix dactylifera*), fig (*Ficus carica*), jojoba (*Simmondsia chinesis*), jujube (*Zizyphus jujuba*), olive (*Olea europaea*), papaya (*Carcia papaya*), pineapple (*Ananas comosus*), pomegranate (*Punica granatum*), guava (*Psidium guajava*), sapodila plum (*Acharas zapota*), black plum (*Syzygium cuminii*), and grewia (*Grewia asiatica*).

While going through the literature, we often come across plant species which are common to different stress conditions. One striking example is a general similarity between drought and salinity tolerances. Although not universal, many woody species growing in arid areas cope fairly well with at least moderate salinity levels. This may be due to the fact that the two stresses of salinity and aridity have one thing in common. Whereas a shortage of water per se is an impediment in arid drought–affected soils, salinity causes ''physiological drought'' due to a lowered osmotic potential, which is of course accompanied by specific ionic effects.

Nearly one third of the earth's surface, excluding polar regions, has been classified as arid or semiarid. About 15% of world population lives in these regions where conventional crops may not be successful. Some woody species relevant to such conditions are *A. albida, A. nilotica, A. auriculiformis*, *A. tortilis* (sand dune stabilization), *A. catachu* (tannin), *A. senegal* (gum exudate), *Albizia lebbek*, *A. procera*, *Azadirachta indica* (nonedible oil, pesticides, fertilizers), *Cassia siamea* (pepper), *Leucaena leucocephala*, *P. juliflora*, *P. cineraria*, *Sesbania grandiflora* (paper, pulp), *Phyllanthus emblica*, and *Zizyphus mauritiana* (fruit) [27].

A number of other species may tolerate exclusively either salinity or drought stress, but many of the above-mentioned drought-tolerant species perform satisfactorily under moderate to high salinity levels. It is thus evident that a knowledge of drought-tolerant species narrows our search for identifying salt-tolerant species.

One point worth noting here is that a wide variation may often be found between provenances (stands in a particular area developed through natural selection), because species evolved under certain environmental conditions are expected to have acquired these characteristics [28]. For instance, the Petford provenance of *E. camaldulensis* had 200% greater wood volume than the Walpole provenance at 5 years of age [29]. In fact, in *E. camaldulensis* [30] and *E. occidentalis* [31,32] intraspecific variation is reported to be so wide that to assign a tolerance classification at the species level is not reliable.

Efforts have been made in the past to screen plants for salt tolerance. A number of floras and directories have lately been published which provide information about species suited for cultivation under particular conditions. These also provide a basis for exploiting the potential capacity of these

plants for the benefit of humankind. Aeronson et al. [33], for instance, have evaluated the response of 120 halophytes to irrigation with seawater and subsequently published a data-based record of salt-tolerant plants [34]. Other bibliographies of a similar nature also are available (e.g. see Refs. 35–37).

It is, however, evident that screening of woody species for salt tolerance has received comparatively less attention than field crops. The dynamic nature of salinity and its changing influence on plants during phases of growth makes it easier and probably more precise to study annuals than perennials. The beneficial influence of trees on the earth's atmosphere and their land conservation values are increasingly being appreciated, resulting in diverting the attention of researchers toward this important but relatively less recognized reality of the present day. For instance, this recognition has led to the widespread introduction of *E. camaldulensis* in the saline lands of Pakistan.

Today, attention is being focused worldwide to identify suitable woody species for use as fodder or fuel. Timber is a high-value product of trees, but it often receives a lower priority than fodder/fuel, especially in less-developed countries where energy and food shortage attain immense significance. Table 2 summarizes some such species found to be tolerant to irrigation water salinities of 10–20 mS/cm in sandy areas [38–43].

Woody species from Australia, especially *Acacia*, *Eucalyptus*, *Atriplex*, *Melaleuca*, *Casuarina* species, and mesquites from the Americas, figure prominently in many studies on salt tolerance. *Atriplex* species dominate saline plains over vast areas in Australia and provide useful supplemental fodder for cattle during periods of shortage. These are, however, shrubs and not trees, but in addition to utility as cattle feed, they may be used as fuel. Some other shrubs may be similarly relevant under particular conditions, but they are not fully exploited, and only *Atriplex* species have been studied in any detail for utilizing saline lands.

High salinity tolerance in *Atriplex* is expected owing to it being a halophyte. It attains this tolerance through accumulation of a high salt content (18–21% of dry matter, mostly as NaCl) in the forage. The in vitro dry matter digestibility may be about 75%. Sheep feeding on such diets require an increased water uptake. Limited evidence of diarrhea in the grazing animals was found, which persisted in the lambs born to these ewes, but cleared up within a few days after feeding from the salt bush was stopped [44].

A wide range of *Atriplex* and *Maireana* species were subjected to test under arid and/or saline conditions in a program on the use of forage shrubs for saline areas of Pakistan during 1991–1993. Results from these studies have provided useful information on salt tolerance and other related aspects of these species, which confirm the results from similar studies from other parts of the world. From these studies, it is evident that *A. amnicola*, *A. lentiformis*, *A. undulata*, *and A. halimus* have the potential to tolerate high–salinity/sodicity stress [1].

Felker and his colleagues have worked extensively in the United States on *Prosopis* species and reported them to be generally highly tolerant to stresses like salinity and drought (e.g., see Refs. 45 and 46). Similar reports also have come from other parts of the world [20,47–50]. *Prosopis* species are, however, such aggressive colonizers that they may become troublesome weeds and hence a nuisance.

Some other studies from India and Pakistan have reported *Prosopis* spp. (*juliflora*, *chilensis*, *alba*) to be more tolerant than *A. tortilis*, *E. camaldulensis*, *C. equisetifolia*, *Azadirachta indica*, *E. tereticornis*, *E. microtheca*, and *A. nilotica* [51–54].

In another study, Singh et al. [55] reported that *Dalbergia sissoo* did not perform well in saline/sodic soils of Utter Pradesh, India. This was later confirmed from a pot culture experiment [56], where *C. equisetifolia* was observed to be most salt tolerant (EC_e, 32.5 mS/cm), followed by *A. nilotica*, *Eucalyptus* hybrid, *Pongamia pinnata* (EC_e, 16.3 mS/cm), and *D. sissoo* and *Arucaria cunnanghamii* (EC_e, 8.1 mS/cm). Rankings for salinity tolerance have also been published for a number of species of *Acacia* [57,58], *Casuarina* [13,59], *Eucalyptus* [60–64], and *Melaleuca* [62,64].

Eucalypts dominate a forestation program for cultivating moderately saline lands in many countries, and *E. camaldulensis* is probably the species that has the widest adaptability [65–68].

Other species, like *Casuarina and Melaleuca*, may attain significance under particular conditions; for example, cultivation in sandy/costal areas [13]. A number of *Acacia* species are gaining attention in the context of the utilization of salt-affected lands because of their high utility and land-conservation properties. Aswathappa et al. [57], working on the response of a number of tropical and subtropical acacias of Australia to salinity, found that, based on the classification of Pedley [69], species belonging to the section Juliflorae were generally the least tolerant, whereas those of Phyllodineae generally performed the best and Plurinerves were intermediary. A 50% reduction in the growth of

tolerant species occurred at an average salinity level of about 1500 mM, at 1100 mM in intermediary, and at 800 mM in least tolerant species. Tolerance to salinity in *Acacia* species is generally through exclusion of sodium, as Craig et al. [58], working on the salt tolerance of 10 taxa of *Acacia*, found that the slowest rates of growth were associated with the accumulation of the highest concentration of sodium in the uppermost phyllodes.

In order to capture greater genetic gain, obtain a uniform population rapidly, matching closely with specific environmental conditions, it may often be more desirable to reproduce individuals through clonal vegetative propagation [70]. Shoot/rooted cuttings and micropropagation or tissue culture may be employed for this purpose. Recent studies on the comparison between clones of *E. camaldulensis* and unselected seedlings on saline sites have shown the superiority of such clones [71,72]. However, a wider variation between provenances still remains a comparatively easier option for identifying suitable candidates for particular soil/environmental conditions.

Taking the lead from an Australian Center for International Agricultural Research (ACIAR) publication [73], one of the first screening trials outside Australia, on Australian *Acacia* and *Casuarina* species for salt tolerance was conducted by Ansari et al. [74], where the *Acacia* species were generally more tolerant than *Casuarina* species. Field trials were conducted later by Ansari et al. [16] using more diverse species. Observations recorded at 2 years after outplanting showed that *Acacia* species and *Atriplex lentiformis* were generally more tolerant than other species under test. Among the species of *Acacia*, *A. auriculiformis* and *A. salicina* did not survive, whereas *A. ampliceps* proved to be the best, followed by *A. stenophylla*, *A. machonochieana, A. nilotica*, and *A. victoriae. Casuarina glauca* performed fairly well, but its growth was much slower than that of acacias. Among eucalypts, *E. microtheca* showed better tolerance with *E. occidentalis* and *E. camaldulensis* barely surviving.

Among the indigenous species under test, *Cassia sturtii*, *Azadirachta indica*, and *Prosopis cineraria* did not survive, whereas *Conocarpus lancifolius* and *Parkinsonia aculeata* had better survival but poor growth compared with *A. nilotica*.

Interprovenance differences also were noted. *A. ampliceps* (15741), for instance, had better survival and growth than its counterparts. Similarly, *A. stenophylla* (15736) and *Casuarina glauca* (15929) were superior to nos. 14670 and 15941, respectively, and total mortality occurred in *E. camaldulensis* (15319), but a few plants survived in 15441. This illustrates the need of conducting provenance/progeny trials for more tangible results.

This experiment was badly damaged by the monsoon rains and, consequently, most of the species suffered high mortality. However, the surviving plants of *A. stenophylla*, *A. nilotica*, *E. microtheca*, and *Atriplex lentiformis* grew fairly well even after the waterlogging. Some plants of *Casuarina glauca*, *C. obesa*, *Conocarpus lancifolius*, and *Parkinsonia aculeata* also survived, but the recovery from shock due to waterlogging was not complete, as these plants had very poor growth.

The observations of the growth performance of individual trees of *A. ampliceps* (15741), categorized on the basis of rootzone salinity, irrespective of replicates, showed a typical halophytic response (i.e., stimulation in growth at EC_e 5–10 mS/cm compared with a lower [EC_e <5] salinity level, and a gradual depression at higher EC_e). *A. ampliceps* is not a halophyte, and this response may not be real but more of an illusion due to scatter of the observation points. This, however, illustrates the potential of *A. ampliceps* to withstand the adverse conditions of salinity, but without waterlogging, as the two stresses proved fatal for this species. Table 3 presents a spectrum of broad categorization of some important woody species for their performance under moderate to extreme salinity/sodicity conditions [75].

STRATEGIES TO IMPROVE INITIAL GROWTH

A high seeding mortality and difficulty in establishing at the initial stages is often encountered after outplanting in salt-affected areas due to osmotic and/or specific ionic effects. If this situation could some how be improved, subsequent growth might not be severely hampered. In spite of their high

Table 3 Categories of Woody Species Based on Reasonably Good Performance Under Conditions of Moderate to High Salinity/Sodicity

Severity	Salinity	Sodicity
Moderate	*Acacia auriculiformis*	*Acacia auriculiformis*
	Acacia nilotica	*Acacia saligna*
	Acacia saligna	*Casuarina glauca*
	Casuarina cunnighamiana	*Eucalyptus occidentalis*
	Casuarina equisetifolia	*Melaleuca bracteata*
	Eucalyptus camaldulensis	*Melaleuca halmaturorum*

For severity classes: EC_e 4–8 mS/cm: moderate, 8–16: high, >16: severe salinity, and pH 8–9: moderate, 9–10: high, >10: severe sodicity [75].

salt tolerance, even the tree species need appropriate strategies to reduce the environmental stress during the early establishment phase. This helps to improve growth, as our sole objective is to have flourishing plants on a saline site, without which one cannot expect any tangible effect on the soil as a result of, for example, due to litter fall and root action.

Efforts are, hence, needed to improve the survival and growth of trees through cultural and other methods. Land leveling and subsurface loosening [76], planting on raised beds at nearly one third of the way below the peak [77], and mulching with sand or straw [78,79] have been reported to alleviate the adverse salt effects on trees. Mounding may improve survival under conditions of waterlogging resulting from a shallow water table or poor soil permeability [80]. A combination of treatments may often have greater impact than a single treatment. For instance, in a trial in Thailand, *A. ampliceps* performed best under a combined application of rice hull mulch, gypsum, and NP fertilizers [75].

Preconditioning of tree seedlings before transplanting may affect their subsequent performance in the field. In an experiment, some seedlings, when sown in a field of fairly high salinity (EC_e 20–30 mS/cm) tolerated salts better than those transplanted directly from the nursery [81].

Ahmad and Ismail [82], in their experiments at Karachi University, Pakistan, have observed that a prehardening treatment with saline water of 10 mS/cm resulted in better surival and establishment of *A. ampliceps* and *P. juliflora*.

Another trial conducted at Tandojam, Pakistan, under the same program using *A. ampliceps*, *A. nilotica*, and *C. lancifolius* showed that mulching with wheat straw had a beneficial effect on initial survival, and these effects persisted until the later stages of growth [16]. Here, irrespective of the species, control generally had the lowest survival, whereas mulching alone or in combination with other treatments (extra watering or addition of NP fertilizers) had the best survival. This advantage due to mulching, however, was not reflected in height and DBH (diameter at breast height), where no significant differences between treatments were observed. The effects probably did not last for very long as the plants grew and spread their roots gaining access to deeper soil layers.

TREE WATER USE

The removal of deep-rooted plants and replacement with shallow-rooted ones may often lead to an increased groundwater recharge and a rising groundwater level. Seepage from unlined water channels, low rates of infiltration, and the permeability of soil and poor irrigation management are some other factors responsible for raising the water table.

A shallow groundwater table is not only a deterrant for plant growth, but it also hinders soil improvement owing to a constant upward flux of salts. The difficulty of ameliorating such soils has been demonstrated in one of our earlier studies [83]. A deep groundwater table is hence a prerequisite for improving saline soil conditions.

Suitable trees, owing to their ability to adapt to saline conditions, and because of their high transpiration requirement, may be used in conjunction with mechanical means (i.e., tube wells, tile drains to lower the underground water table). The positive impact of trees and shrubs on the groundwater table has been under study during the last few years, and it has been concluded that these plantations may serve as biological pumps for lowering the water table [84–86]. In fact, tree planting on the banks of canals has often been practiced to check the seepage of water to adjoining areas. A number of species have been identified their for relative tolerance to the combination of salinity and waterlogging stresses [58,63,64,87,88].

Trees have often been incorporated in agroforestry programs for controlling the groundwater table and for salinity control [89–91]. From such studies, it has been observed that pastures consume far less quantities of water than trees; the difference over 1 year may be in the region of 70–80 mm. Among trees, those producing fodder (i.e., *A. blakeyi* and *Chamaecystisus proliferus*, or tagasaste) had better water-use efficiency than the oil-producing eucalypts [90].

High rates of evaporation from tree species is sustained by their greater ability to exploit soil water, which often leads to a reduction in the groundwater level. This will, of course, depend on the species used, the age and density of plants, depth and salinity of the water table, soil type, and climatic factors. In one such study for instance [92], detailed measurements of plantation water use with the help of ''heat-pulse'' or ''sap-flow velocity'' equipment, water table depth and soil conditions were recorded over 2 years in two small plantations with contrasting soil and groundwater salinity at Tandojam, Sindh Province, Pakistan. Species monitored included *A. nilotica*, *A. ampliceps*, and *P. pallida*. Annual water use by 3- to 5-years-old *A. nilotica* was 1248 mm on the severely saline site and 2225 mm on the mildly saline site. Water use by *A. nilotica* was considerably greater than the annual rainfall, implying uptake of groundwater, which was confirmed both by piezometric observations and chloride balance modeling to predict vertical water movement through the rootzone. The plantation water tables fell from 1.7 m below the surface after winter to over 2.9 m after the next summer and then rose again during irrigation of the surrounding farmland. The rootzone salt concentrations remained high at the more saline site throughout the monitoring period, but at the less saline site, there was evidence of increasing rootzone salinity as salt accumulated in the areas of the profile subject to the root water uptake. The salt concentration in the upper profile

decreased as the soil dried and water was absorbed from a greater depth. It was concluded that plantations using saline groundwater may be sustainable if occasional leaching and other salt-removing processes are sufficient to maintain rootzone salinity at a level which does not excessively reduce tree growth.

Tree species in uniform stands at a single location have, however, been observed generally to show little variation in the volume of water moving through the stem per square meter of sapwood per day (sap flux density). This was confirmed from observations on water-use data collected for 2 years at seven different sites in Pakistan, Thailand, and Australia in plantations of several species (i.e., *A. nilotica*, *A. ampliceps*, *P. pallida*, *E. camaldulensis*, *E. microtheca*, *C. cunninghamiana*), where differences in water use between species at any site were largely due to the variation in their growth rates [75]. These results highlight the importance of selection and breeding programs aimed at improving tree growth, as this will determine the sapwood area and, consequently, the total water used by a plantation.

CONCLUSIONS

Adverse soil conditions, especially salinity/sodicity, waterlogging, and drought, in most arid and semiarid regions necessitate the search for suitable plants for cultivation in these areas. The genetic make-up of a species is a predominant factor for survival under hostile conditions. This is evident not only in the performance of plants of different classes (i.e., glycophytes, halophytes, xerophytes) but may be observed in the species of each class and cultivars of a species, and some characters may show variations even within individuals of the same cultivar.

Successful agriculture in such problem areas requires intelligent use of the available information. In saline, soils, with the threshold level of all of our present-day field crops being low, lands not suitable to support these species may be put to some other productive use like growing salt-tolerant trees and shurbs.

It is evident that trees can play an important role on degraded lands, as they are known to be generally more tolerant to adverse soil conditions. There is, however, a need to exploit their genetic potential and to identify species/provenances acclimatized to particular conditions. If this is successful, then it could bring financial benefits from a land where nothing else can grow. There is a chronic shortage of fuel wood in most developing countries. These multipurpose trees not only alleviate this shortage, but their foliage may also cater to the needs of fodder for cattle. Good-quality wood could be sold at as high a price as timber.

Providing a cover on these degraded lands creates a microenvironment which reduces evaporation from the soil surface: the main cause of the capillary rise of the salts. The roots open up the soil, and, if it is a nitrogen-fixing species, add to the fertility. The falling debris enriches the surface soil through the addition of organic matter, and hence there is a good chance that a tree cover will result in an improvement of the soil fertility.

The immediate task for areas with a shallow water table is to lower the level of underground water. This could be achieved through engineering or biological methods. The potential of using trees as biological pumps has been demonstrated. This can provide a basis for calculating the impact of extensive farm planting of suitable tree species in an area with shallow groundwater and eventually develop management plans to reclaim saline lands, enhance farm production, and provide much needed fuel wood and timber. Contrary to our apprehensions [93], one of our studies in an area of low to moderate salinity showed that the rootzone under a block plantation did not deteriorate to any significant extent over a period of 1 year [92]. There is naturally a need for long-term monitoring to gather more data from diverse sites to reinforce the estimates and to explore the effect on the site and other environmental variables.

Soil salinization is, however, a very complex and dynamic phenomenon requiring constant efforts for effective management of the salt-affected lands. There is a need to continue this research

Marcel Dekker, Inc.

and to look in more detail into the problems encountered in such ventures and to find ways and means to deal with the problems as and when they arise.

Photosynthetic Responses of Citrus to Environmental Changes

JOSEPH C. V. VU
University of Florida
Gainesville, Florida

INTRODUCTION

Citrus is one of the most important fruit crops in world trade today. Its commercial cultivation has been extremely successful in tropical and subtropical areas, as well as in semiarid and arid regions with adequate irrigation. Citrus belongs to the subfamily Aurantioideae of the family Rutaceae. Among the six genera constituting the true citrus fruit trees, only three (*Fortunella, Poncirus*, and *Citrus*) are of economic importance [1]. These are native to a large Asiatic area extending from India to China and the Philippines in the east and Burma, Thailand, Indonesia, and New Caledonia in the southeast. An exception is the grapefruit (*Citrus paradisi* Macfadyen), which appeared in the West Indies (Barbados) before 1790 as a mutant or possibly a hybrid of a species introduced from the Far East [1].

Growth and development of citrus is the net result of many interacting processes, including photosynthesis and its direct relationship to crop yield. The photosynthetic rate is dependent on a multitude of reactions, each with a potentially unique response to environmental factors [2]. As with other crop species, the ability of citrus to adapt, acclimate, and/or compensate to environmental stress is critical to survival and performance. Understanding the physiological and biochemical responses, as well as the control mechanisms involved with acclimation and adaptation, of photosynthesis to stress conditions is necessary for devising methods to enhance growth and productivity.

Effort has been expended to improve citrus stress tolerance through breeding and selection. However, limited understanding of the physiological, biochemical, molecular, and genetic bases of the stress response hinders the application of genetic engineering to achieve stable and enhanced production under environmental variation. Increased research efforts should exploit the vast physiological, biochemical, and genetic variability inherent in different germplasms, with the ultimate goal of developing cultivars with more efficient production through tolerance of environmental stress. There is indeed a critical need to explore more deeply the effects of environmental stress on citrus metabolism, to understand the mechanisms of stress responses, and to identify targets for genetic

manipulation [3–5]. This knowledge is basic to any genetic/breeding approach designed to enhance stress resistance/tolerance.

This chapter focuses on the current understanding of the physiological and biochemical responses of citrus photosynthesis to environmental changes. Citrus leaf photosynthetic capacity in relation to solar irradiance, ambient temperature and humidity, soil water availability, and elevated atmospheric CO_2 is discussed. Other more general responses of citrus to various environmental stresses have been reviewed elsewhere [6–8].

SOLAR IRRADIANCE

Photosynthesis consists of both light-dependent and light-independent reactions. In the former, solar radiant energy in the form of quanta (photons) (400- to 700-nm wavelength range) is captured by chlorophyll and converted to chemical energy-rich compounds (ATP) and reducing agents (NADPH) through an electron transport system. The stored energy and reducing power are used in the biochemical light-independent reactions to form carbon skeletons from the ''fixation'' of atmospheric CO_2. Thus, solar energy is stored as chemical energy in the form of carbohydrates and other organic compounds which are ultimately used for plant growth and productivity. A number of enzymes, including ribulose bisphosphate carboxylase-oxygenase (Rubisco), catalyzing the reactions of photosynthesis are regulated by light [2,9–11]. Rubisco ''fixes'' atmospheric CO_2 and thus plays a vital role in plant growth and productivity. This enzyme is a multimeric protein complex consisting of eight large subunits (LSU) and eight small subunits (SSU). It is the most abundant protein in the world, ''fixing'' about 10^{11} tons of CO_2 annually [12]. The LSU, with a molecular weight of 50–55 kDa, is encoded by the *rbcL* gene of the chloroplast genome; and the SSU, with a molecular weight of 12–15 kDa, is nuclearly encoded by the *rbcS* gene. Catalytic activity of the enzyme resides in the LSU, whereas the SSU seems to have a regulatory role [13].

The net CO_2 exchange rate (CER) of citrus is generally low compared with other woody perennials [14–19]. The CER of individual attached, fully expanded top leaves of field-grown citrus trees has a light compensation point (CER = 0) at a solar photosynthetic photon flux density (PPFD) of about 50 μmol m^{-2} s^{-1} and a maximum value (7–8 μmol CO_2 m^{-2} leaf area s^{-1}) at 600–800 μmol m^{-2} s^{-1} PPFD (Fig. 1). This saturation of the leaf CER at relatively low light has been found

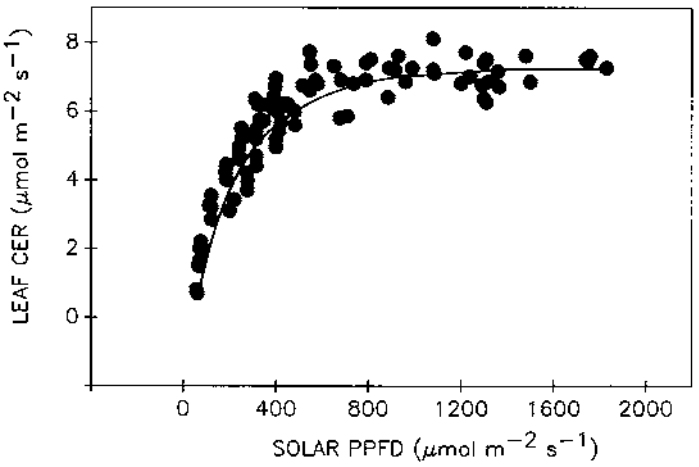

FIGURE 1 Net CO_2 exchange rates of single, attached, fully expanded top leaves of field-grown Valencia sweet orange trees measured during morning hours (0700–1100 EST). Data are plotted against the solar irradiance (PPFD).

for citrus grown both in glasshouses and under field conditions [14,16,18,19]. A solar PPFD of 800–1000 μmol m^{-2} s^{-1} also is the saturating level for activation of citrus Rubisco (Fig. 2). In addition, there is a diel change in Rubisco activity, which is 45–75% greater during the day than during the night [20] (Fig. 2). The percentage of activation of Rubisco, expressed as the ratio of the initial activity (the in vivo activity) to the total activity (the maximum activatable activity) at midday, reaches a light saturation at about 1000 μmol m^{-2} s^{-1} solar PPFD (Fig. 3).

In citrus leaves, the concentration of the Rubisco protein is 19–25% of the total soluble protein fraction [18,20]. The $K_m(CO_2)$ and K_{cat} values of Rubisco average 19 μM and 25 mol CO_2 mol^{-1} enzyme s^{-1}, respectively, which are typical for C_3 species [18]. The total (CO_2/Mg^{2+}-saturated)

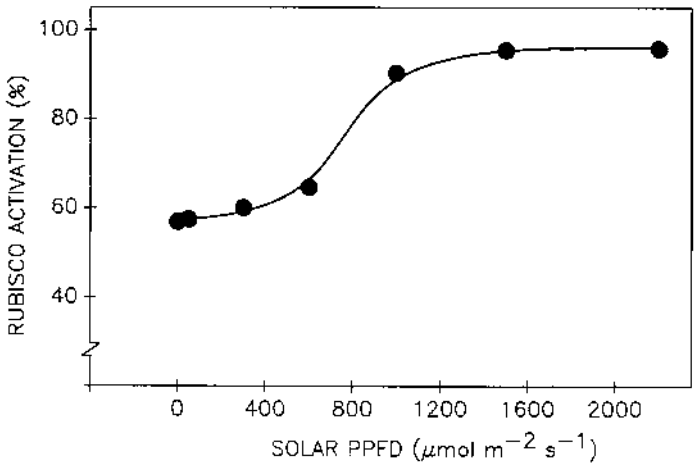

FIGURE 3 Percentage of activation of Rubisco as a function of the solar PPFD from fully expanded top leaves of field-grown Valencia sweet orange trees.

Rubisco activity, about 430 μmol CO_2 mg^{-1} Chl h^{-1} or 73 μmol CO_2 m^{-2} leaf area s^{-1} (see Fig. 2) [18], is more than adequate to support the CER values of 8–11 μmol CO_2 m^{-2} leaf area s^{-1} (see Fig. 1) [14–16,18,20,21].

COLD TEMPERATURE

Various aspects of plant responses to chilling or low temperatures (LT) have been extensively reviewed [22–30]. Temperature affects the rates of biochemical processes differently, thus inducing imbalances among metabolic processes [27]. Adjustments to alleviate LT effects are observed in most plant processes such as growth, photosynthesis, dark respiration, and reproduction [31]. Plants of tropical and subtropical origin, including citrus, have a limited ability to adjust to LT, as well as to develop resistance for survival under freezing conditions. In contrast, plants of temperate origin have significant freezing tolerance, a characteristic thought to involve a genetically programmed process enabling plant survival under severe winter conditions [26]. Citrus is typically an evergreen, and continual replacement of 1- to 2-year-old leaves occurs as trees grow; this process and ultimately growth and productivity are affected by temperature [32]. The continued existence of the U.S. citrus industry, with a 1996 production area of 347,300 ha for Florida, 13,300 ha for Texas, 15,200 ha for Arizona, and 109,200 ha for California [33], would greatly benefit by a common potential to survive devastating freezes. In Florida, three severe freezes in the 5-year period of 1981 through 1985, which destroyed 130,000 ha of the 340,000 ha total in 1980 [34], had a serious impact on the agriculture of the state, resulting in a shift of citrus production southward.

Of all the physiological processes, photosynthesis appears to be the most extensively investigated. It is one of the first processes to be affected when chilling-sensitive plants are exposed to LT [35]. LT effects on CER reduction involve changes in stomatal and nonstomatal characteristics [22]. Regarding the former, the primary change consists of reducing the physical diffusion of gases into and out of the leaf. This is likely due to lower stomatal conductance as a result of partial closure of the stomata. Nonstomatal characteristics, however, appear to change over a wide temperature range and require sufficient time following exposure of plants to the contrasting growth temperature regimen [22,36]. LT alters gene expression and protein metabolism, and it can cause impairment of photosynthesis through effects on catalytic proteins and carbon metabolism [26,28,37–42].

Few studies have been done on citrus carbon assimilation and the effects of temperature, and less is known about chilling effects on the component reactions of photosynthesis. LT reduces leaf stomatal conductance, transpiration, chlorophyll content, and CER of Valencia sweet orange [43]. Activities of Rubisco and phosphoenolpyruvate carboxylase (PEPCase) in fully developed leaves of Valencia orange trees maintained for 30 days at LT (15.6°C day/4.4°C night) are higher than their counterparts maintained at warm temperature (WT, 32.2°C day/21.1°C night) [43]. Of particular interest is a twofold increase in the activity of PEPCase in leaves of trees grown at the LT regimen, causing a change of the Rubisco/PEPCase ratio from 6.6 for the WT treatment to 3.5 for the LT treatment. Transfer of the 30-day WT-treated trees to a LT regimen for 4 days increases PEPCase activity by 45% and decreases the Rubisco/PEPCase ratio to that of the 30-day LT-treated trees [43].

Exposure of citrus trees to LT also alters the expression of several leaf proteins, among which the expression of Rubisco and PEPCase is differentially regulated by LT in the various genotypes [44]. Cold acclimation results in an increased amount of the Rubisco LSU but a decreased amount of the SSU in both cold-hardy and moderately cold-hardy citrus genotypes. In addition, the amount of PEPCase is enhanced by cold acclimation in the cold-hardy genotypes [44]. For C_3 plants, such as citrus, the role of PEPCase is anapleurotic, functioning in gluconeogenesis and nonautotrophic CO_2 fixation. Increased PEPCase activity would be an important part of the metabolic adjustment to the constraints imposed by LT. Thus, the capacity to enhance PEPCase expression during cold acclimation may be important in the acquisition of citrus freezing tolerance.

Accumulation of low molecular weight metabolites, such as soluble sugars and proline, with demonstrated cryoprotectant characteristics, has been reported for many plant species [26]. Sucrose accumulation is most commonly found in chilling-tolerant plants. Its concentration increases significantly during chilling exposure and is accompanied by a decrease in starch [45]. Although starch-sucrose conversion is well documented in cold-hardened plants, little is known about the enzymology of carbohydrate metabolism during cold acclimation [26]. Carbon translocation and regulatory mechanisms as related to carbon partitioning at source/sink under chilling temperatures are not understood [46]. In citrus, the association of sugars with cold hardiness is based primarily on the fact that there is a rapid accumulation of sucrose in the leaf and woody tissues during the cold-acclimation period [47–49]. Valencia sweet orange leaves accumulate more ^{14}C in the sugar fraction at 10°C than at 25°C [50]. In addition, sweet orange trees having high sugar/starch ratios in the leaves and wood withstand the −6.7°C freeze test without injury, whereas trees with low sugar/starch ratios are killed [51]. In plants, many sugar-modulating genes have both direct and indirect roles in sugar metabolism, suggesting that their altered expression may represent a valuable mechanism for adjusting to environmental change [52].

The accumulation of proline also is well known in plants subjected to cold temperatures and other environmental stresses [53]. The mechanism leading to proline accumulation, however, is still obscure. Free proline levels, which are associated with citrus frost hardiness, increase up to 10-fold in citrus leaves during chilling growth temperature regimens [43,49,54]. Proline is the most abundant amino acid found in the tracheal sap of orange trees throughout the entire year, and it is especially high in concentration during the winter season [49]. Whether the proline content is high enough to help protect citrus against frost injury is an enigma at the present time.

The association of proteins with cold hardiness is not as well documented in citrus as in other plant species. However, recent reports of three cold-induced polypeptides (glycoprotein-24, COR11, and COR19), which accumulate in *Poncirus trifoliata*, the most cold-hardy citrus germplasm, exposed to LT pose new and interesting questions as to the role of these proteins in citrus tolerance and survival to cold temperature [55,56].

For many plant species, light is required during exposure to LT in order to attain maximum tolerance [57,58]. In citrus, light has been reported to increase cold hardening for a number of cultivars exhibiting a wide range of cold tolerances [59]. Citrus trees conditioned in controlled-environment growth chambers at low temperatures in the light are injured less than those conditioned at similar temperatures in the dark during subsequent freeze tests. This increased cold hardening in the light has been postulated to result from the accumulation of excess fixed carbon (sucrose) from photosynthesis during the cold-acclimation period [58,59].

All commercial citrus trees are essentially combinations of scions and rootstocks [60,61]. These scion-rootstock interactions, along with different cultural environments and practices, complicate comparative ratings of citrus cold hardiness at various freeze intensities and durations [49]. Among the scion cultivars, mandarin (*Citrus reticulata* Blanco) is the most cold hardy, followed by sweet orange (*C. sinensis* L. Osbeck) and grapefruit (*C. paradisi* Macf.), whereas lime (*C. aurantifolia* Christm. Swingle) and lemon (*C. limon* L. Burm.) are the least cold hardy [49]. In addition, the rootstock definitely has a pronounced effect on the cold hardiness or tolerance of a citrus tree [61–64]. Trifoliate orange (*Poncirus trifoliata* L. Raf.), a deciduous relative of the genus *Citrus*, is a superior cold-hardy rootstock, whereas sour orange (*C. aurantium* L.) is an intermediate, and rough lemon (*C. jambhiri* Lush.) is one among the most cold-sensitive rootstocks. For citrus, it is not known whether protein alterations during cold acclimation are different in seedlings than in budded trees, but there is an indication that rootstocks influence protein alterations of budded trees [49,65].

HIGH TEMPERATURE

Numerous reviews of the effects of high temperatures or heat stress on different processes in plants, including acclimation, carbon fixation, carbohydrate metabolism, and protein synthesis, have been

compiled [2,22,66–72]. Virtually nothing is known of the biochemistry of citrus photosynthesis at high temperature (see section on Elevated Atmospheric CO_2). Heat stress in citriculture is of some concern, because major producing areas are between 35° north and south latitudes. Estimates of lethal temperatures for sweet orange fruits and leaves suggest that damaging heat stress probably does not occur on a large scale in most citrus plantings [73,74]. However, high-temperature effects on citrus growth and yield [75] do cause concern in light of global warming scenarios [76].

Citrus trees grown in subtropical climates generally bloom heavily in the spring, but many flowers and flower buds drop before fruit setting [77]. Furthermore, although the young fruits that remain after the first period of dropping are presumably capable of developing into mature fruits, there is generally a period of accelerated fruit drop as the weather becomes hot in the early summer months; this is referred to as the ''June drop'' [77,78]. As the result, only a small percentage of citrus flowers, about 0.2–7.0%, produce mature fruits [77,79]. However, if severe heat or hot, dry, and windy weather continues for several days, heavier fruit drops result in more serious crop losses. Although the actual mechanism controlling the dropping of flowers and young fruits is still not well understood, there is an indication that growth regulators, as well as nutrients and carbohydrates, may play a role in these abscission processes in response to environmental and/or internal changes [77–79].

The response of CER in citrus under conditions of elevated temperature, high evaporative demand, and low soil water availability is not well understood. Leaf photosynthetic rates of citrus, as previously discussed, are relatively lower than those of other tree crops. In addition, midday depression of leaf photosynthetic rates occurs frequently with outdoor citrus trees on days when atmospheric temperatures and vapor pressure deficits are high [16,18,19,80]. Diurnal measurements made on field-grown citrus trees on cloudless warm spring days in central and south Florida show that leaf CER increases in the morning, reaches the saturation level of 8–11 μmol m^{-2} s^{-1} when solar PPFD approaches 600–800 μmol m^{-2} s^{-1} at about 0900 Eastern Standard Time (EST), and remains relatively stable until late morning as solar PPFD reaches 2000 μmol m^{-2} s^{-1} [16,18]. However, there is a midday depression in CER which starts at about 1230 EST, and by 1330 EST, leaf CER is only one fourth of the saturation level. By 1530–1600 EST, a partial recovery of CER is observed [16,18]. Under hot and dry summer conditions in Phoenix, Arizona, leaf CER of sour orange trees is highest (about 7 μmol m^{-2} s^{-1}) at the morning's first measurement at 0700 Mountain Standard Time (MST), but it steadily decreases to about 1.5 μmol m^{-2} s^{-1} at 1300 MST, and then remains unchanged until 1700 MST [81]. Data collected over a 4-year period on sour orange trees also show that leaf CER declines from about 6.1 to 0.1 μmol m^{-2} s^{-1} as temperature rises from 31 to 47°C [82].

The response of leaf CER to high temperatures also is dependent on the atmospheric humidity [22]. As leaf temperature increases, the water vapor pressure difference (VPD) between the leaf and the surrounding air (i.e., leaf-to-air VPD) increases unless supplemental humidity is provided [2,22]. The increase in VPD promotes closure of the stomata, thus further depressing CER at high temperatures. Stomata of citrus close under these circumstances, presumably as an evolutionary adaptation to conserve water [8,16,83]. Studies conducted on glasshouse-grown sweet orange and grapefruit show that leaf CER is highest when measured at 22–26°C and 8 mbar VPD, but large reductions occur at leaf temperatures above 30°C or when VPD is increased to 24 mbar [15]. The reductions in leaf CER due to high temperatures are associated with reductions in mesophyll conductance to CO_2, whereas those due to high VPD are attributed to decreased total leaf conductance to water vapor [15]. When leaf photosynthesis of sweet orange is measured under controlled conditions at constant temperature (26°C) but varying VPDs, the CER and total leaf conductance determined at 24 mbar VPD are only one half and one third, respectively, of those measured at 8 mbar VPD [15]. For citrus grown under field conditions, although part of the midday depressions in leaf CER may be due to the direct temperature effects on the nonstomatal component reactions, there is indeed an implication of stomatal control mediated by VPD [16,18]. The midday depressions in CER are observed mostly on warm days with high VPD at midday, and stomatal closure occurs in response to such adverse climatic conditions [16]. Continuous monitoring of the leaf gas exchange of field-

grown citrus during several weeks in the spring in South Florida shows the majority of leaves exhibiting midday CER depression on days when the midday VPD is more than 28 mbar and maximum temperature is higher than 31°C [16]. Stable, maximum rates of leaf transpiration existing even with increasing VPD imply a changing stomatal conductance to restrict water vapor loss [16].

In a study with irrigated citrus grown in sunlit, controlled environmental chambers under three dry-bulb temperature (DBT)/VPD regimens, the photosynthetic rate and water-use efficiency are greatest at 24°C/17 mbar treatment and remain high even when the soil water content becomes low [83]. At DBT/VPD levels of 29°C/24 mbar and 37°C/36 mbar, CER and water-use efficiency are reduced, and midday CER depressions occur when the soil water content is low [83]. These findings suggest that midday depression of photosynthesis in citrus, which results in part from stomatal closure at high VPD but perhaps more significantly from increased mesophyll resistance induced by low soil water availability at high DBT/VPD levels, would not occur as long as soil water is easily available [83]. Thus, the rate of water supply to the leaves may be an important factor in mediating the control of stomatal conductance and the resultant midday depressions in CER [16].

SOIL WATER DEFICIT

Soil water deficit, or drought, affects plant growth and metabolism in numerous ways and is the single most important factor limiting crop yield [84,85]. Production of agricultural crops in semiarid and arid areas of the world is heavily dependent on irrigation. Even in normally humid areas, irrigation systems are installed to prevent yield reduction resulting from short dry periods. In Florida, 60% of agriculturally available water is used to irrigate citrus crops [86]. Problems created by drought are critical worldwide and present challenges to plant breeders for long-term solutions to improve yield in dry crop-producing regions. Breeding approaches need to identify drought-tolerant characters that can be genetically transferred to new crop cultivars to enhance drought tolerance and adaptation. A more comprehensive understanding of the metabolic processes affected by water deficit is essential, as are recovery mechanisms once drought stress is relieved.

Among the most prominent effects of drought on plants are the reductions of growth, carbon fixation, photosynthate translocation, protein synthesis, and enzyme activities [57,68,84,87–90]. Of prime importance is the reduction of the leaf photosynthetic rate of plants exposed to drought conditions. Although the pathways and enzymes involved in normal photosynthesis are well defined, the effects of drought on individual processes are not well understood. Exactly how much water deficit affects photosynthesis and its component reactions and the correlation between stomatal function and photosynthetic rates during stress exposure are still presently unclear [91]. In addition, plant responses to the environment also are related to the type of photosynthetic carbon metabolism, as C_3 plants are generally less tolerant to hot, dry conditions as compared with C_4 plants [92].

For many crops, including citrus, an increase in drought stress is followed ultimately by decreasing CER, but the mechanisms contributing to the reduction are incompletely understood. Reduction in CER has been partially attributed to stomatal closure which occurs during drought stress [93,94]. Nonstomatal components, such as decreased enzyme catalysis, also are involved in CER reduction [18,94–100]. In sweet orange, water deficit reduces the catalysis and protein concentration of Rubisco and shifts carbohydrate distribution in the leaves [18,101]. During short periods of drought, reduction in stomatal conductance and leaf transpiration and increases in proline concentration also are commonly observed for citrus [102,103]. Soil water deficit affects both citrus vegetative growth and tree size, as well as fruit yield and quality [104,105].

FLOODING

Temporary or continuous flooding is common in many land areas throughout the world, and soil waterlogging is a major problem in the growth and productivity of many crop plants, including citrus. In Florida, many new planting sites, especially in the south, are vulnerable to soil waterlogging

owing to the low elevation and shallow water table. The prospect of more citrus plantings in southern counties, because of winter freezes and severe losses in north central Florida during the 1980s, significantly increases concerns of anaerobiosis resulting from flooding and its impact on crop growth and productivity. Newer methods of land development that emphasize good drainage do not totally guard against excessively wet summers, and the annual threat of excessive rainfall during hurricanes intensifies the flooding problem in low, flat areas.

Soil flooding inhibits root and shoot growth, depresses root respiration, and reduces leaf photosynthesis in many plant species [106–115]. For citrus, root system deterioration in flooded soils is a major problem [116,117]. Leaves of root-flooded citrus trees show reduced Rubisco activity and dark respiration [117,118], but little is known about photosynthetic carbon metabolism or photosynthate partitioning due to soil waterlogging. There are survival differences among citrus rootstocks subjected to soil flooding [61,117,119]. For example, flooding for 10 days inhibits leaf photosynthetic rates up to 98% in various citrus rootstock seedlings [116]. Hamlin sweet orange trees flooded for 24 days show senescence, wilting, and abscission of leaves; these symptoms are more evident with Hamlin trees grafted on sour orange rootstocks than those grafted on rough lemon rootstocks [117]. Similarly, leaf CER, stomatal conductance, chlorophyll content, and Rubisco activity are significantly reduced in Hamlin trees grafted on sour orange. Dark respiration rates are greatly decreased in the fibrous roots of flooded trees but not in leaf tissues, whereas total nonstructural carbohydrates are higher in leaves (50% for Hamlin on sour orange and 80% for Hamlin on rough lemon) but lower in roots (60% for Hamlin on sour orange and 45% for Hamlin on rough lemon) [117]. This indicates that the selection of rootstocks is critical in reducing the impact of waterlogging.

ELEVATED ATMOSPHERIC CO_2

The global atmospheric CO_2 concentration ($[CO_2]$), presently at about 365 parts per million (ppm), is increasing and is expected to double by the end of the next century [120,121]. The increase in $[CO_2]$ and other ''greenhouse'' gases (e.g., methane, chlorofluorocarbons, nitrous oxide, ozone) may cause global air temperatures to rise, possibly by as much as 3–6°C, and shifts in regional scale rainfall patterns [122–124].

Approximately 95% of terrestrial plants are C_3 species, about 1% are C_4 species and 4% undergo crassulacean acid metabolism (CAM) [125]. The present atmospheric $[CO_2]$ limits the photosynthesis, growth, and productivity of many crop plants, especially C_3 species which could benefit from elevated CO_2 [125,126]. Numerous studies have shown that atmospheric CO_2 enrichment has beneficial impacts on crop growth and yield [127–129].

Elevated $[CO_2]$ enhances the photosynthesis, growth, and yield of citrus crops [81,130–133]. Citrus trees grown at about twice ambient $[CO_2]$ have a greater number of and larger leaves, a higher trunk and branch volume, and a greater fine-root biomass than their ambient-treated counterparts [130,132–135]. Under long-term growth (5 years), fruit production of sour orange doubles in CO_2-enriched trees as compared with ambient grown [133]. Trees of Valencia sweet orange grown under enriched CO_2 also produce more fruit, although similar in size and weight to that of control trees [131].

Rubisco activity is higher in leaves of Swingle citrumelo plants grown at twice ambient $[CO_2]$, a finding not seen in leaf samples from Carrizo citrange [130]. The net CER of citrus, measured at the $[CO_2]$ used for growth, is substantially enhanced by elevated $[CO_2]$ [19,81,131,136]. At elevated $[CO_2]$, the inhibitory effects of high VPD and decreased available soil water on citrus CER are lessened, and the CO_2 assimilation rate does not exhibit the midday depression commonly observed in trees grown under ambient $[CO_2]$ [19]. Elevated $[CO_2]$, in addition, can compensate for the adverse effects of high growth temperature relative to the net photosynthetic rate [81,82], as seen in other crops [137]. In sour orange, the mean daylight photosynthetic rate of the leaves under summer conditions in Phoenix, Arizona, is about 2.2-fold greater for the elevated (700 ppm) CO_2 treatment in comparison with the ambient (400 ppm) CO_2 treatment [81]. Also, there is a negative

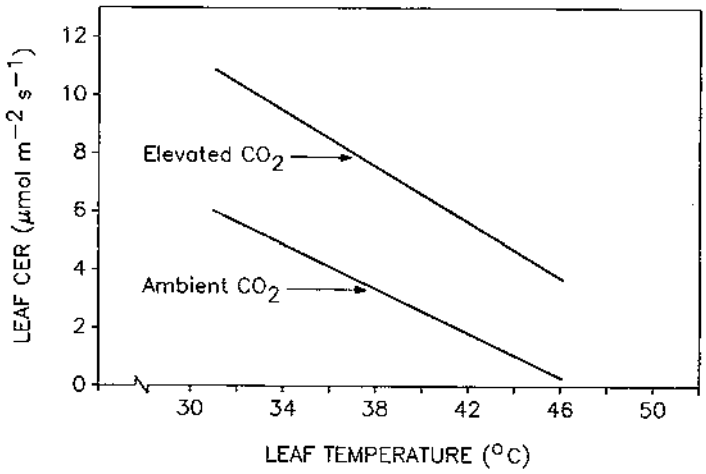

FIGURE 4 Linear relationship between net CO_2 exchange rate (CER) and leaf temperature (T) of foliage of sour orange trees maintained outdoors in Phoenix, AZ, at ambient (400 ppm) (CER = 17.68–0.375 T; $r^2 = 0.737$) and elevated (700 ppm) CO_2 (CER = 25.53–0.472 T; $r^2 = 0.475$). (From Ref. 82.).

linear relationship between the net photosynthetic rate and the leaf temperature from 31 to 47°C for both ambient and elevated CO_2-grown trees (Fig. 4), indicating that this range of temperature is above the optimum for net photosynthesis of this citrus species [82]. However, the degree of enhancement of net photosynthesis by CO_2 enrichment is 75% at a leaf temperature of 31°C, 100% at 35°C, and 200% at 42°C [82]. These enhancements fall in the range of the predictions for an idealized C_3 plant, showing that a rise in temperature from 28 to 40°C increases the degree of enhancement from 66 to 190% when the atmospheric [CO_2] is raised from 350 to 650 ppm [138]. At 47°C, the net photosynthetic rates of sour orange trees grown at ambient CO_2 drop to zero and become negative thereafter, whereas the CO_2-enriched trees still maintain their photosynthetic rates at a significantly high level [82]. Theoretically, a 300-ppm increase in atmospheric [CO_2] could raise the temperature optimum of light-saturated CER of C_3 plants by 5°C [138].

Citrus trees grown under long-term CO_2 enrichment and natural field conditions do not experience the downregulation of the photosynthetic capacity or growth rate [139] that occurs in some other plant species [125]. In a crop canopy, photosynthesis is light limited for all leaves for part of the day and for all of the day for the leaves of the lower canopy [129]. For a citrus canopy, although the absolute benefits of CO_2 enrichment on CER are greatest at high-light intensities, the relative benefits are, however, more significant at low-light levels [140]. The positive direct effect of enriched CO_2 on citrus photosynthesis more than compensates for the negative self-shading effect due to the increased leaf area under elevated CO_2 growth conditions [140].

CONCLUSIONS

Freezing and drought are excellent examples of stress-related agricultural catastrophes that threaten the ability of the world to feed itself. Producing crops under stress conditions is a growing problem in world agriculture, and new strategies are required to improve and maintain world food supplies and nutrition. Citrus, with its high value for nutritional and palatable qualities, will enter the 21st century as a major world crop. A better understanding of the regulatory mechanisms of citrus metab-

olism in response to environmental changes will aid in finding and/or developing cultivars with stress tolerance.

Physiological and biochemical studies have shown a reduction in the photosynthetic capacity owing to environmental stress; however, the mechanisms involved have yet to be identified [141,142]. In recent years, there has been a rapid advance in our understanding of the molecular biology of the metabolic pathways in the photosynthetic carbon reduction cycle [143], and effort has focused on genes encoding key photosynthetic enzymes [144]. Current technical advances offer the opportunity to understand the molecular mechanisms involved in plant stress responses, which will be useful in designing experiments for genetic engineering and breeding to produce stress-tolerant crop species [145].

Ecophysiology of *Ajuga reptans* L. at the Northern Boundary of Its Distribution

TAMARA K. GOLOVKO AND O. V. DYMOVA
Institute of Biology
Russian Academy of Science
Syktyvkar, Komi Republic, Russia

INTRODUCTION

This chapter provides information on the changes in some morphological and physiological traits of a perennial herbaceous plant *Ajuga reptans* L. (bugle), growing in the taiga zone of the northeastern region of Europe as compared with that growing in the broad-leaved forests of Europe. *A. reptans* L. has recently been shown to contain biologically active substances, known as ecdysteroids [1]. It also is widely used in Europe and North America as a decorative plant for landscape gardening. There are different cultivated varieties of bugle, which are distinguished by the leaf color. The plant is important as a good source of honey in apiaries. Wild *Ajuga* plants grow only in Europe.

Growth conditions in the northern part of bugle's growing area differ significantly by climatic and edaphic factors from those in central Europe. The adaptation of plants to habitat differences occurs via coordinated changes at the morphophysiological, anatomical, and biochemical levels. The acclimatory responses ensure maximal fitness by balancing resource uptake under varying environmental conditions. CO_2 exchange is the major external manifestation of plant metabolism. Hence, investigation of the dependence of photosynthesis and respiration on light, temperature, nutrition, and other factors is important to characterize the plant metabolic activity and adaptability in different environmental conditions [2,3]. Experiments were carried out with the plants growing in the birch-aspen forest floor in the vicinity of Syktyvkar, Komi Republic, Russia. To estimate *Ajuga* plants' interactions with the environment, we studied the growth and CO_2 exchange responses to temperature and light conditions. We also transplanted about 100 rosettes into an open site where they grew for 2 years.

AJUGA REPTANS L., A RARE AND RELICT SPECIES IN EUROPEAN NORTHEAST FLORA

The present global distribution of plants reflects both their evolutionary history and effects of past and recent climatic conditions. *Ajuga reptans* L. is a nemoral herbaceous plant widely spread almost all over Europe [4]. The northern boundary of distribution of *Ajuga* extends to the middle taiga subzone of the European northeast of Russia. It is a rare and relict species in this region. Nemoral and nemoral-boreal species appeared here during the second part of Atlantic period of the Holocene era (6–7 million years ago) after considerable warming. At that time, broad-leaved forests with heat-loving herbaceous accompanying species moved to the north farther than they currently exist. On the following climate recooling, many warm-adapted species disappeared and boreal forests (dark coniferous taiga) again became dominant in the northern region. Nemoral species, which were adapted to unfavorable environmental conditions, remained here as relicts of the Holocene climatic optimum. The current boundary of many nemoral species extends to the middle taiga subzone and is limited by the Vychegda River [5].

The growing season in this region does not exceed 90–110 days. Spring begins commonly in late April. Frosts can occur at the end of June and at the beginning of August. The mean annual air temperature only slightly exceeds 0°C. The mean January temperature is −15.2°C and the mean July temperature is +16.8°C. Annual precipitation is typically about 650 mm and exceeds evaporation by 30%. Most of the precipitation occurs during the frost-free season. Approximately 40% of the precipitation falls in summer.

Day-length variations of the vegetative period are determined by the location of the northern region up to the latitude of 60° N. At the latitude of Syktyvkar (62°52′ N), the sun is less than 6°C below the horizon in early summer.

Podzolic soils of the middle taiga according to their temperature regimen are classified as moderately cold soils [6]. In winter, the temperature at the soil surface drops to −2°C. Soil temperatures optimal for plant growth (near 15°C) set in the middle of June and persist for about 1 month. Heat deficiency and poor natural fertility of the soil are unfavorable for plant growth.

BIOLOGICAL AND ECOLOGICAL TRAITS OF *AJUGA* PLANTS

Ajuga reptans L. (Lamiaceae) is a herbaceous perennial semirosulate summer-winter green plant with clonal type of growth (Fig. 1). The plant forms runners (stolons) and two generations of leaves [7]. Spring-summer leaves grow on the stolon nodes. Rosulate leaves are formed in summer and most of them overwinter. In the broad-leaved forests of the Temperate Zone of Russia (at the Moscow latitude), *Ajuga reptans* is characterized as a species with a reactive life strategy [8]. The spacing of stolons allows large areas to be rapidly but loosely occupied, and this allows rapid formation of the new vegetative units which separate rapidly from the old ones. *Ajuga* plant shoots are developed dicyclically and flower in the second year of life. Flowering of plants lasts from the middle of May until July and sometimes until the end of August. Plants from the optimum part of the area typically propagate by seeds [8].

In the middle taiga subzone of the European northeast of Russia, *Ajuga* plants are developed polycyclically. A recent study [9] also indicates that the sensitive features of the species decrease and the tolerant features appear. The growth and development of plants are delayed and they remain for longer time in the same area. The average leaf length and the number of runners are 2.0 and 3.5 times less, respectively, as compared with broad-leaved forests (Table 1).

Expression of vegetative reproduction is one of the most remarkable adaptations of *Ajuga* plants to the environmental stress conditions at the northern boundary of its distribution. The individual shoots (ramets) of a clonal plant are produced from the apical buds of runners. The connections

FIGURE 1 Plant of *Ajuga reptans*. (A) Floriferous shoot. (B) Rooting rosette at the end of runner.

that initially exist between older (mother) and new (daughter) ramets of the plants remain for longer periods than those in the central part of the area.

In the middle taiga subzone, *Ajuga* plants grow in a floor of mixed and parvifoliate forests. It is suggested that nemoral plants cannot compete successfully with spruce roots for nutrients, especially nitrogen [10]. Therefore, plant growth is impeded in the floor of pure coniferous stands. Small-leaved trees, such as *Populus tremula* L., *Betula pubescens* Ebrh., and *Betula pendula* Roth, predetermine (through the leaf fall) more favorable conditions. The soil nitrogen content is higher, and soil acidity is low in such sites.

It should be noted that an elevated ambient CO_2 concentration usually occurs near the soil surface in a forest floor. Carbon dioxide is produced by aboveground plant respiration and by microbial and root respiration from soil, and it is consumed in plant photosynthesis. Depending on the amount of organic matter in the soil and its temperature and moisture, the soil can be the main source of CO_2 for the forest floor vegetation. Elevated CO_2 is expected to increase leaf photosynthesis of the forest floor herbs under both cases: when they are shaded from direct sunlight, and when sunflecks penetrate under the forest canopy [11]. Bugle has a prostrate growth form. This allows it to photosynthesize at 30–50% higher CO_2 concentration in the forest floor, especially in the early morning [12]. *Ajuga* plants apparently use a substantial amount of CO_2 that has been respired by other vegetation and soil organisms as a substrate for photosynthesis.

The available data characterizing the physiological traits of *Ajuga* plants growing in the central

part of the area of distribution are very scarce. Bachmann et al. [13] studied photosynthesis and seasonal carbohydrate changes in different parts of *A. reptans* Atropurpurea in the Zurich area. In *Ajuga*, significant seasonal variations in soluble nonstructural carbohydrate levels in aboveground-grown plant parts and the predominance of RFO (raffinose family of oligosaccharides) were found throughout the whole year. RFO was lowest in summer (75 mg g^{-1} fresh weight) and highest in fall/winter (200 mg g^{-1} fresh weight). The maximal net photosynthetic rate attained 6 μmol CO_2 m^{-2} s^{-1}. The temperature optimum of net photosynthesis was decreased (from 16 to 8°C) during cold treatment. According to Masarovicova [14], the chlorophyll content was about 0.44 g m^{-2} for *Ajuga* plants growing in a temperate hardwood deciduous forest in southeast Slovakia. Our studies show that at the northern boundary of distribution, *Ajuga* plants have twofold less photosynthetic rates, chlorophyll content, and total carbohydrates than those in the central part of the area. The phytoecdysteroid content, products of specialized metabolism, is equal to 24 μg g^{-1} [15] and close to that cited for plant growing in Spain [1].

TEMPERATURE RESPONSE OF NET PHOTOSYNTHESIS

Photosynthesis is one of the most temperature-sensitive aspects of growth. The study of the temperature dependence of net photosynthesis (P_N) indicated that, in midsummer, the leaves of *Ajuga* plants were able to uptake CO_2 intensively at a temperature lower than 10°C (Figs. 2 and 3). We failed

Marcel Dekker, Inc.

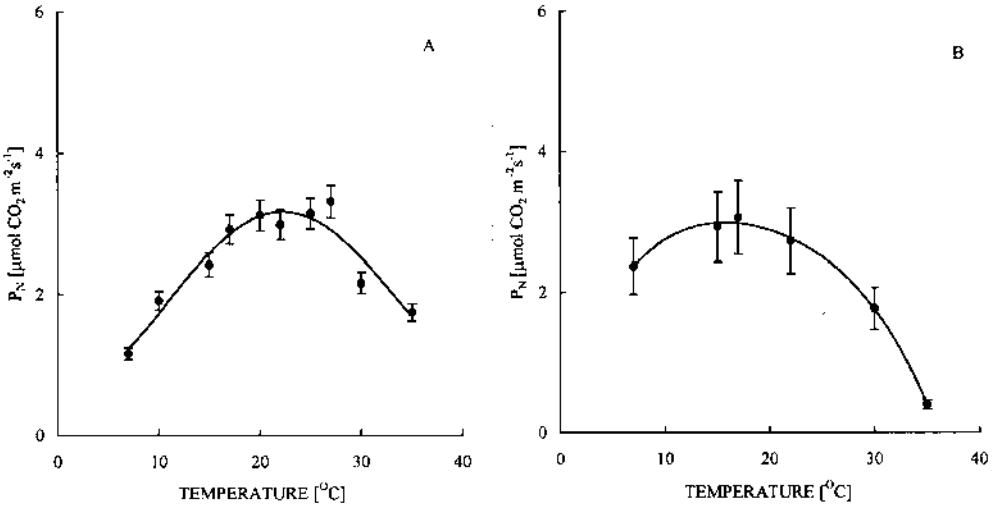

FIGURE 2 Temperature response curves for CO_2 uptake in the leaves of *Ajuga* plants. (A) warm and dry (July 1995) and (B) cool and wet (July 1996) seasons.

to determine the lower temperature limit of photosynthesis, because the temperature in the leaf chamber could only be lowered to 5°C. At 5–7°C, the rate of net photosynthesis was equal to about 60% of the maximum values of P_N. Maximum values of P_N were measured in the temperature range of 15–25°C. In a cool and wet season (1996), the zone of optimum temperature of photosynthesis was 12–22°C (Fig. 2B). In a warm and dry season (1995), the optimum temperature for net photosynthesis shifted to higher temperatures; that is, to 18–26°C (Fig. 2A). The rate of leaf photosynthesis was considerably depressed at temperatures higher than 30°C, especially in a cooler summer.

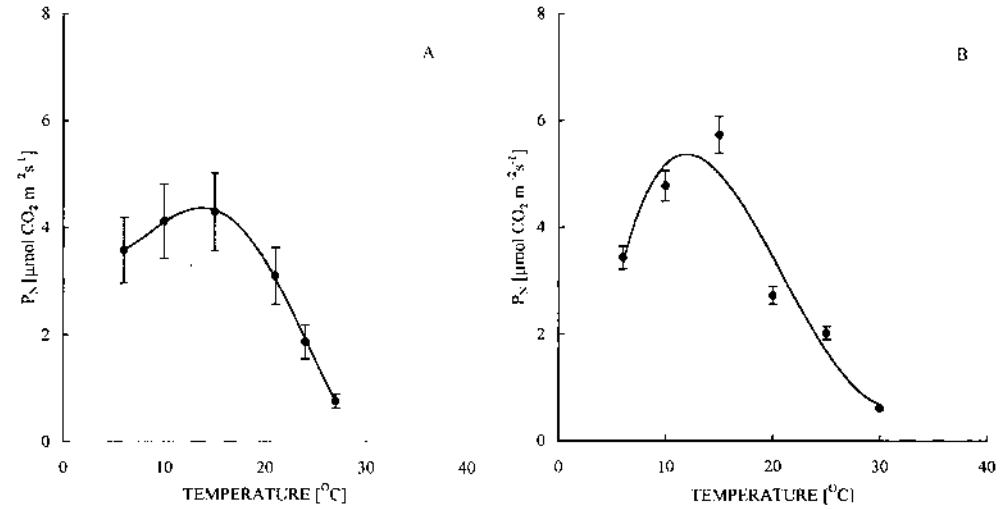

FIGURE 3 Temperature response curves for CO_2 uptake in overwintered (A) and new-grown leaves (B), June 1997.

At the beginning of summer, new-formed rosulate leaves showed maximum values of P_N at 10–15°C (see Fig. 3B). Only small differences in the optimum temperature and rate of CO_2 uptake at optimal temperatures between new-grown and overwintered rosulate leaves were obtained at this time (see Fig. 3A). Overwintered leaves commonly died by the end of June. New rosulate leaves were able to uptake CO_2 after the first frost in autumn. Leaves collected from *Ajuga* plants after the average daily temperatures near −2°C at the end of October were able to photosynthesize with a rate of about 0.5 μmol CO_2 m^{-2} s^{-1} at 5–7°C.

The optimum temperature for photosynthesis is a genotype-dependent characteristic, and it is modified by environmental conditions. One characteristic of the stress-tolerant species is a strongly developed ability to acclimate photosynthesis, particularly in fluctuating temperatures [16,17]. Our data have shown that *Ajuga* plants had an ability to acclimate thermally their photosynthesis. Plants demonstrated a relatively flexible photosynthetic apparatus which could respond to changing temperatures during the growing season. The photosynthetic apparatus of this species is quite well adapted to the moderate temperatures of the growing season. The optimum temperature of leaf net photosynthesis was comparatively low in *Ajuga* plants.

LIGHT RESPONSE OF NET PHOTOSYNTHESIS

Light is one of the most important factors for plants. Light influences plants as an energy source and as a medium to transfer information from the environment to the plant. Photosynthesis is a major physiological process depending on the light conditions of plant growth. Natural selection to the light environment may favor plants whose physiological and morphological characteristics tend to maximize the effeciency and productivity of their photosynthesis [18].

At the northern boundary of its area of distribution, wild *Ajuga* plants grow commonly in the floor of the birch-aspen forest, where light environment is characterized by a low level of photosynthetically active radiation (PAR) and reduced red/far-red ratio. Approximately 5% or less of light penetrates under the forest canopy in summer. Our measurements of the leaf P_N were conducted in a wide range of irradiance from dark to 1800 μmol m^{-2} s^{-1} PAR. In addition, the content of pigments and nitrogen in the leaves were measured. The light-harvesting complex (LHC) chlorophyll (Chl) contents were calculated as described by Lightenthaler [19]. Plant growth was monitored by measuring biomass accumulation.

Shade plants were distinguished by low biomass and slow growth (Table 2). They had 25–35 leaves per plant. A high total Chl content low ratio chlorophyll a/chlorophyll b (Chl a:b) and high contents of the LHC per leaf area were found in these leaves. The leaves had low values of light compensation point and adaptation irradiance. The photosynthetic rate at saturating irradiance (P_{Nsat}) and dark respiration (R_D) were equal to 1.8 and 0.24 μmol m^{-2} s^{-1}, respectively. The rate of net photosynthesis at adaptation irradiance was 2.5 times lower than P_{Nsat}. The low Chl*a*:*b* ratio, high percentage of Chl belonging to the LHC, and values of the key parameters of the light-response curve of photosynthesis showed the high-shade tolerance of *Ajuga* plants.

Various acclimatory traits were determined in the plants transplanted from the forest understory (shady environment) into an open site (sunny environment) (see Table 2). A month after transfer, all leaves were dropped and new leaves were grown. A year after transplantation, each plant had 70–100 leaves. Their mass and area were 20 and 10 times, respectively, greater than those in the shady environment. Sunlight had a significant impact on the leaf area ratio and specific leaf area. But the leaf weight ratio and root/shoot ratio did not change significantly, and showed no acclimation on the basis of biomass allocation.

The light curves of photosynthesis were modified by a high-irradiance environment. The values of the light compensation point and the adaptation irradiance increased twofold. The growth of plants in a sunny environment led to an increase in photosynthetic and respiratory rate in leaves. But we found no significant impact of light conditions on the respiration/photosynthesis ratio. This ratio was near 0.15 or near 0.37, if the P_N value at saturating irradiance or at adaptation irradiance

30. R/P_g ratio	0.480 ± 0.001	0.670 ± 0.005[a]

[a] Significant differences at $P \leq .05$.

Note: Leaf net photosynthetic rate (P_N) was measured by an open system with an infrared analyzer as described in detail recently [17]. Leaf chlorophyll (Chl) and carotenoids (Car) contents were determined at 662.0, 644.0, and 440.5 nm spectrophotometrically after extraction by 100% boiling acetone. Total nitrogen (N) was measured with an automatic analyzer ANA-1500. Total nonstructural carbohydrate (TNC) content was analyzed according to Pochynok [20].

Means and standard errors are presented.

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

were used for calculation, respectively. The chlorophyll content, as well as Chl*a*:*b* ratio and chlorophyll/carotenoids ratio were modified by sunlight conditions. Both Chl *a* and *b* contents per leaf area decreased and their ratio increased. Although there were no differences in the content of carotenoids between leaves of plants grown in the shade and those grown in sun, the chlorophyll/carotenoids ratio was lower in sunny plants. It is possible that the function of carotenoids in the leaves of plants grown in the sun was related more to the protection of their photosynthetic apparatus against exceeding light energy, whereas in the leaves of shade plants it was related more to the absorption and conversion of light energy.

The data show a twofold difference in the nutrient-use efficiency (NUE), as an amount of CO_2 assimilated per unit of nitrogen content, in the leaves of sun-grown and shade-grown plants. The low NUE of shade-grown plant leaves was related to their high nitrogen content rather than to the low photosynthetic rate. There are reasons why plants growing in the forest floor can accumulate more nitrogen: (a) the ground cover is rich in humus, (b) plants grow slowly, and (c) leaves contain more chlorophyll. The leaf chlorophyll content is a stable informative parameter for the evaluation of soil nitrogen uptake at different growth conditions [21]. In turn, a high nitrogen content can reflect the accumulation of pigments in the leaves of shade-grown plants.

Our data show that *A. reptans* is a shade-enduring plant also capable of growing at a high irradiance. Since at significant differences in the light environment the morphophysiological parameters of the photosynthetic apparatus were changing within a narrow range, it can be concluded that the shade tolerance is a genetically determined trait of *Ajuga* plants, and a weak trade-off exists between the ability to achieve high photosynthetic activity in the sun and the ability to survive in the shade.

VEGETATIVE REPRODUCTION AND CARBON BALANCE

Northern environmental pressures led to the dominance of vegetative reproduction. It is one of the most remarkable adaptations of *Ajuga* plants growing at the northern boundary of its distribution. There is a great interest in clonal growth owing to its importance in ecological and evolutionary consequences. *Ajuga* plants produced more ramets and they were distinguished by intensive growth in a more favorable light environment. The number of runners and their biomass were 7 and 25 times higher in the sun-grown plants than in those grown in the shade (see Table 2). Since the root/shoot ratio was 0.12 in both shade- and sun-grown plants, we can assume that distribution of the plant biomass strongly depends on genotype.

The accumulation of the plant biomass results from an interaction of the photosynthetic assimilation of CO_2, respiratory losses, and growth. A quantitative investigation of the carbon balance parameters based on the CO_2 exchange measuring showed that the daily photosynthetic productivity (PP_N) correlated with the leaf area and was by a factor of 10 higher in the sun-grown plants (see Table 2). Absolute respiratory losses (R) and gross photosynthesis (P_g) accompanying the greater net photosynthetic productivity were higher in sun-grown plants. Conversely, the relative growth rate (RGR) decreased with the increasing leaf area and was twofold lower in the sun-grown plants than in the shade-grown ones. The growth rate is controlled by the leaf area rather than the net assimilation rate (NAR). The NAR was fairly constant under different environmental conditions.

The increase in respiratory losses (R) in sun-grown plants had a direct effect on their R/P_g ratio (0.67), which was 30% higher than that is shade-grown plants. The decrease in RGR in the sun-grown plants resulted from the reliable biomass accumulation and the rise of respiratory losses for maintenance.

A positive carbon balance is regarded as a criterion of adaptation [22]. At adaptation to high-light conditions, *Ajuga* plants maximize the net photosynthetic carbon gain, which promotes the formation of new ramets and successful vegetative reproduction.

SUMMARY AND CONCLUSIONS

We found that the variance of *Ajuga* characteristics depends on different habitat conditions. At the northern boundary of its distribution, this species is represented by the ecotype which is characterized by slow growth and development, as well as by the predominance of vegetative reproduction over seed multiplication. Comparatively, a low leaf photosynthetic rate of the shade-grown plant is the main factor limiting plant growth in the forest floor. As *Ajuga* plants have been transferred from the forest understory to an open site, higher CO_2 uptake promoted an increase in the leaf area and number of stolons. Vegetative reproduction predominating in northern conditions provides for considerable success through a lower reproductive cost, because stolons carry out both photosynthetic and multiplication functions simultaneously. The ability of the *Ajuga* northern ecotype in a temperature range of 10–15°C to photosynthesize closely to the maximal possible intensity is the most important component of the plant adaptation in a cold climate. Light appeared to be more critical for growth than temperature in determining the plant biomass in northern conditions.

Ajuga reptans L. has a prostrate life form and a creeping type of growth, which allows it to benefit from leaf fall and snow cover, thus alleviating the effect of low temperatures in winter. Also, accumulation of osmotically active compounds (sugars, free amino acids) contributes to frost resistance by decreasing the freezing point of the plant tissues. This is especially important for overwintering leaves.

Adaptation of Plants to Anthropogenic and Environmental Stresses: The Effects of Air Constituents and Plant-Protective Chemicals

KLAUS P. BADER

Assiut, Egypt

INTRODUCTION

Although precise calculations and detailed evidence are still lacking with respect to many parameters, it is generally ''expected'' that the earth's climate, in general, and the average temperature of the atmosphere, in particular, will increase within the decades and centuries to come. During the last 100 years, an increase in the mean values which have been registered worldwide has been observed already and amounts to about 0.7%. According to the actual state of science, the forms of air pollution which affect the environmental climatic conditions include carbon dioxide, nitrogen oxides, photooxidants, especially ozone, dusts, which often contain heavy metals, acid precipitation, and organic compounds [1,2]. Recently developed models deal with the participation of sulfur compounds and aerosols which might counteract the increasing greenhouse effect. It is discussed in this context that sulfur particles which derive from the oxidation of fossile fuels function like a type of mirror and reflect large amounts of the irradiation from the sun. As a second effect, it has been proposed that, in combination with clouds, the sulfur particles might alter the size of the aqueous drops thereby influencing the washing out of air pollutants, micro particles, and aerosols from the atmosphere. In any case, it might be necessary to use sulfur-containing aerosols as a correction factor for the calculation of the expected increase in the average temperature. Under the assumption

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

that the amount of emitted components of any type is not changed, an increase in the average temperature of 3°C in the next 100 years was calculated taking into account the absence of sulfur-containing aerosols, whereas a prediction of 2°C was the result when these additional parameters were included in the calculations. In order to illustrate the complexity of the problem, it should be mentioned that, in many cases, modern computer processors need several months to calculate the respective values, and that not even a change in the solar radiation intensity can be reliably excluded. (From paleoclimatic studies, it is known that about 6000 years ago this radiation was in fact slightly more intense than it is today, but it is not clear whether such alterations and ''periodicities'' might really suffice for the problem in question.)

Without any doubt, CO_2 is the most prominent gas in connection with the temperature on earth, and this also can be derived from the conditions on our neighboring planet, Venus, with its extremely dense atmosphere, a carbon dioxide partial pressure of 95%, and a homogeneous temperature of 470°C. (On Mars, the dilute atmosphere results in a temperature range between −10 and −150°C whereas on Mercury—with virtually no atmosphere at all—temperature changes between +350°C during the day and −180°C during the night have been calculated!) For this planet, it has been calculated that CO_2 contributes 75%, CH_4 about 24.5%, and N_2O about 0.2% of the warming expected in the 100-year period beginning in 1993 [3], but many more parameters have to be included. For example, methane and N_2O are several times more radiatively active than CO_2 [4]. The estimated emissions from vegetation burning in the subcontinental African countries are 0.5 Tg CH_4, 14.9 Tg CO, 1.05 Tg NOx, and 1.08 Tg of particles smaller than 2.5 μm. The 324 Tg CO_2 emitted is expected to be reabsorbed in the following years [5]. Senegal's total emissions are estimated at 17.6 Tg ECO_2. The major gases emitted are CO_2 (61%) followed by CH_4 (35%) and N_2O (4%) [6]. Nigeria is one of the 13 low-latitude countries with significant biomass-burning activities; trace gas emissions were estimated to be 300 Gg CH_4, 2.4 Gg N_2O, and 24 Gg NO_x. CO_2 emissions from burning, decay of the biomass, and long-term emissions from soil amounted to a total of 125,561 Gg [7]. The emissions from motor vehicles in the northwest of England make up 52% of the NO_x emissions, whereas those from fossil fuel–fired power stations make up 20% and 58% of SO_2 emissions [8]. The largest contribution to NH_3 emissions is from cattle, but humans may contribute some NH_3 [8]. With the emission of HCl from the oxidation of polyvinylchloride (—CH_2—CHCl—) in waste-burning industries as an example, one might conclude that deposition of pollutants is heaviest in the immediate vicinity of the source; however, new forms of forest damage appear to show up even in so-called clean-air zones far from any polluting source [1]. The transport of air pollutants leads to a widespread distribution and can entail both chemical and physical transformations at different sites.

In general terms, it can be concluded that the effects of pollutants on the global climate does not necessarily show up as a dramatic and immediate negative impact. It is rather discussed that long-term influences with initial time lags—even intermediate positive effects—and only subsequent negative effects have to be assumed [9]. Observations like premature aging is a typical nonspecific stress symptom and reflects something like an alarm phase of the stressed plant; in the young parts of the plant, this is coupled with more or less efficient resistance processes which might work until the continued stress situation leads to definitive damages and to premature senescence of the whole plant [10]. However, the influence of air pollution on flora and fauna varies in intensity according to the ecosystem involved [1]. Analyses of the significant forest damages realized since 1983 in European countries shows that, besides conifer species, broad-leaved forest trees also appear to suffer from the stress conditions—in particular, alterations in the crown morphology, damages of foliage, and changes in the pigment content are among the relatively unspecific symptoms. On the other hand, many of the conclusions with respect to the details of the reaction mechanisms in this context turned out to be somewhat hasty—at least for such complex phenomena. As an example, the amount to which Al^{3+} ions contribute as a phytotoxic agent to the forest decline is far from clear.

It is obvious that the responses of plants (e.g., conifers) to air pollutants (ozone, sulfur dioxide,

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

nitrogen oxides) are strongly influenced by additional factors like temperature, light intensity, water availability, and the overall nutrient content of the soil [11]. The microbial activity and the humus content influence both the carbon and the nitrogen cycles in forest soils [12]. When air pollutants decrease the photosynthetic activity, they appear to alter the structure of the chloroplasts as the most prominent cellular target [13]. Therefore, in young Norway spruce trees fumigated with nitrogen oxides, no damage was found and the trees' ability to fix carbon dioxide was even increased. Following the application of SO_2, there was a substantial decrease in photosynthetic activity, but as soon as the fumigation was stopped, the effect was reversed. The effect of ozone, however, was not reversible [14].

The plum poxvirus strongly influenced the level of economic feasibility and was in turn affected in its toxicity by various exhalations. The production of trees has no economic value to exceed in regions attacked by strong acid emission with the predominant component SO_2, NO_x, etc., acid emissions with ash and compounds of fluorine and chlorine, acid emissions with metallurgical ash, acid emissions with a significant proportion of organic matter, as well as by alkaline magnesium emissions [15]. However, a low or zero negative effect was observed when no industrial fertilizers were applied on evaluated trees and where calcium is predominant in the exhalates, i.e. in the ''alcalic-calcium'' emission types. Accordingly, Vanek, et al. [15], presumed that the deharmonization of ecology causes a restriction, almost a loss of the induced plant resistence to pathogens which renders these plants inadequate for production purposes. Foliar application of kinetin and ascorbic acid has minimized the foliar injury in *Oryza sativa* L. cv. GR 3 grown near a fertilizer plant which emits SO_2, NH_3, NO_2, and F as major air pollutants, thereby improving the photosynthetic leaf area, and increasing the number of panicles with high total dry standing crop. However, unfavorable climatic factors acted as an additional stress to hamper the productivity [16]. The reduced growth of mycorrhizal and nonmycorrhizal fine roots at the pollution (SO_2, NO_x, alkaline fly ashes)–impacted sites is seen as an adaptation mechanism of the root system to high nutrient inputs [17]. Buecker and Ballach [18], however, stated that the energy normally needed for growth and the development of frost hardiness is used for maintenance purposes and to repair damages (an air pollution–dependent demand for energy and carbon), which may be reflected in an increase in the susceptibility to freezing damage and a decrease in growth. Another point to be described in this context is the sensitivity of lichens to gaseous pollutants, which has been the subject of a number of experimental approaches in recent decades [19]. Although fumigation experiments have so far been concentrated mostly on the effects of sulfur dioxide, Loppi, et al. [20], however, pointed out that changes in lichen frequencies, as bioindicators of air quality, are largely determined by nitrogen oxides.

The effects of modern plant-protective chemicals on the physiology and on the metabolism of plants are often neglected even in modern experimental approaches. Generally, it is assumed that pesticides—other than herbicides—only have an effect on the respective target organisms without influencing the host plants. At this point, it should be emphasized that plants normally come into very close contact with, for example, insecticides, fungicides, nematicides, and that this might well represent serious problems. Following the application of a liquid-formulated plant-protective chemical, the solution or suspension dries and remains for a relatively long time on or near the plant, with all the implicated problems for the soil, the water, and the environment as a whole. Another very important aspect, however, is the question whether and how plants are affected or injured by the enormous amounts of substances which are used in modern agriculture. To date, there is little information about this point; few investigations dealt, for example, with the effects of the insecticides Thiodan (Hoechst), Carbaryl (Union Carbide), and other pesticides on the glycolipid and phospholipid contents of maize seedlings [21], but extended work on this subject is almost completely lacking. Therefore, we refer in this context to investigated details of the effects of synthetic pyrethroid insecticides with different molecular structures on higher plants—not least under the applied aspect that such analyses might help in the selection of efficient but less phytotoxic chemical products with less environmental problems [22].

Marcel Dekker, Inc.

AIR CONSTITUENTS

Carbon Oxides

Carbon Dioxide

Since the beginning of modern industrialization, the carbon dioxide partial pressure of the atmosphere has constantly increased, and this process appears to continue. Projection of the observed development for the next 50 years suggests that the carbon dioxide content of normal air will increase from the actual 340 ppm to about 700 ppm CO_2 or more. This increase will cause an additional ''greenhouse effect'' which will have enormous abiotic consequences on the general climate. The resulting gradual increase in the average temperature will entail further liberation of carbon dioxide from lakes and oceans, as the solubility of gases in liquids is strictly temperature dependent. Initial biological effects will surely impact plants (and only secondarily animals and human beings), because carbon dioxide, in contrast to the so-called air pollutants, is unproblematic for animals and humans, whereas plants, on the other hand, virtually always live under a strict limitation of this gas, because it is the necessary carbon source for carbohydrate formation. In terms of agricultural efficiency, the questions of how crop plants react to an elevated carbon dioxide content of the atmosphere and also how weeds perform under such altered conditions are of enormous both scientific and economic interest.

As C_4 and crassulacean acid metabolism (CAM) plants possess an internal CO_2 concentration mechanism, an impact of an increase in CO_2 concentration on plants is first of all expected for C_3 plants. Also, however, C_4 plants appear to react to alterations in the carbon dioxide partial pressure [23,24]. In recent years, an increasing number of publications is dealing with this problem which might have on a long-term level in particular both positive and negative implications. Many papers have been published thus far describing the details of the behavior of plants in reaction to an elevated carbon dioxide partial pressure. In conclusion, from these reports, we have learned that an increase in the CO_2 concentration is (in the first instance) largely beneficial for C_3 plants. For rice, an optimal carbon dioxide content of even 1500–2000 ppm has been calculated with respect to growth and yield of the plants [25]. In relation to the number of investigations on the effects of carbon dioxide (or other components of the air) alone, only scattered reports are available at present on the possible (and expected) joint effects of carbon dioxide together with other air constituents or pollutants. This is certainly due to the fact that such complex investigations pose enormous specific problems in terms of definite and unequivocal interpretations because of the complexity of the experimental approaches. Comprehensive and informative reviews on the effects of ozone on plants have been published (e.g., see Refs. 26–28).

When normally grown C_3 plants are analyzed under a 700-ppm CO_2 gas atmosphere, it is generally observed that the plants perform better as far as the overall photosynthesis, growth and a variety of parameters like, for example, biomass production, plant height, fresh and dry masses, are concerned. The experiments have been carried out with different crop plants such as tobacco, cowpea, sweet potatoe, tung-oil tree, and others [29–32]. Even the increase in the production of lateral branches has been investigated in the cases of white pine and crab apple seedlings [33,34]. The number of stomata increased [29], whereas the stomatal aperture was clearly reduced in the case of maize in a short-term experiment [35]. For stomata, however, long-term adaptation processes also have to be taken into account [36]. Similar adaptation phenomena have been described for the increased P_N values which are observed under conditions of high CO_2 concentrations but return to normal with time [37]. Details on the mechanisms of this ''backreaction'' have been proposed but are still unclear [38]. Respiratory processes also appear to be affected by high CO_2 values; in the case of *Eucalyptus*, a decrease of the dark respiration rate to about one half together with the concomitant increase of P_N has been described [39].

It should be noted, however, that in a variety of cases no or only minimal effects were described. Thus, in the case of soybean, the plant height appeared to be more or less unaffected by the elevated CO_2 concentration [40]. However, not only the impact of an elevated carbon dioxide partial pressure on crop plants has to be considered; the predicted alteration in the environmental

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

conditions will also affect growth and photosynthesis of weeds, thereby indirectly influencing growth rates and efficiencies of agricultural crop plants. Beside the suggested stimulation of photosynthesis of C_3 plants and the reduced opening of stomata and the increased water-use ability of both C_3 and C_4 plants, the control of perennial weeds might become more difficult, as an increased photosynthetic rate also enhances the production of rhizomes as storage organs. In this context, not only the rate of individual survival but also the distribution of certain weeds and weed families in different regions might be altered [41]. Also, the interrelationship between a stimulated accumulation of mineral substances by a high CO_2 partial pressure and the need for and the doses of fertilizer applications are and will be of agricultural interest [42]. This aspect might be of particular interest not least because the nitrogen supply in particular will be influenced. If one assumes a substantial increase in photosynthetic power, it is easy to predict that the C/N ratio of plants will be one of the problematic points. The necessity of a higher nitrogen supply either by fertilizers or by symbiotic nitrogen-fixing organisms might be a consequence of agricultural reality [43]. Figure 1 summarizes the most relevant interrelationships between carbon dioxide and plant activities showing that via direct and indirect effects, a multitude of physiological and metabolic processes in plants are linked to the partial pressure of carbon dioxide.

Until now, it could not be predicted that an increased CO_2 partial pressure of the atmosphere would entail an elevated carbon dioxide content of the soil, thus affecting parameters like, for example, root respiration. Recent investigations, however, deal with the fraction of carbon required for root respiration and other processes [44]. In any case, it is obvious that an increased photosynthetic activity based on a higher carbon dioxide partial pressure in the atmosphere will also (directly or indirectly) lead to an elevated carbon content of the roots which in turn might influence mycorrizal symbioses. It has been reported that under such conditions, for example, the uptake of phosphorus is increased, whereas the nitrogen uptake remained unaffected. Apparently, changes in the activity of uptake processes have to be regarded here, as the overall mycorrhizal colonization inside the roots did not increase [45].

One of the striking observations in this context was the result that apparently photorespiration,

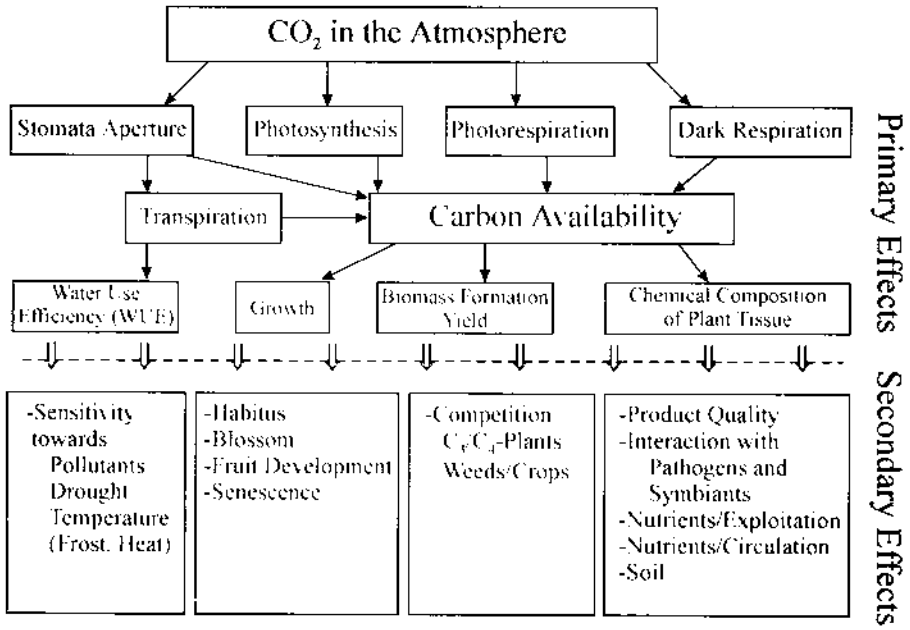

FIGURE 1 Summary of primary and secondary effects of an elevated carbon dioxide partial pressure in the atmosphere on plants. (Modified from Ref. 26.)

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

which is still a somewhat unclear phenomenon, is not necessarily reduced under the conditions of an elevated carbon dioxide partial pressure. Via the bifunctionality of the ribulose bisphosphate carboxylase oxygenase (Rubisco), the enzyme also reacts with oxygen and not exclusively with carbon dioxide, thereby having an oxygenase activity besides a carboxylase function and ''counteracting'' the photosynthetic yield (to about 50%) by the formation of phosphoglycolate and phosphoglycerate instead of two molecules of phosphoglycerate. Consequently, it had been expected earlier that the amount of photorespiration of crop plants would decrease or even disappear when breeding experiments would have selected versus high yields exclusively. Today, we know that this is not the case, and that mutants with artificially lowered photorespiration showed even substantially impaired activity as soon as photorespiratory conditions prevailed (e.g., dislocation from low to normal oxygen partial pressure values of the test plants). In many cases, photorespiratory conditions even turned out to be lethal for such mutants. One of the principal technical problems in context with this and similar gas exchange reactions being composed of simultaneous but counteracting partial reactions like, for example, the oxygen uptake from respiratory processes and oxygen evolution derived from photosynthetic water oxidation is that many conventional analyzing techniques cannot discriminate between these two phenomena. This leads to the ''principal falsification'' of the quantitation, as only the net difference between the two rates is determined (Fig. 2).

This problem can, however, be overcome by mass spectrometric analyses with the application of appropriate gas isotopes [31]. Under the assumption that a reaction assay is composed of normal

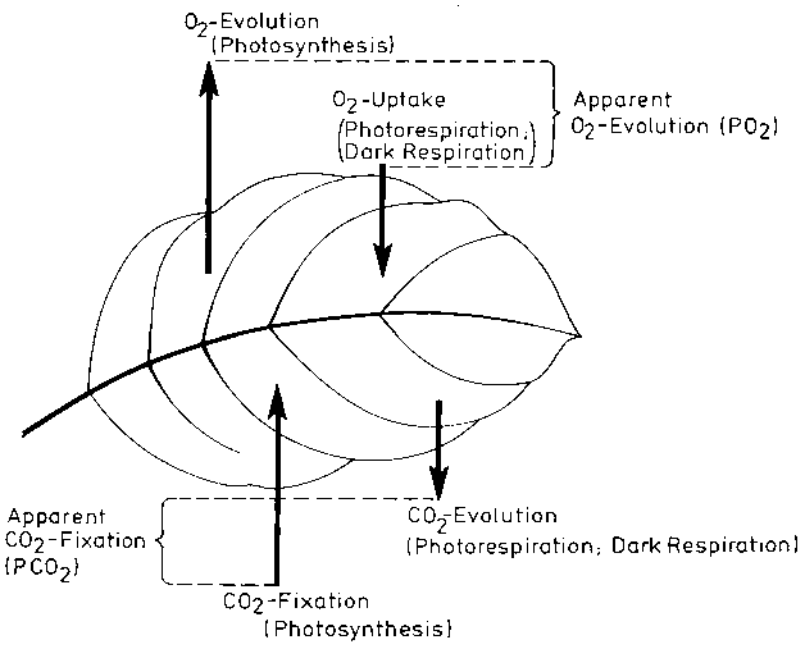

FIGURE 2 Schematic representation of the specificities of carbon dioxide and oxygen gas exchange reactions measuring intact leaves from higher plants, cell cultures from higher plants, algae, or cyanobacteria. The overall gas exchange is in any case composed of two counteracting parts; namely, uptake and evolution reactions. Thus, conventional electrodes can only measure the respective differences between the partial reactions. Mass spectrometry with the application of appropriate isotopes can, however, discriminate between the two partial reactions so that independent but simultaneous measurements (e.g., of photorespiration and photosynthesis) are possible (cf. Fig. 3).

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

water (i.e., $H_2{}^{16}O$) and the (artificial) gas atmosphere is supplied with the stable oxygen isotope $^{18}O_2$, any oxygen evolution will show up as mass $^{16}O_2$, whereas the *concomitant* oxygen uptake can be *independently* detected at mass 36. (In many cases, analysis of the mixed oxygen isotope $^{16}O^{18}O$ as mass 34 allows the most decisive and specific conclusions with respect to details of a given reaction mechanism.) Principally, the same holds true for other gas exchange reactions and isotopes; for example, carbon dioxide (CO_2 fixation/photorespiration) or nitrogen fixation. Figure 3 depicts, as an example, the oxygen gas exchange in whole leaves from tobacco analyzed by means of mass spectrometry.

Figure 3 also shows that normally grown tobacco plants are carbon dioxide limited with respect to the photosynthetic capacities and that the phenomenon of photorespiration quantified as $^{18}O_2$ uptake is decreased on increasing the carbon dioxide partial pressure. Under these conditions, the competition between carbon dioxide and oxygen molecules for the binding site of Rubisco favors the carboxylase and diminishes the oxygenase function of the enzyme. Surprisingly, this interpretation turned out to be valid only for normally (350 ppm CO_2) grown plants; the effect disappeared as soon as plants were adapted to an elevated carbon dioxide concetration. Provided the tobacco plants had been cultivated (adapted) for several weeks under the conditions of 700 ppm CO_2, absolutely no reduction in photorespiratory activity was observed (Table 1).

In this case, photosynthetic activity was mass spectrometrically measured both as carbon dioxide fixation and as oxygen evolution ($^{16}O_2$). Both rates were enhanced when 350 ppm–grown plants were compared with 700 ppm CO_2–grown tobacco. When the gas atmosphere over the respective assays, however, was supplemented with the stable oxygen isotope $^{18}O_2$, it was clearly shown that high CO_2-adapted plants did not reduce their photorespiratory activity. Plants which had been cultivated under 350 ppm CO_2 or under 700 ppm CO_2 revealed exactly the same photorespiratory activity when they were analyzed in 700 ppm carbon dioxide. Thus, increased photosynthetic activity under an elevated carbon dioxide partial pressure is principally independent of the (completely

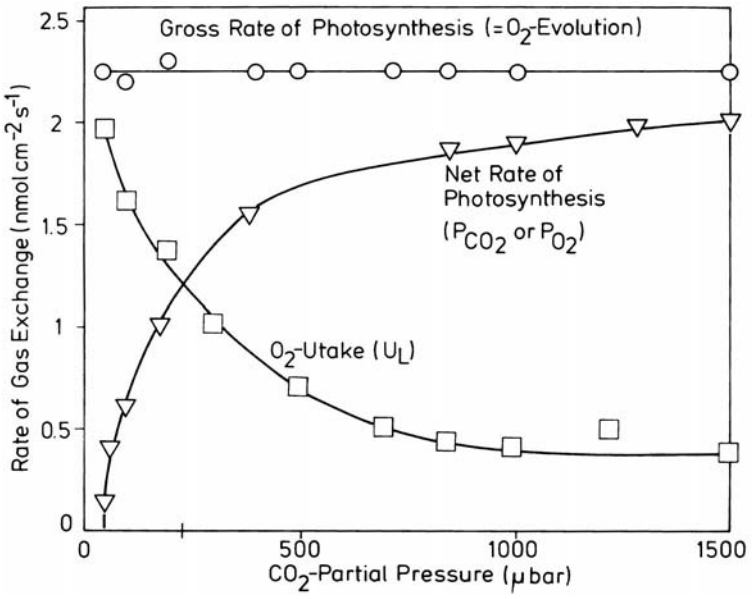

FIGURE 3 Oxygen gas exchange in leaves of *Nicotiana tabacum* var. John William's Broadleaf. Dependence of $^{16}O_2$ evolution in the light (photosynthesis) and of $^{18}O_2$ uptake in the light (photorespiration) on the CO_2 concentration in air. Measurements have been carried out simultaneously by mass spectrometry at a light intensity of 250 μE. (From Ref. 31.)

TABLE 1 CO_2 and O_2 Gas Exchange Rates in *Nicotiana tabacum* var. John William's Broadleaf in Normal Air (350 ppm CO_2) or in Air Enriched in CO_2 (700 ppm)

	Rates of photosynthesis (μmol CO_2 or O_2)					$^{18}O_2$-uptake (μmol O_2) in light (U_1)		
	P_{CO_2}		P_{O_2}		Ratio			Ratio
	mg Chl^{-1} h^{-1}	dm^{-2} h^{-1}	mg Chl^{-1} h^{-1}	dm^{-2} h^{-1}	P_{O_2}/P_{CO2}	mg Chl^{-1} h^{-1}	dm^{-2} h^{-1}	U_1/P_{O_2}
Control plants measured under 350 ppm CO_2	15.3 ± 1.3	79.6 ± 4	21.3 ± 2.8	109.9 ± 15	1.4 ± 0.12	17.7 ± 2.2	64.2 ± 8.6	.83 ± 0.22
Control plants measured under 700 ppm CO_2	22.9 ± 1.3	124.9 ± 8.7	26.0 ± 5.6	142.6 ± 23.6	1.1 ± 0.18	11.7 ± 1.9	42.4 ± 8	.45 ± 0.23
"700-ppm plants" measured at 350 ppm	26.4 ± 7.5	126.5 ± 22.8	34.6 ± 10.5	164.9 ± 32	1.3 ± 0.03	13.7 ± 2.4	49.0 ± 10.2	.400 ± 0.07
"700-ppm plants" measured at 700 ppm CO_2	43.9 ± 4	215.1 ± 5	45.0 ± 12.2	216.0 ± 36	1.03 ± 0.17	10.9 ± 1.9	39.2 ± 8.2	.243 ± 0.03

Age of the tobacco plants: 3 weeks after transplantation (i.e., 6 weeks after sowing). Control plants are grown in normal air containing 350 ppm CO_2. "700-ppm plants" are grown all the time under air having a CO_2 content of 700 ppm. Measured at 350 or 700 ppm CO_2 means that the leaves have been conditioned before the gas exchange measurement in the measuring cell in the respective atmosphere. The values are averages of three independent measurements on different leaves. The variations given represent absolute variations inherent to the performance of different leaves tested. The mass spectrometric technique itself works with an internal precision of less than 0.5%.

unchanged) photorespiration rate, and this result might match with the breeding experiments concerning yields of crop plants (see above).

Consequently, many investigations deal with the question of whether an elevated carbon dioxide level will generally result in higher yields of crops. At present, a variety of analyses suggest this to be the case, although precise calculations are difficult to obtain—not least because of the complexity of the approaches. Taking results from the German Agricultural Research Institute as an example, one might predict that the cereal production has already increased owing to the higher amount of carbon dioxide which is available for the plants. Recent estimations proceed on the assumption that the annual average hectare yields might increase by about 0.6% with 2 ppm increase in the CO_2 content of the atmosphere [45a]. Table 2 summarizes the results from experiments with various growth and yield parameters of both C_3 and C_4 crop plants in relation to CO_2 concentrations of 372 ppm, 459 ppm, and 539 ppm, respectively. In this case, maximum stimulations of about 80% for the grain yield of barley and 25% for the grain yield of wheat were observed; these increases, however, also were brought in line with an increase in the number of ears per plant and also with a greater number of grains per ear. Based on the newly developed free air carbon enrichment (FACE) technique, one might hope that investigations on the effects of elevated carbon dioxide

TABLE 2 Effect of a CO_2 Enrichment on the Yields of Crop Plants

Crop	CO_2 concentration Cultivar	CO_2 response 372 ppm	459 ppm	539 ppm	% Yield ppm^{-1}

		±0.55	±0.90	±1.1	

Yield values (g pot^{-1}) are given as means (± standard error, n = 14 for cereals and maize, and n = 20 beans, respectively). The value of the "CO_2 response" was calculated as the ratio of the increase in % yield per increase in the atmospheric CO_2 concentration (% ppm^{-1}). Values were calculated as the slope of the CO_2-yield curve (maize, barley) or from the 372-ppm and 459-ppm treatment level (wheat). Values within a row followed by the same letter are not significantly different at the 5% level.

[a] Cobes were harvested before ripening.

concentrations will supply more reliable and consistent results and allow more unequivocal conclusions. (Hitherto, one of the basic problems in this context is the fact that modified stable and homogeneous carbon dioxide concentrations for field experiments are not easy to establish.) Experiments of the American Ministery of Agriculture resulted in increased yields of about 10% for wheat and about 50% for cotton and citrus. Moreover, adaptation processes to drought stress appeared to be substantially improved. However, long-term adaptation processes of plants to the elevated carbon dioxide partial pressures might mitigate increased yields of the relevant crop plants that might be correlated with the different nutrient supply in natural and agricultural ecosystems. Therefore, recent and promising experiments are investigating a large area in North Carolina equipped with the FACE technique with respect to the concerted analysis of all possible parameters from plant behavior to the microbial activity within the soil. Recent analyses using the FACE technique dealt with the effects of higher CO_2 values on leaf and canopy specificities in a pine tree forest. Minor changes were observed with respect to the water use, the sap flux density, and direct stomatal responses. The net photosynthetic rate of the leaves, however, was substantially increased with trees of similar foliage but grown at 550 μM/M CO_2 [46]. The FACE technique also proved to be useful for investigations on the effects of an elevated carbon dioxide partial pressure on root morphological characteristics under free-air conditions. In this case, an increase in both the number of lateral roots and the dry weight of the roots was observed [47].

Carbon Monoxide

Carbon monoxide (CO) is a colorless gas with little water solubility, no smell, and hardly any taste. It most probably represents the most important pollutant with respect to its negative impact on animal and human life; that is, warm blooded organisms. This effect is, in part, based on the property of carbon monoxide to react in a competitive manner and with a more than 300-fold affinity (in relation to oxygen) with the 6 coordinative position of the iron in the heme group of the hemoglobin molecule. Consequently, the oxygen transport system of the organisms substantially impaires what affects many essential metabolic functions inside the central nervous and the cardiac circulatory systems. For plants, this pollutant is much less problematic; but some effects have been described. To date, there is still debate about the extent to which carbon monoxide is emitted from natural or anthropogenic sources. Values for the latter differ to about one order of magnitude between 4 and 50%. In any case, industrial processes, traffic, and private housekeeping are among the most significant sources. In general, oxidation of carbohydrates (vegetation burning), but also degradative reactions of, for example, chlorophyll play a role. Bullock, et al. [48] reported that when cheese whey was applied to growing alfalfa (Fortress variety) on silt loam calcareous soil, large amounts of carbon monoxide were emitted from the soil, which indicates a concern for whey disposal on agricultural ground and the resultant production of CO. Unfortunately, the oxidation of carbon monoxide to carbon dioxide, which is catalyzed by ultraviolet light or high temperatures, does not reach significant reaction rates. (In some cases, this oxidation is enhanced and accelerated by microbial activities within the soil.)

Detailed analyses of the effects of carbon monoxide revealed that this pollutant essentially acts as an inhibitor of respiration in plants, cyanobacteria, and photosynthetic bacteria. The principal target is the cytochrome oxidase complex, so that any reduction of oxygen at the level of complex IV is obviated. Visible spectra of mitochondrial and enzyme preparations showed that CO bound to cytochrome (cyt) oxidase at heme a_3, whereas N_2O and D_2O did not directly affect the ligand-binding site [49]. Specifically, carbon monoxide binds to a high-spin cyt *b* in the cytochrome *c* oxidase enzyme of the facultative phototrophic bacterium *Rhodobacter capsulatus* [50]. Mitochondrial CO effects were dose dependent and readily reversible, with maximal activity inhibition of 58 and 81% for mitochondria and oxidase, respectively, in the presence of 80% CO. However, a cytochrome P450 with low affinity (about $3 \cdot 10^{-3}$ M) for CO appears to be the major microsomal P450 in some plant tissues. The presence of such a low CO affinity cytochrome P450 correlates with its lack of NADPH reducibility and with the presence of high levels of 13(S)-hydroperoxy-

9(Z), 11(E)-octadecadienoate peroxidase activity [49]. Low CO affinity is characteristic of the allene oxide synthase P450s, and these P450s constitute a major portion of the microsomal P450 in a variety of plant tissues, particularly in monocot species. Carbon monoxide (CO), nitrous oxide (N_2O), and deuterium oxide (D_2O) as respiratory effector molecules revealed that cytochrome *c* oxidase (EC 1.9.3.1) activity is the first step in seed deterioration, resulting in the loss of seed viability or vigor. Seed germination was not changed in the presence of these molecules, but reductions were observed in seedling respiration and root length corresponding to reductions in cytochrome oxidase activity [51]. Unlike the other gas pollutants, little, if any, information is available concerning the morphology, growth, or productivity of CO-polluted plants. However, several pieces of evidence revealed a clear inhibition by CO of cytochrome oxidase–mediated pathways.

The conversion of (R)-reticuline to salutaridine, the key intermediate in morphine biosynthesis, is catalyzed by microsomal preparations from *Papaver somniferum* plants (roots, shoots, and capsules but not in latex) and inhibited by carbon monoxide (in darkness but not in light), suggesting that the enzyme is a cytochrome P450–dependent oxidase [52]. Carbon monoxide also significantly inhibited ethylene production and ACC (1-aminocyclopropane-1-carboxylic acid) conversion to ethylene in soybean (*Glycine max*) seedlings, indicating the existence of a relationship between cytochrome P450 activity and ethylene-forming enzyme activity [53]. These and many more investigations with different plant species suggest that the main site of action of carbon monoxide is the metabolic pathway of respiration and, in particular, the cytochrome oxidase (e.g., see Refs. 54–58)

However, positive effects of carbon monoxide also have been reported; for example, the (albeit slight) stimulation of cocklebur (*Xanthium pennsylvanicum* Wallr.) seed germination by CO [59]. In addition, Traunecker et al. [60] reported that a strictly anaerobic bacterium (tentatively called strain MC) could grow on carbon monoxide. Several C_3 plants (*Triticum aestivum, Gossypium hirsutum, Oryza sativa, Cicer arietinum, Arachis hypogaea, Cajanus cajan*) turned out to be relatively insensitive to CO and required a high CO to O_2 ratio of 40 to promote significant nitrate reductase activity [60]. On the other hand, the leaves of the C_4 plants (*Zea mays, Sorghum bicolor, Pennisetum americanum, Echinochloa crusgalli, Eleusine coracana, Panicum miliaceum, Chloris gayana, Panicum maximum*) were highly sensitive to CO even at CO to O_2 ratios of 5 or less. In these leaves, the uncoupler was without any effect, probably because the mitochondria, either from mesophyll or bundle sheath cells or both, lacked tight respiratory control [61]. Moreover, defined $CO:O_2$ ratios distinguish one C_3 plant from the other with respect to its CO sensitivity of cytochrome *c* oxidase [62]. In the leaves of C_3 plants (wheat, chickpea, and groundnut), the optimum ratios of $CO:O_2$ for the inhibition of cytochrome *c* oxidase were found to be 40, 30, and 10, respectively. Moreover, Cai et al. [63] found that the use of carbon monoxide provides a simple and specific test to differentiate between the multiple polyphenol oxidase activities laccase and catechol oxidase activity. ^{60}Co gamma-irradiated grains of allspice, cinnamon, cumin, polished rice, and wheat could be distinguished from nonirradiated ones by the level of retained CO gas even after 2 months of storage at room temperature [64].

Sulfur Dioxide

Sulfur dioxide appears to be the most prominent source of emission-dependent plant injuries. It originates from the burning of charcoal and oil products, metal roasting, and many other industrial processes. Owing to its specific weight, it accumulates near the soil—thus in the immediate vicinity of many plants. It is easily water soluble and reacts forming sulfuric acid. In contrast to other gaseous pollutants like ozone, SO_2 (and NO_2) can principally act as nutrients as sulfur-containing compounds are required by the plants. SO_2 affects the sulfate and the organic sulfur pools of the leaves and causes an enhanced export of sulfur. Thus, sulfur from atmospheric pollution can interact with the sulfur nutrition of plants [65]. As a consequence, plants fumigated with SO_2 also contained higher amounts of reduced sulfur compounds, mainly glutathione, in their roots. The interrelationship between sulfur dioxide (and other pollutants) and the whole-plant nutritional status has been expressively described (Fig. 4).

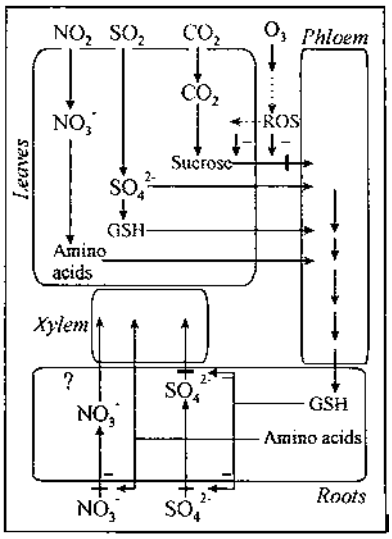

FIGURE 4 The influence of atmospheric pollution by O_3, SO_2, and NO_2 on shoot-root interactions in plants. Reactive oxygen species (ROS) released by ozone impact inhibit sucrose export from leaves. Absorbed NO_2 or SO_2 is used to synthesize amino acids or glutathione (GSH), respectively, which are translocated in the phloem to the roots. Amino acids may affect nitrate uptake; glutathione reduces sulfate uptake and the xylem-loading process in roots. (Modified from Ref. 65.)

However, any positive effect is strictly limited by the redox active capacities of the plants to detoxify sulfur dioxide into sulfate and then to organic compounds. Thus, some plants can very efficiently oxidize sulfur dioxide to sulfate, so that no macroscopically detectable damages are observed at moderate sulfur dioxide concentrations. Specifically sensitive plants are conifers, leguminoses, spinach, oats, maize, and citrus. The oxidation of sulfite to sulfate by intact chloroplasts isolated from spinach (*Spinacia oleracea* L. cv. Yates), which are capable of photoreducing carbon dioxide, was slower in the light than the reductive formation of sulfides [66]. Under these conditions, the electron transport inhibitor 3-(3,4-dichlorophenyl)-1, 1-dimethylurea (DCMU, diuron) decreased not only the reduction but also the oxidation of sulfite and the formation of additional compounds. In the dark, however, both the oxidative and the reductive detoxification of sulfite were very slow. Figure 5 summarizes the involved redox reactions as well as the relevant detoxification starting from stomatal sulfur dioxide uptake.

However, sulfur was found to behave conservatively within the canopy in the sense that the sulfur dioxide uptake balanced, within certain limits, the sulfate originating from the soil [67]. Comparison of the uptake rates of SO_2 by 11 lichen species which had been fumigated with increasing concentrations between 0.036 and 2.0 ppm sulfur dioxide revealed a linear correlation with the applied concentrations. No differences were observed when the fumigation was performed in the light or in the dark [68]. Moreover, thalli which had been inactivated by heat treatment or in which respiration was inhibited by azide treatment did not show SO_2 uptake significantly different from that of active thalli. After the first hour of fumigation, the uptake rate was almost constant during the following 5 h for concentrations up to 1.0 ppm SO_2, whereas at higher concentrations the uptake declined continuously. For *Arabidopsis thaliana* (L.) Heynh, it has been demonstrated that sulfur is accumulated preferentially in the shoots following the exposure of the plants to SO_2 [69]. However, the SO_2 flux to spruce (*Picea abies* (L.) Karst.) seedlings treated with 12.5 ppm Mn was about twice as high as to trees treated with 0.5 ppm Mn [70]. This is due to a synergism between manganese leaching and catalysis of the SO_2 oxidation by the leached Mn^{2+} ions.

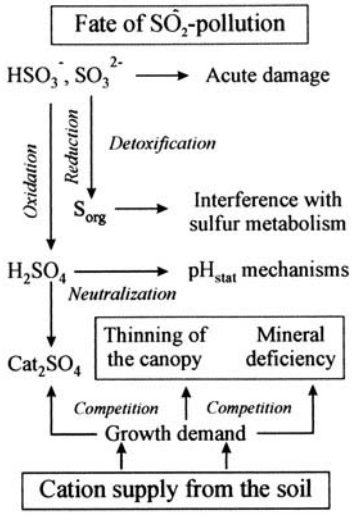

FIGURE 5 Overview of chronically activated detoxification ($SO_2 \rightarrow S_{org}$ or $SO_{2-} \rightarrow SO_4^{2-}$) and compensation pathways in spruce trees after long-lasting SO_2 pollution at ambient SO_2 concentrations in the field. Concerning NO_x (= NO_2 + NO), only reductive detoxification ($NO_x \rightarrow N_{org}$) is observed in the field at ambient NO_x concentrations. (Modified from Ref. 81.)

As mentioned before, sulfur dioxide, after being hydrated in the aqueous phase of the stomatal cell walls of spinach to form sulfite, can be oxidized to sulfate. This is based on the activity of an apoplastic peroxidase normally involved in phenol oxidation [71]. With no ascorbate present in the aqueous phase of the apoplast, a fast sulfite oxidation is catalyzed by a radical chain reaction, whereas in the presence of ascorbate, chain initiation and sulfite oxidation are inhibited with the participation of scavenging radicals. Even after exposure of leaves to high concentrations of SO_2, which inhibited photosynthesis, the redox state of ascorbate remained almost unaltered in the apoplastic space of the leaves. On the other side, any deleterious effect of sulfur dioxide on the leaf photosynthesis can be observed only with more or less intact plant systems. If, on the other hand, the flash-induced oxygen evolution in chloroplasts from higher plants (tobacco) is analyzed, absolutely no inhibitory influence of sulfur dioxide on the isolated organelles could be detected (K. P. Bader, unpublished results). Hence, the investigations on sulfur dioxide–induced damages require the analysis of whole plants or intact leaves on principle and cannot be studied with isolated organelle suspensions, as can be done in many other cases of pollution stress.

As mentioned above, the reaction rate of sulfur dioxide detoxification by oxidation is slow; its rate depends on the generation rate of apoplastic hydrogen peroxide and on the steady-state concentrations of phenolics and sulfite. The affinity of the peroxidase for phenolics is higher than that for sulfite. It has been reported that SO_2 was either oxidized to sulfate or converted into extra organic sulfur compounds in a sulfate/organic sulfur ratio 3:1, and this ratio was independent on the SO_2 concentration prevailing in the atmosphere [69].

The phytotoxic effect of sulfur dioxide consists mainly of the inhibition of the major enzyme of carbon dioxide fixation, Rubisco. The damage of leaves by sulfur dioxide due to the effect on Rubisco is mediated through the production of reactive oxygen species. Thus, the site of action of sulfur dioxide is mainly the chloroplast and both light, and the photosynthetic electron transport system affect the negative influence on the foliar tissue [72].

Partial pressures at around 0.3 ppm SO_2 resulted in dramatic effects on plants. In the case of *Aleurites montana* leaves which turned brown after 5 days and after 6–8 days, a strong leaf-shedding

occurred which affected 0.75% of the leaves [32]. Most interestingly, the two to three youngest leaves were always more resistant and survived with an apparently effective adaptation. Detailed analyses of cell components revealed the background of this drastic stress situation (Table 3).

Virtually all tested parameters were substantially decreased by the SO_2 stress; chlorophyll *a*/*b* decreased by 50%, soluble sugars by 52%, and Rubisco/area by 35%. In these experiments, it was clearly shown that any negative effect of a higher sulfur dioxide concentration on plants appear to be mitigated by the concomitant increase of the carbon dioxide concentration to 700 ppm (Table 4).

Similarly, chlorosis and browning were observed on the leaves of tomatoes cv. Pusa Ruba grown at polluted sites of a coal-fired thermal power in India [73]. The amount of sulfur in leaves was greatly enhanced and foliar injury was invariably greater on nematode-infected plants. Also, seriously deteriorated needle surfaces of Scots pine (*Pinus sylvestris* L.) was related to higher atmospheric SO_2 concentrations [74]. In full accordance with this, acute injury symptoms—leaf necroses in the vegetative period—appeared on *Picea abies* after average daily SO_2 concentrations of more than 200 $\mu g \cdot m^{-3}$. Higher concentrations of SO_2 (nearly 300–400 $\mu g \cdot m^{-3}$) often caused leaf necroses on *Picea omorica, P. pungens*, and *Pinus strobus*; the most tolerant conifers to acute pollution stress were *Pinus contorta* and *Abies alba* [75]. In two cultivars of *Cicer arietinum*, growth rate, stomatal index, amount of chlorophyll and carotenoids, total carbohydrate, and phosphorus content and, consequently, the yield were adversely affected by SO_2 exposure; the specific sensitivity against sulfur dioxide was dependent on the cultivar and of course on the concentration [76]. In other cases, SO_2-treated cultivars of wheat showed a significantly reduced leaf area; hence, the total plant biomass and the yield substantially decreased [77]. Even the root shoot ratio and also the leaf weight ratio were altered in plants grown at different nutrient levels and with different SO_2 treatments. Total chlorophyll, ascorbic acid, starch, and protein contents were as well reduced by SO_2 exposure, whereas total soluble sugar and reducing sugar levels were increased in quantity. A decreased activity of glutamine synthetase, lower concentrations of soluble protein, leaf pigments and P and K, and an increased activity of glutamate dehydrogenase were found in 3-year-old seedlings of Scots pine (*Pinus sylvestris*) exposed to SO_2 [78].

In a variety of cases, however, no substantial differences following exposure to SO_2 were observed with respect to the overall growth rate and the pigment contents of young Norway spruce (*Picea abies* [L.] Karst.) trees; neither the content of ascorbic acid nor its redox state was affected. [79]. Moreover, chlorophyll fluorescence measurements showed values of F_v/F_m ratios which are typical for plants with a healthy photosynthetic apparatus and a functional electron transport system. Other affected parameters, however, were the ''epoxidation state'' of the xanthophyll cycle, an increased foliar contents of sulfate, total glutathione (reduced and oxidized form), cyst(e)ine, and a slightly higher reduced redox state of glutathione; the latter appeared to act as a signal to control sulfate uptake from the soil and to inhibit the process of xylem loading [63]. Apart from an increase in water-soluble nonprotein sulfydryl content and a slight increase in the amount of glucosinolates (play a minor role as sinks for excess sulfur) no negative effects of exposure to SO_2 were observed for shoot biomass of *Arabidopsis thaliana* (L.) Heynh. [69]. Even the organic nitrogen to organic sulfur ratio did not change despite the increased sulfate content, which means that no changes in the composition of sulfur-containing compounds have to be assumed in such plants.

For tobacco (*Nicotiana tabacum* var. John William's Broadleaf), we observed that fumigation with 0.3 ppm SO_2 resulted in substantial damages of the older leaves of the plants (cf. Table 3). The youngest leaves, however, got adapted within the application period so that absolutely no injuries could be observed—not even under continued treatment (K. P. Bader, unpublished results). Similar effects have been described for the extent of visible injuries on soybean (*Glycine max*) seedlings fumigated with SO_2; no further damage of younger leaves were observed under long-term fumigation [80]. Accordingly, the increase of membrane permeability showed a significant recovery under prolonged fumigation. Even the SO_2-induced increase in free amino acid content was decreased down to the level of the control during the experimental fumigation. Moreover, pretreatment with low SO_2 concentration increased the resistance of soybean seedlings to high SO_2 concentration. In comparison, chronic SO_2 pollution was found to be 2.0–2.6 times more phytotoxic to Norway

TABLE 3 Protein, Chlorophyll, Sugar, Ribulose 1,5-Bisphosphate Carboxylase Oxygenase (Rubisco) and Content of Coupling Factor of Photophosphorylation (CF_1) as Well as Fresh Weight of Leaves of the Chinese Tung Oil Tree *Aleurites montana* Under the Influence of 14 days of 0.3 ppm SO_2 in Air

spruce trees than equally high NO_2 concentrations in air [81]. Over a long period, fumigation with environmentally reasonable concentrations of SO_2 could, at least, affect leachate chemistry, and this might affect the decomposition rate of leaf litters of Scots pine (*Pinus sylvestris* L.) which was more affected than those of mixed angiosperms [82].

As with other pollutants, the response of plants to the gas varied among different plant species and within a given species with the age of the plant. When malonaldehyde and soluble protein were taken as parameters of cellular injuries, damages were more pronounced in *Dalbergia sissoo* than in *Cassia siamea*. The relatively smaller effects in *C. siamea* could be correlated with a generally faster sulfite turnover rate and also with substantially enhanced peroxidase and superoxide dismutase activities. Accordingly, older leaves of two *Populus* cultivars (*P. nigra* L. cv. Loenen and *P. maximowiczii* Henri) exhibited a severalfold increase in sugar (raffinose) after exposure to SO_2 [83]. In contrast, younger leaves were not affected [84]. With respect to the seasonal shift of the raffinose pool in poplar leaves, the alterations may be related to an acceleration of senescence. Unfavorable climatic factors were described as an additional stressor influencing the productivity of rice (*Oryza sativa* L. cv. GR 3) growing in the immediate vicinity of a fertilizer plant emitting SO_2, NH_3, and NO_2 [85]. It has been emphasized that sulfur deposition during the winter might have an impact on the total sulfur content in the needles of Scots pine (*Pinus sylvestris* L.) [86]. Investigations with *P. sylvestris* also revealed an inhibition of the photochemical efficiency of photosystem II (PSII) following fumigation with SO_2 and NO_2 in samples collected in December 1989 and January 1990 [87]. Moreover, low concentrations may have significant long-term effects and can possibly be triggered by unfavorable environmental conditions (particularly in fall and winter), and also here the relative or the absolute altitude of the fields is effective [88].

Up to a certain degree, there might be some protection against these deleterious effects by components of the antioxidant (photo) scavenging cycle. Relative resistance to sulfur dioxide and cross resistance to other oxidative stresses which originate in the chloroplast have been correlated in many cases with elevated levels of various antioxidant proteins and/or substrates. Recent studies utilizing differentially sensitive cultivars, antioxidant enzyme analyses, and genetically engineered plants have provided new insights into the mechanisms of resistance to sulfur dioxide and other stresses. It is suggested that complex regulatory mechanisms function at both the gene and the protein levels and coordinate antioxidant responses, and that a critical role is played by organelle localization and intercompartmental coordination [72]. When soybean (*Glycine max*) seedlings were exposed to a certain dosage of SO_2, an apparently freshly synthesized 15-kDa protein appeared in the leaves, increased during fumigation, and gradually declined again when the fumigation had ceased. The appearance of this polypeptide was accompanied by an increase of the resistance to SO_2 [69]. The effects of O_3, SO_2, and UVB on the ''antioxidant genes'' are very similar, although the response to SO_2 is generally less pronounced and delayed in relation to the other [89]. In wheat (*Triticum aestivum* L.), superoxide dismutase activity decreased with the increase of SO_2 fumigation dosage (but still higher than the controls) and produced a new isoenzyme pedigree [90]. However, peroxidase activity increased with SO_2 fumigation and showed an effect of relative gain with phosphate buffer; the isoenzyme pedigree increased markedly. The change of the protective enzyme system of scavenging free radicals was possibly because phosphate buffer eased the SO_2 insult of wheat seedlings. The level of two bands of superoxide dismutase isozymes (which did not appear in the controls) increased in the soybean (*Glycine max*) seedlings fumigated with SO_2 followed by increases in superoxide dismutase (SOD), an intense increase in the antioxidative ability which implied a higher resistance of the plant to SO_2 [80]. The availability and the effectiveness of defense systems, the size of internal storage pools, and the actual growth rate of the plant largely influences the significance of SO_2, NO_2, and O_3 in affecting root-shoot interactions [65]. Remarkably, SODs and cytosolic ascorbic peroxidase (cyt APx) were not affected. It is, therefore, proposed that alterations in mRNA levels of catalases and glutathione peroxidase, but not of SODs and cyt APx, form part of the initial antioxidant response to O_3, SO_2, and ultraviolet B (UVB) in *Nicotiana tabacum* L. cv PBD6.

Besides the above-mentioned cellular mechanisms, the nutritional status and some protectants

may be effective to overcome or detoxify the sulfur dioxide stress. In the case of underoptimal nutrient status, the total plant length of wheat (Malviya 206 and Malviya 234) was reduced significantly in SO_2-treated plants, whereas plants grown at twice the recommended fertilizer concentrations were not affected. Thus, the general mineral nutrient status of the soil has been found to modify the response of wheat plants [77]. In agreement, the positive effect of NH_3 (on the concentrations of N and Chl *a*) in Scots pine (*Pinus sylvestris*) counteracted the negative effects of SO_2 [78]. The nutrient balance was affected (NH_3 ''increased'' the concentration of N and SO_2 ''decreased'' the concentrations of P and K), whereas a mixture of both might cause serious nutrient imbalances provided the increased demands for nutrients in shoots cannot be adjusted and equilibrated by components of the soil. This led to the assumption that there might be a positive feedback between (moderate) acidification of soils and SO_2 and NH_3 inputs to terrestrial ecosystems [70]; foliar calcium seemed to be only a short-time buffer even under conditions of optimal calcium supply.

Positive effects were described following the application of kinetin and ascorbic acid to mitigate foliar injuries in *Oryza sativa* [85]. The accumulation of fresh and dry matter of the culms was not affected by air pollution on kinetin and ascorbic acid spray application, but instead plants produced an increased number of panicles. Uniconazole ((E)-(p-chlorophenyl)-4, 4-dimethyl-2-(1,2,4-triazol-1-yl)-penten-3-ol) provided similar protection against SO_2-induced injury [91]. However, high concentrations of uniconazole reduced leaf size and total chlorophyll concentration, decreased malondialdehyde accumulation, increased SOD activity, and delayed flowering slightly but had little or no effect on variable chlorophyll fluorescence nor on the number or dry weight of pods. Absolutely no correlation was found between stomatal resistance and uniconazole treatment.

Ozone

Ozone (O_3), as an important component of the atmosphere, has to be regarded under completely different aspects. First, it efficiently reduces the (short wavelength) UVB radiation which is (depending on the doses) deleterious for humans, animals, and plants. Consequently, the so-called ozone layer is an absolute requirement for higher life forms on earth, and the worldwide application of ozone-depleting substances (such as chlorofluorocarbons and other pollutants) is more than problematic. (This and other questions have been discussed at the recent World Climate Conference in Kyoto, and this turned out to be differently regarded depending on the different political and economical interests.) Apart from the primary effect for UV radiation, oxygen free radicals, peroxides, or superoxides will increase simultaneously as a result of higher UV radiation. Second, in the stratosphere, this gas is involved in many chemical and photochemical reactions (e.g., the conversion of SO_2 and NO_x). As a component of the troposphere, ozone belongs to the so-called greenhouse gases and absorbs those portions of the long-wavelength radiation which are (otherwise) reflected from the earth's surface, thereby trapping the energy and contributing to a global warming. However, increasingly high concentrations of ozone near the soil are themselves problematic for plants. (For information on the negative effects of ozone on animals and human beings, the reader is referred to medical publications; for example, the excellent review by Lippmann [92].) High ozone concentrations in the lower parts of the troposphere (i.e., in the vicinity of plants) are observed as the result of both photochemical reactions near the soil and vertical wind fluxes. Physicochemically, ozone is a molecule composed of three oxygen atoms; it is a colorless gas with a rather specifically pungent smell and with low water solubility. The overall toxicity of ozone can be explained by the fact that it is highly reactive and is one of the strongest known oxidants. At present, there is a strong debate about the qualitative and quantitative participation of anthropogenic activities in the production of high ozone concentrations during the summer months in particular. Industrial productions and automobile emissions appear to be among the principal sources of ozone. Moreover, intentional incendiarisms contribute without any doubt to the phenomenon and sometimes lead to a composition of the air over African and Asian regions which can hardly be distinguished from smog conditions in Los Angeles as far as the ozone concentration is concerned. Not too much is known about the detailed mode(s) of action of ozone in plants. It penetrates preponderently through the stomata and

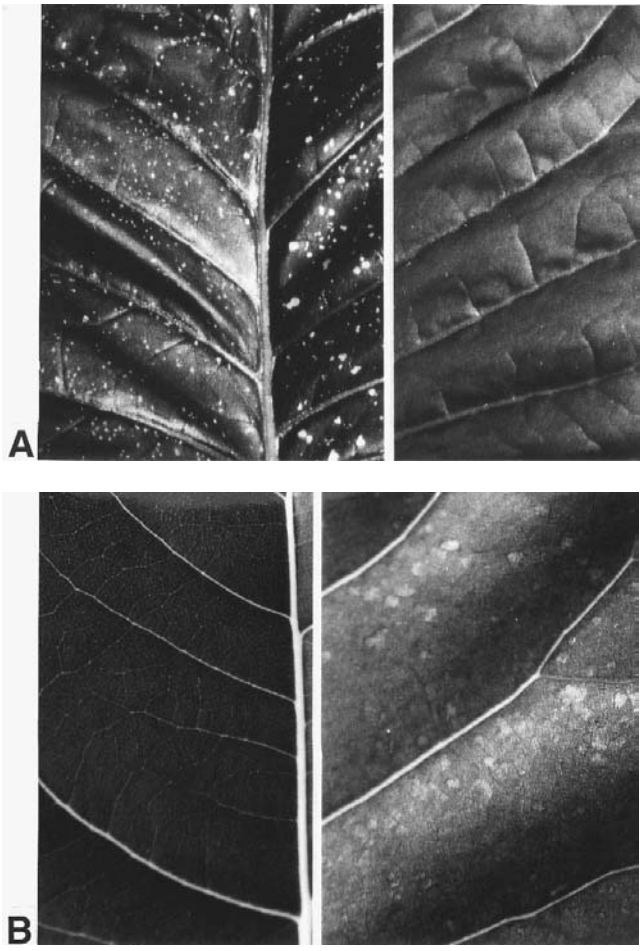

FIGURE 6 (A) Left tobacco leaf with early O_3 symptoms in a shaded place; right leaf exposed in the field in a sunny place. (B) Left poplar leaf grown under filtered air (control); right leaf with necrotic spots under the daytime O_3 treatment. (From Ref. 93.)

appears to affect the selective permeability of membrane structures; as already mentioned, the major deleterious and even destructive effect of ozone on plants and on plant metabolism can be traced back to the strong oxidative capacities of the molecule. In recent years, serious efforts have been made to elucidate the details of the consequences of elevated ozone partial pressures on plants in general and on crop plants, including plant defense mechanisms, in particular. Among the many investigations on the complex reactions of plants to increasing concentrations of ozone, the concerted chamber experiments of Günthardt-Goerg [93] describe results with tobacco (*Nicotiana tabacum* L. var. BelW3), poplar (*populus* X *euramericana* var. Dorskamp), birch (*Betula pendula* Roth), and alder (*Aldus glutinosa* (L.) Gaertn.). Figure 6 illustrates the obvious characteristics of ozone-dependent injuries on the above-mentioned plants. Tobacco exhibits characteristic white chlorotic spots in the shade (Fig. 6a); in the case of poplar leaves, small necrotic areas were detected following ozone treatment (Fig. 6b). In any case, damages were different depending not only on the concentration but also on the uptake into the plants via the stomata. This in turn is related to external factors like relative humidity of the air, light intensity, temperature, humidity of the soil and, again, the

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

concentration of ozone itself. Internal factors are the age and the morphology of the leaves [93]. (Many herbaceous plants close their stomata during the night, whereas trees only diminish the diameter of the stomatal pores by narrowing in many cases.)

Pitcher and Zilinskas described the origin of ozone damage by the action of oxygen free radicals and ozone degradation products, and plants are supposed to develop and to apply cellular antioxidant systems as defense [94]. As with other pollutants, ozone-related damage of any type as well as the defense-related responses are strongly dependent on the plant species, age, and even on the time of in vitro treatment (day/night). Although present ambient concentrations of ozone decrease the yield of several important crops, plants substantially differ in sensitivity to ozone; for example, wheat (*Triticum aestivum* L.) is more sensitive than barley (*Hordeum vulgare* L.) [95]. Owing to its sensitivity, tobacco is even the so-called indicator plant for elevated ozone partial pressures. Fumigation of spring wheat (*Triticum aestivum* L. cv. Drabant) with elevated concentrations of ozone caused chlorosis of the flag leaves, a decrease in the amount of cytoplasm, and an increase in the vacuolization of the cells. In later phases, the chloroplasts became affected by decreasing in area and containing more plastoglobuli. The plasma membranes lost their intimate contact to the cell wall and convoluted. Mitochondria remained largely unaffected until the late phases of cell destruction. However, in most cases, the described changes were quantitatively, but not qualitatively, specific for ozone; they also occurred with charcoal-filtered air, although later in time. This indicates that ozone preferentially causes premature senescence in the investigated flag leaves [96]. A similar acceleration of (the visible symptoms of) senescence and a decrease in the activity and quantity of Rubisco has been described in various cases [97].

Ozone uptake through the stomata has been investigated and described by Luwe et al. [98], who found that fumigation with 0.3 $\mu l \cdot L^{-1}$ of ozone resulted in ozone uptake by the leaves close to 0.9 $pmol \cdot cm^{-2}$ of leaf surface area s^{-1}. As plants take up ozone (and other gases) preponderently through the stomata, the amount of ozone uptake is substantially dependent on and effectively controlled by factors influencing the stomatal aperture like illumination, humidity, and water status (see above). Water vapor pressure deficit was the climatic factor most closely correlated with ambient O_3 concentration [99]. Thus, when O_3 concentrations were highest, O_3 uptake tended to be restricted by stomatal narrowing. Consequently, the deleterious effect of ozone also can be correlated with the elevation of the cultivation area (cf. section on Sulfur Dioxide above), as high tillages are often less protected from soil water stress, so that stomata are in relation and per time unit longer and wider open, as might be the case at low-elevation locations.

It is obvious that the more the stratospheric ozone layer is injured, the more the biosphere will be exposed to higher doses of UVB (290–320 nm) radiation [100]. Damaging effects of such increased UVB radiation received by plants have been described and, at the same time, improved our understanding of the phenomenon of UVB tolerance [100,101]. Even in terms of the indirect effects on rice blast disease, enhanced UVB affected both the fungus itself (*Pyricularia grisea*) and the susceptibility of the rice plant to the fungus [102]. On the other hand, care must be taken in those cases when no direct or macroscopic visible symptoms could be observed when studying the effect of O_3 or UVB, because several plant species exhibited no visible symptoms, although the subcellular structure(s) had been severely affected and altered up to the level of chromosomal aberration [103]. Also, differences in the responses of plants to O_3 and UVB by invoking different antioxidant enzymes were reported [104]. UVB exposure preferentially induces peroxidase-related enzymes, whereas O_3 exposure invokes the enzymes of the superoxide dismutase/ascorbate-glutathione cycle, and in contrast to O_3, UVB exposure generated activated oxygen species by increasing NADPH-oxidase activity.

An important aspect when dealing with the effects of pollutants on plants is that very often laboratory investigations and conditions can by no means be transferred to real in vivo conditions. In this sense, one of the principal improvements of scientific investigations was the construction and application of the so-called open-top chambers. Barnse et al. [105] recorded different responses to ozone treatments between laboratory- and field-grown plants. Under laboratory conditions, seedlings of cucumber (*Cucumis sativus* L.) and tomato (*Lycopersicon esculentum* Mill.) exhibited appre-

ciable (approximately 50%) and rapid inhibition in hypocotyl elongation in response to UVB exposure [105]. For cucumber, it has been described that the UVB-induced inhibition was reversible, was not linked to concomitant changes in dry matter production, and was caused by UVB incident on the cotyledons and not the stem or growing tip. For mixed cultures of wheat (*Triticum aestivum* L.) and wild oat (*Avena fatua* L.), a common weedy competitor, supplemental UVB irradiation in the field differentially altered shoot morphology which resulted in changes in canopy structure, light interception, and calculated stand photosynthesis. It is argued that because of its asymmetrical nature, competition for light can potentially amplify the effects of UVB on the shoot morphology and may, therefore, be an important mechanism by which changes in the solar UVB spectrum associated with stratospheric ozone reduction could alter the composition and character of terrestrial vegetation. Similar expectations concerning modifications of whole ecosystems (plants and plant families) in the future are made with respect to the gradual increase in the carbon dioxide partial pressure of the atmosphere.

Nikolopoulos et al. [106] observed the first effect of UVB radiation on *Phlomis fruticosa* L.; namely, a growth response at late spring. The effect consisted of an inhibition of new leaf development and of a premature falling of (old) leaves leading to smaller leaf numbers and total leaf areas for the rest of the experimental period [106]. However, a single exposure of flowering racemes of *Brassica campestris* L. to 100 nL/L ozone for 6 h had no significant effect on the numbers of reproductive sites produced or aborted [107]. This result was in clear contrast to a related species, *B. napus* L., in which a single exposure to 100 nL/L ozone induced a significant loss of reproductive sites. However, multiple exposures of *B. campestris* to ozone had significant effects on seed abortion and on the number of mature seeds per pod at final harvest. However, the extent of the effect depended strongly on the developmental stage of the reproductive organ at the time of exposure. On the other hand, it was observed that various effects like seed number per plant, mean seed weight, and total seed weight per plant at maturity were not significantly altered, which implies a high degree of compensation during reproductive development.

In the southeastern United States, it was found that current ambient ozone concentrations might influence the carbon-fixation rates and also the growth of various forest tree species [108]. The loblolly pine trees exhibited a significant decrease in the photosynthetic rates of needles, with this effect being proportional to the cumulative ozone exposure (decrease of 50% after 350 ppm $\cdot$ h^{-1}; 12 h summation). The decrease went along with a substantial decline in Rubisco activity. Thus, current ambient ozone concentrations might lead progressively to a biochemical disequilibrium within leaf cells with a reduced production of assimilates and transient increased respiration. In many cases, there is clear evidence that present ambient concentrations of ozone decrease the yield of several important crops (e.g., see Ref. 95). *Arabidopsis thaliana* plants treated with either 150 or 300 parts per billion (ppb) ozone daily for 6 h revealed both reduced growth and extensive leaf curling [109]. Fresh and dry weights of ozone-treated plants were reduced by 30–50% compared with air controls. Nevertheless, the role of ozone in forest decline is still unclear, although several investigations on young conifers have shown that ozone can reduce net photosynthesis, disturb carbon allocation, and reduce growth. Furthermore, little information exists on the effects of ozone on adult trees.

In order to protect photosynthetic tissue from UVB radiation, plants synthesize different types and quantities of UVB-absorbing compounds (e.g., flavonoids). Apparently, plants with an elevated content of total flavonoids were significantly more UVB tolerant with respect to growth rate, pigments, and gas exchange reaction rates [101]. In accordance, Ziska and Teramura [110] analyzed the degree of sensitivity of photochemical reactions at different UVB radiation conditions and found that leaves from different rice cultivars produced completely different amounts of UVB-absorbing compounds. Fujiyama-5 had a significantly higher concentration of these compounds than IR-36 in any of the investigated environments, and the production rate in Fujiyama-5 was stimulated by UVB influence. Greenberg et al. [100] reported the biosynthesis of flavonoids and other UV-absorbing pigments also in *Brassica napus* exposed to such levels of UVB radiation causing cotelydon curling [100]. Approximately 20 distinct UV-absorbing pigments were produced in response to UVB radia-

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

tion. Although synthesis of flavonoids is induced by UVB radiation, its protective role on photosynthetic pigments is still under debate in other cases [101]. Also, the formation of the stilbenes pinosylvin and pinosylvin 3-methyl ether, as well as the activity of the biosynthetic enzyme stilbene synthase, were reported to be induced several hundred- to thousandfold in primary needles of 6-week-old pine (*Pinus sylvestris* L.) seedlings on exposure to a single pulse of ozone of at least 0.15 μL/L [111].

The chlorophyll fluorescence kinetics of broad bean (*Vicia faba*) plants showed significant alterations following the treatment reflecting a perturbation in the photochemical functioning of the thylakoids and specific disturbances of the water-splitting enzyme system of the PSII of two broad bean cultivars; recovery took about 1 week [112]. Absorption, trapping, or electron transport increased considerably under the conditions of elevated O_3 or CO_2. This increased activity seems to be due to an increased antenna size in O_3-treated samples. Similar conclusions have been made in connection with our analyses on the effects of higher carbon dioxide partial pressures on *Nicotiana tabacum* and *Aleurites montana* where we described an increase in the light-harvesting complex and the extrinsic polypeptide of 33-kDa molecular mass [31,32]. An inhibition in the photosynthetic activity was associated primarily with a stomatal limitation rather than a real PSII damage [101]. Although a decrease in Rubisco was obvious, Dizengremel, et al. [108] observed the largest increase in the activity of glucose-6-phosphate dehydrogenase. However, this substantial increase and the slighter increases in phosphofructokinase and fumarase activities (about 25%) showed a tendency to a further decline when the loblolly pine spaldings were exposed to higher cumulative ozone doses. Rennenberg, et al. [65] concluded that ozone interacts with carbon allocation most likely by inhibiting sucrose export which causes an accumulation of carbohydrates and starch in leaves and results in a reduction of photosynthesis. Thus, O_3 exposure can diminish the availability of photosynthetate for growth and development and result in an increased shoot/root ratio and an overall reduction in the biomass. In agreement with this conclusion, Grantz and Yang found [113] that Pima cotton (*Gossypium barbadense* L. cv S-6) exhibited foliar injuries and yield reduction at ambient concentrations of O_3. Eight weeks after planting, stem basal diameter, leaf area, and total plant dry weight decreased by 61, 83, and 88%, whereas the root/shoot dry weight ratio declined from 0.16 to 0.09 g/g. Results from these investigators support the hypotheses that O_3 reduces the allocation of the biomass to the root system, and that the disrupted carbohydrate allocation impairs the root hydraulic capacity relative to the transpiring leaf area even though the leaf area development is itself reduced by O_3. Sensitive birch clones which had been exposed to a single 8-h ozone pulse of 150 ppb suffered from partial tissue chlorosis and necrosis, whereas insensitive clones were unaffected [114].

Guidi et al. [112] observed that in this case, subsymptomatic exposure to 150 ppb of ozone for a single 3-h period led to a rapid and significant reduction in photosynthetic activity coupled with a reduction in stomatal conductance and transpiration in two cultivars of broad bean (*Vicia faba* cvs. *Reina blanca* and Gigante d'Ingegnoli). The two cultivars behaved quite differently in the postfumigation stages. *R. blanca* recovered quickly; its photosynthetic rate returned to prefumigation values within 48 hours [112]. In Gigante d'Ingegnoli, the recovery process took much longer; 72 h after ozonization, the net photosynthesis was only 59% that of the unfumigated controls. The contributions of stomatal conductance and photochemical quantum conversion to the observed reductions in photosynthesis rates also differed between the two cultivars.

The mean of the red/far-red fluorescence ratio from spectra collected 24 h after exposure to ozone was significantly different from the prefumigation R/FR ratio mean ($P = .10$) in white pine (*Pinus strobus* L.). However, a potential recovery of photosynthetic processes from the effects of ozone exposure was also observed [115]. Wallin, et al. [116] studied the effect of ozone at different plant ages of one clone of Norway spruce, *Picea abies* (L.) Karst, and found that in 1- and 2-year-old shoots, the apparent quantum yield decreased with increasing shoot age and ozone concentration, whereas no effect was found in the current-year shoots. The decrease could probably partly be attributed to a lower efficiency of light capture due to a lower content of chlorophyll. In another work, these investigators [116] found no significant effects on photosynthesis or on leaf conductance to CO_2 in current-year shoots. In 1- to 3-year-old shoots, leaf conductance to CO_2 and rates of net

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

photosynthesis at both 330 μM/M CO_2 and saturating concentrations of CO_2, decreased with increasing shoot age and ozone concentration [117]. The carboxylation efficiency significantly decreased in 2- and 3-year-old shoots from the nonfiltered air and nonfiltered air plus ozone treatments compared with shoots from the charcoal-filtered air treatment. The gas phase limitation of photosynthesis decreased with the increasing shoot age and ozone concentration. In the experiments performed by Carlsson, et al. [118], spinach was not at all sensitive, whereas both pea and wheat leaves of different ages reacted specifically to ozone. In pea, the sensitivity to ozone increased substantially with the age of the leaves. A decrease in the relation of chloroplast membrane lipids to nonchloroplast membrane lipids was observed for both pea and wheat, whereas again spinach was unaffected [118]. Similar to what had been described in the section on sulfur dioxide above, older leaves were shown to be more sensitive to the pollutant, whereas younger leaves were generally less sensitive.

Genetics

Although there were no visible symptoms on spruce trees directly after the fumigation had ceased, the treated plants showed a significantly increased number of chromosomal aberrations in comparison with the control plants [103]. Five further investigations of both variants of this experiment up to 2 years after the ozone fumigation had ended showed a long-term hangover in the genetic material of spruce trees. The observed chromosomal aberrations in all variants of the experiment consisted of chromosomal stickiness, chromosomal breakage, and fragmentation. The most important type of observed chromosomal abnormalities was a chromosomal stickiness leading to cell death. It has been suggested that an intensive site effect is significant rather than the soil or the provenance of the individual. This cytogenetic plant test system also was used to investigate 5-year-old spruce trees exposed in environmental chambers to elevated concentrations of carbon dioxide (750 cm^3/m^3) and ozone (0.08 cm^3/m^3). The pollutants were applied singly or in combination; thereafter the plants were transferred to the field for observation of a ''memory effect.'' The fumigated variants showed an increased number of chromosomal aberrations compared with the controls, which carried on as a memory effect in the root meristems far beyond the fumigation period.

When plants were exposed to 0.08 μL/L for 5 h per day, a decrease in the steady-state levels of rbcS mRNA was observed in expanding leaves after 3 days of ozone exposure; the ethylene levels had increased 6- to 10-fold [119]. The expression of OIP-1, a 1-aminocyclopropane-1-carboxylate synthase cDNA from potato, correlated with the increased production of ethylene and the decreased levels of rbcS mRNA. In plants exposed to 0.30 μL/L ozone for 4 h, rbcS transcript levels were reduced to 0.25%. At least in part, the loss of rbcS mRNA might be due to posttranscriptional regulation. The levels of transcripts for other chloroplast proteins, glyceraldehyde-3-phosphate dehydrogenase, and a PSII chlorophyll *a*/*b*–binding protein decreased in O_3-treated plants in parallel with the decrease in rbcS mRNA. The steady-state mRNA level of a cytosolic glyceraldehyde-3-phosphate dehydrogenase increased in O_3-treated plants. The induction of ethylene and changes in transcript levels was followed by visible leaf injuries and decreases in Rubisco protein levels. Apparently, an increase in the chloroplastic Cu/Zn superoxide dismutase is not sufficient to reduce ozone toxicity, as no consistent protection was provided to transgenic tobacco plants (*Nicotiana tabacum* cultivar W38) plants that overproduce petunia chloroplastic Cu/Zn superoxide dismutase under the conditions of exposure to ozone concentrations which harm control plants [120].

Nitrogen Oxides

Nitrogen oxides are unavoidable compounds playing a substantial role both in the projected global warming of the atmosphere and in the depletion of the protective ozone layer. Moreover, NO_2 emission from cultivated areas (soils and plants) leads to nitrogen loss from ecological system of agriculture [121]. Motor vehicles and fossil fuel–fired power stations are important sources of NOx emission. The nitrogen which is contained in wood fuels is mainly converted to molecular atmo-

spheric nitrogen, although under the conditions of high temperatures where the combustion is most efficient, there also is some conversion to nitrogen oxides [122]. On addition of vanadium pentoxide, however, the formation of nitrogen oxides can be decreased during the burning of oil, primarily because of the reduction of the attainable gas temperature [123]. For the practical use of heating greenhouses, low-NO_x propane burners seem to be an effective alternative to liquid CO_2 [124], although it cannot be excluded that, in this case, some nitrogen oxides might also be contained in the oxidation products.

In soils, however, processes which produce and consume both NO and N_2O are principally microbiological in nature and are linked directly and indirectly with the chemical and physical factors that control gaseous transport through the soil medium; such as temperature, water-content soil composition, nutrient availability, vegetation, disturbances (e.g., burning, agricultural practices), and others [125]. About 2–6% of the total annual NO_x emission and 16–64% of the total annual N_2O emission in Great Britain are supposed to stem from agriculture [8]. In this domain, nitrogen fertilizers are without any doubt among the most important sources of anthropogenic N_2O emissions [2]; about 5% of the applied N was lost as N_2O from NH_4NO_3 which had been applied in the spring. This value is significantly higher than the amount lost as N_2O in case of urea fertilizing or NH_4NO_3 which had been applied in fall. On the average, 12.4% of the N input were released as N_2O and N_2 during the vegetative growth and the stem fruit stage of cucumbers. This process corresponds to a mean emission rate of 0.62 kg nitrogen per hectare greenhouse area and day. Additional factors like the growth of green algae on the substrate surface further stimulating the production of N_2O have to be taken into account [126]. For other plants and depending on the cultivated crop, approximately 0.5–3.0% of the added inorganic N fertilizers were calculated to be lost as N_2O [127]. Nitrate addition increased the total N_2O emission rate substantially, but the percentage emitted through rice plants was lowered [128]. Without any tillage, emission of N_2O was generally higher as with conventional tillage, and in the same experiments, more N_2O was emitted from corn fields than from soybean or alfalfa cultivations. However, in a corn system using conventional tillage, legumes in rotation, and moderate fertilizer, N would reduce N_2O emission [129]. The N_2O and N_2 emissions showed clear diurnal variations [130], whereas frost in early winter did not lead to higher amounts of nitrogen loss as N_2O [131].

Precipitation in spring and fall is generally conducive for higher N_2O emissions from wheat fields, whereas in winter, this appears not to be the case; in the case of rice fields, no correlation was observed [132]. It must be emphasized that substantial amounts of (trapped) N_2O were detected within the soil down to a depth of 90 cm, and this observation shows that agricultural production systems might contain a considerable pool of N_2O and this N_2O will subsequently be reduced to N_2 [133]. It has been demonstrated that the presence of manure on and in cultivated fields modifies microbial activity in the soils, and this effect is based on the incorporation of additional quantities of C and N; as a whole, various physical and chemical properties of the soil are modified [134]. In the case of animal manure composts, 0.2–3.3% parts of nitrogen contained in it were lost as nitrous oxide [135], and under these conditions of nitrogen supply, highest annual emissions were recorded [136]. Therefore, in order to make an effective use of animal manure, the respective application time must be correlated with the time of rice planting. In the subsequent fallow periods following the harvest of rice, the soils contribute to significant N_2O emission which is maximal during the drainage period and decreases to about zero at the time of reflooding [4,137].

Denitrification represents an essential factor within the global nitrogen cycle (cf. Ref. 138, for example). Losses of nitrogen by denitrification and N_2O emission from irrigated corn amounts to about 1–5% of the N applied as fertilizer or in irrigation water. Depending on the soil level (upper parts), a significant correlation was found between denitrification activity on the one hand and the level of ground water, water-filled pore space, and nitrate content on the other hand [139]. It also was dependent on the variety of rice [140]. With lucerne, the denitrification rate was nearly four times higher than with rye grass (*Lolium perenne* L.) or from fallow soil [141]. The availability of organic carbon compounds which are easily decomposed was an important limiting factor for the denitrification activity in the subsoil of peat soils [139]. It was observed that when the carbon

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

to nitrate ratio was lower, the amount of the released N_2O increased [133]. Enzymatic activity by the nitrous oxide reductase was another important factor regulating N_2O emission in the case of paddy soils. This enzyme contains the Cu-A center as a structurally novel metal site similar to cytochrome *c* oxidase. Therefore, it has been suggested that both N_2O reductase and NO reductase may be types of ancestors of members of the heme–copper oxidase enzyme family [138]. However, not all the nitrogen oxides released come from real denitrification processes. Additional amounts originate from nitrate reductases produced by plants, algae, fungi, cyanobacteria, or eubacteria acting anomalously on nitrite to liberate small amounts of NO and N_2O, which may further contribute to global atmospheric stocks of nitrogen oxides. Such enzymes are used by nitrifying bacteria, thereby reducing nitrite when oxygen is limiting [142]. Detailed analyses have shown that nitrous oxide was the major gas emitted from less aerated soils (conditions that allowed denitrification to occur), whereas nitric oxide played this role in the case of well-aerated soils (conditions that favor nitrification) [143]. Recent discussions deal with the contribution of nitrogen inputs caused by air pollution to the overall danger for forest ecosystems [144], but as with the general discussion on forest decline, many details of the complex mechanisms and implications remain to be elucidated and early conclusions should be avoided.

Pollution of the atmosphere by oxides of nitrogen can lead to various responses in plants among which are modifications of the amount of nitrate and/or nitrite in plant tissues, the stimulation or the inhibition of enzyme activities, changes in the reaction rates of photosynthesis and CO_2 fixation, and even the general growth of the plants may be affected [145]. Similar effects have been described for conditions of an increased fumigation frequency or enhanced concentrations of nitrogen oxide at a given single application in the case of four *Eucalyptus* species [146]. Saarinen reported that oxides of nitrogen (NO_x) and traffic emissions are possible factors affecting the light reactions of photosynthesis and the pigment content of pine needles in an urban environment [147]. When two spring wheat cultivars (*Triticum aestivum* L. cvs. Minaret and Eridano) were exposed to ozone with and without small amounts of nitrogen oxides, the Minaret plants reacted with less influenced leaf dry weight and inhibition of growth when O_3 contained the by-products N_2O_5 and N_2O, which could be explained by more nitrogen content per plant [148]. In some investigations, nitric oxide (NO) appears to have even a positive effect in the sense that plants better overcome other stress phenomena [149]. This situation of ''stress coping'' can be interpreted by the observation of a substantial deceleration of stress ethylene production. NO_2 fumigation caused no macroscopic damages to the cuttings of a poplar clone (*Populus times euramericana* Dorskamp). Fumigation enlarged the foliar area, elevated the net CO_2 assimilation rate, and enlarged the width of xylem and bark tissue in the main stem. Fumigation also had a stimulating effect on the total biomass production during the exposure period. Exposure of Scots pine seedlings inoculated with the mycorrhizal fungus *Pisolithus arhizus* to low concentrations of NO had no effect on growth, total nitrogen concentration, ergosterol (as a measure of mycorrhizal infection) concentration, or total protein concentration but resulted in a significant uptake of NO and distinct modifications in amino acid composition [150]. Fumigated plants, however, showed elevated activity of nitrate reductase and higher leaf nitrogen concentrations relative to the control, indicating nitrogen assimilation from NO_2 [151]. Despite the fact that germination of bean seeds was not changed in the presence of the respiratory effector molecules N_2O, D_2O, or CO, it was observed that the respiration of seedlings and the length of roots were reduced corresponding to reductions in cytochrome oxidase activity [152]. Pollutants including NO_x induced deesterification of lipids as evidenced by the accumulation of myoinositol, serine, and raffinose, which are components of the hydrophilic head groups of membrane-associated phospholipids and galactolipids [153].

Nitrogen derived from NO was found in the shoots and roots, indicating the transport of such nitrogen from shoot to roots. Nitrate reductase activity can be used as a biomarker for the foliar uptake of nitrogen oxides during periods of air pollution [154], although the nitrate assimilation in leaves can include nitrate taken up from the soil in the case of red spruce (*Picea rubens* Sarg.). In many cases, NO_2-induced nitrate reductase activity was observed within 24 h after the start of fumigation [155]. In contrast, exposure to NO caused a rapid decline in activity within 24 h. Addition

of the nitrification inhibitor dicyandiamide reduced N_2O fluxes form ammonium sulfate, whereas increasing calcium ammonium nitrate (CAN) increased the emitted N_2 on grassland. Accordingly, there is room for reducing N_2O emission from grasslands by choosing the N fertilizer type depending on the soil moisture status. Avoiding excessive N application rates may also minimize N_2O emission from intensively managed grasslands [156]. Dicyandiamide- and polyolefin-coated urea showed the potential to be used to decrease N_2O emissions from N fertilizer [154].

PLANT-PROTECTIVE CHEMICALS AND PATHOGENESIS

Fungicides

In order to maintain and even further increase the yields of crops and other relevant agricultural and horticultural plants, enormous amounts of plant-protective chemicals of any type and specificity are applied every year. Actual calculations and projections proceed on the assumption that, on the average, 35% of the possible yields are lost because of fungal infection albeit the worldwide use of enormous amounts of fungicides.

In recent years, scientists in many laboratories have investigated the mode(s) of action of herbicides under completely different aspects. Besides the application of such chemicals to control weeds generally (and also other plants at undesired locations), some herbicides like dichlorphenyldimethylurea (DCMU; Diuron) have entered all photosynthesis laboratories worldwide as a standard inhibitor for PSII reactions. Consequently, herbicides and their specific properties have been thoroughly analyzed and described, and many excellent reviews are available with respect to their impact on the photosynthetic electron transport (e.g., see Ref. 157) or the so-called bleaching herbicides acting on the phytoene desaturase [158]. Much less attention has been paid to the question whether plant-protective chemicals other than herbicides are in fact as unproblematic for the treated plants as is generally thought (in most cases, without really regarding the problem). Apart from the trivial idea that a fungicide is intended to be toxic for a fungus and an insecticide for an insect, and so forth, only scattered reports have been published dealing with the question whether different chemicals of this kind interact with the treated plants in the sense that physiological and metabolic activities of the plants are affected or even inhibited. We show here for the first time that fungicides, for example, of the Triforin (Saprol) type, exert a strong inhibitory effect on electron transport reactions of higher plant chloroplasts (Fig. 7), whereas on the intact leaf, no macroscopically detectable symptoms are observed. Even under these conditions, recording of the fluorescence emission from the intact leaf shows that, in fact, the photosynthetic electron transport is impaired.

Figure 7 shows the effect of the fungicide on the fluorescence emission of tobacco leaves 1 day after the leaf had been sprayed several times with $2 \cdot 10^{-3}$ M of the fungicide Triforin. The maximal fluorescence is enhanced (what is normally observed, e.g., after the application of a urea-type herbicide and the ratio $F_{max}-F_0/F_{max}$ (significant for the efficiency of the electron transport) is shifted from the normal value of 0.8 for controls to lower values tending to zero. This hints at a substantial interruption of the electron transport chain (most probably in the region of the acceptor side of PSII).

The observation of an impaired photosynthetic electron transport in the region of PS II can be substantiated by the measurement of the flash-induced oxygen-evolution amplitudes in chloroplast preparations from peas in the frame of the coherent Kok model. Figure 8 depicts the typical oxygen-evolution pattern of higher plant chloroplasts (upper curve) and the inhibited yields in the presence of 25 μM of the fungicide (lower curve). Any further increase of the concentration of the fungicide abolished any oxygen-evolution activity of the pea chloroplasts.

Thus, fungicides immediately have significant herbicidal properties which are even more pronounced as soon as accessibility of the product to the inner parts of the plants is allowed. This also means that under such aspects the integrity of the outer plant surfaces like the cell walls and cutin layers are of enormous importance. (Cultivation manipulations of any kind like cutting twigs, branches, and roots should be minimized not least with respect to this point.) In most of the described

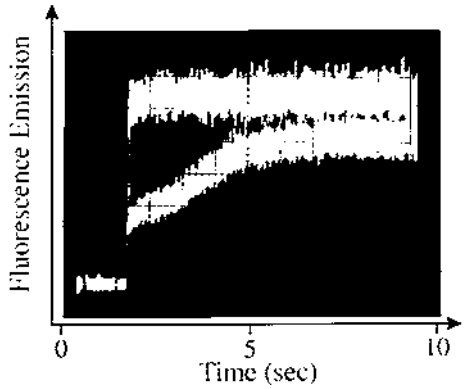

FIGURE 7 Effect of a Triforin-type fungicide on the fluorescence-induction curves in whole leaves from *Nicotiana tabacum*. The control leaf was dark adapted for 10 min before the fluorescence emission was recorded, whereas another leaf (identical in size) has been sprayed several times with a solution of the fungicide ($2\ 10^{-3}$ M). Note that the increase in the maximum fluorescence yield and the disappearance of the Kautsky kinetics are virtually identical to the effects observed with various herbicides.

cases, application of plant-protective chemicals other than herbicides did not in fact harm the plant provided only intact parts of the surface were sprayed. (In general, no inhibitory concentrations of the chemicals were attained via the physiological plant openings like stomata.)

Most interestingly, the type of effect on plants which is induced by some plant-protective chemicals can in fact be very similar or identical to the one observed in other cases; for example, pollutant stresses. It is known that paraquat (a standard herbicide)–induced injuries are attributed

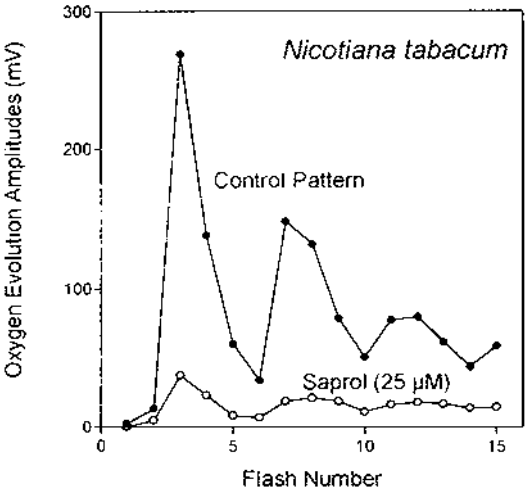

FIGURE 8 Effects of a Triforin-type fungicide on the oxygen-evolution capacity in chloroplasts from tobacco (*Nicotiana tabacum*). The photosynthetic oxygen evolution was detected as the consequence of short (5 μs) saturating light flashes spaced 300 ms apart. The fungicide was added to give a final concentration of 25 μM.

to the generation of free oxygen radicals. Recently, it was described in context with this herbicide that an in vitro translation product was formed at significantly increased levels during paraquat stress, and that this product was identical to the one that was observed in higher amounts during ozone stress [159].

Insecticides

Relatively little research has been done with respect to the effect of insecticides on the physiological and metabolic processes of cyanobacteria and higher plants. The analyses carried out by Bhunia et al. [160] described alterations in the gluthatione content and in the enzyme activity in a cyanobacterium (*Nostoc muscorum*) induced by Carbaryl, an often-used insecticide. This compound is a carbamate derivative which is used as contact and stomach poison and which has slight systemic properties. The chemical is often applied in fields of cotton, soft fruit, top fruit, vegetables, and various other crops. Higher plants have been analyzed with respect to lipids in maize chloroplasts under pesticide stress in the work by Mishra et al. [21]. Recently, we have investigated in a detailed study the effects of the synthetic pyrethroids cypermethrin, deltamethrin, fenvalerate, and permethrin on the photosynthetic electron transport reactions in cell cultures from tomato (*Lycopersicon peruvianum*) and in chloroplast suspensions from tobacco (*Nicotiana tabacum* var. John William's Broadleaf) [22]. These and similar insecticides might deserve specific scrutiny, under environmental aspects in particular, as they are derived from the naturally occurring pyrethrines which are physiological components of several *Chrysanthemum* species. Therefore, analyses of the modes of action of pyrethroids might be not only essential for basic plant physiological research but also could lead to new insights into structural specificities and necessities of modern and ecologically acceptable plant-protective chemicals.

Figure 9 shows that intact leaves from *Nicotiana tabacum* and cell cultures from *Lycopersicon peruvianum* suffer significant stress following the application of permethrin and cypermethrin. In this case, the leaves had been sprayed (wetted) with the chemical, whereas cell suspensions had been supplied with the pyrethroid in the respective concentration only 5 min before the measurements. The maximal fluorescence is substantially increased, and in the case of permethrin, the kinetics of the so-called Kautsky effect are virtually absent. The induction curves strongly resemble the ones which are observed in the presence of standard herbicides like, for example, Diuron. Thus, it might be concluded from the experiments that pyrethroid insecticides can interact with the photosynthetic electron transport chain between PSII and PSI. In this case, the primary acceptor of PSII (Q) is in the reduced state Q^-, which means that fluorescence is principally high, as the excitation energy cannot be dissipated versus PSI. When partial reactions of the photosynthetic electron transport chain were analyzed, it was shown that in fact the pyrethroid insecticide fenvalerat seems to interact directly with the herbicide-binding site Q_B of PSII.

When the photosynthetic electron transport running through both photosystems was analyzed by means of a water → methylviologen Mehler-type reaction, fenvalerat concentrations at about 40–60 μM inhibited the reaction almost completely. The same held true for a ferricyanide-mediated (i.e., a typical PSII reaction) Hill reaction. Both a silicomolybdate-driven Hill reaction and a dichlorphenolindophenol/ascorbate → methylviologen photosystem I reaction (which are normally herbicide insensitive) were not affected by increasing concentrations of fenvalerate (Fig. 10). *It can be concluded from the results that insecticides like the investigated pyrethroids do not only have substantial herbicidal activity, but they do interact with the photosynthetic electron transport chain at exactly the same site as herbicides of the urea type*. Furthermore, pyrethroids interact with the redox state system of the water-splitting system of photosynthesis. When the photosynthetic oxygen evolution is analyzed as the consequence of short saturating light flashes and when—based on the corresponding amplitudes—the dark distribution of the so-called S states is calculated, a strong effect of the pyrethroid deltamethrin was observed.

Figure 11 shows that increasing concentrations of deltamethrin modify the dark distribution of the S states in the sense that the overreduced state S_{-1} is preferentially formed at the expense

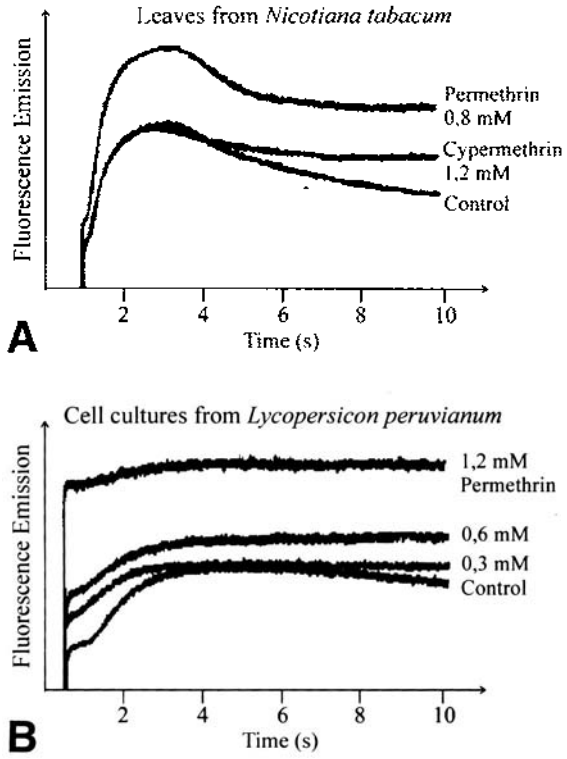

FIGURE 9 Effect of synthetic pyrethroid insecticides on the fluorescence induction curves from tobacco leaves (*Nicotiana tabacum*) (A) and cell cultures from *Lycopersicon peruvianum* (B). Plants were sprayed (completely wetted) with the pyrethroids in the respective concentration 1 day before the measurements. Leaves were cut from the plants and dark incubated 10 min before illumination (A). Cell suspensions were supplemented with the pyrethroid and dark adapted 5 min before the measurements (B). (From Ref. 22.)

of the ground state S_0. However, Figure 11 also shows that the described effects (and others) are highly specific for a given molecular structure. Apparently, the halogen side of the pyrethroid molecule plays a substantial role in this context, as fenvalerate, with its different structure in this region of the molecule, did not absolutely influence the redox conditions of the water oxidation complex (results not shown).

In conclusion, from these and similar results, we might say that more detailed analyses of pesticides (other than herbicides) are required with respect to their specific phytotoxicity and their interaction with the physiological and metabolic reactions of plants. The trivial statement that such compounds as insecticides and fungicides are well tolerated and are plant compatible does not allow us to conclude that plants are not drastically affected and inhibited by treatments with them. Moreover, it turned out that the deleterious effects on plants might well be influenced and up to a certain degree regulated by in some cases minor modifications of the molecular structures without affecting the specific toxicity toward the real target organisms. Thus, these and extended measurements together with the screening of appropriate chemicals and even the directed synthesis of compounds might help in the choice of effective but less phytotoxic and more ecologically acceptable plant-protective chemicals.

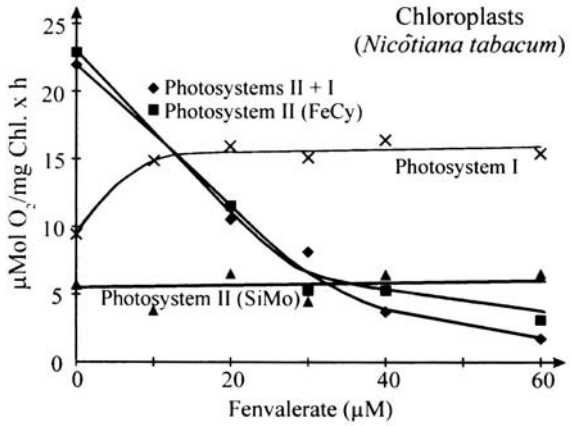

FIGURE 10 Effect of increasing concentrations of the insecticide fenvalerate on partial reactions of the photosynthetic electron transport in thylakoids from *Nicotiana tabacum*. $H_2O \rightarrow FeCy$; $H_2O \rightarrow MV$; PS I-DCPIP/asc $\rightarrow MV$; $H_2O \rightarrow SM$. For comparison, positive values of O_2 evolution and negative values of O_2 uptake are depicted in the same coordinate system. (From Ref. 22.)

Ecophysiological Adaptations and Genetic Variability in Mangroves

Prakash Lakshmanan, Mathai Mathews, and Kowk Ki Ho
The National University of Singapore
Singapore

INTRODUCTION

Mangroves are unique, taxonomically diverse plant communities inhabiting predominantly the estuarine and intertidal regions of tropical coasts. The exact total area of mangrove forests is not known, but it is estimated that mangroves cover nearly 15.2 million hectares worldwide (Table 1) [1,2]. Mangrove vegetation comprises approximately 70 species from 20 different angiosperm families [3]. The distribution of mangrove forests is limited to areas where the mean annual temperature of the coastal water is above 16°C. About 80% of all known mangrove plants are found in the Indo-Pacific region between South India, Oceania, and northern Australia, with 9% occurring in East Africa, 6% in West Africa, 5% in the Caribbean, and 5% in South Africa [2].

Mangrove vegetation in most cases is continuously exposed to harsh environmental conditions, being often dominated by salinity, flooding, high temperature, and high irradiance [4–9]. To withstand these environmental adversities, mangroves have evolved several ingenious solutions, which are well reflected in their distinct morphological, anatomical, and physiological adaptations [1,10]. In the past, much of the research on mangroves has been focused on the physiological ecology, species diversity, and systematics [1,10,11,12]. In this chapter, we discuss the physiological bases of various adaptative strategies, particularly those which are evolved to cope with high salinity and waterlogging, and emphasize the urgent need for more information on the genetic variability of mangroves for effective conservation of this overexploited ecosystem.

TABLE 1 Common Plants of Mangrove Forests

Family	Genus	No. of species	Geographical distribution
Acanthaceae	*Acanthus*	3	India to Western Pacific, Australia, Philippines
Apocyanaceae	*Cerbera*	3	Southeast Asia, New Guinea
	Rhabdadenia	3	Subtropical and tropical South America
Avicenniaceae	*Avicennia*	8	Southeast Asia, Australia, South and West Africa
Bombacaceae	*Camptostemon*	2	Borneo, Moluccas, Australia, New Guinea, Philippines
Combretaceae	*Laguncularia*	1	South America, West Africa
	Lumnitzera	2	East Africa, Western Pacific, Australia, Indochina
	Conocarpus	2	East and West Africa, Tropical America
Euphorbiaceae	*Excoecaria*	2	Tropical Africa and Asia, Western Pacific
Lecythidaceae	*Barringtonia*	2	West Africa, Polynesia
Leguminosae	*Dalbergia*	2	South America, Caribbean, West Africa
Meliaceae	*Xylocarpus*	3	Indo-Malaya, East Africa
Myrsinaceae	*Aegiceras*	2	India, Australia
	Myrsine	1	Malaysia
Palmae	*Nypa*	1	Indo-Pacific, West Africa
Pellicieraceae	*Pelliciera*	1	South America
Plumbaginaceae	*Aegialitis*	2	Australia, Indo-Pacific
Pteridaceae	*Acrostichum*	3	Caribbean, Indo-Pacific
Rhizophoraceae	*Bruguiera*	6	Indo-Pacific, East and West Africa
	Ceriops	2	Indo-Pacific
	Kandelia	1	India, South East Asia
	Rhizophora	8	Pantropical
Sonneratiaceae	*Sonneratia*	6	East Africa, Indo-Malaya, Australia
Sterculiaceae	*Hertiera*	2	Tropical Africa, Indo-Pacific
Tiliaceae	*Brownlowia*	2	Southeast Asia

SALINITY

Salinity Tolerance, Plant Growth, and Distribution of Mangrove Species

Salinity refers to the occurrence of various soluble salts in soil or water in concentrations that may interfere with plant growth. Although NaCl is sometimes the most predominant salt present, the term *salinity* includes chlorides, sulfates, and bicarbonates of sodium, calcium, magnesium, and potassium [13,14]. The concentrations of these salts can be expressed in a multitude of ways, but the preferred expression by physiologists and soil scientists is electrical conductivity, stated as decisiemens per meter (dS/m) or millimhos per centimeter (mmhos/cm). According to U.S. Salinity Laboratory recommendations, a soil with an electrical conductivity of 4 dS/m, or if all the dissolved salt is NaCl with an ionic concentration of 44 mM or more, can be considered as saline. Salinity in the mangrove environment is largely due to NaCl and varies considerably in time and space [10,15]. It is noted that the salinity level in a mangrove habitat fluctuates considerably depending on the season, and occasionally it may even become hypersaline, with salinities ranging from two

to three times that of seawater. Thus, the relative salt tolerance of different mangrove species will largely determine the structure of mangrove forests along salinity gradients.

Mangroves, like many other glycophytes (plants of nonsaline habitat) [16,17] and halophytes (plants of saline habitat) [18], exhibit a variety of growth responses to salinity. For instance, *Sonneratia lanceolata* grows maximally in salinities ranging from freshwater to 5% seawater, but the growth declines drastically in 50% seawater [19]. In contrast, *Ceriops decandra* and *Sonneratia alba* showed extremely poor growth and a time-dependent decline in vigor under freshwater conditions [19]. In the same study, propagules of *Bruguiera parviflora* and *Ceriops tagal* var. *australis* failed to grow in freshwater, but vigorous growth was attained with 5% seawater, indicating that these species could be considered as being obligate halophytes. Of the 16 mangrove species examined by Ball and Pidsley [19], most of them could grow in freshwater, but growth was stimulated considerably in the presence of 5–50% seawater depending on the species. Several previous studies showed that halophytes, in general, grow faster with higher than the standard levels of salt in the growth medium [18,20–22]. The physiological or biochemical basis of this growth stimulation is not clear. However, it is suggested that the excessive accumulation of water and inorganic ions in the cells occurring under saline condition results in increased turgor pressure which in turn causes growth enhancement [23]. Although some earlier studies [22,24] lend support to the concept of a turgor-controlled growth response, there is evidence that increasing salinity in the bathing medium enhances growth by directly influencing various metabolic processes in mangroves. For example, Critchley [25] reported a positive requirement for high chloride levels for photosynthetic electron transport in *Avicennia marina*. In the same species, the stimulation of oxygen uptake and respiration of roots with an increasing salt concentration accompanied a significant stimulation of plant growth [24]. It is, therefore, very probable that, in *Avicennia marina*, a highly salt-tolerant mangrove species, the enhancement of growth by increased salinity levels of the growth medium may not be solely due to turgor-controlled extension growth.

Sensitivity to salinity varies with the developmental stage of plants [26], and this is evident even in highly salt-tolerant mangroves [1]. Like other salt-marsh species [27,28], seeds of mangroves germinate at relatively low levels of salinity. Clarke and Hannon [29], in their studies of mangrove and other salt-marsh species of Sydney swamps, reported a decreased germination rate with increased salinity levels for most species. In fact, seeds of all species examined germinated in tap water. Interestingly, mangrove species showed a requirement for seawater for further growth of seedlings, and maximum seedling growth for all mangrove species was attained in nutrient solution containing 20% seawater. Unfortunately, there are not many studies related to germination of mangroves under saline conditions, and thus little is known about the mechanism(s) by which NaCl inhibits germination in mangroves. In *Avicennia marina*, as in many glycophytes [30,31], salinity affected seed germination by inhibiting cotyledonary reserve mobilization; thus, the viviparous development of the propagules seems to be an adaptation to circumvent the adverse effects of salinity on germination in this species [32]. Although germination was adversely affected by salinity, further growth and establishment of *Avicennia marina* seedlings were maximal in 50% seawater [20,29,32]; again suggesting the requirement for NaCl for optimal vegetative growth in mangroves.

There have been several studies on the various aspects of vegetative growth of mangroves in relation to salinity [10,22,29,33–35], but detailed analysis of relationships between interspecific differences in salt tolerance and species distribution is rather limited [4,36–38]. In a recent investigation, Ball and Pidsley [5] observed distinct interspecific differences in salt tolerance between two mangrove species, *Sonneratia alba* and *S. lanceolata. S. alba* grew in salinities ranging from freshwater to seawater, with growth being maximal in 5–50% seawater, whereas *S. lanceolata* grew in 0–50% seawater, with maximal growth occurring in 0–5% seawater. A change in the net assimilation rate accounted for most of the differences in growth between these two species with an increase in salinity. It appears that there is a tradeoff between the growth rate and the acquisition of salinity tolerance as the less salt-tolerant *S. lanceolata* achieved twice the height, leaf area, and biomass of the more salt-tolerant *S. alba* under low-salinity conditions. Thus, *S. lanceolata* becomes an effective competitor under low-saline conditions and successfully excludes *S. alba* from establishing in such

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

environments. From these results, Ball and Pidsley [5] concluded that the differential distribution of *S. alba* and *S. lanceolata* along tidal river systems may be a reflection of the difference in salt tolerance of these species as the riverine salinity regimens vary with distance upstream from the mouth of the river. A similar conclusion also was made by Smith [39] while comparing the growth and dispersal of the closely related species *Ceriops tagal* and *Ceriops australis* grown under a saline condition.

From the above discussion, it is interesting to note that a saline condition is a requirement for the optimal growth of mangrove species; salinity stimulated growth phenomenally in most of the species studied. Although the physiological basis of this attribute is not clearly understood, it may have some implications in developing salt tolerance and colonizing a saline habitat. The remarkable variation in salt tolerance within the mangrove species may, at least partly, account for their characteristic segregation in different mangrove environments.

Mechanisms of Salt Tolerance

Much of the physiological investigations on plant adaptations to salinity has concentrated on water relations, carbon acquisition and allocation, and metabolite production with the assumption that these processes would be the most severely affected ones under salt-stress conditions. Although physiological knowledge gained in the past helped characterize various patterns of responses, no clear understanding of salt-tolerance mechanisms, either in halophytes or glycophytes, has emerged from these studies. From the available evidence, the consensus is that all plants face qualitatively similar problems in a saline environment. Plants, including salt-tolerant mangroves, need to adapt osmotically and avoid ion toxicity, nutrient deficiency, and water stress to sustain growth under saline conditions [18,40–44]. To overcome such problems, mangroves have adopted several mechanisms, including salt exclusion, salt accumulation, and salt secretion [45–48]. Apparently, some of these mechanisms may interact with each other at the whole-plant level. For instance, salt exclusion is a common strategy to regulate the influx of salts into mangrove roots, but it appears to be less efficient in mangrove plants with salt-secretion glands [15,46,49]. Similarly, accumulation of ions for osmoregulation is a common strategy of mangrove plants, although they differ in the extent to which ions can be accumulated without any adverse effects on metabolism [50–52]. Irrespective of the strategies employed, the separation of the osmotic and metabolic roles of ions remain crucial for the survival of mangroves under saline conditions.

Osmoregulation and Ion Toxicity Avoidance

The ability to regulate the transport of ions and water in relation to growth is a distinguishing feature of mangrove species. Most of the glycophytes do not possess an efficient mechanism to adjust salt influx to maintain a favorable water balance [30,41], whereas halophytes accumulate large amounts of Na^+ and Cl^- to maintain osmotic adjustment and turgor to sustain growth [45]. But maintaining high intracellular ion concentrations without affecting growth can be achieved only if the plants possess high metabolic tolerance of the resulting ion build-up. If Na^+ is selectively excluded as in some species, then osmotic adjustment is normally achieved with an increased uptake of K^+ as the cation [45]. But high concentrations of K^+ are as inhibitory as Na^+, and again metabolic tolerance becomes necessary. Apparently mangroves accumulate large amounts of Na^+ and Cl^- for osmoregulation [50,53]. For instance, the salt concentration in the leaves of *Avicennia marina* reached around 600 mM NaCl when plants were grown in the presence of 500 mM NaCl [53]. A similar situation also was evident in *Agiceras corniculatum* grown under high-saline conditions [53]. In another independent study, Downton [22] observed a large accumulation of inorganic ions in the leaves of *Avicennia marina* exposed to salinity stress. Together these results indicate that the leaves of *Avicennia* species accumulate high levels of inorganic ions, which were in fact more than sufficient to maintain leaf osmotic pressures at higher levels than those experienced at the roots. But several studies have shown that enzymes and metabolic processes such as protein synthesis have a narrow

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

range of ion concentration for optimal activity in both glycophytes and halophytes [26]. Enzymes extracted from salt-adapted halophytes were found to be salt sensitive. Conspicuously, the activity of these enzymes was considerably inhibited in vitro at salt concentrations similar to those that were found optimum in the medium for growth of the source plants [54,55]. Also, the salt sensitivity of amino acid incorporation into proteins by microsomes from salt-adapted halophytes indeed did not differ from that of microsomes obtained from glycophytes [56]. So it is apparent that high levels of inorganic ions cannot be maintained in the cytoplasm, and mangroves, like other halophytes, overcome this problem either by salt secretion [47,57] or probably by compartmentation of ions to less metabolically active sites [46]. Analysis of the chemical composition of Australian mangroves grown under saline conditions showed a substantial accumulation of low molecular weight organic compounds and compatible solutes that did not interfere with cell metabolism [50–52]. Although there is a lack of direct evidence, the above findings indicate that, in mangroves, the excess ions entering into the cells may be sequestered in vacuoles to minimize ion toxicity, as synthesis of metabolically compatible solutes to balance the osmotic potential of the cytoplasm is a common response of salt-stressed plants compartmentalizing excess ions in vacuoles [18,26]. In vitro studies have shown that low molecular weight organic solutes such as proline and glycinebetaine are compatible with enzyme activity even at 1000 mM [58].

At the cellular level, salt balance must be maintained either by the effective exclusion of Na^+ and Cl^- ions initially or by other strategies like salt secretion or ion compartmentation. In many salt-tolerant plants, ion compartmentation seems to be a highly effective mechanism to minimize ion toxicity [59], and the importance of this adaptive strategy to metabolic processes is well exemplified by the Na^+ compartmentation of cell organelles, chloroplasts, and mitochondria in the leaf cells of the halophyte *Suaeda maritima* [60]. In *Suaeda maritima* grown at 340 mM NaCl, Na^+ was about 150 mM in the cytoplasm and 600 mM in the vacuole of the leaf cells, thus showing an efficient compartmentation of Na^+ in the vacuole under a saline condition [60]. Unfortunately, the regulatory aspects of transmembrane ionic movements in relation to salinity stress have not been studied extensively in mangroves. Also, little is known about the significance of this strategy to physiological functioning in mangroves. Only a few investigations on the subcellular estimation of ions have been undertaken in mangroves [47,61]. Salt-tolerant plants usually accumulate large quantities of Na^+ and Cl^- ions in their leaves, but there is no evidence that chloroplasts and mitochondria are the sites of salt adaptation capable of tolerating large amounts of Na^+ and Cl^- [62]. For example, analysis of the ionic composition of chloroplasts isolated from salt-tolerant and salt-sensitive plants showed similar levels of Cl^- [63–67]. It has been observed that chloroplasts of both salt-tolerant and salt-sensitive plants maintained K^+ as the major cation, but in salt-tolerant species, Na^+ may be substituted for K^+ to a considerable extent, as Na^+/K^+ ratios in chloroplasts of salt tolerant species were much higher than those found in salt-sensitive ones [66]. This indicates that, in halophytes, the entry of Na^+ in the chloroplasts may be selectively regulated. However, the mechanism of ion compartmentation appears to fail under higher salinity levels even in highly salt-tolerant mangroves. For instance, in *Avicennia marina*, high concentrations of NaCl in the growth medium caused severe disorganization of photosystem II, thus making the plants more vulnerable to photoinhibition [68].

Control of Ion Uptake

Control of ion uptake is perhaps one of the most poorly understood salt-adaptive mechanisms of mangrove species. There have been very few investigations into the structure and function of the mangrove roots in relation to ion uptake [69,70], although the anatomical features of mangrove roots have been studied extensively with respect to certain functions such as aeration, water absorption, and mechanical support [1,71]. Also, there appears to be very limited information on the ionic status, particularly of Na^+, K^+, and Cl^-, in the xylem sap of mangroves [47,72]. It is estimated that the xylem sap of field-grown *Aegialitis annulata* contained 118 mM Na^+, 14 mM K^+, and 122 mM Cl^- [46]. In the case of *Avicennia marina* grown in seawater, Field [72] gave a value of 792 mM Na^+, 118 mM K^+, and 799 mM Cl^- for the xylem sap of the stem. A comparable level of Na^+ and

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

Cl^- ions also was found to be present in the xylem sap of root, but the K^+ content was twice that recorded for the stem xylem sap. In another study with *Avicennia marina* grown under a natural habitat, it was found that the ion concentration fluctuates considerably during the day [47]. All the three ions measured, Na^+, K^+, and Cl^-, had higher concentrations in the mornings and evenings. The average concentration of Na^+, K^+, and Cl^- was, respectively, 130, 30, and 120 mM, with a Na^+/K^+ molar ratio of approximately 4/1. Clearly, more quantitative data of the ion content in the xylem sap of various mangroves are required to ascertain the true relationship between different ionic species as well as to gain more insight into the regulation of ion uptake.

A quantitative analysis of the contribution of various factors regulating the salt balance of *Avicennia marina* leaves indicated that salt filtration by the root is by far the most important salt-exclusion mechanism operating in this species [47]. With the salt filtration by the roots, *A. marina* prevents nearly 80% of the salt, which is carried toward the root surface by the transpiration stream, from entering the plant [47,48]. Such a system for salt exclusion may require energy for its operation. In the case of *A. marina*, Waisel et al. [47] noted that the extremely low water potential in the xylem would serve as the driving force for the operation of this ultrafiltration system. A similar explanation also was advanced by Scholander [15] to account for the operation of the salt-exclusion system existing in *Aegialitis*.

The mechanism by which mangroves regulate the uptake of ions at the root surface is not understood. In an earlier study, Lawton et al. [69] found that the inability of *A. marina* to prevent salt influx completely resulted from a structural gap existing between the fully developed endodermis and the proximal end of the root tip. Using the same species of *Avicennia*, Moon et al. [70] demonstrated that the access of external salt solution to the symplasm was restricted to the distal 17 mm of the third and fourth order roots, and a barrier to apoplastic transport in the periderm and endodermis isolated the bulk of the root system from the external salt solution. It is noted that the location of an apoplastic barrier at the root periphery helps prevent the cortex from accumulating deleterious levels of Na^+ and Cl^- from the salt solution. With fluorescent tracer dyes, Moon et al. [70] also showed that only minimal apoplastic uptake of water and ions took place in *A. marina* grown under a saline condition. Obviously, this functional attribute and the structural barrier at the periderm and endodermis to apoplastic ion transport in *A. marina* roots are well suited to cope with a highly saline environment. However, the occurrence of similar characteristics in other mangrove species remains unknown.

Control of Salt Balance in the Shoot System

Continuous absorption of salts even at limited amounts and consequent transportation into the shoot system eventually raise the salt concentration of leaves to harmful levels. Apparently mangroves and other halophytes accumulate large amounts of Na^+ and Cl^- [73–76], and thus balancing of the salt content in photosynthetically active leaves and growing tissues becomes a necessity to sustain growth. There are several mechanisms by which mangroves and other halophytes maintain the salt balance in the leaves. These include salt secretion, salt accumulation in bladder hairs, retranslocation to other organs, shedding of old leaves, and temporary growth adjustments. The relative importance and efficacy of each mechanism varies among different species of mangroves and different ecological conditions [26,57].

Salt secretion is one of the best-known adaptive mechanisms whereby mangroves regulate the salt content of their leaves [47]. Species of *Acanthus*, *Aegialitis*, *Aegiceras*, and *Avicennia* possess salt-secretion glands in their leaves [46,73,77]. Salt glands are regarded as being highly selective and salt secretion by them as a fast-operating mechanism. However, in *A. marina*, salt glands are nonspecific and secrete a variety of ions [78,79]. The composition of salt gland secretion, nonetheless, is largely a reflection of the ionic composition of the root-bathing medium; thus, Na^+ and Cl^- were the predominant ions present in the secretion of *A. marina* salt glands [78,79].

In spite of its wide occurrence, the structural and functional aspects of salt secretion have been studied only in a limited number of plant species. High rates of secretion of Na^+ and Cl^- were

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

shown for different species of mangroves [46,73] and some species of coastal halophytes such as *Spartina anglica*, *Limonim vulgare*, *Armeria maritima*, *and Glaux maritima* [75,80]. In a detailed investigation of salt balance of *A. marina* leaves, Waisel et al. [47] found that salt secretion accounted for the removal of approximately 40% of the salts entering the leaves. Contrary to the expectation, no correlation between the rates of transpiration and salt secretion was noticed in this plant species. Such a correlation would have been expected if the salts brought in by the transpiration stream were the direct and sole source for secretion. The lack of such a correlation indicates that the salts which reach the leaves via transpiration are sequestered in the cells initially, and then they are probably channeled to the salt glands for secretion by some hitherto unknown mechanism. It is suggested that the salt-secretion process in *A. marina* is possibly supported by the higher concentration of salts in the xylem sap [47]. Indeed, in another study [61], the salt content of the gland cells of *A. marina* was decidely lower than that of the mesophyll. In this species, a downhill salt gradient was found to exist from cells near the xylem through the mesophyll to the gland cells. A similar effect of salt concentration on salt secretion also was observed in other salt-secreting plants [80,81]. Although the mechanism controlling salt secretion is not precisely understood, it must be noted that ''ion pumps'' have been proved to participate in salt excretion in *Atriplex* [82] and *Limonium* [83,84], and it is likely that they are a feature of other salt gland–bearing plants as well.

Although highly efficient, salt secretion is not a common salt-adaptive feature of mangrove species. Indeed, most mangrove species lack salt-secretion glands. As Na^+ and Cl^- are continuously transported to the shoot by the transpirational stream, it is imperative that the leaves of nonsecreting species must evolve adaptive mechanisms to maintain the leaf salt concentration to physiologically acceptable levels. Available evidence indicates that the nonsecreting species usually maintain constant concentrations of Na^+ and Cl^- in the leaves. This is often achieved by modulating growth, increasing succulence, and retranslocating ions to older tissues [1,57,74,85]. It is suggested that a considerable amount of accumulated ions will be channeled to actively growing tissues, such as expanding leaves, as the demand for ions will be greatest in those tissues [86]. However, the requirements of salt utilization for cell growth are not sufficient to balance the rate of salt influx to leaves even in fast-growing systems [46].

The development of succulence appears to help maintaining salt balance and osmoregulation in mature nongrowing leaves of some mangroves. For instance, the leaf thickness of *Rhizophora mangle* grown under fluctuating salinity conditions almost doubled when they were exposed to continuous salinity [85]. An increase in leaf succulence with increasing salinity of the growth medium also was observed in seedlings of *A. marina* [24]. In *Laguncularia racemosa*, Biebel and Kinzel [87] reported a fourfold increase in leaf thickness from the youngest to oldest leaves along a shoot. Such an increase in leaf thickness is probably representative of many mangrove species.

Although leaf succulence alleviates the problem of salt accumulation to some extent, it is argued that retranslocation of ions to older leaves/tissues seems to be a more useful strategy to maintain a favorable ion concentration in growing and metabolically active tissues for some mangrove species. As seen from the data presented by Waisel et al. [47], about 25 and 19% of the absorbed Na^+ and Cl^-, respectively, were transported out of the leaves of *A. marina* at the rate of 0.205 mmol NaCl per gram dry weight per 24 h. It is well established that any retranslocation of ions from leaves must take place via the phloem, but there is no convincing evidence that reexport of excess ions are transported via the phloem. Furthermore, in species where retranslocation of excess Na^+ and Cl^- ions were documented, the distances to which ions were transported were short [47]. Taken together, it is apparent that more indepth analysis of ion transport under salt-stress conditions is required before making any definite conclusion about ion retranslocation strategy in mangroves.

Causes of Growth Limitation and Costs of Salt Tolerance

The distribution of mangrove species along salinity gradients is primarily determined by the extent to which a species can tolerate different levels of salinity. Detailed analysis of energy requirements

for various cellular processes associated with salt adaptation [48] indicates that an increase in salt tolerance incurs considerable energy costs to the species. In mangroves, this aspect is best studied in relation to conservative water use and photosynthesis.

Mangroves follow C_3 photosynthetic pathway, and there is no evidence that these plants can shift from the C_3 to C_4 or crassulacean acid metabolism (CAM) pathways even under different environmental conditions [10]. In their elegant studies, Ball and others [6,48,53,68,88] found that mangroves possess an array of functional and structural attributes to maximize photosynthetic efficiency under stressed conditions. For instance, the gas exchange and water-use characteristics of mangroves are unusually conservative for the C_3 pathway [62]. Also, depending on the environmental conditions, the amount of water used for carbon assimilation varies considerably between species. This is exemplified by the water-use characteristics of *Aegiceras corniculatum* and *Avicennia marina*, two mangrove species with different salinity tolerances, grown under different salinity (50, 250, and 500 mM NaCl), and leaf to air vapor pressures (6, 12, and 24 m bar) [48]. With increasing salinity and decreasing humidity, the net water-use efficiency declined in more salt-sensitive *A. corniculatum*. On the other hand, the net water-use efficiency in the more salt-tolerant *A. marina* remained almost constant under similar environmental conditions. Thus, the water-use efficiency was more conservative in the more salt-tolerant species and became increasingly conservative with increase in salinity. Conservative water use may be a consequence of the high-energy cost of water uptake. But it can be viewed as a desirable adaptation to maintain a favorable carbon-salt-water balance, as restricted water uptake limits the entry of undesirable salts into the transpiration stream [48]. Evidently, the slow growth of highly salt-tolerant mangrove species such as *A. marina* in both freshwater and seawater could be probably due to the maintenance of high water-use efficiencies at the cost of carbon assimilation [89]. At this juncture, it is interesting to note that the hydraulic conductance of *A. marina* roots even under freshwater conditions was about two orders of magnitude lower than those of salt-sensitive species and decreased with an increase in salinity [72]. Although the reduced intake of water helps regulate the influx of ions, it necessitates the development of a massive root system to meet the water demands of the shoot. This results in the preferential allocation of photosynthates to root development at the expense of canopy development, as seen in *A. marina*.

Restricted photosynthetic gas exchange and the inability to exploit high irradiance are the other two major factors limiting the productivity of mangroves under saline condition. Conservative use of water imposes severe limitations on leaf functioning under field conditions. For example, high water-use efficiency could be related to the necessity to regulate the salt balance in the tissues and to minimize energy loss in eliminating accumulated salt. High water-use efficiency can be attained only by close coordination between the photosynthetic metabolism and the functioning of stomatal aparatus [90,91]. In a detailed study of the leaf functioning of mangroves in relation to the leaf temperature, Ball et al. [6] observed that stomatal conductances of *A. marina, Bruguiera gymnorrhiza*, and *Rhizophora apiculata* were considerably lower than those typically found in well-watered C_3 species. This reduced leaf conductance restricted the influx of CO_2 and the efflux of water vapor, causing photosynthesis to operate at a low intercellular CO_2 concentration but with high water-use efficiencies (i.e., mmol CO_2 gained per mol water lost). Indeed, Ball et al. [6] reported water-use efficiencies ranging from 3.2 in *B. gymnorrhiza* to 4.6 in *A. marina*; values which are exceptionally high for C_3 plants under salt-stress conditions.

Although restricted stomatal conductance results in very high values of water-use efficiency, it inevitably increases the leaf temperature to inhibitory levels [90]. In mangroves, photosynthetic activities and stomatal conductance are maximal between 25 to 30°C and decline dramatically above 35°C [6,32,90,92]. Considering the fact that photosynthesis in mangroves becomes light saturated at quantum flux densities ranging from 30 to 50% sunlight [88,92,93], and that stomatal conductances are highly restricted, it is conceivable that mangroves must avoid high light intensities if leaf temperatures are to be maintained within physiologically favorable ranges. In all the mangrove species thus far examined, evaporative cooling was found to be insufficient to prevent the leaf temperature from rising above the ambient temperature [10]. Thus, mangroves evolved other additional strategies to overcome leaf temperature build-up to undesirable limits. Ball et al. [6] identified

three properties, leaf angle, leaf size, and heat capacity per unit area, which are involved in the maintenance of a desirable leaf temperature in mangroves. In all the five mangrove species studied, *B. gymnorhiza* (L) Lam., *Ceriops tagal* (Perr.) B. Rob. Var. *australis* (White.), *R. apiculata* Bl., *R. lamarckii* Montr., and *R. stylosa* Griff., increasing the leaf angle (i.e., the inclination of leaf to the horizontal plane) greatly reduced the intensity of heat loading. The leaf angle, considered as a compromise between the requirements for illumination and reduction of temperature, was increased from approximately 0° in full shade to about 75° in fully exposed leaves. Apparently, the response of the leaf angle to irradiance displayed a distinct species specificity, with the leaf angle increasing with increasing salinity tolerance of the species [6]. The effect of leaf orientation in minimizing leaf to air temperature differences was also striking in *R. stylosa* Griff. growing in its natural environment [90].

The leaf size is another attribute shown to influence the maintenance of the leaf temperature in mangroves. Heat transfer between the leaf and the ambient air is determined by the heat-transfer resistance imposed by a boundary layer, the characteristics of which are a function of the leaf size and other environmental variables such as the air temperature and wind speed. It has been shown that a decrease in leaf size enhances the boundary layer conductance and thus helps maintain the leaf temperature closer to that of the ambient air. Interestingly, there is a correlation between the leaf size and the salt-tolerance trait of mangrove species. For example, the leaves of *Ceriops tagal*, the most tolerant of the five species studied [6], were the smallest and most sensitive to a variation in exposure to sunlight. Similarly, the leaves of mangrove species growing in hypersaline coastal environments such as *A. marina, C. tagal var. australis, Excoecaria ovalis, Lumnitzera racemosa*, and *Osbornia octodonta* are much smaller than those dominating low-saline habitats [10].

Another important leaf characteristic regulating the leaf temperature is the heat capacity per unit area. It is shown that leaf succulence increases the heat capacity per unit area and thus minimizes fluctuations in the leaf temperature due to variation in irradiance and other environmental variables [6]. In mangroves, the leaf heat capacity increases with an increase in the leaf dry weight and the water content per unit area. Evidently, the heat capacity showed a positive correlation with the salinity tolerance of the mangrove species [6].

It appears that there is an inverse correlation existing between water-use and salinity tolerance in both salt-secreting [10,53] and nonsecreting species [6]. Under normal field conditions, mangroves usually control the entry of excess Na^+ and Cl^-, regulate the leaf temperature build-up, and capture maximum irradiance to maintain optimal carbon fixation. Excessive levels of transpiration inevitably lead to the accumulation of ions in leaves resulting in several metabolic dysfunctions. It is therefore reasonable to assume that leaf conductance (stomatal transpiration) should be minimized to sustain photosynthetic processes at the required threshold.

WATERLOGGING, SOIL REDOX CONDITIONS, AND GROWTH AND DISTRIBUTION OF MANGROVES

Like soil salinity, waterlogging is a common environmental condition in mangrove swamps. The roots of mangroves in flooded habitats must endure anoxic soil conditions, since waterlogged soils become devoid of oxygen within a few hours after flooding [94]. Mangroves evolved several structural and functional adaptive mechanisms to cope with this stressful condition. These include the development of pneumatophores (*A. marina*), stilt roots (*R. stylosa*), and knee roots (*Bruguiera exaristata, Xylocarpus granatum*) with extensive aerenchyma, numerous lenticels [1], and the occurrence of anaerobic root metabolism [95]. Although the aerenchyma is extensively developed,which is estimated to be as much as 70% of the total root volume in some species [96], its ability to provide sufficient oxygen for complete aerobic metabolism in the roots of mangroves and other wetland plants growing in flooded soils has been questioned [97–99].

Although several studies have been conducted with herbaceous marshy plants and flood-toler-

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

ant tree species [100–106], little is known about the root metabolism in mangroves [95,107]. In response to hypoxia, the root metabolism in the black mangrove, *Avicennia germinans* (L.), became anaerobic by increasing the capacity for alcoholic fermentation dramatically [95]. Oxygen concentrations in the roots decreased markedly under anoxic soil conditions, and this low level of oxygen was observed even after 96 h of flooding. The intact roots of flooded plants responded metabolically by increasing the activity of alcohol dehydrogenase and malate dehydrogenase; however, no change in phosphenol pyruvate carboxylase activity was discerned. The build-up of oxygen tension and the increased capacity for alcoholic fermentation in hypoxic roots indicate that, as in many other marshy plants, oxygen diffusion from the aerial parts of the roots of *A. germinans* was not sufficient to maintain complete aerobic metabolism in the hypoxic environment.

Among the other metabolic changes observed, an alteration in adenine nucleotide production was the most pronounced. In the hypoxic roots of *A. germinans*, adenine nucleotide concentrations and the adenylate energy charge ratio were significantly lower than those of the aerobic controls [95]. However, in this system, increased glycolysis and alcoholic fermentation helped maintain sufficient ATP production when aerobic metabolism was limited. These observations clearly suggest that metabolic adaptations will be as important as the enhanced internal oxygen diffusion attained by structural adaptations to tolerate waterlogged conditions.

The functioning of mangrove roots under saline, flooded conditions seems to be highly complex [38,95,107]. There is a pronounced interaction of salinity and flooding on nutrient availability. For instance, the salinity tolerance of all the species studied was found to be markedly decreased under waterlogged conditions. This reduction in salt tolerance has been ascribed to, at least in part, soil hypoxia associated with flooding, as it affected both salt-exclusion and salt-selective absorption of K^+ over Na^+ [108,109] even in highly salt-tolerant mangroves like *A. marina* [22,53,110]. Studies with Australian mangroves [111] found that nitrogen and phosphorus also were limiting under salt-water flooding. In continuously flooded soil, ammonia will be the major form of combined inorganic nitrogen which readily adsorbs onto organic sediments, making it less available for uptake by roots. In contrast, when soil is less frequently flooded, mangrove growth is evidently limited by the availability of phosphorus [111]. At less frequent inundation, soil becomes more aerated and hence more oxidized. Under this condition, a considerable amount of phosphorus may be precipitated with calcium, aluminium, and iron or may be adsorbed onto clay particles.

Waterlogging in mangrove swamps results in various intensities of soil redox potential, which on its own imposes substantial levels of stress, especially nutrient stress, on plants. The redox status of the sediment, which affects both the form and availability of inorganic nutrients, is largely determined by the degree of soil saturation. In a recent study, *A. germinans* and *R. mangle* displayed distinct species specificity in their tolerance to soil redox potential under saline condition [112]. Seedlings of *A. germinans* showed a greater sensitivity to low redox potential than *R. mangle*, and the level of sensitivity was closely related to the intensity of the soil reduction.

In addition to the effect of the soil redox condition, the presence of sulfides in interstitial water also was found to have a significant influence on the growth and succession of mangroves [113,114]. An interesting pattern of sulfide sensitivity was, however, noticed in *A. germinans* and *R. mangle* [115]. *A. germinans* seedlings were more sensitive to sulfide than those of *R. mangle*. But mangrove zones dominated by *A. germinans* were characterized by strongly reducing soils with high sulfide (2–4 mM), whereas the zone dominated by *R. mangle* had moderately reducing soils with low-sulfide concentrations (about 0.3 μM). This is intriguing, as the sensitivity to sulfide reversed almost completely during the adult phase. It is believed that the sensitivity of the root system of *A. germinans* seedlings to sulfide is related to the oxygen status, and the development of various structural and functional adaptations during the adult phase probably alleviates root hypoxia and hence the sensitivity to sulfide. From this example [115], and the other studies reported earlier [116–118], it is apparent that the soil redox conditions and the sulfide concentration in the soil environment have a major role in the growth and species distribution of mangroves under waterlogged conditions. However, it must be noted that the growth of mangrove plants in a flooded environment may be affected by the accumulation of the reduced forms of iron and manganese [119], organic acids [120],

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

and gases such as ethylene, methane, and carbon dioxide [121]. Involvement of these factors in the species distribution of mangroves therefore cannot be excluded.

GENETIC VARIABILITY AND CONSERVATION OF MANGROVES

Mangrove forests are valuable natural resources with a unique habitat value. This highly productive salt-tolerant ecosystem is not only a habitat for several unusual plants and animals but also supports the economic life of many coastal communities in the tropics [2]. Mangroves offer an enormous variety of natural products which include timber (species of *Avicennia*, *Bruguiera*, *Ceriops*, *Excoecaria*, *Heritiera*, *Nypa*, *Oncosperma*, *Rhizophora*, *Sonneratia*, and *Xylocarpus*), food (fruits, seeds, and young sprouts of *Avicennia*, *Acrostichum*, *Bruguiera*, *Nypa*, *Rhizophora*, and *Sonneratia*), medicinal plants (species of *Bruguiera*, *Ceriops*, *Excoecaria*, and *Xylocarpus*), fuel wood, tannins, and dyes (mainly members of Rhizophoraceae), and saponins (species of *Barringtonia* and *Dorris*). In addition, mangroves also are utilized for fisheries, agriculture, coastal protection, wildlife management, and sewage treatments [1,122].

The extensive and indiscriminate utilization of mangroves for industrial and developmental purposes resulted in rapid, massive destruction of this potentially renewable vegetation. This is best exemplified by the decline in mangrove forests in Kerala, a coastal state in South India. At the turn of the century, some 70,000 ha of pristine, rich mangrove vegetation bordered the coastal line of Kerala, but owing to rapid urbanization, it is now almost reduced to about 250 ha occurring as small patches of vegetation along the shoreline [2]. Although not so acute, mangrove forests are being cleared in Southeast Asian countries as well. Unfortunately, little effort has been made to prevent the rapid destruction of the mangrove ecosystem until recently. Of late, however, several countries have passed Regulatory Acts to protect mangrove forests. In addition, many national and international programs are now in place for the conservation of this unique ecosystem.

A major stumbling block for effective conservation and afforestation program is the lack of knowledge about the genetic make-up of plant species within the mangrove ecosystem. Conventional genetic analysis is difficult in mangrove species, and so far no detailed studies have been carried out in this group of plants. Further, available information on the reproductive biology and population genetics is rather scanty and restricted to selective species [123–127]. In a recent study aimed at identifying distinct genotypes for long-term conservation. Lakshmi et al. [125] analyzed 48 genotypes of the mangrove *Acanthus ilicifilius* and representing eight distinct populations. In this investigation, the first report on the use of molecular markers in assessing intrapopulation and interpopulation variability in mangroves, they detected a low level of (4–6%) polymorphism at the intrapopulation level through both random amplified polymorphic DNA (RAPD) and restriction fragment length polymorphism (RFLP) techniques. However, at the interpopulation level, the polymorphism of RAPD and RFLP was about 28%. In a similar study (see Ref. 125 and unpublished results quoted therein) with *Excoecaria agallocha*, a dioecious mangrove tree species, the extent of polymorphism detected was of much higher magnitude. The intrapopulation polymorphism ranged from 20 to 31%, whereas as much as 65% of the amplification products were polymorphic at the interpopulation level. These examples indicate that considerable genetic variability exists between populations, and that different mangrove species may display varying degrees of polymorphism depending on their edaphic preferences and adaptations, as suggested earlier.

Although the DNA marker–based analysis done by Lakshimi et al. (see Ref. 125 and unpublished results quoted therein) showed considerable genetic variability among different populations of *Acanthus ilicifolius* and *Excoecaria agallocha*, the findings of Lowenfeld and Klekowski [127] revealed very high genetic similarity among three different populations of red mangrove, *R. mangle*. From the segregation ratios for the chlorophyll-deficiency mutation, Lowenfeld and Klekwoski [127] concluded that selfing is very prevalent in the populations studied and that *R. mangle* forests may be essentially single-species ''natural monocultures'' with little genetic diversity. As this study is

soley based on a single genetic marker, a more definite conclusion on the genetic variability of *R. mangle* can be drawn only after an indepth analysis of a large number of populations of this species using modern DNA marker–based techniques.

CONCLUSIONS

Mangroves are one of the much neglected and overexploited ecosystems in the world. Fortunately, owing to the activity of various environmental interest groups, there is now an increased awareness and appreciation of the importance of mangroves in protecting coastal and estuarine ecosystems. It is now recognized that there is an urgent need to devise management practices which optimize the conservation of mangrove resources on a sustainable use basis [12]. As mangroves are nonhomogeneous open ecosystems that are extremely dynamic, a thorough understanding of the interaction of physical and biological processes occurring in this system is essential to develop effective management practices. In the past, we have achieved reasonable success in defining the physiological manifestations of dominant mangrove species under different environmental conditions [5,10]. However, we still do not know how different plant species establish and survive the harsh conditions of a mangrove habitat where they are continuously challenged by different environmental stresses simultaneously. Plants are complex organisms and they possess sophisticated control mechanisms, both at the cellular and organismal levels, to deal with different environmental situations [26]. It appears that integration of the knowledge gathered in the past may help achieve a better understanding of these mechanisms/processes which are required for developing a comprehensive model for mangrove ecosystem dynamics. We hope that a detailed knowledge of the mangrove ecosystem dynamics [10], the genetic diversity [125–127], and the exploitation of biotechnological applications would eventually pave the way for the development of a management program for the conservation and sustainable use of this ecosystem.

Advances in Water Relation and Moisture Stress Studies of Plants

J. P. Srivastava and D. N. Tyagi
Banaras Hindu University
Varanasi, India

INTRODUCTION

Early plant scientists focused on understanding the two main physiological processes in plants—absorption of solutes and water. Water is the major constituent of plants. Like other organisms, life in plants takes place in an aqueous medium. Besides being the primary constituent of protoplasm, water is used as reagent in photosynthesis and hydrolytic proceses. It is a solvent in which salts and gases move into and through the plant and maintains cell turgor. The hydrophilic force between water molecules and the cell wall components like the cellulose, lignins, and pectins has a significant role in maintaining the plant structure. Nevertheless, water is required for the integrity of cells, tissues, and the organisms. The comprehensive work related to plant water studies was documented by workers like Kramer, and by Crafts, Curtis, and Stocking [1]. Since 1949 a number of papers have appeared in this field. In this chapter, an attempt has been made to summarize the work carried out in understanding plant water status, their quantification and possible mechanism by which plants sense moisture deficit.

BASICS OF PLANT WATER RELATION STUDIES

Earlier there were a number of ways to express plant water status; that is, absolute water content, relative water content, water saturation deficit, and so forth. But later on it was suggested that the chemical potential be used as the basis for the property of water in plants as well as in soil systems, [2]. The free energy per unit quantity of a substance, specifically per gram mole, is called as the chemical potential. The chemical potential of a substance is independent of the quantity of the substance. The water potential of a system, or part of a system, that contains water or could contain water is equivalent to the chemical potential of water in that system, or of the part of the system, compared with the chemical potential of pure water at atmospheric pressure and the same temperature [3]. It is suggested that the water potential of pure water be considered as zero. Hence, the

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

chemical potential of water in a system will be negative if it is lower than that of reference pure water. The water potential of a system is expressed as

$$\psi_w = \mu_w - \mu_w^0$$

where

ψ_w = Water potential of the system
μ_w = Chemical potential of water in the system
μ_w^0 = Chemical potential of pure water

Here, the water potential is expressed in terms of units of energy; for example, joules per gram, joules per mole, calories per mole, or calories per kilogram. If, however, the chemical potential is divided by the specific volume of H_2O, which is 1 $cm^3\ g^{-1}$, the energy unit of the water potential is expressed in the units of pressure [4]. The current accepted unit of water potential, in terms of pressure, is the megapascal (MPa, 1 MPa = 10 bars= 1×10^6 dynes cm^{-2} or 9.87 atmospheres). The pressure unit is most acceptable one in the field of plant water relationship studies. The water potential of pure water is zero. When a solute is dissolved in water, the water potential of the system becomes negative, as the presence of solutes decreases the free energy of water. Substances in a liquid or gas phase move in response to differences in their chemical potential. Similarly water too diffuses in response to differences in the water potential; that is, from a higher water potential to a lower water potential. The gradient in the water potential generates the driving force for the movement of water between systems.

In plants, the water potential is mainly governed by the osmotic potential (ψ_s) and the pressure potential, or turgor pressure (ψ_p), of the plant and expressed as

$$\psi_w = \psi_s + \psi_p$$

The osmotic potential of plants is always negative and ranges between -1.0 and -2.5 MPa. It is generated by organic and inorganic solutes in the cell cytoplasm and vacuoles. Photosynthesis and ion absorption are the basis of the metabolic control of ψ_s [5].

The pressure potential may be generated in the turgid cell, where it is positive or in water columns under tension where it is negative. In plants, negative turgor may develop in the lumen of the cell, particularly when the intracellular osmotic potential difference (i.e., between the apoplastic space and the cell) is larger than the turgor pressure. Such a condition may occur when transpiration is larger than the absorption of water through the roots [6]. It is argued that reports on negative turgor are fallacious owing to the techniques used [7]. Recently, this aspect has been extensively reviewed [8]. If a cell containing a constant number of solutes reaches zero turgor and the water potential further drops, it will adjust its water potential to the new condition by changing the volume and/or pressure [9]. If the cell walls are elastic, this may cause a shrinkage and maintenance of turgidity [10]. A cell with a rigid wall will resist such a shrinkage and turgor will be reduced to a constant volume [11,12]. In such a case, negative turgor also might be possible, as the environment dries and the tissue water potential falls. Negative turgor in mesophytic tissues has been reported [13].

In all living systems, there is another component of the water potential; that is, the matric potential (ψ_m). This component also is negative in value and very low in magnitude (less than -0.1 MPa). The matric potential arises from the microfibrillar cellulose matrix of the cell walls. Practically it is not possible to separate ψ_m from ψ_s, and it is hardly referred to in the literature. Imbibing seeds and some nonvascular plants like, for example, algae and lichens with large extracellular pools of polysaccharides may represent a matric potential component of some magnitude [5].

QUANTIFICATION OF PLANT WATER STATUS

Earlier studies were restricted to the measurement of the absolute water content on the fresh or dry weight basis of plants. But there is the significant diurnal and temporal variations in the water content of the plant, so it is an unsatisfactory parameter.

The relative water content (RWC), which is expressed as

$$\text{RWC} = \frac{F_w - D_w}{T_w - D_w} \times 100$$

where F_w = fresh weight, D_w = dry weight, and T_w = fully turgid or saturation weight or water saturation deficit (WSD), which is expressed as

$$\begin{aligned}\text{WSD} &= \frac{T_w - D_w}{F_w - D_w} \times 100 \\ &= 100 - \text{RWC}\end{aligned}$$

have been found to be more satisfactory parameters [14].

Quantifications based on the water potential are widely accepted [4]. It is difficult and cumbersome to measure the water potential of the whole plant; hence most of the measurements are made on the leaves, and the leaf water potential has been the primary index of the crop water status [15]. The pressure chamber is the equipment widely used to measure the water potential, although it has some limitations [16]. It is suggested that the presence of mucilaginous substances in the vessels renders the use of the pressure chamber obsolete [17], because the measured balancing pressure may merely reflect the pressure required to squeeze water out of the gel structure and it may poorly correlate with the in situ xylem pressure [18]. In the presence of mucous substances in the xylem, a number of tiny gas bubbles may persist establishing a liquid/air interface and interfacial flow, which is termed Marangoni streaming, and may cause an error in the water potential measurement. The thermocouple psychrometer is another important and standard instrument for the measurement of the total water potential [15].

The osmotic potential of a solution can be measured by changes in the freezing point, boiling point, or vapor pressure of the solution as compared with pure water. The vapor pressure osmometer is the most preferred instrument to measure the osmotic potential of a solution even if the solution is available in very small quantity (few microliters). Before measuring the osmotic potential of a tissue, it is necessary to reduce the pressure potential to zero. This is achieved by freezing the tissue for a sufficient time followed by thawing and squeezing to extract the sap. All these processes cause mixing of the cytoplasmic contents, cell wall water, and other vacuolar substances and result in an erroneous estimation of the osmotic potential of the vacuolar sap, which is much larger in volume as compared with the cytoplasm and, thus, is primarily responsible for the osmotic behavior of plant tissues [3]. Another method of estimating the osmotic potential of a plant organ is by the pressure volume relationship [19]. Besides estimating the osmotic potential of a tissue, this method also provides, for example, an estimation of the water potential at incipient plasmolysis, the volume of free water in the tissue, and the total volume of tissue water. The twig or leaf is cut from the plant and hydrated for a sufficient time, generally overnight, by placing it in water in a closed chamber. The hydrated material is placed in the pressure chamber and the pressure is applied gradually. At a particular pressure the volume of the exudate is determined. This exercise is carried out at several increasing pressures. A graph is plotted between the reciprocal of the balancing pressure (1/P) and the reciprocal of the volume of exuded sap (1/V). A curve obtained for these characters is shown in Figure 1. With a decrease in 1/P, the relationship is curvilinear up to point B, and then it becomes almost linear. If this line is extrapolated, intercepts A and C are obtained on axes Y and X, respectively. Point C represents the reciprocal of the volume of free water in the tissue, whereas point A represents the reciprocal of the water potential of the hydrated tissue. Point B designates the reciprocal of the water potential at which incipient plasmolysis occurs, that is, the reciprocal of the osmotic potential of the tissue. If the same tissue is oven dried and the absolute water content is determined, this amount minus the volume of water in the tissue corresponding to point C gives the amount of bound water in the material.

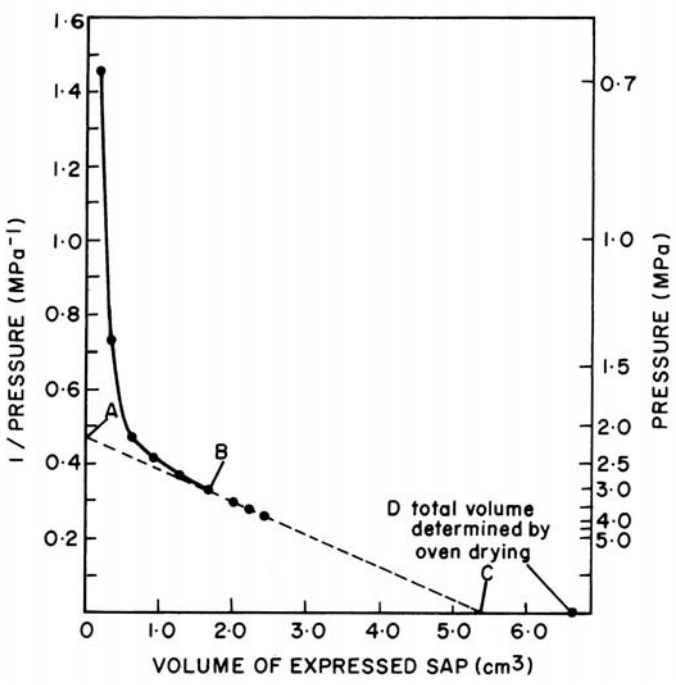

FIGURE 1 Pressure-volume relationship to measure several parameters of plant-water-relationship. (A) Water potential of hydrated tissue; (B) water potential at incipient plasmolysis or osmotic potential; (C) volume of free water; (D) total volume of water; and (D–C) bound water in the tissue. (From Ref. 3.)

The pressure potential is generally calculated from the measured water potential and the osmotic potential values as

$$\psi_P = (-)\psi_w + \psi_s$$

However, ψ_P also can be measured directly by using a pressure probe [20–22].

According to the gas equation

$$P = n\frac{RT}{V}$$

where P = pressure, R = gas constant, T = absolute temperature, V = volume, and n = number of solutes. Any change in P is possible by changes in n, V, or both at a constant temperature. A negative value of P is equal to the osmotic potential. For a hydrated tissue (fully turgid), where V is to its maximum, an increase or decrease in P may be due to a change in the number of solute molecules (n). Thus, a plant sample with a lower osmotic potential at full turgor indicates a higher concentration of solutes in the cell sap. This parameter is taken to ascertain the active accumulation of solutes; that is, the amount of solute molecules over and above the value which could be expected by reduction in the volume of the system [23].

MOVEMENT OF WATER IN SOIL-PLANT-ATMOSPHERE SYSTEM AND DEVELOPMENT OF MOISTURE STRESS IN PLANTS

Water moves in liquid form from soil to the leaves through the root and stem. In the intercellular spaces in the leaves, water is converted to vapor form and crosses the leaf epidermis and air boundary layer and finally to the atmosphere. The major portion of water from leaves is lost through the stomata. The extent of stomatal opening does regulate the water loss from plants as well as the assimilation of carbon dioxide [24].

Absorption of water by plants may take place by three processes: (a) osmotic uptake, which depends on the osmotic potential of the cell sap; (b) metaosmotic uptake, which depends on the binding of water by adsorptive forces in the cell; and (c) non-osmotic or active uptake where water movement is caused by energy released in respiration. The first two processes are passive, whereas the third process is an active. However, the bulk absorption as well as the transport of water is very much dependent on passive movements downhill in terms of the free energy status or the water potential. The leaf and shoot water potentials must be lower than the root and soil water potentials for water absorption and transport to the leaves. The resistance created by the transporting channel also has significant role in regulating the rate of water absorption and translocation. Transpiration, by reducing the leaf water potential, gives rise to the water potential gradient for uptake. As the water uptake is dependent on transpirational losses, the higher evaporative demand from the atmosphere leading to higher transpiration results in a lower leaf water potential [24]. Obviously, the plant water potential is determined collectively by soil, plant, and atmospheric factors, which is given as [25]

$$\psi_{leaf} = \psi_{soil} - T\,(R_{soil} + R_{root} + R_{shoot})$$

where ψ_{leaf} = leaf water potential, ψ_{soil} = soil water potential, T = transpiration rate, and R = resistance of the soil, root, and shoot to the liquid water flow. The equation emphasizes that, for a given leaf water potential the soil water potential must be more positive by a factor of the transpiration rate times the sum of the liquid phase resistance in the soil plant pathway [26]. A low leaf water potential may be caused by soil drying (low soil water potential, high transpiration, high soil resistance, or a combination of two or more of these factors). Plants in general cannot store moisture; hence, a control mechanism is required to regulate the plant water status, which may be achieved by regulating transpirational losses, absorption of water through roots, or a combination of both. When transpirational losses exceed the absorption, plants experience moisture stress [15].

EFFECT OF MOISTURE STRESS ON WATER RELATION PARAMETERS OF PLANTS: POSSIBLE MECHANISM OF SENSING MOISTURE STRESS

A voluminous literature is available to explain the influence of moisture stress on water relation parameters; that is, the relative water content, the leaf water potential and its components, and various plant processes [27–31]. With most crop plants, the maintenance of function and ultimately survival depends on the maintenance of a relatively high water content of the protoplasm.

Under a moisture stress condition, derangement in the leaf water potential and its components takes place [Table 1] [32]. It is reported that the water relation and transpirational parameters are closely correlated [Table 2], and in the laboratory, where equipment to quantify plant water potential and its components are not available, determination of the RWC is still a valid parameter to quantify the plant water status [27,33,34]. In wheat genotypes, a linear, quadratic, or sigmoidal relationship has been reported between the RWC and the leaf water potential [35]. However, in maize, when

Table 1 Effect of Moisture Stress on Transpirational and Water Relation Parameters of Two Genotypes of Wheat

	Genotype			
	Kharchia 65		Kalyansona	
Parameter	Control	Moisture stress	Control	Moisture stress
Transpiration rate ($\mu g\ cm^{-2}\ sc^{-1}$)	12.59	2.76	7.26	2.43
Leaf conductance ($cm\ sc^{-1}$)	0.72	0.13	0.46	0.21
Leaf water potential (−MPa)	1.23	1.45	1.26	1.45
Osmotic potential (−MPa)	1.67	1.69	2.95	2.59
Turgor pressure (MPa)	0.45	0.24	1.69	1.14

Plants were raised on normal Hoagland solution (osmotic potential − 0.33 MPa). After 25 days, moisture stress was imposed by polyethylene glycol − 6000 (osmotic potential − 0.61 MPa). Observations were made after 14 days of stress.
Source: From Ref. 32.

Table 2 Correlation Coefficient (r) Between Various Components of Water Relation and Transpirational Parameters in Wheat

Parameter	Osmotic potential	Transpiration rate	Leaf conductance	Relative water content
Water potential	0.97	0.55	0.51	0.87
Osmotic potential		0.77	0.69	0.93
Transpiration rate			0.98	0.71
Leaf conductance				0.71

Two wheat genotypes, C306 and Kalyansona, were raised in pots. After 70 days of sowing, irrigation was checked in some of the pots, observations were recorded for above parameters on control, and stressed plants at an inveral of 2 days for 22 days and correlation between various parameters were determined.
Source: From Ref. 27.

the water supply is withheld from only a part of the root system, the leaf expansion rate is sometimes decreased with no apparent change in the leaf water status [36]. In wheat, separation of seminal and nodal root systems resulted in a significant decrease (14%) in the leaf elongation rate of the main stem and first tiller even when both the systems were well irrigated. In the same experiment, stress of the nodal or seminal rootzone increased the nodal root growth [37].

During periods of water deficit, the amount of water lost depends on the way in which the cells respond to the reduction in the water potential. Where cells are turgid, perhaps the most common response is loss of water and a decrease of the turgor and osmotic potentials until a new equilibrium is established. The rate of change of the relative cell volume or of the water content with a change in the water potential then depends on the elasticity of the cell walls and the initial osmotic potential [38]. The potential difference may be partly or fully eliminated by a decrease in the osmotic potential due to an increase in the amount of solute in the protoplasm; that is, due to

osmotic adjustment. The osmotic adjustment may lead to little change in the turgor and water content [35], maintain extraction of water from the soil [39,40], stomatal opening, and photosynthesis [41]. The factor(s) that induces solute accumulation in response to increasing water deficit are not known in higher plants. A reduction in cell volume is one cause [41], whereas other causes might be continuous accumulation of photosynthates and reduced leaf growth under moisture stress, as photosynthesis is less sensitive to moisture stress than the leaf growth [39].

Attempts to correlate plant growth with the water potential indicated that although movement of water in the soil-plant-atmosphere system and transpiration may be dependent on it, but morphological and physiological processes are closely correlated to the osmotic and turgor potentials [15]. There are, however, a number of reports that leaf growth, leaf conductance, and photosynthesis decrease as the soil dries even when the leaf turgor is maintained and before there is any significant change in the total water potential of the plant [31,42–53]. All these observations point to the fact that the leaf turgor and osmotic potential are not the only transducers of water deficit for growth, transpiration, and photosynthesis. It now seems likely that, at least in maize and sunflower, soil drying results in the increased synthesis of abscisic acid (ABA), which moves in the transpiration stream to the shoots to inhibit stomatal opening and leaf growth [50,51,54]. The evidence of the involvement of root signals in the response of plants to soil drying results from field observations and from the use of three experimental systems: i.e., (a) split roots [37], large soil columns [36,50,51], and a whole-plant pressure chamber [46,55]. Root exposure to a drying top soil may cause the induction of a root hormonal signal to the shoot, thereby causing a reduction in plant assimilation and growth [56–62]. As soil moisture is further depleted and/or the atmospheric evaporational demand increases, a hydraulic gradient develops between the leaf and the drying soil. This gradient incites the development of a leaf water deficit followed by turgor loss [31]. ABA accumulates in the shoot as a result of influx from root [63,64] causing stomatal closure, a reduction in assimilation, and reproductive failure [65]. A comprehensive model describing involvement of the soil, plant, and atmospheric variables and incorporating the ABA in regulating the soil–plant–water–relationship is given in Figure 2 [61].

The concentration of ABA in the xylem stream has been found to be a sensitive indicator of the water status of the soil around the roots of the plant. In certain studies, it has been found that the stomata close down before any detectable change in the concentration of ABA. It is observed that, under drought conditions, accumulation of some large molecular weight substances (not ABA) other than normal ones takes place [66]. Involvement of more than one substances in sensing soil moisture stress in plants has been reported [67].

Additional evidence that several chemical components may be involved in chemical signaling comes from studies on plants where mycorrhizal symbiosis occurs [68–72]. It is well known that mycorrhizal association influences the ion balance and hormone balance of the plant and there is an interacting effect of ABA and cytokinins on the growth and stomatal behavior of mycorrhizal plants [69]. It is proposed that probably a reduced supply of cytokinins and perhaps other promoters from the roots in drying soils contribute to the signaling process.

CONCLUSIONS

Plant water relation studies are attaining greater significance in order to explain the movement of water in the soil-plant-atmosphere system, the influence of moisture stress on morphophysiological and biochemical parameters, and the mechanism of moisture stress resistance in plants. Although the quantification of moisture in plants on the basis of the energy status (i.e., water potential and its components) seems to be more realistic, but still there is a need for a method which is rapid, less cumbersome and with the least errors, and suitable for a wide range of experimental conditions. The concept that, under the moisture stress condition, a change in the turgor pressure and the osmotic potential of the leaf leads to derangement in the morphological and biochemical processes of plants, but involvement of ABA and other hormones in sensing moisture stress has shifted attention from

the shoot to the root of the plant to investigate the process of sensing and the plant response to moisture stress. Such studies certainly have not eliminated the role of the plant water relation parameters, especially the turgor pressure and the active accumulation of solutes in regulating the physiological and biochemical processes and confering moisture stress resistance in plants. The scenario has changed with respect to the attention of scientists from the shoot to the root of the plant in characterizing the signal(s) and understanding the mechanism of moisture stress resistance in plants.

Crop Responses to Salt Stress: Seawater Application and Prospects

M. P. Reddy and E. R. R. Iyengar
Central Salt & Marine Chemicals Research Institute
Bhavnagar, India

INTRODUCTION

Salinity is a significant environmental stress for crop plants. Soil salinization may arise from intrinsic soil components, the excessive use of low-quality water for irrigation, or the excessive use of fertilizer. It was estimated that salinization impacts between 4×10^8 to 9×10^8 ha of land, an area that is three times greater than the land currently used for agriculture [1]. With a decline in the quality of irrigation water, salinization of arable land is increasing [2,3]. Salinity was shown to account for about 70% of the losses in crop yield [1,4,5]. The growing demand for food and plant products to feed the expanding world population with ever-decreasing soil resources and dwindling fresh water supplies warrant the need for biological and technological solutions to overcome the physiological limitations that restrict crop productivity. The technological approach is to use advanced soil management and irrigation technology [1], and the biological approach is to select and improve the species of plants, introgression of desirable agronomic traits [6], if necessary, transfer of salt-tolerant characters into crop plants, and development of halophytes as alternative crop [7].

The majority of crop plants are glycophytes [8–10], and the manipulation of glycophyte plants to adjust and produce under conditions of moderate or low levels of salinity is important [11]. Efforts were made to improve salt tolerance through breeding involving introgression of the genetic background from wild salt-tolerant relatives to cultivated plants [2,10,12–14]. However, the progress is very slow, primarily due to an inadequate knowledge of the genetics and mechanism of salt tolerance [15].

Recent advances in plant biotechnology may play a crucial role in the development of superior crop plants with better environmental stress tolerance and higher yield potential under stressful conditions. Appropriate research strategies are, however, required to harvest the fruits of the recent explosion of information in the field of molecular genetics.

SEED GERMINATION AND PLANT GROWTH

Salinity, whether natural or induced, is a widespread environmental stress that limits the growth and development of salt-sensitive plants [16,17]. Plants vary greatly in their tolerance to salts. Halophytes can complete their life cycle under saline conditions [18]. Glycophytes, although generally more sensitive to salinity, exhibit differences between species and even varieties [16,19–22]. Such genotypic variation has been explained for certain crops. However, the performance of crops under saline conditions depends on seed germination and establishment and also tolerance at later stages of growth [23,24].

When the seeds are sown in an environment with a high concentration of salt, both the rate and percentage of germination decreases [19,22,25]. The capacity of seed germination relates to the extent of imbibition of solutes by the seed and the resultant activity of the embryo. Thus, water absorption plays a key role. In the growth phase, mobilization of reserve food from the cotyledons and their transportation to the growing embryo becomes a critical factor. Weakening of the physical restraints imposed by the surrounding endosperm tissue on the embryo can play an important role in germination, suggesting that radicle protrusion across the seed relies on weakening the endosperm wall hydrolysis [26–28]. According to Fooland and Jones [29], endosperm additive and testa dominance effects were highly significant and the embryonic genotype played no significant role in germination performance under saline conditions.

The reduction in germination under saline conditions also could be attributed to the increased osmotic pressure of the soil solution, which diminishes the water absorption rate, leading to moisture stress in the seeds [30] and mobilization of food reserves [31] by effecting the enzymes responsible for hydrolysis of reserve food material and its translocation to the growing embryo axis.

Iyengar et al. [19,32] extensively studied the varietal differences in different crop plants under saline conditions and reported the different behaviors of varieties of a particular crop to salinity. Maliwal and Paliwal [33] demonstrated significant varietal differences in the salt tolerance of important crops during germination. Patolia [34], Shannon and Noble [22], West and Taylor [35] also observed significant varietal differences in the salt tolerance of wheat and clover during germination and seedling growth. Differences in the salt tolerance of *Arabidopsis thaliana* mutants was correlated with differences in the absorption of reactive cations (Na^+, K^+) during imbibition [21].

It is known that salt stress interrupts metabolic activity by ion excess, imbalance, and interference of toxic ions on the uptake of essential nutrients [36], which are detrimental for seed germination under saline conditions. The recent work of Thomas et al. [37] on *Arabidopsis* shows that metabolic engineering may be a potential approach for the improvement of salt tolerance. A better understanding of the underlying mechanism involved in seed germination and the subsequent growth under saline conditions is essential to confront this agronomic problem.

SALINITY-TOLERANCE MECHANISM

Salinity in the soils and ground waters has become a major environmental issue [38], and excessive salinity in the soil or irrigation water has been considered as the main limiting factor for the distribution of plants in natural habitats [4,5]. In irrigated areas where decreasing pasture yield due to salinity is a major concern, there is a need for plant species with greater salt tolerance [22]. The presence of halophytes (natural salt-tolerant plants) which can tolerate the 0.5 M NaCl present in seawater [39–41] indicates that there is a potential to increase the salt tolerance of plant species for which understanding the mechanism of salt tolerance is very important. Despite its importance, the physiology and molecular basis of salt tolerance has been investigated less than that of tolerance to water and temperature stresses [15,16,42–47].

Morphological Adaptations

The response of plants to salt stress is complex. It varies with the salt concentration, the type of ions, other environmental factors, and the stages of plant development. The root may be considered

to be the plant's sensor in the soil, since it is through the root that the whole plant is affected by changing soil conditions.

Besides growth inhibition, salinity causes several specific structural changes that disturb the plant water balance or status [45]. These structural changes include fewer and smaller leaves, increased succulence, thickening of the leaf cuticle and surface layers of wax, reduced differentiation and development of vascular tissue, increased development of tyloses, and earlier lignification of roots. These responses vary with plant species and the type of salinity [43]. Information on the causes and benefits of these structural changes in response to salinity is inadequate.

Chloride salinity causes succluence in many plant species [48–49]. Succulence, whcih is manily due to the increased elongation of palisade cells, tends to dilute the interal ionic concentration and reduce the leaf surface significantly.

The salinity effects on vascular tissue seem to be structural adaptation that reduces water conduction, possibly in relation to lower transpiration losses. Reduced transpiration under saline conditions has been reported for many plants [45–48].

Since roots are directly exposed to the saline environment, it seems remarkable that the root growth is usually affected less [45–50] than the vegetative shoot growth. The resultant decrease in the shoot/root ratio presumably improves the water balance by maintaining the potential for water absorption while reducing transpiration. Studies have shown that plants can tolerate high-salinity levels in part of the rootzone if the remaining roots are exposed to low-salinity levels [51].

Effects on Metabolism

Studies on the responses of the growing regions to salt stress have been limited. The results of Munns et al. [52] with barley and Taleisnik-Gertel et al. [53] with tomato suggest that the primary cause of reduced shoot growth under saline conditions is located in the growing tissues, not in the mature photosynthetic tissues. Salt inhibition of cell division or enlargement (or both) in the growing regions may be direct or indirect [16,54]. Salt may affect growth indirectly by decreasing the rate of photosynthesis or by preventing growth factors from reaching the growing regions [16,52]. The amount of photosynthates reaching the growing regions may decrease because of the inhibition of photosynthesis due to stomatal closure [55] or by the direct effect of salt on the photosynthetic apparatus. In addition, the transport of photosynthates in the phloem may be inhibited. Results with barley [16,52] suggest that inhibition of growth involves a water deficit rather than a direct adverse effect of ions on metabolism. The greater inhibition by salt on the growth of salt-sensitive compared with salt-tolerant tomatoes could result from an adverse water balance or from the direct toxic effects of the ions [53]. Mass and Neiman [43] suggested that salt ions can damage growing cells indirectly by depriving them of essential substances. Leopold and Willing [56] reported various symptoms of salt damage that may result from membrane damage by salt ions. Salt also affects the cellular and nuclear volume [57] and inhibits or stimulates nucleic acid and protein synthesis [54–57].

Regulation of Ion Contents

The regulation of transport and distribution of ions in the various organs of the plant and within the cell is an essential factor of the mechanism of salt tolerance. The knowledge on the regulation of ions in the whole plant has been extensively reviewed [16,22,42,45,58].

There are larger differences in ion concentration between different parts of the same plant. Older leaves of glycophytes, grown at high salinity, usually have a higher Cl^- concentration than the younger leaves of bean [59] and soybean [60]. These trends are probably due to a combination of a rapid volume increase in expanding leaves and the prolonged intake of the ions by expanding leaves via the transpiration stream. The latter could account for the large increases in ion (i.e., Cl^-) concentrations in older leaves. Maize plants accumulated 7–10 times more Na^+ in the mesocotyl than in shoots and 2–3 times more in mesocotyl than in roots [61]. Rice, although morphologically

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

distinct, concentrated four times more Na^+ in the sheath than in the leaf laminae [62]. Na^+ and Cl^- concentrations were more in older leaves, whereas K^+ was greater in younger leaves [63]. Two rice cultivars differing in salt tolerance differently accumulated Na^+ and K^+. A tolerant variety (Pokkli) used Na^+ exclusion, whereas a sensitive variety (IR29) accumulated significantly more Na^+. However, in the absence of K^+ in the medium, the tolerant variety also increasingly accumulated Na^+ similar to the sensitive variety [64].

In rice, salt tolerance was found to be through Na^+ exclusion and increased the absorption of K^+ to maintain a good Na-K balance [63–65]. In a relatively salt-tolerant variety, the growth is faster than the absorbed Na^+, so that the absorbed Na^+ undergoes a greater dilution than the sensitive variety [66,67].

The capability of plants to maintain an adequate K^+ content under saline conditions is enhanced by an ample K^+ supply. Salt-adapted *Sorghum* plants [68] were able to grow in 0.3 M NaCl in the presence of Hogland solution supplemented with K^+. The plants did not grow in 0.3 M NaCl without half-strength Hogland solution. Salt-tolerant glycophytes, such as *Atylosia sericea* and *Glycin max c.v. Lee*, maintained a constant K^+ content or even increased in the presence of NaCl [69,70], whereas sensitive glycophytes fail to maintain the K^+ content in the presence of high salt concentrations [69–71]. Such a decrease in the K^+ content may indicate damage [71]. However, Leigh and Wyn Jones [72] observed a decrease in the K^+ content in *Lyopersicon esculentum, Solanum pennelli*, and *Sorghum bicolor* with an increase in external salt concentrations without concommitant damage. The maintenance of an adequate K^+ content under saline conditions seems to be dependent on K^+-selective uptake as well as selective K^+ and Na^+ compartmentalization within the cell and distribution in the shoot. Glenn et al. [58] are of the opinion that salt tolerance of *Atriplex canescens* genotypes depends on initial leaf Na^+ levels.

Seemann and Chritchley [73], using x-ray microanalysis, found little difference in the cytoplasm, chloroplast, and vacuolar Na^+Cl^- ion levels in bean plants exposed to 150 mM NaCl even though the growth was reduced to 70%. A study with a halophyte (*Salicornia* species) showed that the compartmentation of ions takes place in different tissues. The ion content was greater in spongy mesophyll cells than in palisade cells [74] where active photosynthesis takes place. This ability to regulate ion concentration through compartmentation is an important aspect of salt tolerance.

The rate of Na^+Cl^- transport are much higher in salt-sensitive varieties at the initial seedling stage causing a greater accumulation of ions in the shoot [63], whereas in *Aster tripolinum*, x-ray microanalysis has revealed that the sodium content of the stomatal guard cells remains much lower than that of other leaf cells when plants were grown at high salinity. Large amounts of sodium did, in contrast, accumulate in the epidermal and subsidiary cells and particularly in the mesophyll cells suggesting that a mechanism exists to limit the extent of entry into the guard cells and that the ability of the guard cells to restrict the intake of sodium ions may be an important component of sodium-driven regulation of transpiration and hence salinity tolerance [75,76].

Many salt-tolerant plants exhibit greater K^+/Na^+ selectivity than salt-sensitive plants. This is usually manifested by a higher K^+/Na^+ ratio in tolerant plants and is thought to be a significant salt-tolerance adaption [77–79].

The mechanisms that are involved in K^+/Na^+ selectivity are not clear, but they may include increased extrusion of Na^+ and increased uptake of K^+. The uptake of K^+ was shown to increase in cells adapted to grow in saline media [80]. In suspension cultures of *Brassica napus* and *Nicotiana tobaccum*, enhanced NaCl tolerance has been attributed to the capacity of the selected cells selectively to take up K^+ [81–82]. These results indicate that at the cellular level an increase in K^+ uptake and a decrease in Na^+ accumulation are involved in K^+/Na^+ selectivity. The enhanced K^+ uptake is an adaptive mechanism that allows the cells to evade K^+ starvation in the presence of higher levels of NaCl. There are indications that a myraid of mechanisms are involved in K^+/Na^+ selectivity, and the mechanisms employed may change with genotypes. A molecular model for Na^+ and K^+ fluxes has been proposed in yeast, and two genes involved in K^+ and Na^+ transport system have been cloned [83].

Osmoregulation

When exposed to a saline environment, plants generally accumulate inorganic ions commonly present in the environment, but these become detrimental to cellular biochemistry at high concentrations and must be sequestered into the vacuole. To keep the cytoplasm osmotically balanced, the plants usually accumulate organic molecules such as proline, glycinebetaine, dimethyl sulfonium, propionate, fructanes, trehalose, and polyamines such as mannitol, sorbitol, and myo-inositol, which are correlated with salinity tolerance of plants [84–90] and termed as ''compatible solutes.'' In osmotic adjustment, they act as osmolytes to facilitate the retention of water in the cytoplasm and the protection of membranes, protein complex, and cellular structures [44].

The free proline content in glycophytes is normally negligible compared with halophytes, and their concentration increased markedly in plants subjected to salt stress [90,91]. Simultaneous treatment of salt-tolerant cells of tobacco with high temperature (40°C) and NaCl (170–340 mM) resulted in transient overproduction of proline accompanied by an increase in thermal tolerance [90]. The transient initial raise in the proline content under stress and its further decrease can be explained by protein transmethylation to form derivatives (N-methyl proline, proline betaine, hydroxyproline betaine) capable of protecting the cell under more severe stress [92]. Salt-tolerant cell lines are capable of overproducing methionine and have a high transmethylating activity [93]. Moreover, salt-tolerant cells are capable of accumulating betaines under long-term salt stress, and they could compensate for a dramatic drop in the proline content of NaCl-containing medium at 40°C [90].

The accumulation of proline in response to environmental stress indicated that its synthesis is a nonspecific response to a decreased water potential. The role of proline during stress is a subject of controversy and interesting because it accumulates to very high levels under adverse conditions [94].

Testing of high concentrations of proline and glycinebetaine on isolated enzymes has shown that they have essentially no deletarious effects, and in fact they protect various enzymes against a range of perturbing effects [95]. It appears that osmoregulating substances affect the conformation of enzymes, thereby stabilizing the active conformation and in this way protect enzymes against conformational perturbances caused by ions [86,96]. These metabolites may also replace water at the surface of biopolymers, stabilize macromolecular structure, or act in scavenging of radical oxygen compounds [15,44,97,98]. The protection through mass action has been termed osmotic adjustment [44,99].

Biochemical pathways that lead to the production of some of these osmoprotectant solutes are known [15,100]. Genes encoding several of the relative enzymes have been cloned, and expression of specific genes indicated that tolerance is conferred by genetically encoded mechanisms. Genetic modification of plant species to increase the contents of the compatable solutes mannitol [101], fructans [89], proline [88], and glycinebetaine [102] have revealed that overproduction of these compounds is strongly correlated with resistance or tolerance of plants to abiotic stresses. Thus, the genetic modification of plant species to increase the content of osmotic solutes that is now technically possible may be one of the approaches to increase salt tolerance in plants. However, transfer of individual genes confered only marginally increased stress tolerance strategies are to be developed to transfer several or many genes at once to increase the salt tolerance of plant species reasonably [15].

Membrane Changes

Membranes form barriers between the plant and its environment, organelles, and tissues. They are the major sites for controlling active and passive solute fluxes, and thus membranes may be of special importance to plants for regulating the ion content. Mineral imbalances of the root environment, such as those commonly encountered by plants in salty soils, often affect the structure and chemical composition of root cell membranes [103–105] and may thereby interfere with nutrient aquisition, transport, and compartmentation.

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

Sterols and phospholipids are the principal structural components of the lipid matrix of the plasma membrane and tonoplast [106]; the two membrane systems at which salt-tolerance mechanisms are likely to operate [107]. The significance of the quality and quantity of membrane lipids to control ion transport in salt-tolerant plants has been reviewed [56].

The free sterol content was higher in the roots of salt-tolerant grape variety as compared with their sensitive variety [108]. The levels of free sterols and sterol esters in the roots of salt-tolerant *Plantago maritima* and *P. coronopus* was maintained on exposure to salinity and it decreased in salt-sensitive *P. media* [109]. In wheat, salinity increased the free sterol composition (cholesterol, stigmasterol, and brassisterol) and decreased the levels of phospholipids and phosphatidyl choline [110]. In *Kostletzkya virginica*, the relative percentage of sistosterol decreased, whereas that of camposterol increased with an increase in salinity [105]. The enhanced free sterol content in the root of salt-tolerant plants contribute to a higher molar ratio of free sterol/phospholipids. Changes in the free sterol/phospholipid ratio affect the membrane permeability minimizing the potassium leakage from cells and, thus, energy required for efficient transport and subcellular compartmentation [105].

Free sterols also are known to interact with the fatty acid chains of phospholipids and restrain their mobility [111]. Thus, the higher proportion of stigmasterols in plants under stress may have led to lower mobility of lipid molecules. In addition, the looser binding of stigmasterol to phospholipid acyl-chains might alter the lipidic environment of intrinsic membrane enzymes [112], altering the protein-phospholipids interactions, in a similar way as pH affects the solubility of aqueous proteins [113]. Interaction with membrane phospholipids through their constituent fatty acids with sterols and intrinsic membrane proteins [111] may change the activity of intrinsic membranes/proteins such as H^+ ATPase [114,115].

Oxidizing Enzymes

When plants are subjected to environmental stress, the balance between the production of reactive oxygen species such as superoxide ($O_2^{\cdot-}$) hydroxyl radical (—$^{\cdot}$OH), and hydrogen peroxide (H_2O_2) and the quenching activity of antioxidants is upset, often resulting in an oxidative damage [116–119], suggesting active oxygen species play an important role in the mechanism of stress injury. Both enzymatic and nonenzymatic mechanisms have evolved to overcome the potential toxic effects [118,119]. Plants with high levels of antioxidant enzyme activity are reported to have greater resistance to this oxidative damage [116,120].

The role of superoxide dismutase (SOD) in protecting aerobic organisms against oxidative damage is well established [117]. An increase in the activity of oxidizing enzymes increases salt tolerance [121–124]. Singha and Choudhuri [125] have reported that, in *Vigna catjang* and *Oryza sativa*, the $O_2^{\cdot-}$ radical and H_2O_2 could play an important role in the mechanism of salt injury. Gossett et al. [118] examined the relationship between NaCl tolerance and antioxidant enzyme activities in different salt-tolerant and salt-sensitive cotton cultivars and reported that leaves from the NaCl-tolerant cultivers contained significantly greater constitutive levels of catalase and NaCl induced peroxidase and glutathione reductase. In contrast, callus tissues from the NaCl-sensitive cultivars showed no difference from that of nonstressed leaves in the activity of these enzymes. The NaCl-induced enhancement of ascorbate peroxidase in adapted callus indicates that these cells have a higher capacity for the decomposition of H_2O_2 generated by SOD [126]. The increase in the activities of oxidizing enzymes may be essential for the survival of plants under saline conditions to overcome the peroxidation of membrane lipids known to occur in plants under adverse conditions [116,120,127].

Recent attempts to improve salt tolerance through the overexpression of enzymes involved in scavenging reactive oxygen intermediates by gene transfer technology has provided new insights into the role of these enzymes [122,123,128]. Physiological and genetic evidence clearly indicates that the reactive oxygen intermediate scavenging system of plants is an important component of stress tolerance, and raised hopes that in future this approach can be used to improve the stress tolerance of economically important plants [122–124].

Adaptation to Salinity at the Plant Cell Level

Plant cell culture and regeneration of plants from potential cell mutants has led to the expectation that these techniques could be used to generate useful mutant traits from plant cell cultures. Stress-tolerance selection in plant cell cultures has suggested that salt- and water-stress tolerance may be characteristics which are linked in the selection processes at the cellular level and therefore can be manipulated in culture [129–131].

Recent reviews of Tal [132], Dracup [133], Binzel and Revueni [134], and Hasegawa et al., [135] provide extensive summaries of research that has been carried out toward the goal of utilizing cell line selections to obtain salt-tolerant plants. Cell lines were selected for many plant species which can grow in the presence of high concentrations of NaCl [81,136–139]. In many instances, tolerance to salinity was lost when the cells were recultured in the absence of salt, and the plants regenerated from these plants did not show increased salt tolerance [32,140]. However, McHughen [141] in flux, Waskom et al., [142] in barley, and Winicov [130] in alfalfa demonstrated improved tolerance to salt from the plants regenerated from the selected cell lines as compared with the original explant source, whereas Flowers et al. [143] illustrated an example where tolerance in culture cells exceeded that exhibited by the whole plant. Comparison of the salt tolerance of the whole plant and cell cultures derived from them indicated that, for certain species, tolerances were similar for whole plant and cell cultures [144,145], indicating salt tolerance of at least certain species was based on an intrinsically cellular process and established the use of cell cultures as a means to elucidate a cellular mechanism of salt tolerance. However, the results of Smith and McComb [145] and Cherian et al. (personal communication) has shown that tolerance at the whole-plant level is substantially greater than the cell lines, suggesting, in some plants, anatomical organization is responsible for salinity tolerance. Plants regenerated from salt-tolerant cell lines did not show increased tolerance to NaCl stress [80,146] even though cell suspensions obtained from these regenerated plants retain their tolerance to NaCl [80,146], indicating both cellular and whole-plant traits contribute to NaCl tolerance, and the adopted cell lines can contribute to our understanding of the physiological and biochemical mechanisms that are the basis for salt tolerance. These results point out the necessity of integrating information regarding the mechanism of salt tolerance derived from studies at the cellular level with those from the whole plant.

Adaptation of Cells in Suspension Culture to Salinity

Salt-sensitive cells in suspension culture can, in some cases, be adapted to grow at higher levels of salinity by a stepwise increase in NaCl and can therefore serve as useful models for studying the mechanisms of salinity resistance at the cell level. Using this technique, tobacco cells were adapted to grow in a medium containing 500 mM NaCl [80,81,146]. These cells retained their adapted character even if grown for many generations in the absence of salt. The process of adaptation of the cells to salinity is accelerated by the addition of abscisic acid (ABA) to the medium.

Maintenance of intracellular K^+ concentrations that are not growth limiting in an environment of high Na^+ is characteristic of the NaCl-adapted cells of tobacco. Potassium uptake into NaCl-adapted cells was 1.5 times higher than NaCl- unadapted cells at 0 NaCl and 3.5-fold greater when cells were exposed to 160 mM NaCl. At lower NaCl levels, salinity caused an increase in intracellular Na^+, whereas intracellular K^+ was decreased. Above 200 mM NaCl in the medium, the intracellular K^+ remained constant, whereas intracellular Na^+ increased gradually. According to Lerner [96], there seems to be a mechanism limiting the K^+ and the Na^+ accumulation in these cells. The difference in the net K^+ uptake between adapted and unadapted cells is primarily due to the higher rate of entry than the reduced K^+ uptake into adapted cells [80,146]. K^+ uptake and K^+ secretion have been shown to be influenced in some systems by turgor pressure [147,148].

An alteration in the cell wall structure [81]; composition [149]; differences in the accumula-

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

tion of amino acids, sugars, and organic acids [150,151]; changes in the activity of enzymes; expression of new isoenzymes [152]; and plasma membrane transport [153] of salt-adapted cells was reported.

Integrating results from cell studies with those emerging from research with the whole plant should result in a more comprehensive understanding of the complex array of mechanisms that together enable a plant to tolerate salinity. Cell culture studies enable us to focus on the influence of environmental stimuli on genetic expression without the added complexity of developmental and tissue-specific controls.

Proton Pump

Plants that grow successfully in saline soils must maintain a much higher K^+/Na^+ than generally present in the surrounding medium [16,154]. Transport of ions at the plasma membrane and tonoplast is thought to play an important role in the process by which certain plant cells maintain a very high ratio of K^+/Na^+ in the cytoplasm [154]. Minerals enter the root through transport proteins located in the root plasma membrane. The detailed mechanism of transport of K^+ and Na^+ across the plasma membrane and tonoplast are not fully understood. However, the net effect of the ion transport process is selectively to take up K^+ into the cytoplasm and to extrude Na^+ both into the vacuole and to external medium.

The plasma membrane H^+ ATPase is the primary pump of plant cells that drives all secondary transport systems [155–157]. Cloning, expression, the structure-function relationship of the plasma membrane P-type H^+ ATPase [157,158], the vacuolar H^+ ATPase [159], and vacuolar H^+ ATPase [160,161] have dramatically increased the knowledge about the transport proteins which energize secondary ion transport, regulation of cell turgor and cell wall extension, and intracellular pH regulation [157]. H^+ ATPase has been shown to be involved in salinity tolerance [162]. Plant cells exposed to a high ionic environment increased proton fluxes [147,148,163] accompanied by changes in the activity and kinetic properties of the plasma membrane H^+ ATPases [164,165]. In suspension cultures of *Atriplex nummularia*, the steady-state transcript levels of P-type H^+ ATPase increased only when adapted cells were expressed to NaCl, and the induction was dependent on the developmental stage of the cultured cells [162]. The in vivo activity of this ATPase, as assessed by proton flux measurements, seems to increase during osmotic adaptation in tobacco [163] and carrot [148] cell cultures. However, salt stress has no effect on in vivo activity of the ATPase in sunflower roots [166]. In citrus cells adapted to grow in 200 mM, NaCl the activity decreased [167]. Proton efflux from plant cells has not been rigorously demonstrated to correspond to the activity of plasma membrane H^+ ATPase [156]. However, Braun et al. [164] have demonstrated that salinity during growth increases the in vitro activity of plasma membrane H^+ ATPase in *Atriplex nummularia* (halophyte). Apparently this phenomenon has not been reported in nonhalophytes.

The transport of Na^+ across the tonoplast and its accumulation in the vacuoles is an important mechanism of plant tolerance to salinity [47,168,169]. The Na^+/H^+ antiport mechanism catalyzes the accumulation of sodium into the vacuole, and other antiport systems may accumulate, for example, sugars, amino acids, and phosphates [156,170]. The functionality of the Na^+/H^+ antiport system depends on the establishment of a proton gradient generated by the vacuolar electrogenic pumps [171,172]. An Na^+/H^+ antiport activity has been detected in the tonoplast vesicles from the leaves of halophytes such as *Atriplex gmelini* [173] and *Mesembryanthum crystallinum* [174], as well as in roots of *Atriplex nummularia* [175]. In glycophytic plants, it has been reported to occur in tonoplast vesicals isolated from salt-tolerant species such as sugar beet in the storage tissue [176], the root of barley [177], cotton [169,175], *Plantago maritima* [178], and *Cathrantus roseus* [179].

Comparmentation of Na^+ Cl^- at the vacuole also has been investigated using x-ray microanalysis and efflux kinetic analysis [180] in different plant tissues, and it has been reported that the capability for vacuolar compartmentation correlates with the NaCl tolerance. The vacuolar ATPase

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

seems to be induced by salt stress in barley roots [181]. In tobacco, the specific activity of this enzyme is increased during NaCl adaptation, but the amount of protein quantified by antibodies decreased [152]. According to DuPont [172], the regulation of vacuolar ATPase during salt stress is due to increased coupling between proton transport and ATP hydrolysis. The induction was not dependent on protein synthesis, and activation by posttranslational modifications has been suggested. However, activation of the antiport mechanism by salt in sugar beet correlated with the enhanced synthesis of a 170-kDa tonoplast polypeptide. Antibodies against this protein inhibited antiport activity, suggesting that it is a component of the system [182]. A polyclonal antiserum raised against the denaturated 170-kDa protein inhibited antiport activity in vitro, indicating that the 170-kDa protein is identical with a part of the Na^+/H^+ antiport.

The tonoplast H^+ ATPase activity increased substantially in a facultative halophyte within 8 h after treating 4-week old plants in the C_3 state with 400 mM NaCl. This rapid effect was confined to the roots and young leaves, whereas in fully expanded leaves, only subunit C was increased, and this increase was transient suggesting that like P-type H^+ ATPase, the V-type H^+ ATPase also depends on the plant developmental stages [183,184].

The driving force for the vacuolar accumulation of Na^+ in salt-stressed plants is provided by the H^+ electrochemical potential difference generated across the tonoplast by H^+ pumps. The salt-induced increase in tonoplast H^+ ATPase activity ensures the existence of a sufficient driving force for significant accumulation of Na^+ through the Na^+/H^+ antiport. An increased H^+ transport activity was considered to be homeostatic mechanism to cope with the salt stress, since it can provide the energy necessary for the operation of the Na^+/H^+ antiport in the vacuolar membrane required for the sufficient control of the cytosolic concentration of Na^+ [152,169,174].

Salt-Inducible Gene Expression

The identification of genes whose expression enables plants to adapt or tolerate salt stress is essential for development of salt-tolerant species. The recent focus on identification of genes induced under environmental stress led to an overexpanding list of cDNAs that detect upregulation of mRNA under conditions of drought/salinity [44,185–187]. Such genes with a known function broadly fit into the categories of energy metabolism ion transport, osmoprotectant synthesis, and macromolecules that contribute to the structural stability of cellular components. Many more other genes have been identified to date, although they lack functional identity. Second, minor components which may have important catalytic or regulatory role would be missed using the usual strategies of differential screening of cDNA libraries and two-dimensional protein gels by which only relatively abundant mRNAs and proteins can be isolated. It is becoming increasingly clear that these genes are responsible for only minor stress-tolerance effects. Strategies to identify regulating molecules that coordinately regulate these genes are required to elicit the greater effects on salt tolerance [44].

Serrano and Gaxiola [47] are of the opinion that most of the current research on salt tolerance can be considered as being ''phenomenological,'' because it concentrates on phenomena occurring during salt adaptation without establishing a hierarchy of physiological significance.

A new approach for identifying genes that function in plant salinity-stress tolerance is based on the use of a model, cellular-based, molecular genetic system (e.g., yeast, *Chlamydomonas*) to isolate plant genes that cause functional sufficiency for salt tolerance or complement the phenotype for salt-sensitive mutants [188–190]. Because this approach utilizes a screen for genes that can ''function'' in stress tolerance rather than screen for genes, whose expression is regulated ''in response'' to stress imposition. Further, the use of appropriate mutants in these systems makes it possible to dissect salt adaptation into more precise mechanistic entities from components of the salt-stress signal cascade to tolerance determinants that are regulated by this cascade; for example, the Na^+ transport system. The only problem to this approach is the need to generate a random collection of genetically modified organisms that need to be screened for salt tolerance.

Calcineurin (CaN) is a calcium-dependent protein phosphatase that a focal intermediate of the principal salt-stress signal cascade in yeast that regulates Na^+K^+ homostasis through the modulation of plasma membrane influx and efflux transport systems [188–191]. The expression in yeast of a constitutively active recombination form of CaN substituted for Na^+ stress signaling to induce salt-adaptation responses mediated through the regulation of ion homeostasis [189]. CaN-deficit mutants fail to convert the K^+ transport system to the high-affinity state that facilitates better discrimination for K^+ over Na^+ [83,188] resulting in substantially greater Na^+ accumulation and consequently a salt-sensitive phenotype. Similarly, expression of activated yeast CaN in transgenic tobacco plants resulted in increased NaCl tolerance [192]. Certainly these and similar studies will increase our underatanding of the basic cellular mechanisms contributing to salt tolerance.

FERTILIZER MANAGEMENT AND SALINITY TOLERANCE

With the increasing use of saline water or saline soils for agriculture, fertilizer application under saline conditions has been the subject of considerable interest, because salt damage to crops involves not only the osmotic effect but also specific ion effects [193]. It has been postulated that crop salinity tolerance can be improved by the use of suitable nutrients [194,195].

Salinity and fertility, because of their economic implications, have been the subjects of many greenhouse and field studies [194–197]. These studies were conducted to evaluate improved fertilization management as a means of alleviating growth inhibition by salinity. The effects of fertilization on nutrient uptake by plants, on the chemical composition of plant tissues, and on crop yield were studied under various salinity conditions and soil and crop interactions, since salinity and soil fertility are determined by the concentration of various ions in the plant rootzone.

The availability of N, P, and K in soil is too low for an economical yield of agricultural crops. The addition of fertilizer to maintain an adequate soil fertility level is therefore a standard practice in agriculture. The optimal concentration of nutrient elements in the soil is usually well below the level needed to cause a salinity effect. However, excessive application of fertilizer, particularly N and K because of their high solubility, may result in a salinity build-up in the soil. This is typically reflected in decline in yield when the fertilizer exceeds the optimum level.

The simultaneous presence of salts and nutrient elements in the rootzone can influence ion uptake by plants and affect the plant's chemical composition. Synergistic and antagonistic effects can increase or decrease the intensity of this process [198,199]. For instance, Award et al. reported [200] a positive effect of P on the yield of foxtail millet (*Setaria italica* L.), clover (*Trifolium alexandrinum* L.), and tomato (*Lycopersicon esculentum* L.) grown in saline soils, whereas Bernstein et al. [196] detected a reduction in the yield of corn (*Zea mays* L.) grown in sand cultures when a high salinity level was coupled with a high concentration of P. Champagonal [198] reported that 34 of 37 crops studied responded positively to P fertilizer. Application of higher dose of N fertilizer to crops growing under a saline environment has provided a beneficial effect by minimizing salt-induced damage [201].

INTERACTIVE AND ANTAGONISTIC EFFECTS OF SALINITY AND FERTILITY

Some cations influence the uptake of other cations by plants. Such antagonism occurs between K^+ and Na^+ and Ca^{2+} or Mg^{2+}. These effects may be involved in the occurrence of nutritional disorders in plant tissues. There is abundant evidence that Na^+ and the Na^+/Ca^+ ratio can affect K^+ uptake and accumulation within plant cells and organs [202]. Salt tolerance appears to be correlated with the selectivity of K^+ uptake over Na^+. Ben-Hayyim et al. [202] and Lauchli and Stelter [203] found

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

that the growth of cultured citrus cells in various NaCl and $CaCl_2$ concentrations was a function of the internal K^+ concentration independent of the NaCl concentration.

Ben-Hayyim et al. [202] reported that K^+ application can reduce the deleterious effect of salinity on plant growth and development. However, contradictory results on the effects of K^+ fertilization under saline conditions on field crops have been reported. Potassium uptake by plants is affected by high salinity and the Na^+ concentration in the soil.

Under saline conditions, a high Ca^{+2} supply alleviated the inhibition of NO_3 uptake [204] and increased Na^+/K^+ selectivity. Cramer et al. [205] and Martinez and Lauchli [206] showed that P translocation from roots to young shoots increased in the presence of an additional supply of Ca^{2+}. The effect of salinization on P nutrition depends on the available P in the substrate. A low supply of P to young tissues could become a limiting factor to their growth under saline conditions. An increased Ca^{2+} supply to the plant could be more efficient than P fertilization in restoring the P supply to young tissues under saline conditions.

High levels of $CaCl_2$ in the nutrient media resulted in a greater increase in the Ca concentration and reduced in the K^+ and Mg^{2+} levels in the tissues of bean plants. On the other hand, the addition of K as KCl increased K^+ and decreased Ca^{2+} and Mg^{2+} concentrations in maize plants [207]. Corn (*Z. mays* L.) plants tested in the same study responded differently to different Cl salts. Plant growth was better in the presence of $CaCl_2$ than with any combination of NaCl, $MgCl_2$, or KCl at a comparable osmotic pressure. A high Ca^{2+} content depressed the K^+ and Mg^{2+} levels; however, a mixed solution (Ca + K + Mg + Na) corrected the imbalance. Elevated Ca^{2+} levels may protect the plant from NaCl toxicity by reducing the displacement of membrane-associated Ca^{2+} [208] by reducing, Na^+ uptake and transport to the shoots [209] or by a combination of these effects. The Ca^{2+} also improves K^+ uptake under NaCl salinity, effectively increasing the Na^+/K^+ ratio in the tissues [205,208].

An increase in the Cl^- concentration in the nutrient media led to a reduction in the NO_3 content of tomato plants [194]. However, an increase in the concentration of NO_3 in the nutrient media, from 7.5 to 20 meq L^{-1}, in the absence of Cl^- had no effect on the NO_3 concentration. It seems unlikely that the composition between H_2PO_4 and Cl ions is important because of the greater differences in the physical and physiological properties of these ions [198].

The effect of salinity and fertilizer on grains and several vegetables is independent and additive when stress imposed on them when nutrient deficiency and salinity are moderate [196]. When either of these factors severely limit growth, the other has little influence on yield. Okusanya and Unger [210], with two halophytes and a glycophyte, also reported similar results. Nutrient application increased the growth of the halophyte under saline conditions, presumably because salinity was moderately growth limiting. On the other hand, nutrient application did not improve the growth of the glycophyte under saline conditions, presumably because salinity was severely growth limiting. Under low-salinity stress, nutrient deficiency limits plant growth more than salinity and a positive interaction or increased salt tolerance response occurs. Under moderate salinity, nutrient deficiency and salinity stress may equally limit plant growth and no interaction occurs. Under highly saline conditions, salinity limits growth more than fertilizer. According to Grattan and Grieve [211], the plant performance would always exhibit a negative interaction or a decreased salt-tolerance response if nutrient element was limiting growth under saline conditions and the upper salinity treatment was lethal or severely growth limiting.

Salinity tolerance under suboptimal conditions is important only under dry land conditions, where high levels of fertilizers are not economical or the availability of fertilizer is limited [210]. The disagreement between some of the publications dealing with the salinity-fertility relationship may stem from the use of different salinization techniques and the use of different chemicals to change the level of salinity. The difference between species varieties, the duration of the experiments, and growth conditions also could explain the variations in crop responses. Standardization of methodology, when feasible, could reduce variations between experiments. Chemical analysis of plant tissues and studies of the physiological and biochemical process involved in salinity fertility relationship are essential to explain salinity-fertility interactions.

SELECTION AND BREEDING FOR SALT TOLERANCE

Breeding programs to improve salt tolerance are particularly important in countries that would benefit from stress-tolerant crops [212–216]. Improvement of crop plants for salt tolerance depends on the existence of biological variability for salt tolerance. Variation to salinity tolerance has been observed not only between species but also between the cultivars of species [32,215,216].

Genetic variability of salt tolerance has been characterized for certain agronomic crops [2,32]. The work of Abel [217] on *Glycine max* was one of the first attempts to analyse salt tolerance genetically. The tolerance in the Lee variety was associated with the exclusion of chloride from the leaf, and exclusion is controlled by the root [60,70].

Breeding for improved salt tolerance has been reviewed extensively [218–221]. The transfer of genes that can improve salt tolerance from wild species to crop plants has been attempted by traditional techniques [8,13,14,222]. However, in spite of the presence of potential donors of salt tolerance and successful hybridization, no cultivar suitable for commercial growing has been developed so far [15,223]. Wild hybridization has been successful in the quest of characters such as insect and disease resistance where a single gene may be introgressed and selection to maintain that character is relatively straightforward in the backcross generations which are needed to dilute the rest of the alien gene from the resulting hybrid. The situation for salt tolerance is different. The limiting factors in developing salt-tolerant plants appears to be the quantitative nature of salt tolerance [66,214,224], the lengthy backcrosses which are required to recover useful agronomic features together with the halotolerant genes [223], and the difficulties involved in detecting the introduced variation [225]; and not all crop plants have salt-tolerant relatives capable of cross fertilization [47].

Richards [212,213] infers that there is no need to breed for salt-tolerant crops because of the complexicity of the problem and patchiness of salt-affected fields. It is preferable to concentrate on yield potential, plant the highest yielding cultivar, take the yield from the areas with lower salt concentration, and accept any losses on the more salt-affected patches rather than accept any losses in potential yield that might be associated with breeding for stress resistance (Disregard tolerance per se and select instead only for yield as the only ultimately interesting parameter [212].)

In contrast, Blum [226] supported the theme of selection of plant species to breed for salinity tolerance. Usually, the variety with superior yield, under optimum conditions, also yields relatively well under suboptimal conditions, assuming that the same genes control both high and stable yield. The advantage of this approach, if valid, is that selection for yield is more efficient under optimal conditions. However, the more commonly accepted approach in breeding for salt tolerance is that the maximum potential yield and the stability of yield are largely independent of each other. Stress-tolerant cultivars should thus be selected under the stress to which tolerance is desired [5]. This assumes that yield stability in various environments, with many attributes desired by the breeder, can be transferred from wild stress-tolerant plants independently of their low growth rate and metabolism.

Neverthless, tolerance of salt, water or other kinds of stress is still considered ''complex'' and can be resolved through a coordinated physiological genetic approach. In the breeding of multicellular organisms, genetics cannot be separated from epigenetics, which includes the biochemical and physiological aspects of gene action. These factors, along with environmental factors, determine the final phenotype.

AGRICULTURAL PRODUCTION OF HALOPHYTES

Boyko [227] drew attention to the possibility of crop production using seawater as an irrigant. Even though this idea was supported and experiments undertaken by many workers, the fact remained that no conventional agricultural crops are grown with undiluted seawater on dune sand without a significant reduction in yield. Successful seawater irrigation depends on the use of halophytes. In

recent years, several investigators have promoted the use of halophytes for the seawater irrigation problem [228–229]. Mudie [228] explains the potential of halophytes and the transfer of halophytic germplasm to glycophytic crops. Somers [230] promoted the cultivation of wild halophytes directly with seawater.

DRAINAGE WATER REUSE FOR GROWING PLANTS

Water is a limited natural resource in many arid and semiarid regions of the world and in populated metropolitan areas, large quantities of sewage effluents are discharged making the groundwater polluted. Drainage water reuse also has been promoted as an environmentally sound method for the disposal of saline drainage water [231]. Screening and cultivation of suitable plant species can not only prevent the groundwater pollution but productivity can be obtained. Plant species like *Atriplex, Medicago, Trifolium heymus, Puceinellia, and Truf* were grown using drainage water [232]. Plant species respond to different ions differently. For example, *Chemopodium ruburum* grew better with chloride salinity, whereas *Kochia* performed better with sulfate salinity [233]. *Portulacia oleracea*, a valuable nutritive vegetable for human consumption, can selectively accumulate selenium, and it has been suggested that the species can be included in a saline drainage water-reuse system where the selenium concentration is very high [234].

Halophytes irrigated with seawater have a remarkable potential as crop plants despite the high salt content in their tissues. It was reported that *S. bigelovii* could be substituted for conventional safflower oil and its seed cake is a good poultry feed, and that *Portulaca oleracea* could be a source of food for human consumption and fodder for livestock.

SEAWATER APPLICATION—CROP PRODUCTION

The need for salt-tolerant crops increases each year, as the growing population seeks to feed itself with ever-decreasing soil sources and dwindling freshwater supplies. Besides humanitarian reasons, there are economic reasons for developing salt-resistant crops. Recent work in the field of plant physiology and breeding has pointed out the possible utility of underground saline water for growing salt-tolerant plants on sand dunes.

The basic approach to seawater irrigation is to develop a range of new crops from wild halophytes that will result in economically worthwhile yields with seawater irrigation and/or to acclimatize the glycophytic crop plants through forced selection to take up seawater as an irrigant [32–34].

The use of water with higher salt levels and even of seawater for irrigation of various food, feed, fiber, and fodder crops has been reported [7,8,19,36,68,229,235] and has produced grains and oil seeds, vegetables, fodder, fuel and fibers, pharmaceuticals, and other products using highly saline water.

The World Health Organization (WHO) [236] and Norleyn and Epstein [237] reported that selected barley strains grown with full-strength seawater yielded at least 50% of the yield obtained under irrigation with freshwater.

The responses of crop plants to seawater irrigation are being extensively studied by scientists at the Central Salt & Marine Chemicals Research Institute in Bhavnagar, India, to investigate the potential of using seawater on coastal sand dunes as a supplemental irrigation for the production of food grains and oil seeds. Germination, a critical stage of plant growth, was evaluated for different varieties of crops irrigated with seawater. The crops tested were cereals (wheat, barley, rice, and maize), millets (bajra, jowar, and ragi), pulses (red gram, green gram, and lentil), and oil seeds (sesame, peanut, sunflower, and mustard). Many of the crop varieties tested tolerated up to 10,000 ppm seawater without a significant reduction in the germination percentage. The tolerance to seawa-

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

ter salinity is in the order cereals > pulses > millet > oil seeds and grass > legumes. The growth development, biomass production, and final yield also differed considerably for different crops and for different varieties (Table 2). Depending on the genotypic variation, crop species such as wheat variety Karchia (local) and the bajra variety Babapuri (local) were selected for improvement for salinity tolerance and for productivity.

Acclimatization

Most of plants are capable of tolerating a certain range of salinity and the range varies for different species, varieties, and ecotypes. In glycophytes, the range is rather narrow, whereas in halopytes, it is wide. A large part of the research on salinity is carried out with the intention of accommodating crop plants to grow in salinities outside the natural range of tolerance and neverthless obtain an appropriate agriculture yield called ''adaptation or acclimatization.'' Acclimatization is achieved during a specific treatment and involves changes in plant behavior and expression of certain properties which are not evident before the treatment. A plant is considered adapted when the mean growth rate of salt-treated plant increases or when the plant has acquired the capacity to complete its life cycle in a saline environment in which the nonacclamitized plants fail to do so [235,238].

When *Phaseolus vulgaris* was exposed to NaCl (48 mM), at first the growth was inhibited and leaf Na^+ Cl^- concentrations increased rapidly. However, after 25 days of continuous salinization, the relative growth rate was restored similar to control, suggesting that the plant had adapted to salinity [239]. Similarly, *Sorghum bicolor* was acclimatized to grow at 300 mM NaCl without a reduction in the relative growth rate, and Na^+ Cl^- concentrations also were stable and controlled [68].

The period required for adaptation was shortened by ABA treatment, and the process of acclimatization was inhibited by exogenous CK and/or GA [68,235], and adaptation to salinity by ABA pretreatment was developmentally regulated. The defined period of time required for adaptation of a particular species was considered as the developmental window [240]. However, Greenway [241] is of the opinion that the response of plants to salinity is often not by adaptation but rather through the preexisting tolerance mechanisms.

A gradual acclimatization from lower to a higher grade of salinity is considred an inherent characteristic of the species combating the stress. Using the technique of forced selection, Karchia wheat and Babapuri bajra were acclimatized to grow with seawater (20,000 ppm for Karchia wheat) and direct seawater (35,000 ppm for Babapuri bajra) with little reduction in the yield. The addition of nutrient elements (N, P, and K) improved the growth, biomass production, and yield under seawater irrigation. Although a reduction in the growth and yield was apparent, there was no change in nutritive values of seeds (Table 3). Seawater utilization has been a recent effort to explore the possibility of obtaining a reasonable yield and quality of products from the plant species.

PROSPECTS

The salinization of soil and water is becoming an increasingly serious constraint for crop production, particularly in the arid and semiarid regions of the word. With the human population expected to reach over 10 billion by the year 2050, to meet the requirements, increasing areas of land in arid and semiarid regions are to be brought into production. Overirrigation with inadequate drainage facilities and the use of low-quality water for irrigation are causing concern for secondary salinization [242]. The long-term survival of the present agricultural system depends on tackling the problem in a more integrated manner using management and biotechnological approaches. Improved salt tolerance in crop plants appears to be a desirable trait in view of the large percentage of agricultural land that are saline and or salinized by local irrigation practices.

The biological options open the way for the novel concept of using halophytes as an alternative

TABLE 2 Percentage Reduction in Crop Varieties Under Seawater Irrigation

Crop	Total no. of varieties	Seawater tolerance in varieties: Tolerant (15,000 ppm & above)	Moderate tolerant (up to 10,000 ppm)	Susceptible (up to 5000 ppm)	% Reduction over control	Remarks
Cereals						
Wheat	15	Karchia	NP-324, J-1-7	J-18, J-40, Sona Lok-1, Sonalika, A-206, JU-34, Raj 1781	30	Pot, sand bed, and field studies
Barley	7	BG-131	BG-1, BG-7 BG-137 and BG-138	BG-161, BG-24	40	Pot and sand bed studies
Millets						
Bajra	38	Babapuri (local selection)	HB-3, IJ-1934, NHB-5, GHB-14, GHB-12, GHB-11	Remaining inbrid and hybrid varieties	25	Pot, sand bed, and field studies
Sorghum	16	Swarna, S-105-1 S-105-2 and S-100-1	604, Chandisor	Remaining varieties	45	Pot, sand bed, and field studies
Kodomillet	2	—	—	CO-2	75	Sand bed studies
Oil Seeds						
Safflower	3	—	NP-30	2-3-P1, B-38-5	40	Pot studies
Castor	9	—	Junagadh-1	Remaining varieties	50	Pot and sand bed studies
Fiber crop						
Cotton	3	—	1AN-579-189	Remaining varieties	38	Sand bed studies
Sugar crop						
Sugar beet	20	—	Dobroivica C and USH-9	Remaining varieties	4	Pot and field studies
Sugarcane	2	—	CO-577	CO-419	2	Pot studies
Vegetables						
Onion	8	—	Local-1 (white selection)	Remaining varieties	4	Sand bed and field studies
Garlic	2	—	Local-1	Anand-I	4	Pot studies
Topioca	8	—	H-97, H-226,A-2304	Remaining varies	35	Sand bed studies
Chillies	5	—		Highly susceptible	—	Pot studies
Knol-khol	2	—		Highly susceptible	—	Pot studies
Raddish	5	—		Pusaresham	28	Sand bed studies
Cabbage	5	—		Early wonder	80	Pot studies

crop [6,7] and making use of seawater as an irrigant for the production of food and plant products using relatively salt-tolerant varieties along the coastal line [238], which at present lie idle for lack of crops that can be grown in these regions.

With the low number of varieties released for agricultural production on saline soils or using seawater as an irrigant [2,220], it appears that the criteria followed for salt tolerance is not appropriate. Salt tolerance appears to be a quantitative trait and is controlled by many genes [67,214].

Today, we know many biochemical mechanisms that form the basis for salinity tolerance [86,88,89,101] and tools are available to accomplish metabolic engineering of crop plants [44]; although not enough to speak of generation of salt tolerance for growing in the field but significant enough to recognize the underlying mechanisms.

Sodium transport across the tonoplast and its accumulation in the vacuole by the sodium proton antiport system have been described biochemically [186]. Certain plants use Na^+ as a signifying molecule to stimulate the activity of the transport protein which sequesters Na^+ away from the salt-sensitive metabolic machinery through the sodium proton antiport system. Plant genes are not yet available to test how sodium efflux at the plasma membrane or increased sodium influx at the vacuolar membrane can provide advantages to plants under stress.

The success in molecular engineering of improved salt tolerance in crop plants depends on understanding not only the contributions that the individual genes make to tolerant phenotype but also the control exerted by the molecular regulating circuits that integrate endogenous program for development and differentiation with those of exogeneous stress stimuli.

More concerted attempts should be made toward understanding the molecular mechanisms by which crop plants could acquire improved salt tolerance. We hope that wild relatives of crops will play a more prominent role than hitherto in the development of salt-tolerant crop varieties, since in naturally tolerant plants, the mechanisms are fully developed and functional to make the species productive under stress. However, much remains to be done, and an active collaboration between plant breeders, genetists, molecular biologists, and plant physiologists is essential to make significant advances in this field of research.

Acknowledgments

INTRODUCTION

Salinity is a condition of excess salts in the soil, which affects plants by increasing the osmotic pressure of the soil solution, interfering with normal nutrient uptake, and inducing ionic toxicity and associated nutrient imbalances. Osmotic stress under saline conditions, termed physiological drought [1], subjects plants to dehydration. Ionic toxicity resulting from the accumulation of specific ions, such as Na and Cl, in the cytoplasm or apoplast interferes with plant metabolic functions [2].

Under low to moderate salinity (actual salinity levels may vary from low to moderate depending on the crop species), plants adjust osmotically by using a portion of their photosynthates to increase internal solute concentrations and thus do not show dehydration symptoms. Also, plants regulate their ionic balance to maintain normal metabolism. For example, uptake and translocation of toxic ions, such as Na and Cl, are restricted, and uptake of metabolically required ions, such as K, is maintained or increased.

Although plants may not show water-deficit symptoms and metabolize normally under low to moderate salinity levels, the additional energy requirements for maintaining normal metabolism demand substantial photosynthate diversions from growth [3]. This leads to a reduction in leaf area, light interception, light utilization efficiency (due to partial stomatal closure and the resultant decrease in CO_2 fixation), and, ultimately, a reduction in growth and yield. Plants die when salinity levels exceed a certain critical level (which varies from crop to crop). Death is the result of physiological mechanisms breaking down and consequent ionic toxicity. Poor plant stand is one of the factors causing low yields under saline conditions, as salinity is nonuniform in its distribution under field conditions.

The main objective of this chapter is to present an overview of the current status of the knowledge and approaches to the genetic improvement of salinity tolerance in crop species. Management aspects that could alleviate salinity problems for crop production also are discussed, however, because genetic improvement cannot be considered in isolation in confronting a salinity problem. The chapter is focused on giving a conceptual framework for the genetic improvement of salinity tolerance. This demands an interdisciplinary team approach; to our knowledge, there is little evidence of this in present-day research efforts.

SALINITY AND CROP PRODUCTION

The expected yield losses under different levels of salinity for various crops are given in Table 1. Data on regional yield losses for various crops due to salinity are not readily available. Irrigated agriculture contributes substantially to crop production in arid and semiarid regions of the world. Secondary salinization, which is associated with irrigated agriculture, is becoming a serious concern in these regions. Nearly 40% of irrigated lands are affected by some degree of salinity [4]. Considering that nearly 240 million ha land worldwide is under irrigated crop production [5], the economic impact of secondary salinization on crop production could be astronomical. Rain-fed agriculture also can be affected by salinity through the effects of deforestation and other vegetation changes in altering underground movement patterns of water and salts.

We discuss in this section the various aspects related to the understanding of crop response to salinity, including the growth-stage response, the role of environmental factors in modifying the salinity response, and the management options that could alleviate the crop tolerance to soil salinity.

Measurement of Soil Salinity

It is important to quantify and characterize salinity distribution in a production area to make decisions regarding the selection of a crop and the management practices necessary to minimize yield reduction. Appropriate sampling techniques and salinity measurement methods are necessary to assess salinity levels properly and map their distribution in the production area during a cropping season.

Soil Sampling

Generally, major root activity occurs in less saline strata of the soil profile [6], and this should be taken into account when relating plant growth and yield to soil salinity status. Soil samples should be taken from the active rootzone and should not be contaminated by surface salt encrustations. Since salt concentrations can vary markedly with soil depth, samples are best collected at several depths, such as 0–15 and 15–20 cm, depending on the rootzone [7].

Determination of Salinity

The electrical conductivity of a saturation extract, EC_e, expressed in dS m^{-1} at 25°C, is recommended for correlating salinity level with growth [8]. The electrical conductivity of the saturation extract is directly related to the soil soluble salt concentration. The relationship between EC_e and osmotic potential Ψ_o is $\Psi_o = -0.36\ EC_e$. Use of EC_e is recommended by the U.S. Salinity Laboratory, because the saturation percentage is easily determined and is accurate for soils that vary widely in texture [8]. For most soils, the soluble salt concentration in the saturation extract is about one half the concentration of the soil solution at field capacity and about one fourth the concentration at permanent wilting point [9].

Crop Tolerance to Salinity

There are different ways of defining crop salinity tolerance, depending on the context in which it is used. Some of these are as follows:

1. ''The capacity to persist in the presence of increasing degree of salinity'' [10]: a given species may make little or no growth at higher salinity levels but does survive. This is the criterion generally used by ecologists in evaluating halophytic environments. Ecologists maintain that the species most capable of persisting in a saline area become the climax vegetation of that area.
2. ''The degree to which osmotic adjustment can be made without sacrifice in growth'' [11].
3. ''The absence of negative effects on growth in plants that accumulate salts in their tissues'' [1].
4. ''Yield decrease expected for a given level of soluble salts in the root medium as compared with yield under non-saline conditions'' [9].
5. ''The sustained growth of plants in an environment of excess salts in the growth medium'' [12].

In the context of crop production under saline conditions, definitions 4 and 5 are more relevant. Crop salt tolerance has usually been expressed as the yield decrease expected for a given level of salinity in the root medium compared with yield under nonsaline conditions [8]. Therefore, salt tolerance is a relative value based on the growing conditions of the crop.

Growth Stage Response

Information on the growth-stage response to salinity within a crop is important in adopting suitable genetic and management strategies for saline soils. For example, if a crop is more sensitive during one stage than another, there is an opportunity to regulate the salinity of irrigation water during the season to minimize salt injury at the sensitive stage.

Ontogenetic drift, a change in genotypic expression with plant development, is one of the factors that can modify the relationship between phenotype and environment. During plant growth, the form and function of various organs change. The plant's ability to respond to salt stress depends on the genes that are functioning at the stage of development during which the stress occurs [13]. Thus, salinity effects may vary depending on the growth stage at the time of stress. One example, often cited, is that salt tolerance at germination is not consistently related to tolerance during emergence, vegetative growth, flowering, or fruiting. Sugar beet, barley, and cotton are among the most salt-tolerant agricultural crops, but each is relatively sensitive during germination or early seedling growth [14,15]. On the contrary, corn, pea, gram, and beans are more sensitive during later stages of development [15,16].

Relative sensitivity could change from one developmental stage to another. Rice is tolerant during germination [17] and becomes very sensitive during the seedling stage and again somewhat sensitive during fertilization of florets [18]. Corn is more salt sensitive during emergence and seedling growth but becomes more salt tolerant by the flowering stage [19]. Salt resistance is low in young tomato plants, becomes much higher by the bud stage, and decreases during flowering [20].

Sensitivity to salinity in durum and bread wheat decreases with age, indicating the importance of keeping soil salinity levels low during germination and seedling emergence [21]. Similarly, cowpea becomes increasingly more salt tolerant as plants develop during the growing season [22]. One of the reasons for the decreasing sensitivity with age could be a gradual acclimation of the crop to salinity. This indicates that if cowpeas or wheat are irrigated with water containing salt levels below the threshold, before the flowering stage, higher levels of saline irrigation water could be used at later growth stages without any deleterious effect on yield [21,22].

Within a species, varietal rankings could change with the growth stage, and this has been observed with rice [23]. For barley, varietal differences increased with the plant development stage

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

[24]. Changing varietal differences (i.e., relative tolerance rating) over time were also reported in sugar cane [25]. This would complicate the screening and selection process, if it is based on a single growth stage.

Environmental Interactions

Interactions between salinity and soil, water, and climatic conditions change the plant's ability to tolerate salinity. A basic understanding of the interactions between salinity and the environment is necessary for an accurate assessment of salt tolerance. In addition to precipitation, temperature and atmospheric humidity can markedly influence salt tolerance. Many crops are less tolerant when grown under hot dry conditions than under cool humid conditions [9]. This is mainly due to decreased ion accumulation and/or improved plant water relations [26,27].

Rice suffered more salt injury at 30.7°C and 64% relative humidity (RH) than at 27.2°C and 73% RH [28]. High humidity overcame lethal levels of salinity on *Phaseolus vulgaris* L. [26]. In wheat, a higher transpiration rate occurred at low RH and high temperatures, thus increasing the mass flow of salts into the transpiration stream and their accumulation to toxic levels in the shoot [29]. Further, salts may accumulate in the rhizosphere with increased transpiration [29].

Suboptimal soil conditions also can affect the apparent salt tolerance of crops. For example, plants grown on low-fertility soils may appear to be more salt tolerant than those grown with adequate fertilization [30]. A reason for this could be that soil fertility, not salinity, is the prime limiting factor for crop growth. In this case, proper fertilization would increase yields under saline as well as nonsaline conditions but proportionally more under nonsaline conditions.

Comparative Effects of Different Salts

Specific ion toxicity is the primary cause of plant mortality at higher levels of salinity [1]. Different salts have different threshold osmotic concentrations for injury, and the relative toxicities of specific salts are not constant for all crop plants under all conditions [1]. For example, cotton, rice, and wheat are less resistant to NaCl than Na_2SO_4 salinity [31–33], but *Phaseolus*, guayule, flax, and chickpea show the reverse relationship [34,35]. Alfalfa is more affected by Na_2SO_4, K_2SO_4, and NaCl salts than $MgCl_2$ and $MgSO_4$ salts [36], whereas the reverse is the case with mung bean and red kidney bean [37,38]. Beans and wheat are more affected by $CaCl_2$ compared with NaCl salinity [39,40], whereas the response is the opposite with corn [34]. Mung bean and red kidney bean were equally affected by NaCl, Na_2SO_4, KCl, and K_2SO_4 [37,38]. For many crops, carbonates are more toxic than Cl and/or SO_4 [34].

Protective Effects of Calcium

The importance of Ca in maintaining membrane stability and for selective ion uptake by plants is well documented [41]. Under saline conditions, the ratio between required ions (e.g., K) and unessential ions (e.g., Na) is reduced, and thus selective ion transport by plant roots becomes crucial for survival. Low levels of Ca (<1 mM) in the absence of NaCl salinity support normal growth in most crop plants [2]. Under saline (NaCl) conditions, however, such levels of Ca in the medium result in Ca deficiency in many crop plants [42,43]. Under NaCl salinity, a decrease in the membrane-associated Ca content due to the displacement of Ca by Na leads to the disruption of membrane integrity [43]. This causes an increase in passive Cl and Na transport and results in ion toxicity [44]. The NaCl salinity (at low Ca levels) also inhibits Ca transport from roots to shoots by interfering with the active loading and release of Ca into xylem vessels [45].

Several reports indicate that supplemental Ca (usually up to at least 5 mM) may alleviate the reduced growth caused by NaCl salinity. In *P. vulgaris*, dry weights increased with increasing Ca levels up to 3 mM at 50 mM NaCl in the ambient solution, and there was no further improvement at higher Ca levels [46]. A positive growth response to increasing Ca under NaCl salinity was also

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

reported for barley [47]. The germination and seedling growth of Wimmera rye grass under NaCl and $MgCl_2$ salinity improved with the increasing Ca concentration in the growth medium [48]. Some crops, however, including rice and lettuce, do not respond positively to Ca addition under NaCl salinity [49,50].

Supplemental Ca, under NaCl salinity, normally improves Ca absorption of the plants [51]. Calcium also protects NO_3 transport under saline conditions [52]. In pigeon pea (*Cajanus cajan*), a positive growth response to a decrease in the Na/Ca ratio was observed at a constant salinity of 6 or 8 dS m^{-1} [53]. A decrease in the Na/Ca ratio in the medium improved K/Na in the shoot and thus improved plant growth. With a decrease in Na/Ca ratio, however, tissue Cl levels increased and to some extent counteracted the positive effects of improving the K/Na ratio.

Management Practices that Minimize Yield Reduction Under Saline Conditions

Although the main objective of this chapter is to document the scope of genetic options to improve salinity tolerance in crop plants, this topic cannot be considered in isolation from various management options that reduce salinity damage. Further, we emphasize that a practical approach to alleviating salinity effects is a close integration of genetic and management options. Management practices that can be used to minimize yield reduction under saline conditions are mostly related to the control of rootzone salinity and reduced damage to the crop plants [54]. Control of rootzone salinity can be achieved by irrigation and leaching. For example, intermittent leaching can be more advantageous than leaching at each irrigation [55,56]. Similarly, by increasing the irrigation frequency, the salinity effect on crop growth can be considerably minimized [57]. The control of rootzone salinity in the initial stages of germination and early seedling growth could play a major role in plant stand establishment.

Several cultural and management practices have been developed to enhance plant stand establishment under saline conditions [54,58]:

1. Irrigate lightly each day after seeding with a sprinkler system until the stand is established, and then convert to furrow irrigation.
2. Leach salts from the soil surface before planting to allow stand establishment before salts can accumulate at levels that would interfere with germination or damage seedlings.
3. Prepare seed beds in such a way that salts accumulate at the top of ridges, and then sow seeds in the furrow or on the slope between the furrow bottom and ridge top [54].
4. By applying a mulch to reduce evaporation, increase water uptake by plants and increase leaching of salts [59].

Although soil salinity reduces the plant growth potential, this may not necessarily reduce the total field yield, the field yield is the product of stand density and yield per plant. Using the crop growth model of Maas and Hoffman [9], the predicted reduction in individual plant growth due to salinity can be estimated. Therefore, plant populations could be adjusted to compensate for reductions in individual plant growth [60].

Salinity and Fertilizer Use

By changing the fertilization regimens (type and quantity of fertilizers and method of application) from those considered to be appropriate for nonsaline conditions, it is possible to alleviate the effects of salinity on agricultural crops [61]. Salinity interfered with P translocation in cotton [62] and the uptake of NO_3 in barley [63]. Reduced P translocation is caused by inadequate Ca levels in the roots, and thus the primary response is on Ca uptake [62]. This can be corrected by either foliar P fertilization or Ca fertilization. The latter is more desirable, because it corrects the primary effect and thus improves the salinity tolerance. Different crops and genotypes are known to have differences in

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

their ability to take up Ca during NaCl salinity [2]. Tolerant genotypes are able to maintain Ca uptake, whereas sensitive genotypes are not. Therefore, depending on the crop or genotype used in a particular fertilizer trial, different responses can be expected. Positive growth responses to fertilization under saline conditions are reported in clover [64], wheat [65], tomato [66], bean [67], and pepper (*Capsicum annuum* L.) [68]. On the other hand, negative growth responses were reported in cotton [69], rice, barley [70], corn [68–70], and soybean [71].

GENETIC IMPROVEMENT IN SALINITY TOLERANCE

Several points must be considered before initiating a breeding program to improve salinity tolerance. In the first instance, alternative cropping strategies should be evaluated. Selection of a different crop that is more salt tolerant may result in productivity far exceeding the genetic limits of the crop originally targeted for salinity-tolerance breeding. For example, by changing the cropping system from wheat to barley, the necessity of genetically improving wheat salinity tolerance can be avoided: Considerable genetic improvement in wheat is needed to raise its tolerance to the level already existing in barley.

This strategy of expanding the use of salt-tolerant species without going through selection within a species could be sufficient to circumvent salinity problems to some extent. However, economic considerations, food habits of the region's population, and cropping systems that have evolved based on these crops and that fit well into existing agroecological niches may not allow replacement of existing crops with a more salt-tolerant crop. For instance, salinity problems that confront lettuce, tomato, and other vegetable growers in California could be eliminated if these vegetable crops were replaced by barley. Vegetable production is a highly commercialized system and the economic backbone of California's agriculture, which does not permit such an option [12].

Legumes are very sensitive to salinity in comparison to cereals [72]. The semiarid regions, which include a large proportion of the world's irrigated agriculture, are now under threat from secondary salinization. Legumes play an important role in these production systems, which are largely based on cereal-legume cropping patterns. Such patterns contribute to the maintenance of soil fertility and soil structure and long-term sustainability of these production systems. For example, in rice-based cropping systems, such legumes as green gram and black gram play an important role in this cereal-legume cropping pattern in the Krishna and Godavari delta regions of peninsular India. This production system has recently been threatened by secondary salinization, and the legume component is being affected first because of its higher susceptibility to salinity. Although the long-term sustainability of this production system requires the development of suitable management practices to arrest the further build-up of salts, this process could be enhanced by the use of legume genotypes with higher levels of salinity tolerance than are now available.

For many biotic and abiotic stresses, the feasibility of a genetic approach in improving crop tolerance has been demonstrated convincingly. For certain abiotic stresses, however, such as drought and salinity, genetic improvement remains a challenging task because of the difficulties in defining precisely the target environment, which is a prerequisite to focusing genetic improvement. Further, serious obstacles to genetic improvement of salinity tolerance are the diversity of physiological mechanisms that determine the level of tolerance to salinity or drought, their multigenic nature of inheritance, and the lack of appropriate screening methodology, appropriate selection criteria for evaluation of germplasm, and segregating material. These points are discussed in detail in this section.

Screening Methodology

Field Environments

Field salinity is inherently variable (levels can vary from <4.0 to >40 dS m^{-1}); variation occurs both horizontally and vertically and changes temporarily within and between growing seasons (depending

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

mainly on the amount of precipitation and evapotranspirational demands) [73]. Spatial variation in a saline soil can be enhanced further by irrigation [73]; on the other hand, an insufficient moisture supply exacerbates the variability in plant growth by the development of variable moisture-stress conditions in addition to variable salinity effects. Plant roots avoid more saline soil areas and take up water and nutrients from less saline areas [74]. Plant growth under such variable saline conditions may be more a result of escape than of genetic differences in tolerance [75].

Because of the natural field variability in salinity levels, it is very difficult to evaluate germplasm lines under field conditions. Environmental variance effects are likely to exceed those of the genetic component, thereby making selection for genetic improvement difficult.

An alternative approach is field testing under relatively controlled conditions, as done by the U.S. Salinity Laboratory at Riverside, California [9]. Using a nonsaline, sandy loam soil and by irrigating with different levels of saline irrigation water (usually by adding NaCl + $CaCl_2$ wt/wt), relatively uniform salinity levels, within a given salinity treatment, can be created. By increasing irrigation frequency and by applying excess irrigation water, the build-up of salts can be prevented. A nonsaline control treatment for all genotypes is usually used to determine inherent differences in the growth and yield potential. Therefore, genotypes can be evaluated at different salinity levels on a relative yield basis [76].

Controlled Environments

Most researchers use controlled environments, such as greenhouses or growth chambers, for the preliminary evaluation of germplasm lines. This helps to reduce the number of lines to more manageable levels for more rigorous testing at a later stage under controlled-environment or field conditions. Also, selection of breeding materials in early generations involves exposure of plants to salinity in a relatively controlled environment to minimize environmental variance and maximize genetic variance. Plants are then grown in containers with a salinized media. Salt concentrations for selection vary with species sensitivity. For most glycophytic crop plants, the concentrations used for screening range between 50 and 300 mM NaCl (representing rice and barley, respectively) [75].

In most large-scale screening of germplasm lines for salinity tolerance, an aerated and salinized hydroponic system is used. The principles to observe in any hydroponic system are (a) balanced supply of nutrients, (b) proper aeration, (c) control of salt concentration and solution pH over time, and (d) gradual increase in salinity level in several increments over time until the desired treatment salinity level is reached to avoid osmotic shock to the plants.

Salinity Tolerance Criteria

Genotypes may be evaluated for vigor, leaf damage, survival, and ability to grow under saline conditions. A salinity level is chosen to select about 10% of the material for further evaluation over a range of salinity levels. Sand culture under greenhouse conditions may be used to determine growth response curves at various salinity levels. The parameters that might be used in assessing the effect of salinity on a particular species include survival, leaf damage, and vegetative growth and yield. All are of course interrelated: There can be no yield without survival, although a species may survive vegetatively and yet fail to produce yield. Therefore, knowledge of all these parameters contributes to the assessment of the effects of salinity on a particular crop species.

Based on Germination

Selection on the basis of germination tests shows little promise as a means of improving salinity tolerance in subsequent growth stages [77]. However, lack of association does not mean that germination tests are not useful in a salt-tolerance breeding program. In many situations, the ability to germinate and establish a good plant stand in saline soils is an important factor in crop production. However, this depends on the crop under consideration and the agronomic practices associated with it. In rice, tolerance at germination and initial seedling growth is not important, because this crop

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

is mostly transplanted. Development of genotypes with tolerance at all growth stages requires selection at several points in the life cycle.

Based on Survival

Plant survival at high salt concentrations, irrespective of their growth rate and productivity under moderate salinity levels, has been proposed as a selection criterion for tomato, barley, and wheat [78–80]. The philosophy behind this is to focus on tolerance per se, thereby separating yielding ability from salinity tolerance; considering that these two are independent attributes. The ability of a genotype to survive and complete its life cycle at very high salinity levels, irrespective of its yield potential at moderate salinity levels, is considered tolerance in the absolute sense. Also, yield is regulated by a number of genetic factors not contributing directly to salinity tolerance. Once sources of very high levels of salinity tolerance are identified, attempts can be made to combine these with high-yield potential through standard breeding procedures. This is similar to the approach adopted in disease-resistance breeding, in which the initial selection emphasis is on identifying the sources of disease resistance rather than the yield ability in disease environments.

Based on Leaf Damage

Most crop plants are glycophytes and, unlike halophytes, cannot tolerate high-salt levels (mainly Na and Cl) in their leaf tissues. Therefore, one important factor in the physiological mechanisms operating in glycophytes is preventing Na and Cl ions from translocation to the shoot. Beyond a certain critical level of salinity stress, this regulation breaks down, resulting in the translocation of large amounts of Na and Cl to the shoot, causing ionic toxicity. Critical levels vary among genotypes, varieties, and crops and usually determine the differences in the level of tolerance. Leaf damage (bleaching or necrosis) is a symptom of a breakdown in ionic regulation. Therefore, selection against leaf damage should lead to the identification of genotypes that have more efficient ionic regulation and other physiological mechanisms that contribute to higher tolerance levels. In alfalfa (lucerne), selection criteria based on leaf damage of less than 10% resulted in rapid improvement in selection for salinity tolerance [81].

Based on Growth and Yield

Salinity tolerance is usually assessed in terms of absolute and/or relative growth or yield. Although absolute yields have an obvious practical application, they often reflect qualities other than tolerance

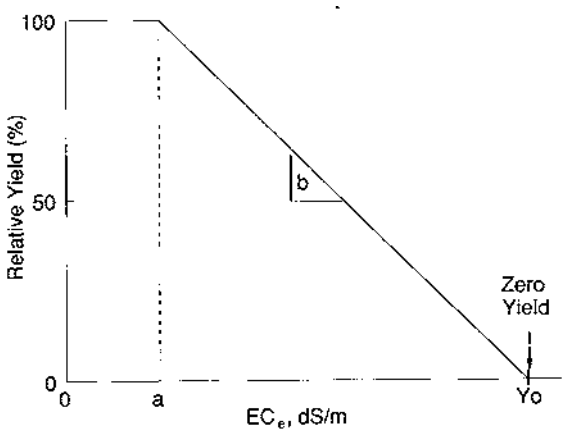

FIGURE 1 Response curve to salinity. (From Ref. 54. Reprinted by permission of Kluwer Academic Publishers.)

to salinity and can lead to illogical conclusions if considered alone. Inherent differences between genotypes in their growth rates or habits does not permit a valid assessment of their relative salinity tolerances using absolute yield or growth criteria at a particular salinity level. For example, a genotype may suffer a severe yield reduction at a given level of salinity and yet yield more than another genotype whose yield is unaffected by salinity [82].

The performance of a genotype under saline conditions in comparison with that under nonsaline conditions provides a measurement of salt tolerance stripped of extraneous influences. Also, this approach provides a means to compare crops whose yields are expressed in different units or that differ widely. However, the reliability of relative salt tolerance data depends on the degree to which yield reductions are unaffected by extraneous interactions [9]. If reductions in relative yield are independent of differences in absolute yield caused by irrigation, climate, fertility, or other variables, the relative yield-salinity relationship permits a useful expression of plant tolerance to salinity [83].

The crop response to salinity is usually described as a decreasing function with an increase in the EC_e of the soil solution. It has been suggested [9,84] that a reduction in crop yield due to salinity can be linearly related to the EC_e of the soil solution after a certain threshold value of EC_e is reached (Fig. 1). This can be expressed as

$$\frac{Y}{Y_{\max}} = 1 - b(EC_e - a) \tag{1}$$

where:

Y = yield
$Y_{\max}$ = yield of nonsaline control
a = salinity threshold value, EC_e units (dS m^{-1}), that is, the maximum soil salinity that does not reduce yields below those produced under nonsaline conditions
b = slope, the relative reduction per unit salinity increase from threshold

Based on the salinity threshold level a, slope value b, and salinity level at which yield becomes zero Y_0, Maas and Hoffman [9] grouped most important crops into four categories: (1) sensitive, (2) moderately sensitive, (3) moderately tolerant, and (4) tolerant.

Genotypes or germplasm lines could be evaluated for their salinity tolerance using this linear growth-response model. However, many data points above and below the threshold level are required to define the threshold level accurately and to measure the slope value [85]. This kind of evaluation should mainly be used to assess the production capacity of selected, contrasting genotypes in saline environments, not for the initial evaluation in which many germplasm lines must be screened.

Conceptual Framework for Genetic Improvement Under Salinity Stress

The linear growth model of Maas and Hoffman [9] could be used as a conceptual framework for the genetic improvement in salinity tolerance. To improve crop performance genetically under saline conditions, it is necessary to shift the threshold value a to the maximum extent possible and to reduce the slope value b to give stability in crop performance across a range of salinity levels and an increase in Y_0. Genetic improvement in these three components would involve screening, selection, and recombination through breeding. This should result in better crop performance under saline conditions.

The three components of the model (a, b, and Y_0) may be considered to the independent crop attributes, because each component refers to a crop response at a given range of salinity (i.e., the a value refers to the crop performance at low-salinity levels, the b value to moderate-salinity levels, and Y_0 to high-salinity levels). Considering the principles of quantitative genetics, Falconer [86]

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

proposed that a characteristic in two different environments may be regarded as two characteristics rather than one.

The criteria for evaluating crop salinity tolerance vary, depending on the level of salinity stress. In a low- to moderate-salinity range, the production capacity of the genotype is the main criterion, whereas survival ability is the main criterion at higher salinity levels [87]. It is likely that the physiological mechanisms that play a major role in maintaining the production capacity of a genotype are not the same as those that contribute to tolerance at extremely high-salt concentrations [88].

Assuming that these three components are independent crop attributes, independent genetic improvement should be sought for each component. Once improved sources of genetic materials are identified for each component, these could be combined into a single genotype through breeding. However, the decision to breed for improved salinity tolerance for a given crop should be carefully considered. The plant breeding approach, although remarkably successful in some instances, is very time consuming and labor intensive when conventional breeding methodologies are used. Also, it must be realized that salinity tolerance is a finite attribute, and genetic improvement through selection and recombination can improve tolerance only up to a certain level within a given crop species. The degree of improvement depends on the availability and extent of the variability for salinity tolerance and the existing tolerance level of the species. Also, higher levels of soil salinity could place considerable pressure on the plant's photosynthetic capability, because physiological defense mechanisms that permit survival and production under saline conditions demand a larger portion of available photosynthate [3]. This leads to a decline in the production potential. If production falls below a certain level, the economics of cultivation of the crop under consideration comes into question.

Potential gains from a breeding program should be realistically estimated. Gains from improving stress resistance may be offset by adverse correlated responses that are inevitable because of the physiological interconnections of plant growth processes. This can result in developing varieties that are salinity resistant and suitable only for saline soils but not for nonsaline soils, since their yield ability may be low and unable to compete with existing commercial varieties that can be grown in these nonsaline soils.

The various management options discussed earlier can also improve crop performance to a greater extent than may be realized through breeding. The physiological requirements for a given crop to perform under saline conditions should be evaluated. Careful assessment of energetic and assimilatory requirements for growth under various degrees of stress can reveal whether it is physiologically feasible to expect an improvement in production in stress environments. Ideally, fundamental growth processes should be well enough understood that crop growth can be modeled at various degrees of salinity stress. The results of such modeling exercises could provide guidance about the extent of physiological improvement required for the known or anticipated level of salinity [89].

The following aspects should be considered in initiating a program for the genetic improvement of salinity tolerance in a given crop:

1. Define the target environment.
2. Define the level of improvement necessary.
3. Define the growth stage response.
4. Choose the screening methodology to be adopted.
5. Choose the selection criteria.
6. Assess the genotypic variation for the various traits under consideration that may have a functional role in improving salinity tolerance.
7. Identify genetic sources for the various components (traits) of salinity tolerance.
8. Determine the genetic basis for traits under consideration and estimate their heritability.
9. Initiate breeding programs that combine various traits from different sources into a locally adapted variety or genotype for the ultimate development of a salt-tolerant variety.
10. Test evolved genotypes in multiple locations, in a range of saline soils within a production environment, to assess their potential adaptability as new varieties.

Strategies for Genetic Improvement

Define the Target Environment

This is one of the most crucial requirements for the success of a genetic improvement program: It is unrealistic to attempt to develop a single variety that can be grown universally in all types of saline soils. The type of salinity (i.e., salt composition) in the target environment and the anticipated salt dynamics during the growing season should be assessed. This should help in designing genetic improvement programs specifically aimed at developing varieties that best fit given target environments. Laboratory or greenhouse studies should reflect the specific ion toxicities (and proportions) in the area where the crop is intended to grow. Even in a specific environment, the concentration of soluble salts changes depending on the soil structure and composition and its equilibrium with a variable moisture content. The amount of salt carried by irrigation water also may vary throughout the growing season. Such changes must be monitored and taken into consideration when developing appropriate breeding strategies to alleviate salinity problems.

Screening and Selection

Once a target environment is well defined, appropriate screening methodologies should be adopted to test the available germplasm for genetic variability in the salinity response. Analyses of variability are needed to establish that genetic variability exists and that it can be utilized in breeding. This requires formal studies on the heritability of the stress response and related physiological and morphological characteristics.

Varietal testing for salt tolerance often reveals only small differences among the limited numbers of varieties examined, such as lettuce [90], muskmelon [88,91], and grapevine [92]. A greater variation for salt tolerance is more likely to occur among species of halophytic origin, such as sugar beet [93]. Based on germination and early seedling growth in barley with 75% seawater, large differences among genotypes were reported [94]. Systematic large-scale screening of available gene pools of wheat and barley using hydroponic systems has been attempted with the specific aim of selecting genotypes suitable for seawater culture [80,95,96]. Nearly 7200 barley genetic lines synthesized from a composite cross (involving a number of lines) were evaluated [97]. Of these, only 22 lines were able to survive, grow, and complete the life cycle by setting seed at 75–90% seawater salinity in a hydroponic system. Tolerance here refers to the ability to germinate, establish seedlings, grow, flower, and set seed at 75–90% seawater supplied throughout the life cycle of the plant [80]. Further, these lines were evaluated under field conditions for their yield ability by irrigating with undiluted seawater. Some of these lines could yield up to 1.58 t ha^{-1}. This shows the feasibility of this approach in developing barley lines or varieties that can be grown with seawater-based irrigation [80]. Therefore, the basic concept of irrigating barley with seawater is at least a ''biological success,'' and the selection approach based on tolerance throughout the life cycle appears to be feasible in identifying lines capable of producing under saline conditions. Similar attempts have been made in rice [98].

There is scope for the selection and development of rice varieties that are high yielding under saline conditions. The IRRI (International Rice Research Institute) has developed a number of salt-tolerant varieties, such as IR 50. This was reported to yield an average of 3.0 t ha^{-1} in multilocational yield evaluation trials in saline fields, where the traditional high-yielding varieties could not survive [99]. It also was demonstrated that, using cumulative crosses involving a number of tolerant cultivars, one could develop varieties with higher levels of tolerance than their parents. Crosses using two of the IRRI most salt-tolerant cultivars have demonstrated overdominance for salt tolerance in F_1, and many progeny lines of F_3 are far more tolerant than either of the parents [100].

Screening plants from germination to maturity using large-scale solution culture systems is the best option for identifying genotypes or genetic materials that are tolerant to salinity at all growth stages. If different genotypes respond differently at different growth stages, however, this suggests that salt tolerance is under separate genetic control at each of the developmental stages. If this is

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

so for the crop under improvement, then genetic sources may need to be identified that possess higher levels of tolerance for each of the growth stages, with the assumption that tolerance at each growth stage could be an independent attribute. Jones and Qualset [89] proposed that by reducing tolerance to similar developmental units, the genetic components of this tolerance potentially also will be simpler. Analysis may therefore be facilitated by reducing the number of segregating loci in crosses, thereby simplifying genetic segregation ratios and identifying the underlying physiological basis of adaptation. It might then be possible to integrate differential tolerances at specific stages into a single highly tolerant cultivar with a high-yield potential.

Role of Wild Relatives

Wild relatives of plants have been used as sources of disease, insect, and nematode resistance, to widen adaptation, to provide alternative cytoplasms and develop cytoplasmic sterility systems, to improve quality, to alter modes of reproduction, to induce short stature, to increase crossability between species, to improve resistance to stress, and to increase yield [101]. The use of wild relatives in crop improvement accelerated after systematic efforts by the CGIAR (Consultative Group for International Agricultural Research) centers to collect, maintain, and make this material available to researchers. Many breeders are reluctant to use wild germplasm in their breeding programs, however, because it takes a long time and much backcrossing to remove the undesirable traits that are linked with the desirable traits.

Several studies have shown that, in many crops, wild relatives can offer higher levels of tolerance to salinity that can be transferred to cultivated crops through breeding. In the tomato, the lack of variation in the cultivated germplasm prompted Epstein and his colleagues to test various wild relatives of tomato [102–104]. *Lycopersicon cheesmani*, a wild tomato collected from the Galapagos Islands, was found to be highly salt tolerant and could survive and produce with 50% seawater, a saline level toxic to the cultivated tomato. Further studies with interspecific hybrids of cultivated tomato demonstrated that the higher level of tolerance is a dominant genetic factor. Recurrent selection for salt tolerance of the hybrids resulting from backcrosses to a domestic cultivar gave plants that survived in up to 70% of the concentration of seawater. Fruit size, quality, and yield increased with successive backcrossing.

In barley, preliminary studies with a limited number of accessions of *Hordeum spontaneum*, an immediate progenitor to cultivated barley and the only wild relative in the primary gene pool, did not show any additional sources of tolerance compared with cultivated barley (G. V. Subbarao and S. Jana, unpublished results). However, a large number of collections are available in this species that could offer higher levels of tolerance than cultivated barley. Other species of *Hordeum*, such as *H. jubatum* and *H. marinum*, have substantially higher levels of tolerance to salinity than that available in cultivated barley [105]. Utilization of this tolerance depends on the development of techniques to overcome incompatibility barriers.

Several wild species related to wheat have shown substantially higher levels of salinity tolerance than cultivated wheat [106]. *Elytrigia elongata*, a wild wheatgrass, had a higher salinity tolerance than cultivated wheat (*Triticum aestivum*). The salinity tolerance trait was expressed in the amphidiploids of *T. aestivum* × *E. elongata*, indicating that the tolerance trait is a dominant genetic factor [107]. By transferring five chromosomes and a telosome from *E. elongata* to *T. aestivum* in the BC_2F_4 derivative, it was found that the tolerance trait was expressed in these derivatives. These derivatives grew to maturity even at 35 dS m^{-1} salinity, similar to the tolerant parent *E. elongata* [108]. *Oryza coarctata*, a wild rice species, tolerates salinity up to 40 dS m^{-1} [109]. The cultivated rice (*O. sativa*) could tolerate only 5 dS m^{-1}. Some pigeon pea wild relatives were found to have higher levels of tolerance to salinity than the cultivated pigeon pea [110].

FUTURE OUTLOOK

The salinization of soil and water is becoming an increasingly serious constraint for crop production, particularly in the arid and semiarid regions of the world. These areas are under immense pressure

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

to produce more food per unit area of land because of ever-increasing human populations and expectations of economic improvement. Increasing areas of land in arid and semiarid regions are being brought into production through the introduction of canal irrigation, without taking into account the salt balance of these production systems or providing suitable drainage [111]. Secondary salinization, which is usually associated with irrigated agriculture, is becoming a serious problem in many areas of the world, threatening the long-term sustainability of these production systems. Nearly 1.5 million ha of prime farmland in the world is going out of crop production each year because of secondary salinization [112]. The long-term survival of present agricultural production systems based largely on irrigation depends on tackling salinity problems in a much more integrated manner. This is suggested to be through a proper balance between the management approach in containing further salinity build-up in these soils, coupled with the biological option of genetic improvement in salinity tolerance.

The biological option, apart from contributing to the survival of present production systems, also opens the way for the novel concept of using seawater irrigation for food production along coastlines at present lying idle for lack of crops that can be grown in these regions. Early attempts by Epstein and his colleagues with barley demonstrated the feasibility of this approach. However, much more needs to be done to realize this dream. Not all barley germplasm collections have been systematically evaluated for their potential to grow with seawater irrigation. Apart from this, wild relatives of barley have not been thoroughly explored for their potential to contribute to the genetic improvement in salinity tolerance. The *Hordeum* species, such as *H. spontaneum, H. jubatum*, and *H. marinum*, could provide the necessary ''genetic means'' to develop barley cultivars that could be grown with seawater to give reasonable yield levels. We hope that future efforts will be directed toward realizing this goal.

Improving salinity tolerance in many crops whose production systems are being threatened by secondary salinization is of immediate importance to the continuation of these crops in their present production environments. ''Genetic support'' should be recruited from wild species should sufficient variation not be found among cultivated germplasm collections.

Traditional breeding approaches can be used for genetic improvement in salinity tolerance in a target crop species, and these may have a higher level of success if integrated with physiological research. Biotechnological approaches, such as using somaclonal variation in tissue culture for generating salt-tolerant cell lines and, finally, plants, have been projected to have much promise [113]. Consistently, however, no salt-tolerant plants have been regenerated from these so-called salt-tolerant cell lines [114]. Salt tolerance is much more of a whole-plant phenomenon. It depends on a number of physiological processes that need to coordinate at the whole-plant level to provide the necessary stable ionic environment in the cytoplasm and the required osmotic adjustment for the turgor-driven water uptake under saline conditions. It is thus not surprising that plants regenerated from the tolerant cell lines have not shown the same level of tolerance as the original cell lines [114].

However, other aspects of biotechnology show promise for use in the genetic enhancement of salinity tolerance. For example, RFLP (restriction fragment-length polymorphism) or RAPD (random amplified polymorphic DNA) markers could be used for tagging the physiological components of salinity tolerance. These methodologies could be effectively integrated into breeding programs for the genetic improvement in salinity tolerance in crop plants [115].

More concerted attempts should be made to integrate physiological research in plant salinity tolerance with genetic aspects so that a combined physiological-genetic approach may be realized. We hope that wild relatives of crops will play a more prominent role than hitherto in the development of salt-tolerant crop varieties.

INTRODUCTION

The scientific community is considerably concerned with the increasing CO_2 concentration [CO_2] in the atmosphere. There is clear evidence that the rise is linked to industrial emissions and is strongly correlated with the rapid increase in the global consumption of fossil fuels. Deforestration is considerably concerned with the increasing CO_2 concentration [CO_2] in the atmosphere. The level of atmospheric CO_2 in Europe has increased from about 280 μmol CO_2 mol^{-1} before the industrial era to 358 μmol CO_2 mol^{-1} in 1995 [1]. This trend is expected to continue and result in an increase to over 700 μmol mol^{-1} by the end of the next century if no steps are taken to limit emissions [2]. In parallel with the recent trend of rising atmospheric [CO_2], ozone (O_3) also has increased and is regarded as being one of the most phytotoxic of the air pollutants commonly encountered in the developed countries of the Northern Hemisphere [3]. Owing to industrial emissions of nitrogen oxides and volatile organic compounds, background concentrations of tropospheric O_3 have roughly doubled during the last century from the rural mean concentration of less than 20 nmol mol^{-1}. The current trend of the increase is about 1–2% per year [4]. Owing to their ability to trap terrestrial radiation and so warm the atmosphere, CO_2, O_3, and other radiatively active gases—methane, nitrous oxide, chlorofluorocarbons—contribute to the ''greenhouse'' effect which is predicted to affect the global pattern of temperature and precipitation and have direct impacts on plant physiology and crop production [5,6]. The increase in the global mean temperature is likely to be of the order of 1.5–4.2°C. It is generally considered that the increase in temperature will be greatest at high latitudes and minimal at low latitudes [7]. Although models suggest that increasing [CO_2] may result in a

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

slight increase in the global mean precipitation, large uncertainties exist on the regional scale due in part to the large spatial and temporal variability inherent in precipitation events and their intensity. Some regions might receive increased precipitation, whereas others might receive less. However, these projected changes in climate are uncertain [8,9]. The resulting precipitation shifts could have considerable agricultural impacts, especially in regions that become drier [10].

Plants respond to elevated levels of atmospheric CO_2 in a wide variety of ways [11]. Many aspects of the plant life cycle depend on the importance of the photosynthetic response to elevated [CO_2], with notable examples being growth and yield, structure and anatomy, photosynthetic and respiratory gas exchange, and C and N assimilation [12]. Among other factors for plant growth to be sustained by photoassimilate, turgor must be maintained [13]. In addition to enhancing photosynthesis and growth, elevated [CO_2] also affects stomatal conductance which in turn affects transpirational water loss and water-use efficiency [14]. The various aspects of the effects of elevated [CO_2] on plant water relations include gas exchange, morphology, and stomatal and internal water stress regulation. Accordingly, [CO_2] and water vapor pressure will have direct and possibly interactive effects on leaf expansion and biomass accumulation by virtue of their combined impact on transpiration and assimilation.

Multidisciplinary studies are necessary to understand the impact of changes in the atmosphere on plant life. A large number of papers, reports, and reviews have been devoted to the impact of elevated [CO_2] on several aspects of plant physiology, biochemistry, and photosynthetic carbon metabolism. Moreover, various studies have recently been initiated to investigate the effects of high [CO_2] on the regulation of photosynthesis-associated genes, PAGs [15], with the aim to develop a comprehensive understanding of the mechanism of the plant response to changes in [CO_2]. Some other studies were concerned with elevated O_3, or high temperature, or drought. The objective of this chapter is to gather the current knowledge on the different aspects of the effects of the expected climatic changes which plants will very likely have to face during the course of the next century.

This chapter describes the action and interaction of elevated [CO_2], [O_3], temperature, and drought on some aspects of plant physiology; mainly carbon and water acquisition and use. It deals with major crop plants (e.g., wheat, rice tomato, tobacco) and also herbaceous plants which are components of the grazing ground. In addition, because of the standing biomass they represent, their significant role in the global carbon balance and their economical importance, trees also are mentioned.

EFFECTS OF ELEVATED CONCENTRATIONS OF ATMOSPHERIC CO_2 ON PLANT PHOTOSYNTHESIS AND RELATED PHYSIOLOGICAL PROCESSES

Experimental Approaches

Field conditions are variable in time and space. Interactions with other environmental factors occur. Species can differ in their response to CO_2 concentration [16] and strong year-to-year variations in weather are found [17]. To study the responses to elevated [CO_2], experimental plants have been exposed to enriched [CO_2] in different ways. Initially, phytotronic chambers were used; subsequently, in order to reproduce field conditions as closely as possible, open-top chambers (OTCs) were used in the field [18], and more recently an open-field method was developed called Free air CO_2 enrichment (FACE) [19]. In OTCs, a ''chamber effect,'' mainly due to an increase in temperature compared with the real field conditions, was often observed. Thus, an ''absolute'' growth effect could not be determined with high confidence with this technique [20]. The FACE approach is preferable, because both absolute and relative responses are reliable. However, it must be mentioned that, because the FACE high technology is very costly, OTCs are still very widely used. The recent addition of a temperature-control system [21] to the OTC technique will probably remove the major flaw limiting its usefulness for global change research.

Growth Response

Carbon dioxide is the substrate for photosynthesis for all terrestrial higher plants. It was formerly assumed that photosynthesis was usually limited by other environmental variables such as temperature, water, and nutrient availability, so that plants did not respond to increased atmospheric CO_2; however, it is now well recognized that increased atmospheric CO_2 concentrations, $[CO_2]$, above normal levels increase the photosynthetic rate of plants and therefore potentially their growth.

CO_2 Fixation and Productivity

Among the wide range of C_3 species that have been examined, including virtually all crop and forest species of northern latitudes, the photosynthesis of some 95% is not saturated by the present $[CO_2]$. C_3 plants require 800–1000 μmol mol^{-1} CO_2 for saturation of photosynthesis. Almost all show significant increases in photosynthesis and dry matter production in response to an increase in $[CO_2]$ of between 500 and 1000 μmol mol^{-1} [22,23]. A doubling of $[CO_2]$ from 330 to 660 μmol mol^{-1} increases the productivity of crops and C_3 plants by 33–41% [24–26].

Although the net photosynthesis assimilation increases by an average of 50% in the short term, the plant weight increases by only 40% over a long period [27]. Such stimulation is modest compared with what might be expected on the basis of short-term increases in carbon fixation at high $[CO_2]$. Also, there is much evidence that the initial CO_2 stimulation of photosynthesis is not maintained and that downregulation of photosynthesis caused by acclimation occurs after prolonged exposure to high CO_2 concentration [6,23].

Because C_4 and crassulacean acid metabolism (CAM) species use phosphoenolpyruvate carboxylase (PEPCase) for their initial fixation of CO_2 and PEPCase can be saturated at current atmospheric $[CO_2]$, a little influence of elevated $[CO_2]$might be expected for these plants. Indeed, elevated CO_2 concentrations have only a small effect on the net CO_2 uptake by C_4 plants [6,28] The effects of CO_2 enrichment and irradiance on the growth and gas exchange of the two tropical grasses *Panicum laxum* (C_3) and *Panicum antidotale* (C_4) were compared. Elevated CO_2 enhanced the plant dry weight at low and high irradiances in the C_3 species but only at high light in the C_4 species.

Elevated atmospheric $[CO_2]$ has varied effects on the net CO_2 uptake and productivity of CAM plants. Some are not affected, but a doubling of CO_2 concentration stimulated growth in two highly productive CAM species, *Agave salmiana* Otto ex Salm. var. *salmiana* and the widely cultivated prickly pear cactus *Opuntia ficus-indica* (L.) Miller [29]. In *Agave salmiana* grown for 4.5 months in open-top chambers, 55% more unfolded leaves and 52% more fresh weight mass was produced at 730 than at 370 μmol CO_2 mol^{-1}.

Temporal and Space Factors

$[CO_2]$ experiments are mostly done in controlled environments. However, there are substantial variations in the absolute values of environmental parameters and in their variability and coupling. Field conditions are variable in time and space, and strong year-to-year variations are observed [16]. Species can differ in their response to CO_2 concentration. This makes necessary the confirmation that the responses to $[CO_2]$ observed in experiments apply in agricultural or ecological situations.

The effect of elevated $[CO_2]$ on the productivity of spring wheat, winter wheat, and faba beans was studied in experiments in temperature-regulated crop enclosures [11]. At an external $[CO_2]$ of 700 μmol mol^{-1}, the maximum canopy CO_2 exchange rate (CERmax) was stimulated by 51% for spring wheat and by 71% for faba bean. At the end of the growing season, the aboveground biomass increase was 35% for spring wheat and 58% for faba bean, whereas the harvest index did not change. This differential effect in the CO_2 response was shown to be at least partly due to differences in the daily air temperatures during comparable stages of growth of these crops. Simulations also showed that variations between years in the CO_2 response can be largely explained by differences in weather conditions between growing seasons.

Results for well-fertilized and irrigated *Lolium perenne* swards grown at elevated (700 μmol

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

mol^{-1}) and ambient atmospheric CO_2 in open-top chambers in Ireland for a 3-year period showed marked seasonal variations in the aboveground stimulation in yield (Fig. 1) [22]. The largest increases in yield were recorded in the early and late growing season, with an overall stimulation in yield for the elevated CO_2 treatments of about 20 (1992), 28 (1993), and 42% (1994).

The effect of CO_2 enrichment on yield is dependent on the stage of growth at which it is applied, as reviewed by Lawlor and Mitchell [30]. Enrichment from emergence to anthesis or from anthesis to early pod development did not increase soybean yield, whereas enrichment from early pod development until maturity and from emergence to maturity increased yields by 27 and 36%, respectively.

Biomass Allocation

The pattern of biomass allocation is a key factor determining a plant's potential for early vegetative growth and yield [31]. Stulen and den Hertog [32] provided a detailed review of the effects of elevated [CO_2] on biomass partitioning in vegetative plants. Rogers et al. [33] also reviewed the subject, focusing on the effect of elevated [CO_2] on the root/shoot ratio of the crop plant.

Plants growing under CO_2 enrichment develop differently from plants growing under ambient CO_2 levels. In cucumber, longer internodes and more male flowers are found than under ambient [CO_2] conditions [34]. It is not clear whether these developmental changes are directly due to an enriched supply of photoassimilates or an altered hormonal signal reflecting changes in the forms and amounts of carbohydrates and amino acids in the transport system.

Increases in yield due to CO_2 enrichment are often more due to an increase in the number of harvested structures rather than to an increase in their mean size [30]. In soybean, yields increased almost entirely as a result of greater numbers of seeds, and this in turn was due to an increased number of pods rather than the number of seeds per pod, which decreased [35]. Similarly for bean, rice, wheat, and sweet potato, increases in yield are entirely the result of more pods, grains, or tubers. Presumably the availability of energy and substrates determines how meristematic tissue develops. The relative insensitivity of seed or tuber size to additional carbohydrates during filling suggests that there is a genetically determined upper limit [30].

A stimulation of root system development has often been found; in a review of the literature, Rogers et al. [36] reported that 87% of the species studied showed a root dry weight increase with elevated [CO_2]. Roots often exhibit the greatest relative dry weight increase among plant organs under these conditions. The most striking effect concerns the root architecture. CO_2 enrichment

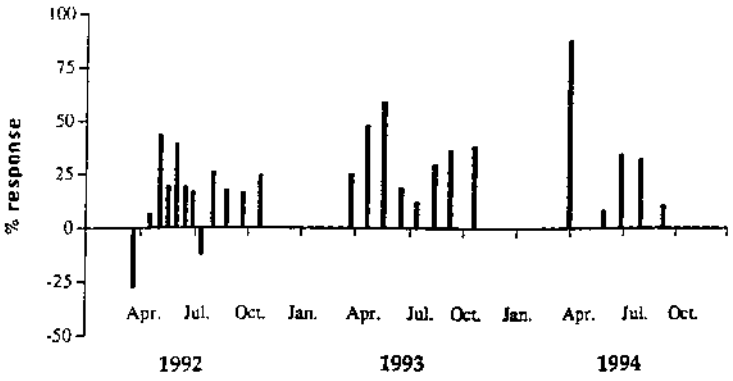

FIGURE 1 The seasonal change in yield stimulation over a 3-year period for *Lolium perenne* swards grown in Dublin, Ireland, in open-top chambers at elevated (700 μmol mol^{-1}) CO_2 compared with an ambient CO_2 treatment. (From Ref. 22.)

appears to increase the length of tap roots and the number of laterals [37]. A study using cotton in the FACE system [38] led to the conclusion that the spread of cotton roots through the soil profile is faster and more prolific under elevated [CO_2]. A change in root architecture and development also was highlighted in the study of Berntson and Woodward [39]. The stimulation of root system development is very likely to be associated with changes in the rhizosphere microbiology which will alternatively act on soil formation processes [40].

No clear trend has been observed in controlled-environment studies on the effect of CO_2 enrichment on the distribution of dry matter between plant organs, which allowed for a greater proportion of plant dry weight at high CO_2. Elevated [CO_2] was found to cause a 24% increase in spring wheat total biomass, with a 25% decline in root mass, and a 29% increase in grain mass [4]. Although earlier papers have demonstrated that [CO_2] favors investment of the biomass in roots relative to that in leaves [41], it has become clear that these are indirect effects due to the more rapid depletion of nutrients in the root environment as a consequence of enhanced growth [32,42]. If the nutrient supply is maintained at an optimum level, there is no effect on the fraction of the biomass allocated to the root. However, if nutrients cannot be absorbed in proportion to the enhanced growth, then CO_2-enriched plants show an increased allocation to roots at the expense of that to leaves [43]. This is the normal plant response found at a suboptimal nutrient supply [44]. The question remains controversial because of the highly variable experimental factors interacting with CO_2.

Controlled-environment studies have shown that CO_2-induced increases in leaf area are largely due to more extensive branching in dicotyledonous plants [36] and tillering in grasses [45], although there also is an increase in expansion rates and a small increase in maximum leaf size [25]. In some species or conditions, elevated [CO_2] produces substantial carbohydrate accumulation within the leaves. The leaf morphology can be changed [46]; massive starch granules can distort chloroplasts [47] and possibly disrupt function by distending the thylakoid membranes and imposing constraints on the diffusion of gases or metabolites.

The leaf mass per unit area (LMA) has been found to increase in response to elevated [CO_2] in soybean but not in maize [30]. The general increase in LMA is presumably mostly due to the increase in starch content [48], but the leaves of bean plants grown at high [CO_2] also are thicker owing to an increase in the number of palisade cells [49], an effect which again does not occur in maize.

Mechanisms which might explain the effect of environmental variables on the pattern of biomass allocation have been discussed by Lambers et al. [44]. Although greater allocation of biomass to leaf area (high leaf area ratio, LAR) has a positive effect on a plant's potential relative growth rate (RGR), Van den Boogaard et al. [50] and Veneklaas and van den Boogaard [51] found no significant correlation between the RGR and LAR in a comparison of wheat cultivars grown well-spaced in soil. The lack of a correlation between the RGR and LAR is due to the negative correlation of the LAR with the net assimilation rate (NAR), which counteracts the positive effect of the LAR.

Chemical Composition of Plants

Several field studies have addressed the question of whether CO_2 enrichment affects the composition of plants [33,52]. No change was found in the N content per unit dry matter of leaves, stems, or grain due to CO_2 enrichment in winter wheat [53]. Crop products consumed by humans have generally not revealed any difference in quality in elevated [CO_2]. However, a recent paper by Blumenthal et al. [54] indicated a loss of protein in wheat grain and poorer quality of bread.

In leaves, the bulk of the dry weight increase is due to massive starch accumulation [34]. High atmospheric CO_2 levels also enhance the synthesis of transport sugars, primarily sucrose [55], or the raffinose series of sugars, such as stachyose, in some species like cucumber [48]. At first glance, sugar synthesis and export seem to compete with starch synthesis and storage, but the two processes are merely components of a general strategy, plants having evolved mechanisms for fixing maximal amounts of CO_2 when optimal environmental conditions for leaf photosynthesis prevail.

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

Elevated CO_2 was found to increase the carbohydrate status (starch, sucrose, and glucose) of soybean under field conditions [35]. Similarly, wheat plants doubled their amounts of sucrose and starch accumulated when grown in high [CO_2], and sweet potato showed increased starch in the storage tuber and leaves [56]. Huber et al. [48] concluded from the above data that most of the additional net photosynthesis was accumulated as starch, as there was little increase in sucrose phosphate synthase or in carbon export.

CO_2-induced changes in chemical composition have been investigated in the leaves of 27 C_3 species, including those of crop plants and fast- and slow-growing wild herbaceous plants, as well as tree seedings [27]. There were two constituents on which CO_2 had a major effect. The most important effect was the increase in the concentration of total nonstructural carbohydrates (TNC) from 137 to 211 mg g^{-1} dry weight at ambient and doubled [CO_2], respectively, with considerable variation in the response of different species, ranging from almost zero to over 100%. The increase also was evident when results were expressed in terms of relative total nonstructural free carbohydrate (Fig. 2). This increase may indicate that at elevated [CO_2] carbon is not the limiting factor. The capacity for accumulation of soluble carbohydrates depends on the leaf development stage [15].

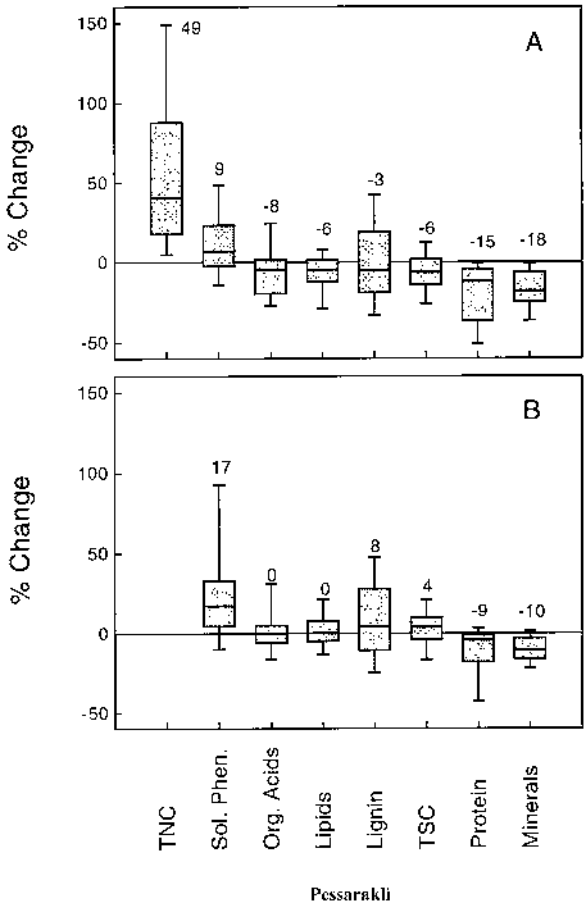

FIGURE 2 Proportional changes in leaf chemical composition of 70 Pa CO_2-grown plants relative to values for plants grown at 35 Pa CO_2 (A) Values on a total dry weight basis; (B) values on a TNC-free basis. (From Ref. 27.)

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

There was no significant difference in the glucose and fructose content in the plants grown at high CO_2 at 60% leaf expansion. At 95% leaf expansion, hexose and sucrose levels significantly increased in response to exposure to elevated CO_2. Starch levels of the control plants remained unchanged from 2 to 60% leaf expansion and then increased up to the 95% expansion stage and declined by maturity. Overall starch significantly accumulated in the plants grown at high [CO_2], especially in the older leaves (Fig. 2). The second largest change induced by high [CO_2] was a decrease in the average protein concentration from 270 to 219 mg g^{-1} dry weight for ambient and doubled [CO_2] [27]. Since the latter was largely a consequence of the decrease in N, the C/N ratio showed increases of up to 80% in some species (Fig. 2).

A differential effect of high [CO_2] on tomato chloroplast proteins has been observed by Van Oosten and Besford [15]. No effects of elevated [CO_2] on the levels of various proteins associated with thylakoïds (D1 and D2 of the photosystem II [PSII] core complex, cytf, and PS I core protein) were detected up to 22 days. However, in the fully expanded and mature leaves, thylakoïd protein levels were observed to decrease as the growth CO_2 level increased. However, major soluble polypeptides (large subunit and small subunit of ribulose bisphosphate carboxylase oxygenase (Rubisco) and Rubisco activase protein) encoded by chloroplast or nuclear genes declined under elevated [CO_2] earlier in the leaf's development than was the case for the thylakoïd proteins derived from chloroplast genes. Thus, prolonged exposure to increasing doses of CO_2 changes the stoichiometry between thylakoïd and soluble photosynthetic proteins. Chlorophyll was found to decline in parallel with the thylakoid proteins only in fully mature leaves.

The only other class of compounds for which the average (negative) change was larger than 10 mg m^{-1} was the minerals [57].

With respect to C_4 plants, it must be borne in mind that no effect of CO_2 enrichment on the element composition nor on the moisture, fiber, oil, protein, or fatty acid composition of maize plants was found [52].

As a consequence of the chemical changes plants have to withstand, plant-insect-herbivore interactions must be given careful consideration, because their consumption, growth, and fitness may be affected by the lower quality of plants grown under high [CO_2] [58].

Respiration

A topic that has raised discussion in the literature is the effect of CO_2 on respiration. Many reviews have been published on this important subject [59–63]. Direct (or short-term) and indirect effects of elevated [CO_2] have been found, although their significance is not yet fully understood.

The short-term effect is characterized by an immediate reduction in the apparent respiration rate. This is observed in any organ and any kind of tissue of C_3, C_4, or CAM plants [63]. Dark CO_2 fixation through PEP carboxylase activity has been invoked in some cases as an explanation [63], and the most recent hypothesis describes a mechanism involving the direct inhibition of enzymes involved in mitochondrial electron transport [12]: Elevated [CO_2] has been shown to reduce the activity of cytochrome oxidase and succinate dehydrogenase in isolated mitochondria [64]. The long-term response to elevated [CO_2] is mainly of a biochemical nature.

The observed decline in the respiration rate is correlated with both an accumulation of total nonstructural carbohydrates (TNC) and a reduction in protein. The accumulation of TNC has a direct effect on growth respiration, as compounds like starch can be formed with little CO_2 production. The reduction in protein has an effect, as protein synthesis is accompanied by a large CO_2 production, whereas protein maintenance is less costly.

The ''construction cost'' was defined by Penning de Vries et al. [65] as the amount of carbohydrate required to synthesis 1.0 g of plant dry mass (carbon skeletons and energy necessary for biosynthetic reactions). The equation quantifies the substrate and oxygen demand as well as carbon dioxide evolution. It accounts for all substrate molecules required for biosynthesis of the carbon skeletons and to provide the energy required for the nonsynthetic processes such as transport of molecules and maintenance of RNA and enzymes. Given that C concentration did not change,

whereas growth respiration decreased on average by 11%, Poorter et al. [27] calculated that the construction cost at high [CO_2] decreased by 3–4%. Their schematic representation of the most important changes in the chemical composition of plants grown at elevated [CO_2] and the consequences for leaf construction cost is shown in Figure 3. The reduction in protein concentration is more important than the increase in TNC in explaining the decreased growth respiration per unit biomass formed. However, it must be remembered that the growth stimulation resulting in larger plants often compensates for all of the above-described reduction in respiration per unit dry weight, and that the overall plant respiration is eventually mostly enhanced after long-term CO_2 enrichment.

Net CO_2 Uptake

The two essential steps of assimilation of CO_2 into organic photosynthetic products are the uptake or diffusion of the gas into the leaves followed by its fixation into a usable reduced form during photosynthesis.

Stomatal Response

Stomata in the epidermis of leaves are the main route if not the only one for CO_2 influx. Photosynthesis is increased in most species when stomata are open, a condition normally favored by high air humidity and low CO_2 partial pressures within the leaf. High CO_2 partial pressures within the leaf, such as occur during CO_2 enrichment, cause the stomata to close and conductance is strongly reduced [66,67]. In some tree and crop species, stomatal frequency was found to decrease as [CO_2] increased from preindustrial levels [68]. But the observed reduction in conductance is more likely to be due to the direct effects of [CO_2] on the stomatal aperture. At high CO_2 levels, the net result of stomatal

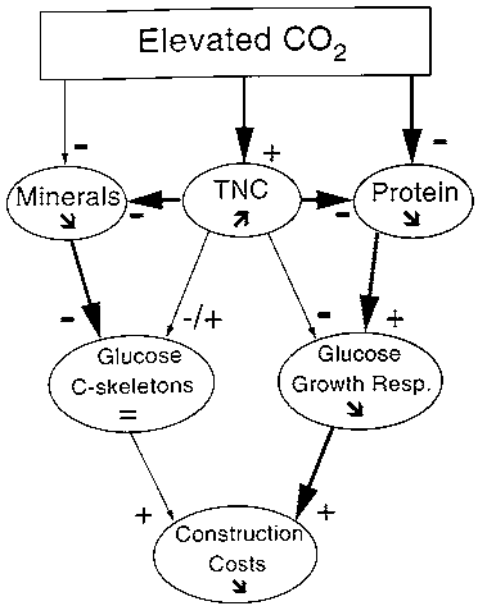

FIGURE 3 Schematic representation of the most important changes in chemical composition of plants at elevated CO_2 and the consequences for leaf construction costs and its components. Thick arrows represent strong effects and thin arrows smaller effects. + indicates a positive effect and − a negative one. The net result of all the effects on the various constituents and glucose costs is indicated by the up and down arrows in the boxes. (From Ref. 27.)

closure is a reduction of the transpiratory flux and therefore an improved water-use efficiency (WUE = dry matter gained/water loss). Nevertheless, with CO_2 enrichment, the gradient of $[CO_2]$ remains steep enough to maintain the net carbon gain.

Morison [69] showed that the stomatal conductances of C_3 and C_4 leaves respond similarly to elevated $[CO_2]$. The two tropical grasses *Panicum laxum and Panicum antidotal*, of the C_3 and C_4 carboxylation types, respectively, respond like most plants to CO_2 enrichment by a strong reduction (50%) in stomatal conductance [70]. The mechanism of stomatal regulation by $[CO_2]$ involves Ca^{2+} ions, cytokinine, and abscisic acid [66]. Since the work of Farquhar et al. [71], an empirical relationship which links the atmospheric CO_2 concentration to the intercellular CO_2 concentration has been used, which shows the interdependence between the assimilation rate and stomatal conductance.

The 30% yield increase reported for wheat and many other C_3 species grown under doubled $[CO_2]$ [24] results primarily from an increase in the net photosynthesis rate but also by the improvement of the whole-plant water-use efficiency resulting from this partial stomatal closure [72].

The increase in production of tall prairie grasses, belonging to the C_4 species, whose photosynthetic mechanisms were originally thought to be ''insensitive'' to increased $[CO_2]$, also has been attributed to this improvement in WUE [73,74].

Net Photosynthesis and Photorespiration

Our current knowledge of the mechanisms of photosynthesis leads us to interpret the effect of a $[CO_2]$ increase in terms of an increased carboxylase activity and a decrease in the oxygenase function of Rubisco. As a direct consequence of CO_2 enrichment, the oxygenase reaction of Rubisco and hence photorespiration is suppressed [75]. This is another direct consequence of CO_2 enrichment that affects the efficiency of the Calvin cycle, phosphate exchange, starch synthesis, and carbohydrate export within a typical leaf. Some temperate crops growing under low irradiance have been found to respond more to CO_2 than those growing at higher irradiance. This is thought to be due to the suppression of photorespiration [76].

When other processes limit photosynthesis, the response to elevated $[CO_2]$ will be smaller. In extreme cases where the rate of photosynthesis is limited by an end-product synthesis, rising $[CO_2]$ has no effect at all on photosynthesis [77].

Rubisco

Rubisco plays a leading role in the response to elevated $[CO_2]$ owing to the fact that this enzyme is both the primary regulatory site for CO_2 fixation and a major storage site of leaf N [78]. There are reports for a number of species with reduced Rubisco activity at elevated $[CO_2]$, as reviewed by Bowes et al. [23]. Rowland-Bamford et al. [79] analyzed the activity, amount, and activity ratio of Rubisco along with other leaf parameters in the C_3 plant rice grown under various $[CO_2]$ concentrations that ranged from that corresponding to the Ice Age to predicted values for the next century. Expressed on the basis of leaf area, Rubisco protein, or chlorophyll content (Table 1), total leaf Rubisco activity decreased with increasing $[CO_2]$. A decrease in Rubisco activity may be caused by a reduction in Rubisco protein concentration, which is consistent with the hypothesis that N is being reallocated. The Rubisco protein content did indeed decline linearly with increasing $[CO_2]$; dropping by as much as 60% (Table 1). Rubisco protein (RuBP) may still decline with seemingly adequate N supplies, possibly because the C/N ratio during growth is unbalanced. [23].

Since the publication of Farquhar's model of leaf photosynthesis [80], photosynthetic responses to CO_2 have needed to be evaluated in terms of potential limitations from RuBP regeneration and P ion (Pi) supply in addition to Rubisco and CO_2 [81].

The substrate RuBP is a potent inhibitor of the activation process. This phenomenon takes place via Rubisco activase, a regulatory enzyme found in the chloroplast stroma that catalyzes the carbamylation of Rubisco and modulates its activity. The substrates for Rubisco activase are the

RuBP-inactivated Rubisco complex and CO_2. Some species show a decrease in Rubisco activation as the CO_2 concentration for growth increases; this does not occur with the activation state of soybean or rice Rubisco, which is not affected by $[CO_2]$ enrichment [16].

An endogenous inhibitor of Rubisco, 2-carboxyarabinitol 1-phosphate (CA1P) [82], is synthesized in the dark. Measurement of Rubisco activities from dark-sampled leaves of rice and soybean indicated that CO_2 enrichment may enhance its synthesis in these two species [23]. The activity ratio (initial/total activity) was used to determine the proportion of the non–inhibitor-bound enzyme which was carbamylated and catalytically competent. The activity ratio declined by 24% in rice leaves grown at 900 μmol mol^{-1} $[CO_2]$ (see Table 1).

Tomato plants are a very well-characterized model system for the plant response to elevated $[CO_2]$ [15]. A regression analysis indicates a differential linear response to $[CO_2]$ at different times. There was little response at 60% leaf expansion, with almost no difference in Rubisco large subunit (LSU), small subunit (SSU), and Rubisco activase (rca) protein level. But there was increasing loss of Rubisco activity as the leaf expanded and was exposed to high levels of $[CO_2]$. At full expansion, the levels of LSU, SSU, and rca decreased as the CO_2 growth levels increased.

For their initial fixation of atmospheric CO_2, CAM plants use PEPCase which can be saturated at normal atmospheric $[CO_2]$. However, the Michaelis constant (HCO_3) for PEPCase was shown to be 15% lower for *Agave salmiana* and 44% lower for *Opuntia opuntia* when the CO_2 concentration was doubled [29]. Doubling the CO_2 concentration increased the daily net CO_2 uptake in another common CAM species *A. deserti*. The increase was up to 49% and lasted throughout the long-term experiment [22]. The substantial increase in the net CO_2 uptake and biomass production that occurs in these three CAM species when the ambient CO_2 concentration is doubled results mainly from higher inorganic carbon levels available to their carboxylating enzymes, a greater substrate affinity for PEPCase, and a greater percentage of Rubisco in the activated state. Also, in C_4 plants, the enzyme responsible for the initial fixation of CO_2 is PEPCase. The major differences between C_3 and C_4 species in response to CO_2 is the use by C_3 plants of Rubisco as the initial carboxylase, and its association with photorespiratory activity [83]. A number of important studies have allowed the observation of actual growth differences associated with C_3 and C_4 *Panicum* species. Growth of the C_3 *Panicum* was increased by CO_2 enrichment, whereas the C_4 *Panicum* was much less affected, as would be predicted from the enzymatic responses of Rubisco compared with PEPCase [84]. High CO_2 strongly reduced the stomatal conductance in both species, whereas it affected the Rubisco content of only the C_3 species exposed to high light [70].

Molecular Biology Studies

A few studies have been carried out on the effects of high [CO_2] on the regulation of photosynthesis-associated genes (PAGs). An upregulation of carbonic anhydrase gene expression was observed in *Arabidopsis* plants exposed to 700 μmol CO_2 mol^{-1} for 3 weeks compared with ambient-grown plants [85]. Studies using very high CO_2 concentrations demonstrated that nuclear PAGs were more sensitive than plastid PAGs in tomato plants exposed to elevated [CO_2] [86]. The model predicts that plants acclimated to high [CO_2] progressively accumulate sugars as a result of insufficient sink strength.

The relationship between aspects of molecular biology (PAG gene transcript accumulation), biochemistry (Rubisco activities, chloroplast protein composition, and sugar content) and photosynthetic gas exchange was investigated by Van Oosten and Besford [15], with respect to leaf development in tomato plants exposed to three CO_2 concentrations (350, 700, 1050 μmol CO_2 mol^{-1}). There was a significant decrease in *rbc*L transcripts (coding for LSU protein) and *psaA-B* transcripts (coding for the A_1 and A_2 proteins of the PSI core complex) throughout leaf expansion in all of the [CO_2] treatments. Exposure of the plants to elevated [CO_2] did not cause any further significant decreases in the *rbc*L and *psaA-B* transcript levels in leaves at any stage of leaf development (Table 2).

According to the ''molecular model'' [87], which takes into account the source-sink status of a plant and the metabolic regulation of nuclear PAG expression by hexoses, it should be possible to predict how and when protein, enzyme activities, and transcript levels of some of the PAGs should respond to elevated [CO_2]. Overall, the transcript levels of PAGs were strongly decreased after 60% leaf expansion. There was a coordinated pattern of expression of *rbcs* and *rca* transcripts and corresponding protein levels during leaf expansion and exposure to elevated CO_2 concentrations. Besford et al. [88] and Van Oosten et al. [89] have shown (using Rubisco kinetics, total activities, and the equation of von Caemmerer and Farquhar [90]) that there is a causal link between transcript levels and the reduction of the amount and activity of Rubisco. Although there were significant changes in the levels of mRNA of nuclear genes caused by the elevated CO_2 concentrations, the levels of nuclear rRNA transcripts were not affected, which indicates the specificity of the molecular effect of [CO_2] on nuclear gene expression. Finally, the model predicts that the chloroplast genes should be much less sensitive to elevated [CO_2]. Indeed, it is only in the mature leaves that some

transcript levels of chloroplast genes are sensitive to high CO_2. When the levels of transcripts of chloroplast genes examined in this work are expressed on a *16S* rRNA basis (which is a marker of chloroplast number), no difference due to elevated [CO_2] was observed in the mature leaves. The mature leaves of plants grown in high [CO_2] might have lower chloroplast numbers, as the level of *16S* rRNA transcripts was lower than in the control plants. This might explain why the level of thylakoïd proteins associated with the PSI or PSII core complexes of cyt*f* and the level of soluble LSU protein were all lower in the mature leaves exposed to elevated [CO_2] than in the control plants. The low responsiveness of chloroplast genes to other environmental factors as compared with nuclear genes has been reported by several investigators [91,92].

Van Oosten et al. [87] found some evidence that the regulatory metabolites responsible for the effect of CO_2 on nuclear PAGs are the hexose glucose and fructose. Jang and Sheen [93] have recently demonstrated that plant hexokinases are involved in the sensing of the level of hexoses. A molecular model invokes the metabolic regulation of gene expression, with glucose providing a regulatory signal to repress the transcription of photosynthetic genes, including those encoding the small and large subunits of Rubisco [94]. This concept is consistent with findings for CO_2-enriched rice [23]. Although Rubisco concentration and activation were found to be downregulated, the activity of sucrose phosphate synthase was found to increase by about 20% at 600 vpm as compared with 330 vpm [CO_2]. A similar situation was found to occur in the sink-limited regions of leaves of transgenic tobacco overexpressing invertase in the cell walls [23].

Acclimation

In a wider perspective, we need to address the problem of photosynthesis rate acclimation: Is the increase in rate maintained throughout the life of the leaf or the plant? As an example, the light-saturated rate of photosynthesis, *A*, of tomato plants measured at growth CO_2 is significantly stimulated by elevated CO_2 concentrations [15]. However, the initial stimulation of *A* by high levels of CO_2 seen during the expansion phase of the leaf is lost at full expansion after 31 days of acclimation. When measured after full leaf expansion, *A* is actually negatively correlated to the CO_2 levels in which the plants were grown (Table 3) [88]. No significant difference was observed between the rate of nonphotosynthetic CO_2 evolution in the light for the plants grown at ambient CO_2 and for those fully acclimated to their elevated CO_2 growth concentration.

Acclimation can be defined as the physiological changes which occur when plants are grown in high [CO_2] [12]. The role of acclimation is presumably to optimize carbon acquisition and utilization [23]. In most instances, downregulation of CO_2 assimilation probably reflects a restricted capacity to handle the extra carbon, because other environmental resources are insufficient, or the plant has inherent metabolic limitations. According to this view, acclimation is an optimization process that reallocates resources from nonlimiting components, such as carbon acquisition, into limiting

TABLE 3 Light-saturated Rate of Photosynthesis, P_{max}, Measured at 350 μmol CO_2 mol^{-1} (1450 μmol m^{-2} s^{-1} PAR) of the Unshaded Fifth Leaf of Tomato Plants at Various Stages of Development and Exposure to Various Concentrations of CO_2

Leaf expansion/% (days exposure)	Growth CO_2 concentration (μmol CO_2 mol^{-1})

components, such as electron transport and carbohydrate handling [95]. The availability of N would appear to be a primary factor, because CO_2 enrichment increases the C/N ratio of plants.

Acclimation of assimilation during extended periods of growth under conditions of elevated [CO_2] has been documented [96]. There is abundant evidence that, in the long term, the photosynthetic properties of leaves which developed at elevated [CO_2] differ from those which developed at normal [CO_2]. Growth in elevated [CO_2] commonly results in decreased photosynthesis relative to controls when measured at normal atmospheric [CO_2]. Arp [97] drew attention to the strong correlation between the rooting volume and the acclimation of the photosynthesis of plants in elevated [CO_2]. In a survey of 163 species, the stimulation of net photosynthesis was about 50% for large rooting volumes and field experiments but reduced by about half of this amount when the rooting volume was limited. The acclimation of photosynthesis involves various aspects of metabolism. It is accompanied by higher carbohydrate concentrations and lower concentrations of soluble proteins, especially Rubisco [12]. This is often attributed to the small rooting volume [97] or to a low nitrogen availability [42], as if the plants were compensating for the change in the rate of their photosynthetic activity by modifying their storage and allocation strategies. In some species or conditions, because the plant may be unable to use all the additional carbohydrate that photosynthesis in elevated [CO_2] can provide, substantial carbohydrate accumulation within the leaves is produced. The leaf morphology can be deformed; massive starch granules can distort chloroplasts and possibly disrupt function by distending the thylakoid membranes and imposing constraints on the diffusion of gases or metabolites [95].

Downregulation in photosynthesis may occur in the assimilation rate over the intercellular [CO_2] (A/Ci) curve, with changes in the initial slope and/or RuBP-limited region. The underlying causes of acclimation in the A/Ci curve are only partially resolved. Potentially it could be a stress response indicating physiological disfunction in plants adapted to low [CO_2]. Alternatively, it may be an optimization process as resources change. In the most recent review published on the effect of elevated [CO_2] on plant photosynthesis, Drake et al. [12] concluded that rising [CO_2] will lead to more efficient plants either in shade or in dense canopies.

There are many reports of a decrease in respiration in elevated [CO_2] [12]. It can be reduced to about 20% for a doubling of the atmospheric [CO_2]. Acclimation of the rate of respiration in wheat was shown to be correlated with reduced activity of enzymatic complexes of the mitochondrial electron transport chain (cytochrome oxidase and complex III) and resulted in a diminished capacity for tissue respiration [98].

For some species, acclimation of photosynthesis resulting from long exposure to elevated [CO_2] is concomitant with downregulation of the amount of Rubisco protein [79]. This coarse control of the amount of Rubisco protein probably serves to optimize CO_2 acquisition with utilization of the fixed carbon [99]. A survey by Drake et al. [12] shows an average reduction in the amount of Rubisco of 15% in eight studies including 11 species and a reduction in the Rubisco activity of about 24%. As Rubisco protein can constitute 25% of leaf N, these reductions affect a major component of the foliage tissue N (15–19%). In wheat grown with an adequate supply of N and water under elevated [CO_2], there was a significant loss of Rubisco followed by other photosynthetic proteins relative to controls at the completion of flag leaf development [100].

Regulation of the expression of photosynthetic genes may underlie acclimation to growth in elevated [CO_2]. Acclimation of photosynthesis to elevated [CO_2] has frequently been suggested to be more marked when N supply is limiting. At high N, the stimulation of net photosynthesis by elevated [CO_2] is about 50%, but this stimulation drops to about 25% when available N is low. Rubisco and Rubisco large subunit rbcL mRNA expression in *Pisum sativum* and *Triticum aestivum* were shown to be unaffected by growth in elevated [CO_2] when the N supply was abundant but showed marked decreases in response to elevated [CO_2] when N was deficient [101].

Interspecific and Intraspecific Differences

Poorter [26] has reviewed the response to elevated [CO_2] in 156 species. It was found evident that large differences exist between different functional types. We have already mentioned large differ-

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

ences due to the photosynthetic pathway used by the plant, with C_3 species having a larger growth stimulation than C_4 species. This will alter the competitive strength for C_4 crops like corn, sugar cane, or sorghum, a possibly significant aspect in weed control. Differences between C_3 species are largely determined by their developmental strategies, with sink size being the major determinant of the maintenance of a higher photosynthetic rate and increased leaf area production having the opposite effect owing to mutual shading of leaves. Crop species usually respond stronger than wild growing species, a response which may be linked to mineral nutrition, which is generally controlled in many crops [102]. In this connection, it must be remembered that nitrogen-fixing species have generally higher growth stimulation than non–N_2 fixers, and that legumes will probably benefit the most from rising [CO_2] levels [103–105]. Woody crops seem to be less responsive than herbaceous crops. This has been attributed to the limitation of the net assimilation rate of tree leaves by higher internal resistance to [CO_2] transfer [106]. Recently, the occurence of intraspecific variations in the response to elevated [CO_2] has been described [107,108]. The conclusions are that intraspecific variations in CO_2 responses are often comparable or even greater than interspecific differences. Thus, in all cultivated crops, there is a genetic potential which could be selected in order to maximize the productivity as [CO_2] concentrations increase. However, additional work is required to identify the best cultivars in each species.

INTERACTIONS BETWEEN ELEVATED [CO_2] AND WATER

Many climate models predict that as atmospheric concentrations of CO_2 increase, the frequency of drought also will increase, and that associated with this higher [CO_2], water-use efficiency will rise owing to reduced stomatal conductance.

The relationship between CO_2 and water is complex, because water interacts at an instantaneous and microscopic scale in the mass flux of molecules in the stomatal pore during gas exchange; at a larger organ scale in the determination of the plant photosynthetic capacity by plant water status; and at the whole-plant scale because of the influence of the history of CO_2 fixation on the leaf area, plant stature, development stage, root mass, and distribution in the soil [109].

Elevated [CO_2] and Water-Use Efficiency

Elevated [CO_2] has been shown to have a direct effect on the plant transpiration rate through stomatal closure. For example, the average daily transpiration was reduced in sorghum (C_4 plant) and in soybean (C_3 plant) under elevated [CO_2] [110], but the transpiration reduction was higher for the C_3 than for the C_4 plant. In C_4 as well as C_3 grasses of the Kansas prairie [74], the relative stomatal closure in high [CO_2] induces as much as a 50% reduction in CO_2 leaf conductance. Moreover, the kinetics of stomatal responses to changes in light were more rapid in elevated [CO_2] [111]. The overall result was an improved water status for plants exposed to elevated [CO_2]. At the canopy level, evapotranspiration was reduced by 22%. This reduced water use under elevated [CO_2] extended the active period when water became limiting and was beneficial to the prairie during drier years. A similar result was found by Samarakoon and Gifford [112] on maize. In wet soil, the transpiration rate was reduced by 29% at high [CO_2]; when the soil was drying, plants in high [CO_2] used about 30% less water, and plant growth accumulated 35% more leaf area and 50% more dry matter owing to the fact that the soil had a greater water content in high [CO_2].

These results are amplified by the fact that elevated [CO_2] very often decreases the stomatal density [113]. Decreased stomatal density with high [CO_2] has been observed on longer experimental time periods of exposure (up to 12 months or several years) even at the historical scale [114] essentially on tree species; they concern differences in stomatal density [113] as well as the stomatal index [115]. But it must be mentioned that, in perennial rye grass, this effect has been shown to depend on temperature and to vary with the season and the anatomy of the leaf being considered [116].

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

As the primary effects of elevated [CO_2] on C_3 plants result in an increase in the rate of assimilation and a decrease in leaf conductance for water vapor, a combination of these two effects often leads to an increase of the instantaneous water-use efficiency (CO_2 assimilation rate/transpiration rate) or the more long-term expression of it; that is, biomass accumulation over water consumption [109].

An increase in WUE may be either the result of a decreased leaf conductance and transpiration with no effect on photosynthesis (this is precisely the case of the majority of C_4 species tested) or, on the contrary, the result of a substantial increase in photosynthesis without any effect on leaf conductance and transpiration [105,117] or a combination of the two.

When plants are well watered, the increased yield is essentially due to the increase of photosynthesis. The result of a reduction in the stomatal aperture is a smaller water loss per unit leaf area and consequently an increase in the leaf water potential provided there is no change in the leaf area and root distribution. However, as stated in the above, this is very rarely the case: The improvement of the water status of the plant is often confounded with differences in the plant leaf area and the consequent evaporative demand and there is often a compensation between the increase in the leaf area brought about by elevated [CO_2] and stomatal control of transpiration [118,119]. In cotton, Samarakoon and Gifford [112] reported that, in wet soil, the approximately 15% reduction in transpiration per unit area owing to CO_2 was only half that for other species, whereas effects on growth and leaf area were relatively larger. Consequently, the rate of water use per plant was higher in elevated [CO_2] plants compared with other species where it was reduced. This greater water use caused the soil to dry faster in elevated CO_2. This contrasts with both maize and wheat species which conserve water at high [CO_2] when wet [120].

From the fact that instantaneous WUE is invariably enhanced in elevated [CO_2], it is often thought that elevated CO_2 will alleviate the impact of drought constraints in C_3 plants and increase drought tolerance [109,121,122]. However, this may not necessarily be the case [123,124]: Resistance to drought may also depend on a large number of factors affecting the water evaporative demand such as the leaf area already cited or the ability of stem and root systems to transport water [125].

The comparison of drought-avoiding or non–drought-avoiding species shows that this effect of elevated [CO_2] and drought is very species specific [118,126]. For example, in *Pinus pinaster*, a drought-avoiding species, the stomatal function was not affected but internal [CO_2] was increased. In contrast, in *Quercus petraea,* a drought-tolerant species, drought avoidance was increased in elevated [CO_2] as a result of stomatal closure. Despite these differential responses of stomata and photosynthesis to elevated [CO_2], intrinsic WUE was increased in both species [118]. In the species *Lotus corniculatus*, elevated [CO_2] ameliorates some of the effects of drought, including reproductive capacity, but reduces flowering time, with the final result of shortening the vegetative period and, in fact, the reproductive capacity [127].

Drought stress is a major environmental limitation for crop growth and is common in rainfed rice production systems. Baker et al. [128,129] showed that elevated [CO_2] significantly increased the P_N and WUE of rice, whereas reducing evapotranspiration by about 10%. This water savings allowed photosynthesis to continue 1 or 2 days longer during drought and should promote growth and yield in rice.

Elevated [CO_2] and Performance of Plants Under Drought

Before analysis of the global response of droughted plants to an increasing atmospheric CO_2 level, the effects of water stress and elevated [CO_2] on photosynthesis will be examined.

Resistance of the Photosynthesis Mechanisms to Drought

The net leaf CO_2 assimilation measured in normal air on many C_3 plants declines rapidly with increasing water deficit, being negligible at around 30% LWD [130,131]. Stomatal closure and leaf

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

net CO_2 uptake decline in parallel during drought [132]. Data strongly suggest that stomatal control explains most of the observed decrease in leaf photosynthesis in plants subjected to mild drought. They also suggest that drought affects photosynthetic mechanisms through an effect on the relative water content. Demonstration of the drought effect on the nonstomatal component of leaf photosynthesis relies on our capacity to know whether the CO_2 concentration in the chloroplast remains high or not during a water shortage [132].

Obviously, the operation of the photosynthetic carbon reduction cycle, including ribulose 1,5-bisphosphate regeneration, is not impaired in spinach leaf disks subjected to a mild drought [133]. By analyzing the metabolite pool size on French bean maintained in normal air and subjected to a mild drought, Sharkey and Seemann [134] found no evidence for a lesion in the chloroplast biochemistry necessary for photosynthesis and came to the conclusion that Rubisco is not a prime target of water deficit.

The maximum apparent quantum yield measured at high CO_2 on several different plants does not vary much over a 40% range of leaf water deficit showing that whole-chain electron transport and related processes also are very resistant to dehydration [132]. As a whole, the photosynthetic apparatus of C_3 plants appears to be very resistant to desiccation with the maximum quantum yield and maximum capacity of photosynthesis decreasing significantly only when the leaf relative water content is reduced below 70% [135]. Tourneux and Peltier [136] demonstrated that the rate of photorespiration increases relative to that of net CO_2 uptake as the leaf net CO_2 assimilation decreases in a plant maintained on a drying soil.

It is clear that the photosynthetic apparatus of C_3 plants is very resistant to dehydration. It was shown that water deficit induces expression of particular genes, and this is associated with the adaptive responses of stressed plants [133]. Nevertheless, the photosynthetic apparatus is eventually damaged as dehydration of leaf tissue increases and, after rehydration, the photosynthetic activity of a leaf which has been severely dehydrated does not resume the rate it showed before the drought. The nature of the inhibition of the photosynthetic mechanism during severe desiccation is not yet well understood.

Less is known about the effect of drought on mechanisms of C_4 plant photosynthesis. In contrast to what is usually observed for C_3 photosynthesis [132], the ability of the mechanisms of C_4 photosynthesis to withstand dehydration depends on the speed of the desiccation.

Combined Effects of Elevated [CO_2] and Drought on Plant Photosynthesis

It was examined whether or not these responses of the photosynthesis mechanisms to drought were likely to be modified under elevated atmospheric CO_2 levels.

The mean variation of the maximum apparent quantum yield measured at high CO_2 molar fraction on different plants does not vary much over a 30% LWD range showing that whole-chain electron transport and related processes are very resistant to dehydration under high as well as under low [CO_2] [133].

Quick et al. [137] have shown that the ratio of 3-phosphoglyceric acid to triose phosphate was decreased and that the ratio of triose phosphate to ribulose 1,5-bisphosphate increased in osmotically shocked spinach leaf disks maintained at a high [CO_2] molar fraction in spinach leaf disks.

Using fluorescence techniques, it is possible to show that, in dehydrated bean leaves (LWD of about 30%), a [CO_2] molar fraction as high as 10–12% is necessary to inhibit the oxygenase function of Rubisco [133].

Global Response of Plants Exposed to Elevated [CO_2] and Drought

In light of the possible precipitation shifts caused by global warming [10] and the importance of rain-fed crop production to the world's food supply, determining the direct and possible interactive

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

effects of CO_2 with water management cultural practices and drought stress becomes extremely important.

The atmospheric concentration of CO_2 and water vapor pressure will have interactive effects on leaf expansion and biomass accumulation by virtue of their combined impact on transpiration and assimilation [13].

There are at least two reasons why a rise in atmospheric CO_2 levels should allow better plant performance under drought or on soils with high impedance [138]. First, as the rate of carbon fixation increases, the amount of carbohydrates available for growth and maintenance of osmotic pressure should be greater. Second, lower stomatal conductance should allow maintenance of higher water potentials at a given soil water content.

The improvement of water relations occurs because of a fall in the stomatal conductance with increasing $[CO_2]$. This fall is often more pronounced for water-stressed plants than well-watered ones, which led Pearcy and Björkmans [83] to refer to the protective effects of high $[CO_2]$.

Under elevated $[CO_2]$, C_3 species usually use less water per plant even if the plants are bigger [139]. Under drought, the correspondingly smaller flow of water through the soil to the roots may reduce the uptake of nutrients. Reduction of plant water use under elevated $[CO_2]$ affects the acquisition of nutrients by the plant in different ways, because the smaller flow of water to the root surface might reduce nutrient uptake. But the faster diffusion of nutrients in wet than in dry soil might offset the reduction in uptake caused by smaller mass flow. Finally, elevated $[CO_2]$ also might increase nutrient uptake via increasing the root length.

Crop Response to Interactive Elevated $[CO_2]$ and Drought

Owing to their importance to the world's food supply and their economic interest, the responses of wheat, rice, maize, cotton, grasslands, and trees to interactive elevated $[CO_2]$ and drought are considered below.

The available data from investigations on the growth response to elevated $[CO_2]$ under edaphic stress show that droughted plants do grow faster at elevated $[CO_2]$ and more so, in relative terms, than well-watered plants [138]. Under a mild or late water deficit developing toward the end of the plant development cycle, elevated $[CO_2]$ may allow plants to overcome totally water-stress–induced growth reduction [140].

Wheat

For drought-stressed spring wheat, elevated $[CO_2]$ increased dry matter production owing to increased water-use efficiency and resulted in adaptation to water stress through osmoregulation [141].

FACE experiments were conducted on wheat at both ample (wet) and limiting (dry) supplies of water [142]. For both wet and dry treatments, the relative increase in the biomass resulting from elevated $[CO_2]$ showed a progressive increase with time. The relative effects of elevated $[CO_2]$ on the root biomass were somewhat larger than on the aboveground biomass for the wet treatment but, for the dry treatment, the effects were larger for the aboveground biomass than for the roots. Elevated $[CO_2]$ not only increased the amount of root biomass but also changed its vertical distribution in the soil [139]. More roots were present at high than at low $[CO_2]$ and in the wet than in the dry treatments. The $[CO_2]$ and watering treatments did not significantly affect the maximum root length.

Elevated $[CO_2]$ accelerated plant development by 2.3 and 1.5 days to mid anthesis for wet and dry conditions, respectively, and shorten time to maturity [142]. The accelerated rates of development were associated with higher plant canopy temperatures under elevated $[CO_2]$. As the crop senesced, there was a dramatic decline in green leaf area, with the dry plot declining first, then the wet, followed by the control.

Under the well-watered regimen, elevated $[CO_2]$ caused a modest but statistically significant average increase in grain yield [142]. On the other hand, under the dry treatment, elevated $[CO_2]$ caused a highly significant increase in final grain yield. Elevated $[CO_2]$ also caused a small but

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

significant increase in the harvest index (ratio of grain biomass to total aboveground biomass) for both wet and dry conditions.

Although CO_2 enrichment had positive effects on growth and development of winter wheat at tillering, these were insufficient to counterbalance the debilitating effects of water limitation, and drought stress was shown to have a large negative effect on leaf development in winter wheat [143]. There was only limited compensation for this decrease when the atmospheric CO_2 level was doubled. Thus, if increased drought accompanies the predicted increase in atmospheric [CO_2], the beneficial effect of the latter on production of winter wheat is expected to be minimal.

In an attempt to investigate how [CO_2] and soil water availability, both singly and interactively, affect nutrient uptake by spring wheat, Van Vuuren et al. [139] grew plants at 350 (low CO_2) and 700 (high CO_2) μmol mol^{-1} CO_2 and with frequent (wet) and infrequent (dry) watering. The total amount of water used by the plants differed significantly between the treatments. Plants grown at low [CO_2] used about 1.25 as much water as plants grown at high [CO_2]. ''Wet'' plants used about 1.4 times as much water as plants from the ''dry'' treatments. This was probably due to the smaller stomatal conductance at elevated [CO_2], as has been shown in C_3 species [144,145]. The reduction of plant water use at elevated [CO_2] left the soil wetter between watering both at frequent and infrequent watering. This affects the acquisition of nutrients by the plant.

The interaction between the effects of [CO_2] and soil water availability differ between nutrients, because nutrients differ in their amounts and mobility in the soil. Thus, the total plant N, P, and K contents increased significantly with watering frequency [139], but only the total P content increased with [CO_2]; for the total plant K, the increase with [CO_2] was only marginally significant. The total plant N contents did not differ significantly between [CO_2] treatments. A difference in the plant N content was indicated by the dry treatment at the last harvest. The plant N contents in the dry treatment were greater at high than at low [CO_2]. In the wet treatment, the plant K content was greater at low than at high [CO_2], possibly reflecting the difference between [CO_2] in water use.

Rice

Excluding irrigated rice, about half of the world's rice land area depends on rainfall and is often subjected to drought stress. In terms of final seed yield, the vegetative phase of development is far less sensitive to drought than reproductive development [146]. The sensitivity of rice reproductive growth stages in terms of yield reduction or sensitivity to drought was ranked in the following order: (a) flowering, (b) gametogenesis, (c) panicle initiation, and (d) grain fill [128]. The effects and possible interactions of elevated [CO_2] and drought stress imposed at panicle initiation, anthesis, and both panicle initiation and anthesis on rice growth, grain yield, and yield components have been quantified [128].

As expected, drought stress reduced biomass accumulation in both ambient and elevated [CO_2] treatments [128]. [CO_2]-enriched plants grown under drought stress have increased growth compared with plants grown under drought stress at low [CO_2]. The [CO_2] enrichment increased stomatal resistance sufficiently to maintain high leaf water potentials and avoid drought. In both CO_2 treatments, the anthesis drought treatment reduced the aboveground biomass far more severely than the panicle initiation or panicle initiation and anthesis treatments. The large reduction in the biomass of the anthesis treatment suggests that the panicle initiation drought, in some way, acclimated or hardened the plants to withstand the subsequent anthesis drought.

In both [CO_2] treatments, the effect of drought stress on final seed yield was small except for the anthesis drought, which reduced grain yield. This decline was due to the significant reduction in individual seed mass [128].

Mild drought can accelerate development, whereas more severe drought stress often delays flowering relative to well-watered controls [147]. The drought at panicle initiation delayed the onset of panicle appearance and anthesis by about 3 days in both [CO_2] treatments.

Baker et al. [129] quantified the effects and possible interactions of [CO_2] at 350 and 700 μmol mol^{-1} and drought stress on rice (*Oryza sativa*, L.) photosynthesis, evapotranspiration, and

water-use efficiency. Carbon dioxide enrichment significantly increased both the canopy net photosynthetic rate and water-use efficiency, whereas reducing evapotranspiration by about 10%. This water saving under [CO_2] enrichment allowed photosynthesis to continue for about 1–2 days longer during drought in the enriched compared with the ambient [CO_2] control treatment. These results indicate that, in the absence of other potential climate change factors, such as increased air temperature, rice grown in the next century may use less water, use water more efficiently, and become better able to avoid drought in some situations.

Maize

The C_3 cycle in bundle sheath cells of this C_4 species is naturally exposed to high CO_2 concentrations, but the extra carbohydrates do not accumulate, because the rate of assimilation export is greater than in C_3 leaves. This higher capacity for sucrose translocation in maize may be supported by the closer proximity of mesophyll cells to the vascular system. It is thus believed that maize plants will cope with elevated CO_2, because they have mechanisms to deal with high rates of carbohydrate synthesis and transport [148]. High [CO_2] was shown to counteract most of the inhibitory effect of drought on *Zea* leaves' photosynthesis. It was shown that, in soil that was drying from field capacity, plants in high [CO_2] used about 30% less water than those in ambient [CO_2]; this resulted in higher soil water content at high [CO_2], and the plant accumulated 35% more leaf area and 50% more dry matter [149]. In drying soil, the increase in WUE was both due to increased dry matter and reduced water use, with the contribution from each depending on the stage of soil drying.

Cotton

In cotton plants, the enhanced dry matter yield due to doubled [CO_2] was 1.6-fold greater at low humidity than at high humidity [13]. Apart from the direct effect of the elevated CO_2 level on photosynthesis, the greater effect of doubled [CO_2] on the dry matter yield at low humidity was probably due to (a) increased leaf water potential caused by reduction of transpiration resulting from the negative response of stomata to increased [CO_2], the consequence being greater leaf area expansion; or (b) reduction of the CO_2 assimilation rate at low humidity and normal CO_2 concentration as a result of the humidity response of stomata causing reduction of the intercellular CO_2 concentration.

Sunflower

Despite the differences in the rate of change of conductance and relative water content during drought, photosynthetic electron transport activity, inferred from measurements of chlorophyll *a* fluorescence in vivo and PSII activity of isolated thylakoids, remained functional until desiccation occurred [150].

Grasslands

Grasslands that regularly undergo drought may profit from reduced evaporation under elevated [CO_2], especially if they contain a majority of C_4 species [74,151], and this effect may be more important than the direct effects of enhanced carbon uptake in prairies with C_3 plants. Field et al. [152] found that soil moisture remained higher under plots receiving CO_2 enrichment in a natural annual grassland. This resulted in an extension of the period of active photosynthesis by about 10 days [145]. In the precise case of *Lolium* and *Trifolium* canopies [105], it was shown that *Lolium* was more sensitive to drought stress in its initial response but divided the available water more proportionally over the stress period than *Trifolium*. WUE was roughly doubled and was affected later by drought stress in high CO_2 for both species. In general, the drought and CO_2 act both directly on the productivity and on the water use of grass swards and indirectly through changes in soil moisture content [153].

Trees

To investigate the combined long-term effects of increased [CO_2] and drought, it is necessary to examine all the processes which take part in the complexity of the tree physiology (Fig. 4). Dixon et al. [154] exposed red oaks and Norway spruce to elevated [CO_2] and followed the effects throughout the vegetation period as natural drought developed. During the first year of growth, drought caused photosynthetic reductions and stomatal closure in both species. During the second year of growth, there were large interspecific differences. The net photosynthesis results showed statistically significant increases in CO_2-treated red oak before drought developed. The relative photosynthesis increase was gradually lost as drought developed. In contrast to red oaks, there was no apparent photosynthetic enhancement under elevated [CO_2] in undroughted Norway spruce. However, as drought developed and caused restrictions in photosynthesis, the trees grown at elevated [CO_2] had relatively higher net photosynthetic rates. From these different results, it appears that the presence of a continued photosynthetic enhancement was dependent on plant water relations.

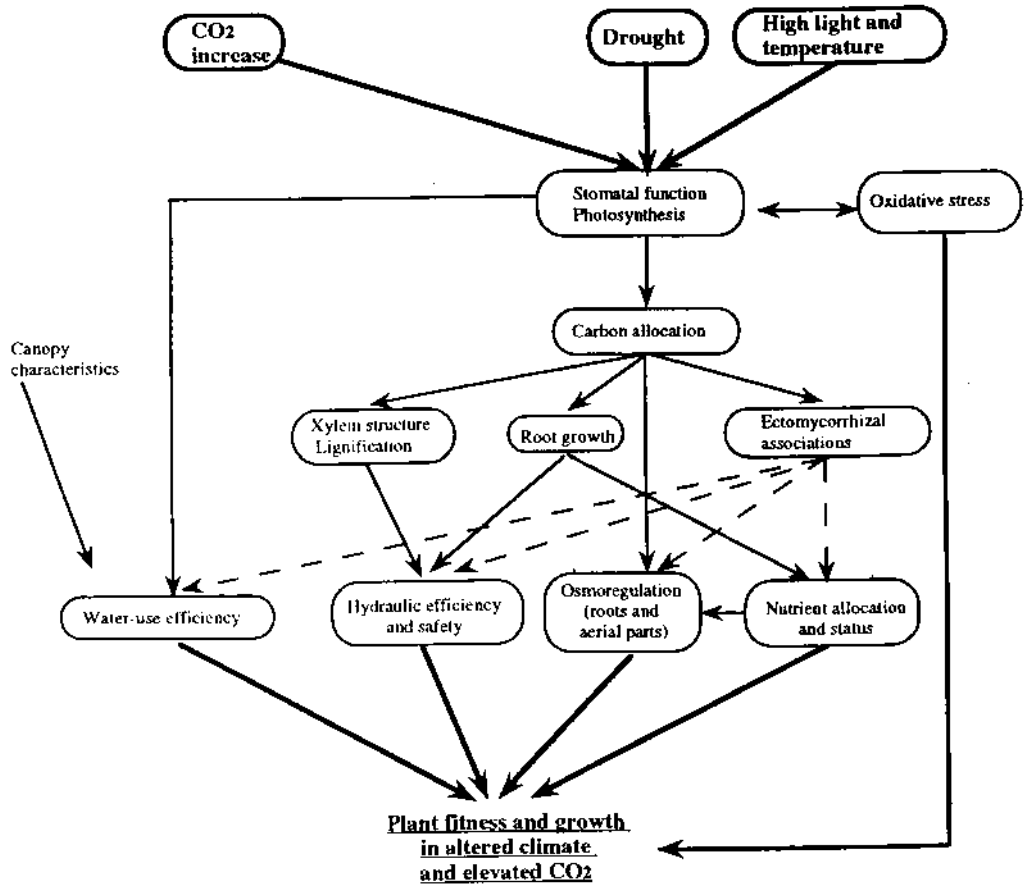

FIGURE 4 Schematic presentation of the structural and functional characteristics investigated for assessing the mechanisms determining plant performance in the context of climate change and elevated CO_2. For sake of clarity, direct effects of drought on growth and allocation processes and the nutrient ''dilution'' effect linked to increased carbon supply to the different plant components have not been represented. (From Ref. 211.)

As the drought develops, there is a decrease in leaf conductance to water vapor under elevated [CO_2], but this level of conductance allows relatively higher rates of photosynthesis than the ambient air. Because of this, the droughted trees under elevated [CO_2] have greater water-use efficiency values compared with droughted trees under ambient air. All trees had increased rates of photosynthesis as stomatal conductance increased. No typical relationships were observed between photosynthesis and intercellular CO_2 concentration.

The only significant difference concerning the stomatal density was an increase in the number of stomata in red oaks exposed to elevated [CO_2] [154]. Changes in stomatal density are important, as they can affect both the uptake of CO_2 and the rate of water loss. The results allowed Dixon et al. [154] to state that the role of any stomatal density effect in influencing the gas exchange measurements is primordial.

A moderate reduction of stomatal conductance has a significant effect on tree transpiration, which is roughly proportional to stomatal conductance. In the studies conducted under the European Collaboration on CO_2 Responses Applied to Forests and Trees program, this reduction of stomatal conductance ranged from 20 to 90%: WUE increased markedly in high CO_2, especially when the plants were droughted (150% in *Quercus ilex* in spring and from 200 to 300% in droughted poplars). Increased CO_2 may thus alleviate moderate water stress and allow some extension of forests in drier areas.

Vivin et al. [155] did not observe any growth increase of *Q. robur* seedlings in response to elevated [CO_2] under drought, although there was a stimulation in net photosynthesis. However, in addition, the respiration rate of the root system was slightly lower in the elevated than in the ambient [CO_2]. These results together with the results from short-term ^{13}C labeling suggest enhanced relative carbon loss (root or aerial respiration) under elevated [CO_2] in the drought conditions. It was shown that osmotic potentials at full turgor were lowered in response to water stress in leaves by 0.4 MPa for the elevated [CO_2] treatment only. In roots, osmotic adjustment (0.3 MPa) occurred in both of the [CO_2] treatments.

INCREASED TEMPERATURE AND RISING [CO_2] LEVEL

It is taken as axiomatic that future elevated atmospheric CO_2 concentrations will probably be associated with warmer temperatures. A rise in temperature lowers the ratio of [CO_2]/[O_2] in solution and higher global temperatures are an important consideration in the rising [CO_2] debate because of interacting effects on photosynthesis [12].

The need appeared for complementary equipment to modify temperature and elevated [CO_2], allowing studies of the interaction of rising temperature and elevated [CO_2] in natural conditions of light, humidity, and wind speed. Just as the FACE method had been introduced to simulate future CO_2 levels and validate responses obtained in the unnatural conditions of chambers, the free air temperature increase (FATI) technique was developed. This system simulates global warming in small ecosystems [156].

C_3 species differ in response to [CO_2] and temperature. In some plants, the stimulatory effect of elevated [CO_2] on plant growth is temperature dependent. Thus, for a 3°C increase in the air temperature at which *Gossypium hirsutum* was grown, the average growth-enhancement factor resulting from increasing [CO_2] to 640 μmol mol^{-1} was an increase from 1.3 to 1.56 [157]. In wheat, the adverse effects of elevated temperature on photosynthesis was moderated by CO_2 enrichment [23]. Long [76] has shown that elevated [CO_2] could alter both the magnitude of the response of leaf and canopy carbon gain to rising temperature and sometimes the direction of response. There is some evidence that elevated [CO_2] may lower the minimum temperature at which some plants grow and complete their life cycle [158].

Conversely, in some cases, the effects of CO_2 enrichment can be moderated by adverse effects of elevated temperatures. The high-temperature treatment was shown to reduce the net photosynthetic rates of rice and soybean by 25 and 38%, respectively. For winter wheat (determinate crop), yield decreased with an increase in temperature, and this decrease could completely negate the

increase attributable to elevated [CO_2] [159]. An increase in yield resulting from enhanced [CO_2] can be canceled by a 2–3°C increase in temperature [160]. This is because, as the elevated [CO_2] causes partial stomatal closure, the resultant decrease in transpirational cooling increases the foliage temperature [157] and the leaf transpiration, thereby counteracting the effect of the CO_2-induced stomatal closure [153]. In contrast, in potato (indeterminate crop), the growth response was found to increase in response to an increase in both temperature and [CO_2]. The effect of elevated [CO_2] on the dry matter yield of perennial rye grass swards also increased with air temperatures above 14.5°C and was promoted by a larger soil moisture in elevated compared with ambient [CO_2] [153].

Because it is an important tropical plant, a major food crop, and the only cereal used almost exclusively for human consumption, rice has been the subject of a number of studies which examined and quantified the effects of elevated [CO_2] and air temperature on its growth and yield. Previous studies were concerned with rice grown in glasshouses or in soil-plant-atmosphere-research chambers [161]. They were complemented by studies which examined the interactions of increased [CO_2] and air temperature for rice under irrigated field conditions in a tropical environment under the wet and dry seasons similar to the conditions where most rice is grown [162]. Overall, increasing the atmospheric [CO_2] resulted in a significant increase in growth, total biomass at maturity, and grain yield for rice over two different growing seasons. The observed increase in the biomass was primarily due to increases in tiller number and stem, root, and panicle weight. Many of the current high-yielding semidwarf rice cultivars are sensitive to high temperatures, with yields decreasing in direct proportion to day temperatures above 33°C [163]. The decline is primarily due to increasing floral sterility associated with decreased viability of pollen and to limited carbon translocation to the developing grain. If both [CO_2] and air temperature increase simultaneously, however, any potential benefit of CO_2 on the biomass and grain yield is negated, but plant development is accelerated at the higher growth temperature. Thus, the biomass and grain yield appear to be insensitive to the [CO_2] at the higher growth temperature [162]. Moreover, a simultaneous increase in [CO_2] and temperature also was found to alter grain quality. Protein content was decreased and overall nutritional quality was reduced. These described effects of a concomitant increase of [CO_2] and temperature on the quantitative and qualitative characteristics of rice crops might hopefully stimulate plant breeders to take such factors into account when developing future breeding strategies.

Interactions between rising [CO_2] and increased temperatures are not simply additive. That the combined effects of elevated [CO_2] and elevated temperature are less than additive indicates a decline in response to elevated [CO_2] as temperature increases. Rye grass growth rates declined as the temperature increased from 10/4°C (day/night) to 22/16°C. This decline was greater at elevated [CO_2]. In contrast, the white clover growth rate increased with temperature and was stimulated by elevated [CO_2] [22]. The grain yield of CO_2-enriched rice showed a 10% decline for each 1°C rise above 26°C [161]. Similar scenarios have been reported for soybean and wheat [159]. This is because growth and reproduction reflect the integrated temperature response of the metabolism and developmental stage.

The effect of temperature is primarily exerted through Rubisco [76]. Rubisco specificity (ratio of carboxylation to oxygenation activity when the concentration of CO_2 and O_2 at Rubisco are equal) declines at elevated temperature, because the affinity of Rubisco for CO_2 relative to O_2 decreases. A rise in temperature shifts the specificity of Rubisco toward oxygenase [23]. With a concomitant increase in mean growth [CO_2] and temperature, the proportion of fixed carbon entering the photorespiratory pathway increases, but as respiratory CO_2 decreases on elevated [CO_2], it is finally the balance between assimilatory carbon fixation and global respiratory losses that determines the net flux response to elevated [CO_2] and temperature. Fine control of Rubisco activation was shown to be influenced by both elevated [CO_2] and temperature [76]. In rice and soybean, there was an interplay between elevated growth temperatures and [CO_2] on the Rubisco parameters [23]. For both species, the Rubisco protein concentration and the activation of Rubisco declined with increasing temperature as well as with elevated [CO_2]. Both temperature and elevated [CO_2] enhanced the Rubisco catalytic turnover in soybean and had no effect in rice. For soybean, the temperature regimen has more effect on the Rubisco protein content than [CO_2], whereas for rice, both environmental

factors exert coarse control effects on Rubisco [164]. Postsunset declines in Rubisco activities were accelerated by elevated [CO_2] in rice and by high temperature in soybean, suggesting that [CO_2] and growth temperature influence the metabolism of 2-carboxyarabinitol-1-phosphate and that the effects might be species specific.

In addition to effects on photosynthetic and Rubisco activity, elevated temperatures influence carbohydrate metabolism. In CO_2-enriched rice plants, sucrose phosphate synthase activity was increased by temperatures up to 34°C but thereafter declined. Total nonstructural carbohydrates declined with increasing growth temperature, but the decline in the starch content was much greater than sucrose [23]. Consequently, the sucrose to starch ratio increased with temperature. Data suggest that high temperatures not only influence the amount of carbohydrate produced but also its composition, possibly shifting the amylose to amylopectin ratio in favor of the former. However CO_2 enrichment moderates the differences. Although ADP–glucose pyrophosphorylase activity was not greatly altered by temperature or CO_2, the starch-branching enzyme activity is enhanced by CO_2 and considerably decreased at high temperature.

Qualitative and quantitative changes also were observed in the lipid fraction (both nonstarch and starch lipid) of wheat plants grown under regimens combining two temperatures with two concentrations of [CO_2] and two nitrogen fertilizer applications [159]. Temperature was by far the most influential growth factor. Growth at elevated temperature had the general effect of reducing the amounts of accumulated lipids, particularly nonpolar lipids. There were changes in the proportions of the major nonstarch (membrane glycosylglycerides and phosphotidylcholine) as well as the starch lipids (mainly lysophosphatidylcholine and lysophosphatidylethanolamine). Significant changes in the acyl composition of individual lipids also were observed; most often in the proportions of palmitate, oleate, and linoleate. The observed alterations in wheat lipids are likely to affect the properties of any flours derived from grain grown under climatic change conditions.

Understanding how cellular processes such as cell expansion and cell division are affected by temperature and elevated [CO_2] is crucial for debate on how plants will react to predicted global environmental change [165]. The subject was addressed by Taylor et al. [166], using the leaf lamina of herbaceous angiosperms and the lateral root primordia in *Populus euramericana*. They have identified cell wall loosening as a critical component of increased cell expansion as a result of elevated [CO_2] treatment. Circumstantial evidence indicates a stimulation of cell division by elevated [CO_2], increased cell number in the leaf lamina, and an increase in the number of lateral root primordia. Measurements of cell division in the meristems of plants exposed to ambient or elevated [CO_2] and incremental temperature treatments were undertaken on two natural populations of the perennial grass *Dactylis glomerata* originating in Portugal or Sweden [165]. Cell division was assessed in the shoot meristem, since it is from the latter that all aboveground tissues form. Elevated [CO_2] resulted in substantial decreases in cell division time compared with the corresponding measurements at ambient [CO_2] in all zones of the meristem and at all temperatures. Differential responses of the two populations were observed. The cells in the young primordia of the Swedish population were much less affected by elevated [CO_2] and temperature than the Portuguese population. It is concluded that the cell division time in the shoot apex of the Swedish population is relatively buffered against temperature change, whereas in the Portuguese population, the cell division time shortens progressively with increasing temperature.

Relationship between alterations to cell division at the shoot apex and the overall growth response of the plant are certainly complex. Cell division in the plant shoot apex is regulated by a number of factors, among which is the provision or withdrawal of sucrose which may sustain or regulate signal transduction, which in turn regulate the expression of cell cycle genes. Faster rates of cell division at elevated [CO_2], most notably in the Portuguese population, may be a response to a greater supply of sucrose at the apex. It is suggested that elevated [CO_2] ameliorates nonoptimal temperatures for cell division [165].

Because of the warming, the winters may become milder, which will predispose the trees to increased risks of frost damage [167]. Frost hardening and dehardening are the result of a multitude of physiological, biochemical, and biophysical changes in cells. Although the elevated [CO_2] in

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

summer increases photosynthesis, plant metabolic activity and accumulation of high-energy compounds in cells, the processes regulating frost hardiness may also be affected. Increased activity during the dormant season, especially at elevated temperatures, predisposes trees to frost damage. Although there were significant differences between treatments and significant variation between trees in frost hardiness, the results suggest that the risks of frost damage are marked in the predicted climatic conditions in the boreal zone.

Finally, it appears that the responses of plants to climatic change variables are the results of both the direct effects of increasing [CO_2] and the indirect effects of rising temperature [22].

EFFECTS OF ELEVATED [O_3] AND [CO_2] LEVELS

Ozone was first described by Richards et al. as a toxic air pollutant originating from reactions between constituents of photochemical smog [168]. Industrial emissions of nitrogen oxides and volatile organic compounds and interaction with ultraviolet (UV) radiation have led to rising background concentrations of tropospheric O_3, in areas of intensive urbanization but also in rural areas [169]. Models predict that tropospheric ozone will increase 0.3–1.0% per year over the next 50 years [170].

O_3 in an aqueous environment can generate OH^-, O_2^{2-}, and H_2O_2. O_3 generation of OH^- is accelerated by Fe^{2+}, thiol groups, amines, and phenolics like caffeic acid [171]. Interactions between plants and ozone (O_3) have all been shown to be associated with the production of other chemical species (e.g., hydroxyl radicals (OH^-), superoxide (O_2^-) anions, and hydrogen peroxide [H_2O_2]), which have even higher oxidizing potentials.

Ozone enters the leaf through the stomata and diffuses within the apoplast where it rapidly decomposes to hydroxyl and superoxide anion radicals, hydrogen peroxide, and other reactive oxygen species. Recent research on the impact of ozone on trees indicates that ozone uptake is an important physiological link in the understanding of differences in the ozone response between tree species as well as between trees of different sizes within species [172].

Ozone Impact on Plants and Crops

A number of reviews are available on ozone phytotoxicity, dealing with visual symptoms and growth effects, as well as with the problem of leaf–internal ozone dose, effects on stomatal regulation, photosynthetic functions, and assimilate allocation [173].

The significant effects on growth and yield are primarily related to changes in the photosynthetic physiology and stomatal conductance. Recent studies have shown that, in combination, the effects of [CO_2] and [O_3] are not simply additive [4]. It was previously shown that elevated [CO_2] protects against the deleterious effects of elevated [O_3] on photosynthesis in spring wheat [174]. The hypothesis that the protective effect of elevated [CO_2] against ozone damage also will be exerted on the biomass and yield of spring wheat was tested [4].

The factors underlying modifications in photosynthesis were investigated with *Pinus sylvestris* L. [175]. Elevated [O_3] led to a significant decline in the CO_2 compensation concentration, maximum ribulose-bisphosphate–saturated rate of carboxylation, maximum rate of electron transport, maximum stomatal conductance, and sensitivity of stomatal conductance to leaf-to-air vapor pressure difference. Calculations showed that elevated [O_3] decreased the apparent quantum yield by 18–35% and the maximum rate of photosynthesis by 21–29%. The interactive effects of O_3 and CO_2 on the maximum ribulose-bisphosphate–saturated rate of carboxylation and the maximum rate of electron transport were significant and closely related to the regulation of the stomatal conductance and stomatal sensitivity induced by elevated [CO_2].

It is expected that the progressive increase of tropospheric trace gases such as CO_2 and O_3 will have a significant impact on agricultural production. Increasing tropospheric O_3 concentrations can appreciably alter the nutritive value of herbaceous legumes that are presently an important source

of N and energy for grazing ruminants [176]. White clover, for instance, is a major perennial pasture legume. Its nutritive value has important implications to herbivore production. Its changes due to O_3 regimens at ambient and enriched [CO_2] was explored. Although in vitro dry matter disappearance of laminae declined linearly with increasing exposure to O_3, the laminae neutral detergent fiber and total nonstructural carbohydrates increased. But at enriched [CO_2], O_3 lacked influence on the nutritive value of white clover. The single and combined effects of CO_2 enrichment and tropospheric O_3 on grain quality characteristics in winter wheat were examined [177]. Milling and baking quality were not significantly changed. Flour yield was increased by elevated [CO_2], but this increase was counteracted when elevated [CO_2] was combined with chronic O_3 exposure. Flour protein contents were increased by greater [O_3] exposure and reduced by elevated [CO_2]. In conclusion, although the single effect of either [CO_2] enrichment or chronic [O_3] exposure had some impact on the grain quality characteristic, it was noted that the combined effect of these gases was minor, and it is concluded that the concomitant increase of [CO_2] and [O_3] in the troposphere might have no significant impact on wheat grain quality [177].

Harmful Effects of Atmospheric O_3 on Vegetation

O_3 sensitive/tolerant bioindicator surveys have used symptoms of visible injury to assess the extent of possible O_3 injury on vegetation over large areas [178]. The phytotoxicity of ozone can be divided into chronic and acute damage, reflecting different defense strategies of the plant [173]. The acute damage resembles the hypersensitive response which occurs after a pathogenic attack or elicitor treatment, leading to lesion development and eventually including cell death. Chronic damage leads to a general reduction of growth that is somewhat similar to a premature senescence.

Necrotic Lesions

Pell et al. [179] have reviewed the mechanism by which O_3 induces necrotic lesions and/or accelerated foliar senescence. Symptoms of acute damage have been observed on a wide range of species [180]. In addition to small or large, reddish or whitish colored necrotic lesions, foliage under acute injury may exhibit accelerated senescence. An early event leading to lesion formation is the loss of semipermeable function in the plasma membrane [181]. Components of the cell wall and membrane become oxidized during the initial O_3 exposure. Given that the cell wall contains phenolic groups, oleic compounds, proteins, and lipids, some of which are unsaturated, there are clearly numerous sites for primary oxidation events. Reactions between O_3 and any of these compounds could result in the production of active oxygen species. To date, we can only speculate that active oxygen species will be produced as a result of primary reactions between O_3 and constituents of the cell.

A central question is whether lesions are a result of rampant oxidation and subsequent unregulated rapid cell death or alternatively a result of some type of programmed cell death. There is little direct information regarding the nature of the reactions which lead to altered plasma membrane function. ATPase activity of plasma membranes from O_3-sensitive *Phaseolus vulgaris* foliage was shown to be severely inhibited owing to a decrease in the K^+-stimulated component [182]. It also was found that O_3 can influence calcium transport in plant membranes [183]. Lipid components of membranes might also be the target of attack by O_3 [184].

Induction of Accelerated Foliar Senescence

An accelerated foliar senescence is a common response of many ozone-treated plants [185]. Multiple oxidation events are responsible for the accelerated foliar senescence (Fig. 5). Even if necrotic responses are absent or of minor importance, foliage begins to exhibit signs of accelerated senescence after a period of weeks of exposure to O_3. More ozone-tolerant species such as potato, cereals, or conifers typically respond with symptoms of chlorosis and also exhibit accelerated senescence. It was determined that O_3-induced foliar senescence is closely associated with the loss of Rubisco

Marcel Dekker, Inc.

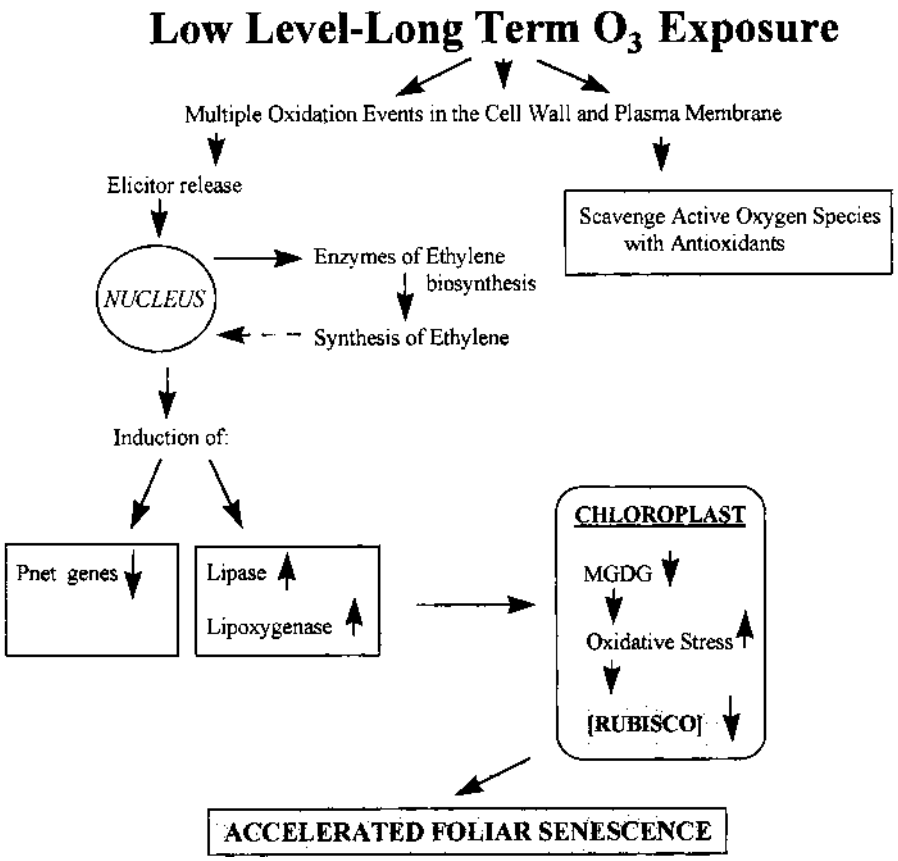

FIGURE 5 Model to explain potential mechanism whereby low level ozone exposures induce accelerated foliar senescence. MGDG refers to monogalactosyl diglycerides. (From Ref. 178.)

and some other less prominent enzyme activity. The decline in the net photosynthesis rate correlates in potato with a loss of Rubisco activity. In vitro and in vivo experiments and the observation that *rbc*S mRNA dropped earlier in the development of potato leaves subjected to chronic O_3 exposure support the notion that the major loss of Rubisco reflects enhanced degradation of the Rubisco protein. Transcript coding for other chloroplastic proteins such as glyceraldehyde-3-phosphate dehydrogenases and a PSII chlorophyll *a/b*–binding protein were found to decline in parallel. In contrast, the cytoplasmic isoform of glyceraldehyde-3-phosphate dehydrogenase, which is involved in glycolysis, increased in response to ozone. Since Rubisco is central to leaf longevity, O_3-induced acceleration in loss of this protein may contribute significantly to the increased rate of leaf loss observed in plants subjected to chronic exposure to the pollutant. Leaf lipid analyses have revealed that plastidic monogalactosyl diglycerides (MGDGs) decline and triglycerides increase. It has been suggested that lipase activity might be induced by O_3 and would react with the MGDGs to provide free fatty acids which would then be the substrate for lipid peroxidation ultimately leading to increased active oxygen species in the chloroplast [186]. Lipid hydroperoxides reduce the membrane fluidity. They are intermediates in the biosynthetic pathway of jasmonic acid. Located within chloroplasts, methyl jasmonate was shown to increase the potential of leaves for the production of volatile compounds found in ozone-treated tobacco [187].

Foliar Emission of Ethylene

Foliar emission of ethylene is an early event associated with O_3 exposure [188]. It has been correlated with visible ozone lesion development in many herbaceous plant species. An explanation of ozone toxicity is related to ethylene emission, a well-known senescence-promoting hormone of plants [189]. Ozone may react with volatile compounds emitted by the plant into the apoplast. Interaction of ozone with ethylene or more complex hydrocarbons such as isoprene and α-pinene are thought to be part of the mechanism leading to injury. Ethylene production in the plant occurs enzymatically through conversion of l-methionine via S-adenosyl methionine (AdoMet) to l-aminocyclopropane-1-carboxylic acid (ACC). This key step in ethylene biosynthesis is catalyzed by the enzyme ACC synthase. The differential expression of ACC synthase may be an important mechanism by which ethylene production is regulated in many physiological processes. Several investigators proposed that ethylene reacts nonenzymatically with O_3 to produce O_2 and reactive aldehydes that might be responsible for plant damage [190]. It also is likely that ethylene acts directly on plant metabolic responses to O_3 through a number of mechanisms, including gene regulation [189].

Potential Mechanism for O_3-Induced Accelerated Foliar Senescence

The model presented by Pell et al. [179] to explain the potential mechanism by which prolonged exposure to O_3 induces foliar senescence is presented in Figure 5. Ethylene is frequently associated with senescence. The amount of visible injury caused by O_3 correlates to the rate of ethylene production. Studies with transgenic tomato plants, which produce low levels of ethylene and have delayed loss of chlorophyll and delayed leaf senescence [191], support the model that the photosynthetic decline is coupled to senescence and that ethylene plays an important role in leaf senescence [192]. Active oxygen species may provide the signal(s) to the nucleus leading to induction of a suite of responses which lead to increased oxidizing stress in the chloroplast. As the leaf ages, the production of antioxidants declines and this stress increases. The role of ethylene may be by facilitating the progress of senescence rather than serving as a necessary signal [193].

Rubisco normally degrades after oxidative modification, and in the O_3-treated foliage, the process will occur more rapidly. In ozone-sensitive species, changes in sugar metabolism are indicated by an accumulation of starch along the veins and the formation of starch granules in epidermial cells. Starch and hexoses inhibit photosynthesis at the level of several Calvin cycle enzymes, including Rubisco. Reduced CO_2 fixation in the light increases the pool of reduction equivalents, such as NADPH in chloroplast. These changes in primary metabolism even have a strong impact, as crop yield is reduced and the whole life cycle of the plants appears to be influenced [194]. In both acute and chronic attacks, the pattern of gene expression changes significantly. However, no genes that are specifically and solely regulated by ozone have been described so far.

Ozone-Dependent Induction or Suppression of Genes

Damage does not seem to be the direct result of ozone toxicity, but ambient ozone concentrations might rather affect signaling pathways within the plants. Ozone induces the genes of several pathogenesis-related proteins [173]. In tobacco, the accumulation of β-1,3-glucanase mRNA is correlated with ethylene formation [195]. The increase in the expression of genes for β-1,3-glucanase and chitinase in response to O_3 is supported by an increase in the activities of these enzymes. These proteins are known to be associated with loosening of the cell wall during development [196].

There have been reports of O_3-induced reductions in the level of transcript for the small subunit of Rubisco (*rbc*S), chlorophyll *a/b* protein (*cab*), and glyceraldehyde-3-phosphate dehydrogenase (*gap*A and *gap*B) [189]. Whether transcription is regulated in response to O_3 or specific Rnase activity is regulated by the pollutant is not known.

Considerable effort has gone into the purification and cloning of the genes for this important

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

regulatory enzyme. Stimulation of ACC synthase activity noted in many developmental and inducible systems results from an increase in the levels of mRNA for ACC synthase [197]. Since O_3-induced ethylene production is closely correlated to the accumulation of ACC, it is likely that O_3 promotes increased ACC synthase activity. Transcripts for ACC synthase were found to be detectable 1 h after the onset of acute O_3 exposure. It increased dramatically after 2 h, with high levels of expression up to 4 h. No ACC synthase mRNA was detected in nontreated plants. Evidence was provided that the increase in ACC synthase mRNA was due to gene transcription. The isolation of a second ACC synthase cDNA whose transcript accumulated very quickly in response to O_3 led to the hypothesis that there are at least two ACC synthase genes expressed in response to O_3, and the timing of expression may reflect differences in the mechanisms of signal transduction and/or gene regulation [198].

Plant Defense Reactions and Acclimation

The probability of disease in plants is determined in large part by defensive and antioxidative reactions of secondary metabolism [173]. These reactions include a local oxidative burst, cell wall reinforcement (lignin, callose, extensins), and the induction of phytoalexins, antioxidative systems, and pathogenesis-related (PR) proteins.

Several ozone-sensitive and ozone-tolerant cultivars, clones, or populations of various species are known which are useful tools in comparing different strategies of plants. These strategies deal with the detoxification of radical species or with signal cascades, leading to common plant defense reactions. Ozone-induced plant responses are probably mediated by interference of at least three different signaling pathways depending on ethylene, reactive oxygen species/lipid hydroperoxide, and salicylate. Reactive oxygen species production and lipid peroxidation take place either on the plasma membrane or in the chloroplastic membrane, and lipid hydroperoxides and derivatives, such as jasmonate, can act as signals for subsequent plant reactions. They react with proteins or lipids of the plasma membrane. Alternatively, they may be detoxified by radical scavengers, ascorbate, polyamines, and tocopherol located within the apoplast. Reactive oxygen species induce detoxifying systems, as demonstrated in cell suspension cultures [199]. Transcripts were found to be elevated after treatment with hydrogen peroxide in a narrow range of 1.8–4.0 mM. Application of polyamines to tobacco roots was found to reduce the level of ozone-induced lesions [200]. Reactive oxygen species–detoxifying systems such as isozymes of dismutases or ascorbate peroxide also are present in the chloroplast. A prominent role for glutathione is indicated by the increase of glutathione during ozone treatment; in beech, the level of glutathione increases in response to high ambient ozone concentrations [201]. Some evidence was provided that the levels of glutathione and glutathione reductase as well as the rates of the transmembrane transport of ascorbate and dehydroascorbate may moderate the ozone susceptibility of plants, although there is no direct correlation between enzyme levels and stress tolerance.

The assessment of the harmful effects of atmospheric O_3 on vegetation has been greatly improved by comparisons between O_3-sensitive and O_3-tolerant cultivars or selections of the same species. A range of species, including poplars and other hardwood trees, conifers, tobacco, corn, soybean, legumes, clover, and plantains, has been used in a number of comparisons [178]. Controlled-environment studies using lower concentrations of O_3 have shown that the O_3-sensitive partner of a comparison pair may also exhibit several signs of invisible injury, whereas the O_3-tolerant cultivar shows evidence of acclimation. For example, Bel-W3 tobacco readily produces stress ethene [202], which can react with O_3 to form harmful radicals [190], whereas Bel-B forms polyamines faster [203] which can function as protective free radical scavengers [204]. Consistent differences in the rates of ethene release between acclimated and nonacclimated plants also were found [202].

Evidence was shown for common differences across different plant species in (a) ethene release (ethene, putrescine, spermidine, polyamines, phenols) and (b) dependence on similar free radical scavenging systems (reduced glutathion, reduced ascorbate) for protection on exposure to O_3. The combined assays with six pairs of O_3-sensitive/O_3-tolerant cultivars, families, and so on (to-

bacco, plantain, clover, radish, poplar, and loblolly pine) clearly indicated that rates of ethene formation after O_3 exposure were always significantly higher in O_3-sensitive selections but were unchanged or lower in O_3-tolerant selections [178]. O_3-tolerant cultivars clearly show several patterns of response. In some cases, adequate endogenous levels of potential antioxidant already exist, whereas in others, they are rapidly expressed and this affords protection against O_3. Conversely, some of the weaknesses of the O_3 cultivars have been detected but not always in the same area. If one were to attempt to specify tolerance to O_3, the following characteristics should be taken into account: (a) reduced ethene emissions; (b) the ability to form putrescine rapidly; (c) enhanced levels of one or more phenylpropanoid, flavonoid, or lignin components; and (d) the ability to form sufficient reduced glutathione and ascorbate quickly [178].

A new concept was recently developed that ozone could act as a powerful and ubiquitous abiotic elicitor [173].

CONCLUSIONS

There is much concern over the possible impact on agriculture of climatic changes. As breeding programs for crop species need to take climatic change into account, the risk of a global increase of atmospheric CO_2 concentration and associated climatic change and their influence on agriculture need to be assessed [205]. Although the broad-scale prediction is for a smooth increase in global temperature, there may be rapid warming in some regions and possibly even periods of cooling in others [206]. Marked drought stress may occur in regions where there is no accompanying increase in precipitation. One important question is whether agricultural systems can adapt to the predicted rates of changes. The use of manipulative experiments to study directly the effects of climatic change on natural and managed systems is expensive if performed on a large scale; it also relies on predictions of future climatic conditions, the accuracy of which is doubtful. Predictive modeling is less expensive and permits a range of scenarios to be considered [207].

In short, the effects of the main climatic changes predicted to occur during the next century (i.e., elevated $[CO_2]$ and $[O_3]$, elevated temperature, and shortage of water supply on plants and crops) can be stated as follows: As current ambient CO_2 levels are suboptimal for most crops, at least for C_3 plants, agricultural productivity will benefit from both direct (fertilizer) or indirect (climatic) effects of increased atmospheric $[CO_2]$ concentration. The significant effects of $[CO_2]$ on crop growth and yield are primarily related to changes in photosynthetic physiology and stomatal conductance, whereas temperature affects metabolic reactions. By increasing the growth rate, elevated temperature shortens the required growing period resulting in a decreased yield. High temperature is a factor of sterility. The pollutant O_3 has deleterious effects on photosynthesis. Water stress alters transpiration rates which in turn disturbs the flow of solutes within the plant and affects the translocation of nutrients.

However, there is clearly no general rule for the response of plants and crops to the predicted changes in climate. In combination, the effects of elevated $[CO_2]$, $[O_3]$, temperature, and water stress are not simply additive. Studies on the interaction of temperature and $[CO_2]$ do not necessarily demonstrate a synergistic effect [162]. It is possible that biochemical phenomena might not always be expressed at the whole-plant or canopy level. Considering the possible interactions which might take place, it is important to allow for the effects of temperature and water supply on the carbon partitioning of wild and cultivated plants when predicting the effects of elevated $[CO_2]$ on growth and productivity. When water is limiting, the effects of a temperature rise and higher $[CO_2]$ levels on crop production are different from the potential production [208]. Both temperature rise and an increase in $[CO_2]$ concentration reduce the water requirements of the crop.

The intensity of plant responses also depends on other environmental conditions, plant species, the age of the plant, and so forth. The effects of $[CO_2]$ enrichment and higher temperatures are variable from year to year and they depend on the weather, N availability, and the variable annual pattern of plant development [209]. They may also be masked by the interannual climatic fluctuations

Marcel Dekker, Inc.

that cause such a high degree of variability in agricultural production in most parts of the world. Any factor which increases environmental stress on crops may make them more vulnerable to attack by insects and plant pathogens and less competitive with weeds [210]. There is a large species imbalance in the data, with some plants being well represented, some less, and totally inadequate information for certain crops, particularly C_4 cereals and tuber crops. Programs concentrating on the most economically important crops are vital.

A detailed understanding of the responses of field-grown crops to elevated [CO_2] and interactions with other factors is essential to assess the impact of the predicted changes in the environment on agriculture. With this knowledge, it may be possible to modify the genetic constitution of plants, by conventional breeding or by genetic engineering techniques, in order to improve their efficiency in the predicted future conditions. It is important to increase substantially the range of current research into how agriculture can best adapt to such changes. It is suggested and recommended that we (a) improve methods for the estimation of probable changes in climate by developing modeling techniques; (b) closely link field studies to the modeling techniques so that specific predictions can be tested; (c) confirm that plant response to climatic factors observed in the large number of controlled environment experiments apply in agriculturally or ecologically realistic conditions; (d) concentrate programs on the most economically important crops, particularly cereals, legumes, and tuber crops (which are actually less represented in this field of research); (e) extrapolate the results of experiments to the population level; (f) compare the response of different genotypes of the same crop with well-established genetic characteristics with the aim of optimizing cultivars to future climates using biotechnological approaches; and (g) consider the type of action required to adapt to climatic change through adjustments at the field level to issues in regional and national policy.

Leaf Development and Acclimation to Elevated CO_2

Adam Miller, Martin Spalding, and Steve Rodermel
Iowa State University
Ames, Iowa

INTRODUCTION

Acclimation to Elevated CO_2

Atmospheric CO_2 levels have changed dramatically since the Industrial Revolution, increasing by almost 40% to a present-day concentration of approximately 350 ppm [1]. It is thought that consumption of fossil fuels is the main contributor to this increase. The outlook for the future is much the same, with the current level of CO_2 expected almost to double by the beginning of the twenty-second century if existing conditions are not altered drastically. How such changes in the atmosphere will affect the growth and development of plants, both on an individual and global scale, is an important but unanswered question.

In many C_3 plants under normal environmental conditions, the photosynthetic rate is limited by the rate of initial CO_2 fixation into the Calvin cycle. This rate-limiting step is catalyzed by Rubisco, which carboxylates ribulose-1,5-bisphosphate (RuBP), generating two molecules of 3-phosphoglycerate (3-PGA). Some 3-PGA molecules are exported into the cytosol for use in sucrose biosynthesis, whereas others are responsible for RuBP regeneration and starch synthesis in the plastid. Rubisco is an inefficient enzyme with a low affinity for CO_2, and it is substrate limited under present atmospheric concentrations [2].

One of the most important responses of plants to growth in elevated CO_2 is the phenomenon of ''acclimation'' (reviewed in Refs. 2–4). Because elevated CO_2 represents an increase in substrate availability, increased rates of carboxylation in elevated CO_2 should result in higher net photosynthetic rates. In many experiments, this is observed in the short term. However, the enhancement of photosynthetic performance is not maintained in plants that ''acclimate'' to high CO_2, and in these plants, photosynthetic rates fall below those predicted on the basis of Rubisco kinetics. It is this loss of the predicted benefit of high CO_2 growth that is referred to as acclimation.

Acclimation has been observed in many agronomically important C_3 species, including tomato, wheat, pea, soybean, sugar beet, cotton, tobacco, and several tree species (reviewed in Ref.

Marcel Dekker, Inc.

4). However, C_3 plants differ in the severity of the acclimation response. Also, C_4 and crassulacean acid metabolism (CAM) plants do not acclimate, because they have biochemical carbon-concentrating mechanisms and are therefore constantly under an enriched CO_2 regimen.

Molecular Mechanisms of Acclimation

Several mechanisms have been proposed to explain the downregulation of photosynthetic rates that occurs during acclimation (reviewed in Ref. 2). One mechanism is that enhanced starch accumulation in high-CO_2–grown plants results in large grains that disrupt chloroplast membrane structure and function. A second mechanism is that growth in enriched CO_2 results in a reduction in stomatal conductance, which restricts the amount of CO_2 entering the leaf; photosynthetic rates consequently fall (e.g., see Ref. 5). Yet a third mechanism suggests that the decreases in photosynthesis during acclimation are a consequence of enhanced rates of sucrose synthesis that accompany increased CO_2 uptake. Enhanced sucrose production results in feedback regulation of sucrose phosphate synthase (SPS) and a sequestering of Pi pools in the cytosol [2,6,7]. Without sufficient levels of Pi returning to the chloroplast, RuBP regeneration, and hence photosynthesis, is restricted. Finally, it has been suggested that a limitation in nitrogen may be a causal factor of acclimation [8]. According to this mechanism, nitrogen assimilation is not able to keep pace with enhanced photosynthetic rates under high CO_2; that is, the photosynthetic mechanisms are nitrogen limited.

Although all of these mechanisms may contribute to the acclimation response, recent evidence has suggested that none can fully explain the long-term decreases in photosynthetic rates that characterize this phenomenon. Rather, evidence favors the hypothesis that long-term exposure to elevated CO_2 results in a downregulation of photosynthetic gene expression. One of the early pieces of evidence in support of this hypothesis was that declining photosynthetic rates in high-CO_2–grown plants are accompanied by a loss of Rubisco protein (e.g., see Refs. 1, 2, 7, and 9–15). In a few cases, it has been further demonstrated that the loss of Rubisco protein is accompanied by coordinate decreases in Rubisco small subunit (*rbc*S) and large subunit (*rbc*L) transcript levels in the nucleus-cytoplasm and chloroplast, respectively [7,15].

Although alterations in *rbc*S and *rbc*L transcription may explain, at least in part, why photosynthetic rates decrease during acclimation, there still remains the question of what factors control the changes in transcription of these genes. These factors are poorly understood, but may include a variety of environmental factors such as nutrient status, water supply, mineral availability, and temperature [16], which have been demonstrated to influence the sensitivity of the acclimation response. There also have been suggestions that acclimation can be influenced by the leaf and plant developmental stage [14–16]. The latter is the focus of the rest of this chapter.

ELEVATED CO_2 AND TOBACCO LEAF DEVELOPMENT

Regulation of Photosynthesis During Leaf Development

Under ambient CO_2 conditions, leaf development can be separated into two distinct phases [17]. The first stage is associated with leaf growth and expansion. During this stage, leaf photosynthetic rates increase over time. There follows a transient peak of maximal photosynthetic rates correlated with the attainment of full expansion, and then rates begin to decline. This is the second stage of development, which is referred to as senescence. As the senescence phase progresses, leaves yellow as chlorophyll is broken down, and resources are reallocated to different parts of the plant, such as reproductive structures. In many species, the changes in photosynthesis that occur during these phases are largely due to changes in the levels of Rubisco protein and activity (e.g., see Refs. 18 and 19). The alterations in Rubisco protein, in turn, are due to coordinate changes in *rbc*S and *rbc*L mRNA amounts. This finding emphasizes the notion that senescence involves a modulation of anabolic processes as well as catabolic processes (cellular breakdown).

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

Previous experiments in our laboratory have demonstrated that genetic manipulation of sink/source balance profoundly impacts plant growth and developmental processes [19,20]. These experiments were performed with Rubisco antisense mutants of tobacco, in which Rubisco levels are decreased up to 90% of those found in the wild type. Source strength (carbohydrate production) also is impaired in these plants. We also have examined growth and development under conditions where source strength is increased by growing tobacco plants under elevated CO_2 conditions. These studies led to some novel observations on the phenomenon of acclimation.

Photosynthetic Parameters

To investigate the effect of increased source strength on leaf development, we examined tobacco plants under ambient CO_2 levels (approximately 350 μL/L) and enriched CO_2 concentrations (950 μL/L) [21]. Leaf 10 (counting up from the base), which is a middle canopy leaf, was chosen for analysis because of its large final size. The elevated CO_2 regimen was initiated at the time of visible leaf 10 emergence. Measurements were taken at varying time points throughout leaf development. We first performed gas exchange analyses and examined the CO_2 exchange rate (CER), stomatal conductance (Cs), and internal inorganic carbon concentration (Ci). As illustrated in Figure 1, ambient CO_2-grown leaves exhibited increasing CERs to day 12, a transient maximum, then a steady decline from day 14 onward; rates fell below zero at day 40. Relative to their ambient-grown counterparts, the high-CO_2–grown leaves displayed a similar pattern of CER change over time as well as a similar photosynthetic maximum. However, these leaves reached their photosynthetic maximum and initiated their photosynthetic decline at day 4; significantly earlier than in the ambient-grown leaves. The rate of photosynthetic decline following this maximum was comparable to that in the ambient-grown leaves except that CER reached zero at day 25. These results suggest that the magnitude and onset of maximal photosynthetic rates and their subsequent decline is similar in plants with enhanced source strength, but that in these plants, the onset of the decline is temporally shifted to an earlier initiation point.

To determine whether stomatal aperture was responsible for the changes in photosynthesis in high CO_2 versus ambient-grown leaves, Cs and Ci were plotted versus relative leaf age [21]. The data indicated that there were no significant differences in Cs between the two treatments, but that

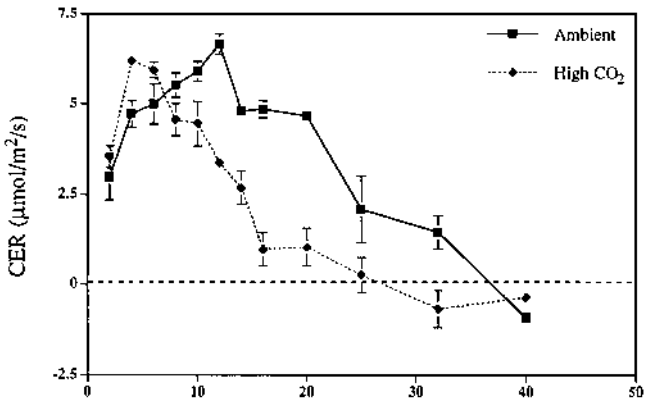

FIGURE 1 CERs during development of tobacco leaves grown under ambient (circles) or elevated CO_2 conditions (squares). Plants were moved into high CO_2 when leaf 10 reached 1 cm in length; day ''1'' status was assigned when the leaf reached 3 × 5 cm in length several days after transfer. Each point represents the average (± SE) of multiple measurements on leaves from at least 4 different plants. (From Ref. 21.)

the levels of Ci were generally higher in the elevated CO_2-grown leaves throughout the developmental time course. Clearly, stomatal conductance did not cause the decline in photosynthesis observed in the high-CO_2–grown plants, since internal CO_2 levels were not reduced. Considered together, these data demonstrate that the CER was not limited by CO_2 availability.

An examination of other photosynthetic parameters supported the conclusion that photosynthetic rates undergo a temporal shift to an earlier photosynthetic maximum in high-CO_2–grown leaves. In the first place, chlorophyll concentrations were similar between the two CO_2 concentrations early in development, but by day 6, chlorophyll amounts had already begun to decline in high-CO_2–grown leaves; levels in ambient-grown leaves remained relatively constant until about day 16. The rates of chlorophyll loss during senescence were comparable between the two treatments. Second, the CER profiles were generally mirrored by similar changes in Rubisco activity and content in both sets of leaves. This suggests that photosynthetic rates may be determined primarily by Rubisco throughout leaf development.

NEW PARADIGM TO UNDERSTAND ACCLIMATION

Temporal Shift Model

We propose a new model to explain the acclimation phenomenon. This model should be applicable to plants like tobacco whose major sinks are developing leaves. Much research over the years has supported the notion that there is a process that initiates the downregulation of photosynthesis via reductions in photosynthetic proteins after a certain length of exposure to elevated CO_2. The end result is a loss of potential photosynthetic gain under favorable substrate conditions. This is especially evident when photosynthetic rates are measured under normal CO_2 conditions. Figure 2 illustrates this process.

To explain this downregulation, we have proposed a ''temporal shift'' model, which suggests that the lower photosynthetic rates observed after prolonged exposure to enriched CO_2 are due to an earlier onset of the natural ontogenic decline of photosynthesis associated with the senescence phase of development [21]. Figure 3 illustrates how our model differs from a photosynthetic downregulation model based solely on a change in the magnitude of photosynthetic rates that would occur during all leaf developmental phases.

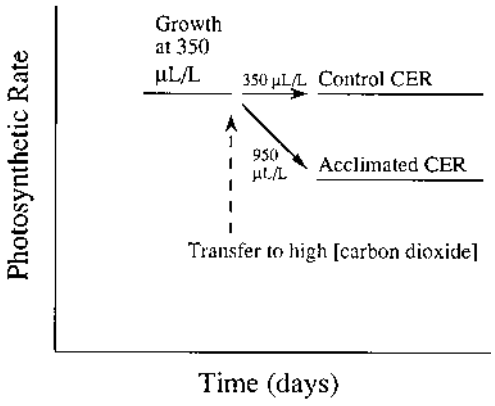

FIGURE 2 Downregulation of photosynthetic rates during a typical ''acclimation'' experiment. Plants in ambient conditions (350 µL/L CO_2) are shifted to high CO_2 (950 µL/L); controls are retained under ambient conditions. Measurements of photosynthetic rates are conducted under ambient conditions after growth for varying amounts of time.

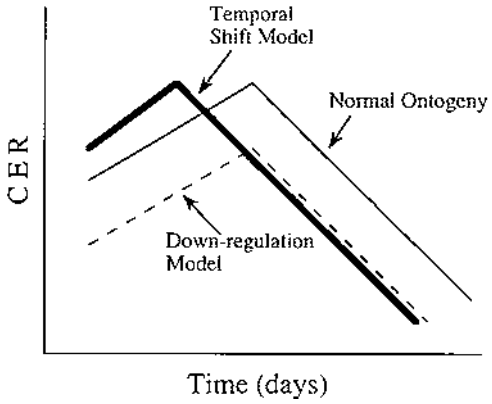

FIGURE 3 The temporal shift model of acclimation. (From Ref. 21.)

Testing the Temporal Shift Model in Reduced Source Strength Conditions

Elevated CO_2 provides an easy method for increasing the source strength of a tobacco leaf. One way to test the validity of the temporal shift model is to decrease the source strength and examine the impact on photosynthetic rates during leaf development. One way that decreased source strength leaves has been achieved genetically in tobacco has been through antisense repression of Rubisco holoenzyme levels [22]. Rubisco is composed of eight large subunit (LS) and eight small subunit (SS) proteins encoded by genes in the chloroplast (*rbc*L) and the nucleus (*rbc*S), respectively. To generate the antisense mutants, a highly expressed member of the tobacco *rbc*S gene family was introduced into tobacco in the antisense orientation behind the highly expressed ''constitutive'' CaMV 35S promoter. The resulting transgenic plants had reduced *rbc*S mRNA and SS protein levels, and the reductions in SS were matched by corresponding reductions in LS and Rubisco holoenzyme amounts in the plastid, indicating that stoichiometric reductions occurred in the accumulation of these proteins in the mutant plants [22]. However, in contrast to *rbc*S mRNAs, *rbc*L mRNA levels were unperturbed in the mutants; it appears that LS accumulation is regulated primarily at the level of *rbc*L mRNA translation initiation in these plants [23]. The reductions in Rubisco range from 10 to 90% of the wild type, and these reductions correlated with antisense copy number—the more *rbc*S antisense DNA present, the greater the repression of Rubisco. The reductions in Rubisco were accompanied by depressed photosynthetic rates, indicating that carbohydrate production (source strength) also was severely reduced in the mutant plants [24].

To test the temporal shift model we have examined CERs and various other photosynthetic parameters during leaf development in the Rubisco antisense plants. We found that CERs are lower throughout development in antisense leaves than in leaves from either wild-type or high-CO_2–grown plants (as expected). However, the onset of the decline in CERs associated with senescence occurred temporally later in leaf development in the mutants (data not shown). This is consistent with the temporal shift hypothesis.

MECHANISM OF THE TEMPORAL SHIFT

As illustrated by the above data, changes in leaf source strength appear to result in a temporal shift in the onset of the decline of photosynthetic rates associated with senescence. Increased source strength caused a shift in photosynthesis to an earlier onset, whereas decreased source strength resulted in a delayed onset. This shift explains why, at a given leaf age, leaves from high-CO_2–grown

plants have lower photosynthetic rates than their ambient-grown counterparts, such as observed in the tobacco acclimation studies of Sicher et al. [12].

The temporal shift model is consistent with the notion that photosynthetic output is determined by the sink status of the plant (sink regulation of photosynthesis) (reviewed in Ref. 2). According to this theory, high photosynthetic rates are maintained in a source leaf as long as there is sufficient sink tissue (sink demand) to consume the carbohydrate that is produced by the source. However, once the demand for photosynthate falls, surplus carbohydrate begins to accumulate in the source. It is thought that this results in a long-term decline in photosynthetic rates due to feedback inhibition of photosynthetic gene expression. Our temporal shift model is entirely consistent with the sink regulation hypothesis. Under increased source strength conditions (as long as the sink status remains unchanged), carbohydrate would accumulate more quickly, resulting in an earlier onset of the photosynthetic downregulation associated with sink limitation. Decreased source strength would have the opposite effect. One possibility is that the changes in source strength are mediated by alterations in gene expression that occur by a sugar-signaling system similar to the catabolite-repression system of yeast (e.g., see Refs. 2, 25, and 26).

There have been suggestions that the acclimation response is modulated by leaf developmental factors (e.g., see Refs. 14–16). The question arises whether the temporal shift in photosynthetic rates is due to changes in photosynthetic gene expression. Our data also raise the question whether the effects of source strength might be more broad and encompass other aspects of leaf developmental programming. We are currently investigating these questions.

Changes in CO_2 Levels and Their Stress Effects on Photosynthetic Carbon Fixation

RAISING OF CO_2 IN THE ATMOSPHERE

As the global carbon dioxide concentration rises, we need to understand the combination of direct stress effects of this gas and the anticipated effects of climatic change, including drought, on the physiology and growth of all crops [1]. The current increase in the atmospheric carbon dioxide concentration along with predictions of possible future increases in global air temperatures have stimulated interest in the effects of CO_2 and temperature on the growth and yield of food crops [2] (Fig. 1). The rise in atmospheric CO_2 has been documented continuously since 1958 by Keeling et al. [3], and currently the concentration of CO_2 in air is about 360 μL L^{-1}. The concentration could increase to about 670–760 μL L^{-1} by the year 2075 mainly because of the burning of fossil fuels [4,5]. General circulation models predict that global warming will result from rising CO_2 and other greenhouse gases [6–11].

The stress effects of rising CO_2 and elevated temperatures on tropical plants have received less attention than the effects on temperate species [12]. Because both CO_2 and temperature have large effects on plants, especially those with the C_3 photosynthetic pathway, it is important to quantify the effects of these climatic variables on C_3 food crops [10]. Concern over the well-documented increase in the concentration of carbon dioxide in the earth's atmosphere has stimulated research on the response of plants to this aspect of global change. Much of this research has focused on the response of photosynthetic carbon dioxide fixation, because the process is often dramatically and directly affected by the carbon dioxide concentration, and it is of fundamental importance both to plant growth and to ecosystem carbon storage. The concentration of carbon dioxide in the atmo-

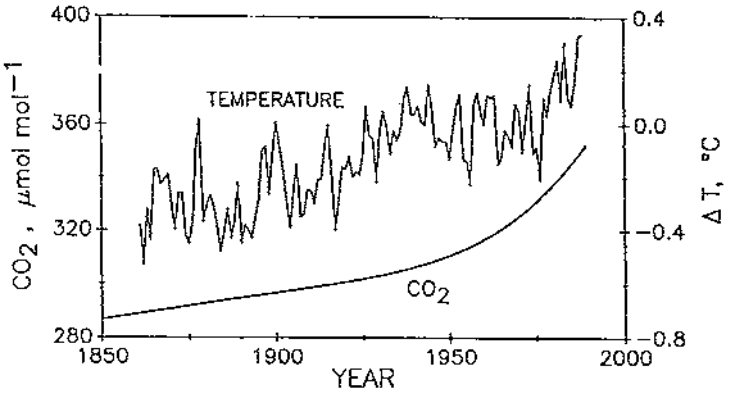

FIGURE 1 Atmospheric CO_2 concentration and estimated mean annual surface temperature changes. (From Ref. 41.)

sphere has increased from about 280 cm^3 m^{-3} prior to the industrial revolution in Europe to approximately 355 cm^3 m^{-3} currently [13]. Depending primarily on future changes in land use and fossil fuel consumption, the concentration may double by the end of the next century [14,15]. As the rate of photosynthesis in C_3 plants is strongly dependent on the CO_2 concentration, this should have a marked effect on photosynthesis, and hence on plant growth and productivity [16].

There is legitimate concern over how the predicted doubling of the CO_2 concentration during the next century will influence the earth's climate, ecosystems, and agricultural production; but substantial fluctuations in CO_2 have occurred in the past [11]. When plants made the transition to land, some 420 million years ago (MYA), the atmosphere may have contained as much as 4000–6000 μmol CO_2 mol^{-1} [17–20]. The rise of vascular plants, and their attendant photosynthesis, was a major factor in the decline of the atmospheric CO_2 concentration, which by 300 MYA may have dropped to near present values [20,21]. Thus, the atmospheric CO_2 concentration has fluctuated perhaps by as much as 20-fold over geological time; so higher values are not a new phenomenon for plants [21]. As CO_2 rises, general circulation models predict increases in mean global temperatures of between 1.5 and 4.5°C and increased, but variable, precipitation patterns [7–9]. However, at regional levels, the magnitude of these changes is uncertain [21].

The principal change to date is in the balance of gases that form the earth's atmosphere. These naturally occurring ''greenhouse gases,'' including carbon dioxide (CO_2), methane, nitrous oxide, and water vapor, keep ground temperatures at a global average of 15°C [22]. Without this natural blanket, the earth's surface would be about 30°C colder than it is today, making the planet a freezing, barren, lifeless place similar to Mars. The greenhouse gases keep the surface warm, because as incoming solar radiation strikes the earth, the surface gives off infrared radiation, or heat, that the gases temporarily trap and keep near ground level. The effect is comparable to the way a greenhouse traps heat. The problem is that human activity may be making the greenhouse gas blanket ''thicker.'' For example, burning coal, oil, and natural gas spews huge amounts of carbon dioxide into the air; the destruction of forests allows carbon stored in the trees to escape into the atmosphere; and other activities such as raising cattle and planting rice emit methane, nitrous oxide, and other greenhouse gases [22].

This chapter examines the stress response of plants to rising atmospheric CO_2 and to the various climatic factors that have been investigated within the last 10–15 years. Within the last 15 years, there have been numerous reports and reviews on stress responses of plants to elevated CO_2 [11,23–42]. Most published studies on the increasing CO_2 concentration in the atmosphere and temperature effects on plants have dealt mainly with temperate crop species, whereas tropical plants

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

have received less attention [12,43]. Since both [CO_2] and temperature can have large effects on plants, it is important to quantify the effects of these climate variables on food crops [43].

BIOMASS PRODUCTION

Above- and Belowground Biomass

The growth responses of crops to elevated CO_2 have been reviewed by Acock and Allen [44] and Acock and Pasternak [45]. They suggest that the order of priorities for the use of photoassimilates by plants is (a) survival, (b) reproduction, (c) growth of existing organs, (d) increase in the number of existing organs (mostly by branching or tillering), and (e) storage. When these needs are met, the plant may decrease CO_2 fixation in the face of an imbalance of the source/sink ratio for photoassimilates. As with photosynthetic rates, growth and yield show a wide range of responses to the increasing CO_2 [41]. Most of the studies that show a lack of response of plants to elevated CO_2 are probably due to the inadvertent limitations imposed by experimental conditions, such as restricted rooting volumes [41].

Allen et al. [46] used a nonlinear model to predict photosynthetic, final biomass, and seed yield responses of soybean to CO_2 relative to a CO_2 concentration of 330 μmol mol^{-1}. Table 1 shows that the rise of CO_2 from preindustrial values to present values should cause a 13% increase in seed yield [47]. Furthermore, a doubling from 315 to 630 μmol mol^{-1} could cause a 32% increase in seed yield; an increase that is in close agreement with the survey of plant responses to a doubled CO_2 increase [41] (Table 1). The seed yield responses were less than biomass responses because of greater vegetative growth and less efficient conversion to seed under high levels of stressing CO_2. Plant breeding and selection may be able to provide more efficient conversion of photoassimilates to seed yield in the future [41,48].

Growth and final yield of rice increased across the subambient to the superambient range of CO_2 treatments from 160 to 900 μmol mol^{-1} but tended to flatten out above 500 μmol mol^{-1} more than soybean [49–51] (Fig. 2). Leaf appearance rates were increased as the CO_2 concentration was increased [52]. Furthermore, the final number of mainstem leaves decreased with increasing CO_2. Imai and Murata [53] found small increases in leaf appearance rates for rice plants exposed to elevated CO_2 at 1000 μmol mol^{-1} versus 300 μmol mol^{-1} controls, but Gifford [54] found no effects of CO_2 on the phyllochron interval of wheat [41]. These results indicate that future increases in [CO_2] are likely to benefit rice production by increasing photosynthesis, growth, and grain yield (Fig. 2) and reducing water requirements. As shown in Table 2, in warmer areas of the world, possible future increases in air temperature may result in yield decreases and increased water requirements [42].

Brakke [55] and Brakke and Allen [56] reported that dense canopies of Carrizo citrange and Swingle citrumelo seedlings had a twofold greater photosynthetic rate when exposed to 840 μmol mol^{-1} CO_2 in comparison with 330 μmol mol^{-1}. The elevated CO_2 alleviated midday depression of

TABLE 2 Effects of Plant Physiological Responses to Rising Atmospheric CO_2 Concentration and Temperature

Elevated CO_2 concentration
enhances photosynthetic CO_2 uptake, especially by C_3 plants
decreases stomatal conductance
results in increased partitioning to roots
directly inhibits plant respiration and may reduce stress tolerance
enhances biomass accumulation of woody plants
enhances C_3 plant photosynthesis at higher temperature
Increased temperature is likely to increase plant and ecosystem respiration.
Higher temperature in combination with elevated CO_2 concentration promotes vegetative biomass accumulation.
Rising CO_2 concentration and increasing temperature are likely to result in a net carbon sequestration by plants.
Under high CO_2 levels, stress effects may be delayed for a few days in some crops because of the higher level of leaf starch build-up and lower stomatal conductance to water loss.
In warm areas of the world, however, possible future global warming may result in both substantial yield decreases and increased water requirements.

Source: From Ref. 42.

photosynthetic rates due to either atmospheric evaporative demand stresses or low available soil water stresses [41]. Jurik et al. [57] also found that species of northern hardwood forests had leaf photosynthetic rates about 2.5-fold higher when exposed to 1900–2500 μmol mol^{-1} CO_2 in comparison with ambient CO_2 [41].

Grain yield increases in both wheat (*Triticum aestivum* L.) [50,54,58–60] and rice [53,61–63] have been shown to result from [CO_2] enrichment. This increased grain yield is often associated with increased tillering and the production of more spikes in wheat [54,58–60] or panicles in rice [50,63]. Yields of rice cultivar IR-30 declined by 10% for each 1°C rise in day-night temperature above 28/21°C, and elevated CO_2 had little effect in ameliorating this temperature response [51]. Sharp decreases in the number of filled grains per panicle accompanied these yield decreases [10]. Total growth duration of rice was shortened by 10–12 days across a CO_2 concentration treatment range of 160–500 μL/L because of a shortened vegetative phase of development and a reduction in the number of mainstem leaves formed during this period [10]. Carbon dioxide enrichment from 330 to 660 μL/L increased grain yield mainly by increasing panicles per plant; whereas increasing temperature above 28, 21, and 25°C resulted in decreased grain yield largely because of a decline in filled grains per panicle. Grain yields were highest at a weighted mean temperature of 26°C and declined by about 10% per each 1°C rise in temperature above 26°C [10].

Net Assimilation Rate

No differences between crops and weeds or between cool- and warm-climate species were found in the responses of growth or photosynthetic acclimation to elevated carbon dioxide [64]. The photosynthetic response and acclimation to elevated carbon dioxide differed depending on the photosynthetic photon flux density (PPFD) used to measure photosynthesis. This could greatly complicate predictions of the relative stimulation of the net assimilation rate (NAR) by stresses at elevated carbon dioxide in variable PPFD environments [64]. In soybean, reduced photosynthesis after acclimation to elevated carbon dioxide assayed at high PPFD was accompanied by a reduction in the quantum yield of photosynthesis [64,65].

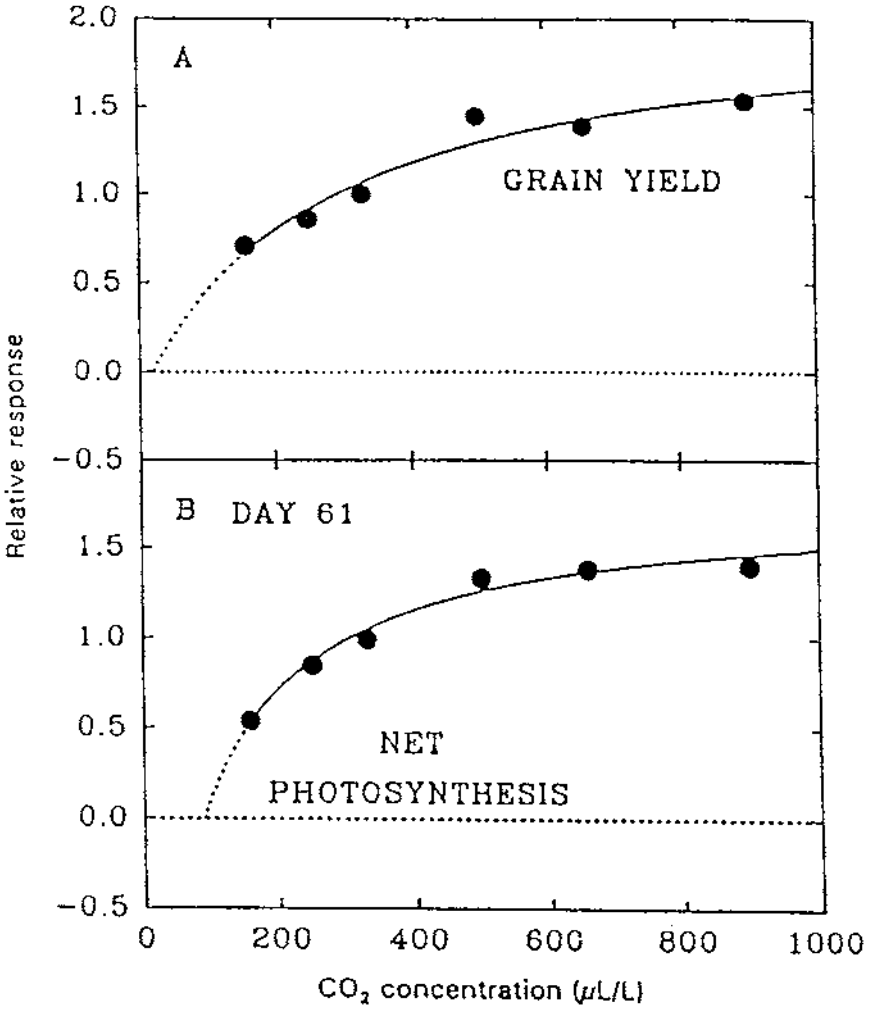

FIGURE 2 (A) Rice grain yields and (B) net photosynthesis of canopy in response to CO_2 concentration normalized to the values obtained from the 330 μl/L CO_2 treatment. (From Ref. 51.)

Relative Growth Rate

Increases in the relative growth rate (RGR) at elevated carbon dioxide were more highly correlated with the relative increase in NAR at elevated carbon dioxide than with the response of the leaf assimilation rate (LAR) [64]. Response curves of the photosynthetic rate to temperature at ambient and elevated CO_2 concentrations indicate that the photosynthesis and biomass accumulation of many C_3 plant species could increase with stresses imposed by increasing CO_2 concentration and increasing temperature [66], at least up to a threshold value or temperature optimum [42].

We do not know how universal the enhancement of photosynthesis and vegetative growth may be when plants are exposed to a combination of elevated CO_2 levels and high temperatures. Nevertheless, higher temperature in combination with CO_2 enrichment appears to enhance vegetative biomass accumulation in C_3 plants, and this relationship might contribute to a negative feedback

on the atmospheric CO_2 increase [42]. Reproductive growth of plants appears to respond quite differently to temperature increases than does vegetative growth [67]. Baker and Allen [51] reported that in a cultivar of tropical lowland rice (cv. IR-30) grain yield decreased linearly about 10% for each 1°C increment across the range of 26 to about 36°C under CO_2 treatments of both 330 and 660 ppm [42].

Atmospheric carbon dioxide is known to affect plant yield. Kimball [24] reviewed 430 observations of carbon dioxide–enrichment studies conducted prior to 1982 and reported an average yield increase of 33% plus or minus 6%, for a doubling of the carbon dioxide concentration [68]. This value has been generally confirmed by many other studies since that time. The yield increases seem to apply for both biomass accumulation and grain yield. Thus, plants may grow larger and use more water as the global carbon dioxide concentration increases. Soybean seed yields and biomass yields are predicted to increase 31 and 41%, respectively, from a doubling of carbon dioxide. A small decrease in the soybean harvest index under elevated carbon dioxide conditions has been commonly observed.

STOMATAL CONDUCTANCE AND WATER-USE EFFICIENCY

The responses of photosynthesis to the stress effect of increasing carbon dioxide concentration in terrestrial C_3 gymnosperms and angiosperms are presented here. Photosynthesis is the only one of several plant processes affected by an elevated carbon dioxide concentration [11,15]. For example, stomatal conductance to water loss is often reduced as carbon dioxide concentrations increase, and this may alter plant resposes to drought [70]. At strongly limiting carbon dioxide concentrations, carbon fixation is thought to be limited by ribulose bisphosphate carboxylase oxygenase (EC 4.1.1.39; Rubisco) activity. Since the pathway of carbon dioxide movement includes the stomatal pore, changes in pore size caused by changes in the carbon dioxide concentration in the substomatal air space [71] also often occur. Thus, in order to predict the response of photosynthesis to carbon dioxide concentration when the concentration is limiting, it is necessary to know the response of stomatal resistance [15].

Although stomatal conductance may be decreased about 40% for doubled CO_2, water use by C_3 crop plants under field conditions will probably be decreased only up to 12%. If the leaf area increases due to doubled CO_2 are small, then the transpiration reductions may be meaningful, albeit small. If the leaf area increases due to doubled CO_2 are large, then no reductions in transpiration are to be expected, and even increases in water use may be possible [41].

Long-term studies show only a small effect of elevated CO_2 on reducing transpiration per plant, because the plants tend to have a larger leaf area with slightly greater foliage temperature. Water-use efficiency (WUE) is increased by elevated CO_2, but the effect on C_3 crops is mediated primarily by enhancing photosynthesis and growth and only secondarily by decreasing transpiration [41]. Stomatal conductance is inversely related to the CO_2 concentration [72,73]. Atmospheric water vapor is the most important greenhouse gas [74], and the effects of stomatal closure elicited by CO_2 stresses on climate via hydrological cycles are unclear [42].

The link between CO_2 and stomatal conductance appears to be at the level of intercellular CO_2 [71]. Because an increase in the CO_2 level accelerates photosynthesis, slows photorespiration, and decreases leaf surface conductance, the instantaneous WUE on a leaf area basis is positively related to the CO_2 concentration [75]. Although decreased stomatal conductance owing to an elevated CO_2 concentration can decrease transpiration on a leaf area basis, an increased leaf area resulting from an elevated CO_2 concentration may offset the leaf-level transpiration decline when transpiration is considered at the level of the canopy [68,70]. Increased WUE under elevated levels of CO_2 may be due to increased CO_2 assimilation rather than to decreased transpiration, especially for C_3 species [75,76]. Decreased stomatal conductance and leaf-level transpiration will tend to increase the leaf and canopy temperature. The increase in the canopy temperature has the potential to accelerate the

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

developmental rate at a given air temperature. Finally, decreased stomatal conductance under elevated CO_2 levels may contribute to a small positive feedback to increasing surface temperatures [42]. Increased carbon dioxide concentrations are known to cause smaller stomatal apertures and hence to decrease the leaf conductance for water vapor [73]. This is a second mechanism whereby stresses caused by increased carbon dioxide concentrations may affect plant transpiration [68]. Kimball and Idso [77] calculated a 34% reduction in transpiration in response to a doubled carbon dioxide concentration in several short-term plant growth chamber experiments. Morison and Gifford [78] also showed that doubling carbon dioxide will cause a more rapid development of the leaf area for many plants and hence an equal or greater transpiration rate in the early stages of plant growth due to a more rapid development of transpiring surfaces. Therefore, increased rates of development of transpiring leaf surface offset the reduced stomatal conductance for water vapor [68].

An increase in WUE of carbon dioxide–enriched crops is largely due to sizable increases in photosynthesis, growth, and yield. Louwerse [79] reported that differences in stomatal behavior are only partly species specific and depend mainly on growing conditions [1]. Allen, et al. [1] reported that leaflets at high CO_2, either water stressed or well watered, had higher photosynthetic and lower transpiration rates, and therefore higher water-use efficiencies than those at control CO_2 levels. Leaf conductances are goverened by CO_2 assimilation rates under water-stressed as well as unstressed conditions [1]. Leaves adapted to high CO_2 had higher WUE than leaves adapted to ambient CO_2 mainly because of a twofold increase in carbon exchange rate [80]. Increases in WUE with increasing CO_2 were realized by both substantial increases in CO_2 uptake and somewhat smaller decreases in water loss. Increasing temperatures greatly increased water use and decreased photosynthetic WUE [10]. The cause and effect relationships can be summarized as follows: Any reduction in stomatal conductance due to increasing carbon dioxide concentration will restrict transpiration rates per unit of leaf area. A reduction in transpiration rates will result in less evaporative cooling of the leaves and the leaf temperatures will rise [68].

PHOTOSYNTHETIC RESPONSES TO CO_2 STRESS

Sites of Action of CO_2

Atmospheric O_2 also interacts with Rubisco; as a competitive inhibitor with respect to CO_2 and as a substrate for the monooxygenase activity of this bifunctional enzyme to produce phosphoglycolate [21]. Through O_2 inhibition and photorespiration, the present atmospheric CO_2/P_2 ratio causes about a 35% reduction in the photosynthesis of C_3 plants at 25°C, and higher temperatures amplify this inhibition. Because of the competitive interaction, as CO_2 rises, it will diminish the inhibitory effects of O_2; a doubling of the present CO_2 concentration should more than halve photorespiration. Thus, increasing the CO_2 supply for C_3 species not only provides more of a limiting resource (carbon) but also has the potential to improve the use of other resources and raise the optimum temperature for photosynthesis [38]. This effect is analogous to the CO_2-concentrating mechanism (CCM) of C_4 species [21]. Somewhat surprisingly, a stress of doubling in CO_2 concentration also reduces dark respiration in a number of species [32].

Another interesting facet of increased CO_2 enrichment is the apparent action of CO_2 as a growth modulator. A doubling in CO_2 can cause changes in anatomy, morphology, and phenology [29,31]. These indirectly influence photosynthesis by altering various plant characteristics, including branching, leaf area, duration of assimilation, and sink capacity [11,21]. Several CO_2-dependent promoters have been detected in the cyanobacterium *Synechococcus*. These may contain regulatory regions that respond directly to CO_2 concentration or indirectly via metabolites in the photorespiratory carbon oxidation (pCO) pathway whose concentrations change with the CO_2/O_2 ratio [81,82]. The CO_2-concentrating mechanism of C_4 plants allows CO_2 to compete more effectively with O_2 for binding sites on the enzyme, ribulose biphosphate carboxylase oxygenase (RuBP; Rubisco) [41]. Therefore, C_4 plants have a more efficient photosynthetic apparatus than C_3 plants (at temperatures above 25°C) under recent atmospheric concentrations of CO_2 (270–355 μmol mol^{-1}) and do not

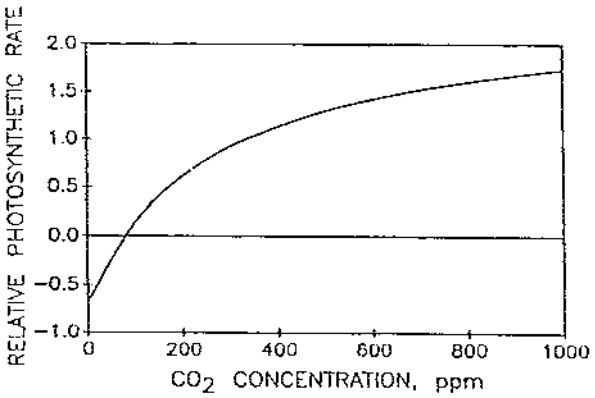

FIGURE 3 Photosynthesis carbon dioxide uptake rate responses of soybean canopy exposed to various carbon dioxide concentrations. (From Ref. 46.)

increase photosynthetic rates as much as C_3 plants in response to increasing levels of CO_2 (Fig. 3); in fact, C_4 photosynthetic rates are near CO_2-saturation under current levels of atmospheric CO_2. As the CO_2 concentration continues to increase, C_3 crop photosynthetic rates should approach or exceed those of C_4 crop plants, because CO_2 can compete with O_2 for binding sites on Rubisco more effectively, and because the C_3 plants would not have to expend energy for the CO_2-concentrating process [41].

Effects of Increasing CO_2 on Crop Photosynthesis and Productivity

An increasing CO_2 concentration confers a selective advantage on the C_3 plants and puts them into an increasingly favorable competitive position. An increased carbon gain by C_3 plants would allow them either to increase root growth and compete more successfully with their C_4 neighbors for nutrients or increased foliage production to compete more successfully for available light. The continuously improving photosynthetic performance of C_3 plants should put great competitive pressure on neighboring C_4 plants, especially in warmer regions where the improvements in the performance of C_3 plants should be most marked [16]. Mechanistic formulations of the direct CO_2 effects on photosynthesis have been incorporated in some physiology-based models, whereas modifications incorporating direct CO_2 effects in nutrient-driven models have usually been more empirical. Physiology-based models predict considerable CO_2-fertilizer effects, whereas nutrient-driven models tend to be less sensitive to an elevated ambient CO_2 concentration [83].

Weed growth was consistently increased by carbon dioxide enrichment, but weed species' composition was unaffected. Canopy carbon dioxide uptake was slightly higher in the elevated carbon dioxide treatments, which was consistent with the increased weed growth. In alfalfa, elevated carbon dioxide significantly reduced canopy carbon dioxide efflux at night for the same daytime uptake rate and temperature [84]. The optimum temperature for photosynthesis is increased at elevated carbon dioxide [15].

Even at limiting photon flux, the photosynthetic rate of C_3 plants responds positively to increases in carbon dioxide concentration [85]. It gradually became recognized that part of the syndrome of the C_4 pathway of photosynthesis was saturation of the rate of carbon dioxide fixation at lower carbon dioxide concentrations than it occurs in C_3 plants. Photosynthesis in C_4 plants is often near or at saturation for carbon dioxide at the current atmospheric concentration even at high photon

flux. This explains why the growth rate of C_4 plants is often relatively insensitive to increases above that concentration [86] and no stress effects whatsoever are observed. Although we now understand the basis of much of the observed variation in the short-term response of photosynthesis to carbon dioxide concentration, the long-term response is still largely unpredictable [15]. It has been recognized for nearly 20 years that long-term exposure to elevated carbon dioxide concentrations can induce metabolic stress and reduce photosynthetic capacity [87]. In spite of considerable research effort and significant progress, the ability to predict the occurrence and magnitude of ''photosynthetic adjustment'' to the stress effects caused by carbon dioxide concentrations remains elusive. In the basic C_3 photosynthesis models, carbon dioxide saturation of photosynthesis indicates limitation by RuBP regeneration. Long and Drake [88] found no long-term reduction in quantum yield after years of exposure of a salt-marsh species to double the ambient carbon dioxide concentration but rather a continued stimulation when leaves were measured at the elevated carbon dioxide concentration. A common symptom of negative photosynthetic adjustment to elevated carbon dioxide is the low nitrogen content of leaves. However, Bunce [89], in soybean and sugar beet, and Wong [90], in cotton, have found that negative photosynthetic adjustment could not be overcome by high nitrogen application rates [15].

Several reviews and assessments of the response of plants to rising levels of atmospheric CO_2 have been published within the last 15 years [11,23–42]. However, decreased rates of photosynthesis have sometimes been reported when plants are exposed to elevated CO_2 for prolonged intervals [41,91].

Direct Effects of Carbon Dioxide on Plants

Growth of C_3 plants at elevated CO_2 levels has resulted in reduction of the photosynthetic capacity and Rubisco activity [92,93], but photosynthetic capacity was maintained [94] or even increased in other cases [33,95–97]. Photosynthesis of C_3 plants generally increases nonlinearly with increasing CO_2 [41] (see Fig. 3). This type of nonlinear response appears to be universal for C_3 plants. Many early studies tended to focus on the negative responses of plants to prolonged exposure to elevated CO_2 [23], but recently the numerous findings of positive responses have gained greater recognition [33,96,97]. A wide range of positive responses of leaves and plants to elevated CO_2 was reviewed by Allen [41] and suggested some inadvertent limits that experimental techniques may have imposed on plant responses to elevated CO_2.

Starch accumulation increased at a greater rate as the CO_2 exposure level increased [98] imposing a stress condition on the photosynthetic apparatus. More starch accumulates in leaves under high CO_2 treatments, with much of the starch being digested and exported at night [98–101]. However, if low temperature, lack of sink, or some other limitation to growth prevents mobilization and translocation of photoassimilates, starch can accumulate in leaves up to 40% or more of dry weight [87,102–104]. The probable cause of decreases in photosynthetic rates after prolonged exposure to CO_2 is an excess of photoassimilate production in leaves with respect to photoassimilate utilization by the plant or crop system [87,105,106]. The process of photosynthetic rate reduction under conditions where source exceeds sink has been called endproduct feedback inhibition of photosynthesis. Endproduct feedback inhibition has been invoked as a concept for downregulating leaf photosynthetic rates and is considered as a marked stress effect to elevated CO_2 concentration [41].

Biochemical feedbacks on enzymes such as inhibition of RuBP carboxylase activity by phosphorylated sugar via competition with RuBP for binding sites [107] and inhibition of sucrose-phosphate synthase would favor starch formation at the expense of sucrose synthesis [108]. Another suggested mechanism is that triose phosphate is inhibited from forming sucrose in the cell cytosol and prevents the normal cycling of inorganic phosphate back into the chloroplast, thus slowing photosynthesis [109]. Loss of capacity for sucrose synthesis is a more likely mechanism involved in downregulation of leaf photosynthetic rates under the duress of the increasing concentration of CO_2 than is a direct effect of endproduct inhibition [41,110].

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

The bonsai syndrome certainly would call into question any attempt to extrapolate quantitatively growth chamber work conducted with small rooting volumes to field agronomic conditions. Furthermore, the changes in photosynthetic capacity that appear to be downward regulation in many studies may be an artifact of the imposed experimental conditions. The downward acclimation of rice canopy photosynthetic rates was accompanied with a 66% decrease in the total Rubisco activity [41]. The flattening out of the canopy photosynthetic rate in response to CO_2 above 500 μmol mol^{-1} was attributed to the reduction in Rubisco activity [51,111].

Crassulacean acid metabolism (CAM) species respond positively to elevated CO_2 [112,113], but they generally display lower photosynthetic rates than either the C_3 or C_4 plants. CAM plants fix CO_2 (actually HCO_3^-) into organic acids such as malate at night. During the day, malic acid is decarboxylated by the similar mechanisms present in C_4 bundle sheath cells and the resulting CO_2 is assimilated by the C_3 pathway. Thus, all three plant types (C_3, C_4, and CAM) use the C_3 pathway during some stage of photosynthesis, but C_3 plants show the greatest potential for response to elevated CO_2 levels. Because most plants are C_3 species, we would expect that on a global scale photosynthesis is likely to increase with increasing atmospheric CO_2 [42].

Many of the early studies on the effects of an elevated CO_2 concentration on plants reported initial increases in the leaf or canopy photosynthetic rates followed by a decrease after exposure for a number of days or weeks as the photosynthetic rates acclimated [42]. Other studies however, have shown no decreases or even increases in photosynthetic rates during long-term exposures to elevated CO_2 levels [11,33,76,80,114–117]. In cases where decreases in photosynthesis have been observed, starch tended to accumulate in leaves [118,119] rather than being translocated to sinks of photoassimilate such as growing leaves, roots, and fruits. Root growth restriction might have played a role in several observed declines in the photosynthetic capacity following the long-term CO_2-enrichment stress effect [104]. Starch accumulation is not, however, always associated with inhibited leaf photosynthesis [101], and the mechanism responsible for the potential feedback inhibition of photosynthesis is likely to involve insufficient organic phosphate for sucrose formation and export rather than direct effects of starch accumulation in leaf chloroplasts [35,110,120].

The response of leaves to an elevated CO_2 concentration may depend on the inherent sink strength of a species [35]. The upregulation or downregulation of photosynthesis may involve anatomical as well as biochemical responses [42]. For instance, photosynthetic capacity per unit leaf area may be increased as a result of increasing leaf thickness accompanied by production of an additional layer of palisade cells, as observed in soybean (*Glycine max* L.) [87,121,122]. On the whole, present data show that CO_2 enrichment enhances net photosynthesis in C_3 plants, and this situation might contribute to a negative feedback on atmospheric CO_2 increase at least in the short term [42].

Valle et al. [115] concluded that during seed fill, leaflets adapted to high CO_2 environments exihibited a capacity to utilize CO_2 and radiation more efficiently at elevated CO_2 and throughout all light levels than leaflets grown at low CO_2.

Response curves of the photosynthetic rate to temperature at ambient and at elevated CO_2 concentrations indicate that photosynthesis and biomass accumulation of many C_3 plant species could increase both with increasing CO_2 concentration and increasing temperature at least up to some maximum value (Fig. 4). However, the reproductive growth and grain yield of crops like tropical lowland rice may decrease steadily with increasing temperature above their temperature optima regardless of the concentration of CO_2 [41].

Increasing atmospheric carbon dioxide levels have caused increasing photosynthetic rates, biomass growth, and seed yield for all of the globally important C_3 food and feed crops [29,44,123]. Some plants, such as cucumber, cabbage, and perhaps tomato, have shown a tendency first to increase leaf photosynthetic rates in response to elevated carbon dioxide concentrations and then to decrease photosynthetic rates after several days. This behavior is called endproduct inhibition of photosynthesis, and it is caused by the failure of translocation of photoassimilates to keep up with the photosynthetic rates [118].

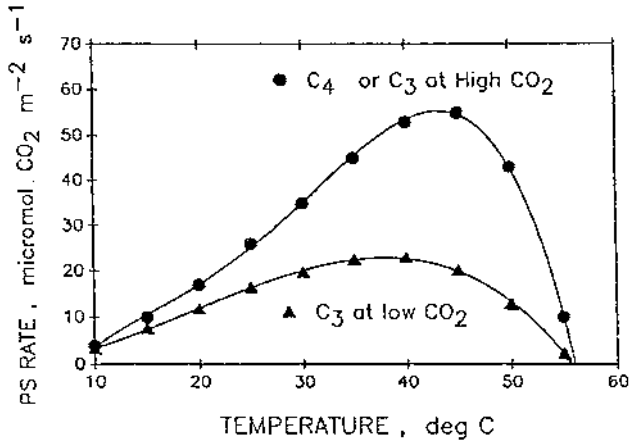

FIGURE 4 Photosynthetic rate versus temperature for C_3 and C_4 leaves. (From Ref. 91.)

Diurnal Changes in Response to Canopy Photosynthetic Rate to Elevated CO_2 in a Coupled Temperature–Light Environment

Photosynthesis is significantly more sensitive to CO_2 at higher temperatures than at lower temperatures. Consequently, growth responses to CO_2 would also be expected to be much more pronounced at higher than at lower temperatures. The interaction between CO_2 and temperature also needs to be taken into account in the interpretation of experimental data [16]. Galtier et al. [124] reported that sucrose phosphate synthase (SPS) activity is a major point of control of photosynthesis, particularly under saturating light and CO_2.

At high CO_2 and saturating light, photosynthesis is limited by the electron transport capacity and the rate of regeneration of the the substrate for carboxylation, RuBP [125–127], which is determined by the rate of electron transport that provides the NADP and ATP to drive the Benson-Calvin cycle. ATP synthesis, in turn, may be restricted by the availability of Pi. The relative importance of each of the above factors in limiting the overall photosynthetic rate depends largely on the prevailing environmental conditions. Increasing irradiance decreases the limitation by the RuBP regeneration phase, whereas increasing the atmospheric CO_2 concentration shifts the limitation away from Rubisco [124].

We do know that leaf photosynthetic rates of C_3 plants are enhanced more by elevated CO_2 at high temperatures than at low temperatures [26,44,128]; therefore, it would seem logical to expect increased growth rates when elevated CO_2 is accompanied by higher temperatures at least up to some maximum temperature. Reproductive growth of plants appears to respond quite differently to temperature increases than vegetative growth [41]. For example, Baker et al. [129] and Baker and Allen [51] reported that rice (cv. IR-30) grain yield decreased linearly about 10% for each 1°C increment across the range of 26 to about 36°C under CO_2 treatments at both 330 and 660 μmol mol^{-1}. The steady decline in rice grain yield with increasing temperatures was accompanied by a sharp decline in the number of filled grains per panicle, small declines in grain mass per seed, and small increases in the number of panicles per plant [41,51,129]. Photosynthetic rates of C_4 plants tend to increase with temperature to a greater extent than those of C_3 plants at current levels of atmospheric CO_2 [42].

All crops will respond more to the combination of increasing temperature with elevated carbon dioxide than to elevated carbon dioxide levels alone. However, during reproductive growth of soybean plants, the opposite trend was found. The complex responses of various kinds of plants to

interactions of carbon dioxide, temperature, water supply, light, and photoperiod (day length) need further research [68]. Temperature excerts a major influence on rice growth and yield. Biomass accumulation increases with increasing paddy water temperature from 18 to 33°C [130,131]. Tillering is similary stimulated with increasing temperature across a temperature range from 15 to 33°C [132]. Rice grain yield is negatively correlated with air temperature during the reproduction phase of growth [133]. Studying grain filling responses to temperature, Yoshida and Hara [134] found that the optimum temperature range for maximum grain weight was 19–25°C for an indica cultivar (cv. IR-20) and 16–22°C for a japonica cultivar (cv. Fujisaka 5) [43].

Raising CO_2 Levels and Their Potential Significance for Carbon Flow in Photosynthetic Cells

Crop biomass accumulation and grain yield are positively related to CO_2 concentration. Fruit trees and some vegetable crops appear to be just as responsive as soybean to increases in atmospheric CO_2 levels [42,55,56,135–140]. Forest tree leaf photosynthesis responds positively to increases in CO_2 concentration [57,117]. Growth and biomass accumulation of woody species under conditions of increasing atmospheric CO_2 will contribute to a negative feedback on CO_2 accumulation [42]. Only a limited amount of work concerning interactions between rising temperature and CO_2 has been conducted [42,66,70].

Adaptation to Changes in Atmospheric CO_2

For the past 20–30 million years, terrestrial vegetation has had to cope with stresses associated with a CO_2-poor atmosphere, and it has become progressively more adapted to such conditions. In contrast, within just the last 200 years, the planet's flora has experienced about a 28% rise in CO_2 concentration. This raises questions as to what extent readaptation is occuring and whether an increase in CO_2 concentration is stressful for plants adapted to CO_2-depleted conditions [21]. By examining herbarium specimens of temperate arboreal species from AD 1787 to the present, Woodward [141] first reported a 67% decline in stomatal density. Concomitantly, Woodward [141] calculated WUE to be improved by twofold during that time period. CO_2 was affecting stomatal initiation and not just epidermal cell expansion [142–144]. From such data it appears that stomatal conductance and atmospheric CO_2 concentration are negatively correlated over the past 16,500 years [142]. Along with decreases in stomatal density, herbarium specimens are suggestive of improvements in WUE with increasing CO_2 concentration [142,145]. Not all studies have reached the same conclusion. Korner [146] was unable to detect significant differences in stomatal density for over 200 lowland and alpine species from literature measurements of the past 100 years [21].

An interesting geological phenomenon that is being exploited to study the adaptation of plants to high CO_2 concentration is geothermal gas vents, whose emissions contain as much as 96% CO_2 [21]. So plants in the vicinity can be exposed to 10,000 μmol CO_2 mol^{-1} potentially over hundreds of years [147]. *Quercus pubescens* growing among natural gas vents in central Italy showed no differences in stomatal density or index as a function of distance from the vents; however, near the vents, the mean guard cell sizes and pore lengths were reduced [21,147,148]. Underground limestone springs in Florida are supersaturated with dissolved CO_2 concentrations of several hundred micromolars [149]; where they exit the ground, they become a source of CO_2 for submersed and terrestrial vegetation in the vicinity. When grown under a CO_2-enrichment regimen, *Boehmeria cylindrica* seeds collected from naturally enriched populations produced plants with significantly greater stem and root dry weights than seeds from a nonenriched population [21].

More studies with naturally enriched populations or with a ''fast plant'' such as *Arabidopsis thaliana* are required to establish unequivocally that photosynthetic adaptations to rising CO_2 occur in a short period (decades) [21].

Diversity in Photosynthetic Responses to CO_2-Enrichment Species Differences and Acclimation Mechanisms

A major recent development in the understanding of photosynthetic responses to carbon dioxide concentration is the proposed phosphate limitation mechanism of feedback inhibition of photosynthesis [150]. Under this hypothesis, chloroplast phosphate concentration limits the short-term photosynthetic response to increased carbon dioxide concentration when the rate of photosynthate production would exceed the rate of photosynthate use in starch and sucrose synthesis. Since phosphate limitation is determined by the photosynthetic rate, it may not occur at lower PPFD [150]. Therefore, photosynthesis at cooler temperatures early or late in the day is not likely to be phosphate limited, because low PPFD would reduce the photosynthetic rates below those capable of causing feedback inhibition [21]. Methodologies to elevate the CO_2 around plants under field conditions, including soil-plant-air research (SPAR) units, open-top chambers, and free-air CO_2-enrichment systems, have drawbacks [151,152]. So possible artifacts have to be taken into account when evaluating responses to elevated CO_2 [21].

The capacity of C_3 species to respond to CO_2 does differ, and it may be related to the species' ecological niche. For an approximate doubling of the CO_2 concentration, growth of C_3 species was stimulated on an average by 41%. Crops, which tend to be C-strategy species, increased more in dry weight than wild species (58 vs 35%) Fast-growing wild species were stimulated more than the slow-growing ones (54 and 23%, respectively). Webber et al. [153] suggested that the differences may be related to sink capacity [21]. Long-term exposure to a doubling in CO_2 concentration leads to a variety of acclimation effects that directly or indirectly influence the photosynthetic capacity of the plant. In addition to changes in photosynthetic biochemistry and stomatal physiology, acclimation has been observed in the leaf area, leaf area index, leaf area duration, leaf thickness, branching, tillering, stem and root dry weights, fruit size, timing of developmental events, and life cycle completion [29,31,38]. Consequently, even if photosynthesis per unit leaf area declines, changes in parameters such as leaf area or duration can result in greater biomass and yield [21, 29,38,154,155].

Downregulation is a common CO_2-enrichment response in the literature, although whether it would be so in nature is still an open question. No downregulation and even upregulation have been reported for C_3 species in these circumstances, including crop plants: cotton, soybean, and kidney bean. In some field situations, acclimation does seem to occur; there are reports of C_3 species that failed to maintain photosynthetic or growth enhancements under natural field conditions; notably the sedge, *Eriophorum vaginatum*, in an arctic tundra ecosystem, and *Poa pratensis* in a tall-grass prairie [156,157]. Low temperature and competition for light, water, and nutrients may have restricted the CO_2-enrichment response.

Is downregulation a stress response indicating physiological dysfunction in plants that over millennia have become adapted to low CO_2? or is it an optimization process in reaction to a change in resources? In some species or conditions, elevated CO_2 produced substantial carbohydrate accumulation within the leaves, which could be stressful. The leaf morphology can be deformed; massive starch granules can distort chloroplasts and possibly disrupt function by distorting the thylakoid membrances and imposing constraints on the diffusion of gases or metabolites [35,158,159]. However, in most instances, downregulation of CO_2 assimilation probably reflects a restricted capacity to handle the extra carbon because of either insufficiency in other environmental resources or inherent metabolic limitations. Photosynthetic acclimation is an optimization process rather than a stress response [21]. According to this concept, acclimation involves the reallocation of resources away from nonlimiting components such as carbon acquisition and into more limiting components such as light harvesting, electron transport, and carbohydrate handling, thereby minimizing single limitations [158–160]. The resource reallocation would predominantly involve N, because CO_2 enrichment increases the C/N ratio of plants [90,161].

Various biochemical components have been implicated in acclimation, with Rubisco having the leading role. Rubisco is modulated by growth at elevated CO_2, with reports of reduced activity

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

in a number of species [90,93,154,162–166]. A decrease in Rubisco activity may be manifested by a decline in the Rubisco protein content, a lowered activation state, an inhibition of the carbamylated enzyme, lower specific activity, or altered kinetics; but not all apply to CO_2 enrichment [158]. Decreases in the Rubisco protein content are observed in some cases as much as 60%; indicating that N is being reallocated [93,164–166]. However, Rubisco protein may still decline in the presence of adequate N supplies, and the reduction is not always sufficient to account for the lower N concentration [89,161,165]. Also, some species show no decline in Rubisco content [88,89,154,167]. Consequently, changes in the Rubisco content alone cannot always account for the acclimation phenomena that have been observed [21].

Perhaps the most often cited rationale for acclimation and the downregulation of Rubisco is that CO_2 enrichment causes an imbalance in the source-sink capacities; especially insufficient sink capacity for the excess carbohydrate production [35,168–171]. Studies on plants with large sinks and manipulations of the sink capacity have led to this conclusion, and there is much evidence to commend it. Accordingly, N would be reallocated to upgrade the sink capcity and/or reduce the source capacity to bring the two into confluence [21]. The mechanism by which the imbalance is sensed, at least in part, is likely to involve feedback effects via endproduct accumulation [35,170]. This was indicated by a number of sugar-feeding studies which resulted in reduced photosynthesis and the Rubisco activity and its content [21]. Similarly, the overexpression of acid invertase in transgenic plants, and the resultant hexose accumulation, decreased photosynthesis and the polymerase chain reaction (PCR) cycle enzyme activities [21,170,172].

How is the feedback exerted? In CO_2-enriched cotton and kidney bean, the presence of O_2-insensitive photosynthesis points to a Pi limitation of the RuBP regeneration capacity, because carbohydrate accumulation ties up Pi [21,167,173]. However, this cannot be the sole reason, as it does not explain changes in extractable enzyme activities and amounts. A molecular model invokes the metabolite regulation of gene expression [35,170]. Glucose provides a regulatory signal that represses the transcription of photosynthetic genes, including those encoding the small and large subunits of Rubisco, *rbc*S, and *rbc*L [21,170,174].

In addition, genes involved directly with carbohydrate metabolism can be positively or negatively regulated by sugars [170]. This could be a means to upregulate enzymes that process carbohydrate and thereby assist in balancing the sink capacity with the source [21]. This concept is consistent with the findings that, in CO_2-enriched rice with increased sucrose and starch, the activity of SPS is upregulated about 20%, whereas the Rubisco activity and its content are downregulated [165,175]. A similar situation occurs in the sink-limited regions of transgenic tobacco leaves which have invertase overexpressed in the cell walls; Rubisco and fructose bisphosphatase activities decline but SPS increases [172]. By way of contrast, CO_2 enrichment of kidney bean causes some reduction in the SPS activity [21,167]. More work is required to determine how CO_2 enrichment influences the enzymes and allocation of carbohydrates in plants that are predominantly starch or sucrose accumulators [21].

In C_3 species, elevated CO_2 not only reduces the amount of carbon entering the PCO cycle but concomitantly the flux of N through the associated photorespiratory N cycle [22]. Photorespiratory N flux is large, being up to 10-fold greater than N assimilation [161]. A high-CO_2–induced reduction in this flux should have a substantial impact on N metabolism, but it has received minimal attention. Leaf N concentration is generally lowered by CO_2 enrichment, as are the nitrate reductase activity and critical nitrate concentrations [176,177]. It has been suggested that nitrate may act as a metabolic signal for protein kinases to regulate the flow of carbon between sucrose and amino acids [178]. If so, a lowering of the leaf nitrate concentration by high CO_2 could divert carbon from amino acids to sucrose biosynthesis in a mechanism ancillary to the glucose repression of gene expression [22].

In regard to C_4 species, the presence of a CCM (carbon dioxide concentration mechanism) would lead one to anticipate little or no increase in photosynthesis or growth from a doubling of atmospheric CO_2. However, reported responses are often positive, although less than for C_3

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

plants. In the survey by porter [179], the average stimulation in dry weight for 19 C_4 species, both cultivated and wild, was 22% as compared with 41% for the C_3 species. What causes stimulatory effects of CO_2 on C_4 species? Several factors that indirectly impinge on Rubisco may be involved. First, elevated CO_2 reduces the stomatal conductance of C_4 as well as C_3 species. In the case of *Eragrostis orcuttiana*, this resulted in a 50% improvement in WUE [22,180]. In water-stressed environments, a CO_2-induced improvement in WUE could enhance growth. This has been proposed as a factor in the increased production by C_4 species in a tall-grass prairie ecosystem and for the improved photosynthesis of the C_4 salt-marsh community [33,157]. Second, a rise in the CO_2 concentration can enhance tillering and increase the leaf area and its duration [29, 38,180], so that total plant photosynthesis is greater even without an improvement in CO_2 assimilation per unit leaf area. There is concern as to how the different responses of C_3 and C_4 photosynthesis will affect competitive interactions in the ecosystems of a higher CO_2 world [31,36]. In several studies, the competitive abilities of C_3 species were enhanced relative to C_4 [21,181–183].

A higher atmospheric CO_2 concentration will not just influence C_3 and C_4 interactions; C_3 species do not all respond alike, so competition among plants within this category may also be modified. The competition studies indicate that the rise in CO_2 will alter the species composition of communities and species distribution. The exact changes cannot be predicted, although it appears that C_3 species are more likely to be favored than C_4 species [21].

The few CO_2-enrichment studies of CAM plants that have been undertaken have yielded mixed results. During the day, CAM plants close their stomates and raise CO_2 to more than 10,000 μmol mol^{-1} by the decarboxylation of malate that was accumulated the previous night via the activity of phosphoenol pyruvate carboxylase (PEPC). Thus, a doubling in the atmospheric CO_2 concentration should have little effect, and this seems true for pineapple [184]. However, if stomates open in late afternoon and fixation by Rubisco occurs, this provides an opportunity for CO_2 enrichment to stimulate photosynthesis. It may explain the 36% stimulation of dry weight reported for one CAM plant and a mean of 15% for six other species [113,179,184,185]. The possibility of greater nocturnal fixation via PEPC needs further examination, as does the photosynthesis of facultative CAM plants operating in the C_3 mode [21].

For marine and freshwater environments, approximately 50,000 submersed photosynthetic species are taxonomically far more diverse than the estimated 300,000 species of vascular plants which constitute the major photosynthetic organisms of terrestrial habitats [186]. The latter are believed to be derived in the past 450 million years from just one division and one class (Chlorophyta: Charophyceae). In contrast, submersed species include cyanobacteria, several algal divisions, bryophytes, lower vascular plants, and angiosperms, and some have histories that date back 2–3 billion years in environments with very variable CO_2 and O_2 concentrations. The diversity and long history gives them a greater potential for variability in carbon-acquisition mechanisms than terrestrial species [38,186]. This, together with the fact that little is known about many of the individual species, makes predictions about stress responses to rising CO_2 tenuous at best [21].

In waters where HCO_3^- predominates, species with a high capacity for HCO_3^- should be less affected by air enrichment than those using only free CO_2. This hypothesis was recently tested using the submersed freshwater angiosperms *Callitriche cophocarpa* and *Elodea canadensis*, a CO_2-only user and a HCO_3^- user, respectively. They were grown in water with 0.2 or 1.0 mM HCO_3^- and sparged with air containing 350 or 800 μmol CO_2 mol^{-1} [21]. The dry weight gain of *Callitriche* was doubled by the elevated CO_2 treatment, but that of *Elodea* was stimulated only about 20% irrespective of the HCO_3^- concentration in the water. Conversely, the higher HCO_3^- concentrations substantially increased the growth of *Elodea* but had only a minor effect on *Callitriche*. Elevated CO_2 caused little photosynthetic acclimation of either species. These data raise the possibility that, for waters low in free CO_2, the species composition may change as atmospheric CO_2 rises, with CO_2 users alone being favored [21].

TRANSPORT OF ASSIMILATES

Partitioning of Dry Matter

Effects of an elevated CO_2 concentration and a nonstructural carbohydrate status on partitioning are poorly understood from a mechanistic perspective. Evidence exists suggesting that elevated CO_2 levels, that is, greater photosynthesis and elevated nonstructural carbohydrate levels, can result in a relatively greater partitioning of carbon to roots versus shoots [39,187]. Increased root growth under elevated CO_2 conditions might permit water extraction from a greater soil volume, which could be important in a future warmer and drier environment [42].

Low temperature results in enhanced storage of nonstructural carbohydrates at the apparent expense of growth. Warming also tends to result in relatively greater partitioning of carbon to shoots compared with roots [169], and this process can enhance photosynthesis by providing increased leaf area and promoting interception of photosynthetically active radiation. Farrar and Williams [169] point out that an increasing CO_2 concentration and an increasing temperature may have opposite effects on partitioning. Warm plants have lower levels of nonstructural carbohydrates and lower ratios of root to shoot than cool plants [42]. Plants in high-CO_2–level environments have large nonstructural carbohydrate stores and increased ratios of root to shoot. The combined effects of warming and an increased CO_2 level on partitioning are less clear. Warming can increase the specific respiration rate, whereas an elevated CO_2 level can slow it. Increased photosynthesis resulting from an elevated CO_2 level in combination with the increased sink metabolism (growth) allowed by warming has the potential to produce larger plants and increase carbon storage in terrestrial ecosystems as the CO_2 concentration and temperature increase [42].

Nutrient Assimilates and Partitioning

Ferrario-Mery et al. [188] speculated on the effects of elevated CO_2 on the composition of plant materials used for human nutrition or animal feed. Their results confirmed that N deprivation of plants grown at high CO_2 can be overcome by optimization of the fertilization regimen and allowing unrestricted growth. Their results support the concepts of gene manipulation to improve the nitrogen assimilation capacity and achieve an improved nutritional quality for sustainable agricultural production in a changing global environment.

PHOTORESPIRATION

With carbon dioxide saturation, insensitivity to oxygen concentration also occurs. A new hypothesis also explains the decrease in the photosynthetic rate at high carbon dioxide concentrations, which is sometimes observed, by decreased photorespiration causing a further decrease in the chloroplast phosphate concentration [15,189]. Oxygen in the choloroplasts can interfere with the photosynthetic reduction of CO_2. As the CO_2 concentration increases, CO_2 would more likely than oxygen bind to the active site of RuBPC, because more CO_2 molecules would be present there. Indeed, in some experiments, photorespiration was reduced by 50% when the CO_2 concentrations increased to 600 $cm^3\ m^{-3}$. Limiting photorespiration means that plants can use more of their energy to build tissues [190].

DARK RESPIRATION

Bunce [191] and Amthor [32] reported that the dark respiration rate is sensitive to the instantaneous concentration of CO_2 and decreases as CO_2 increases (Fig. 5). Growth of plants under conditions of elevated CO_2 often results in a decrease in the respiration rate [89,192,193]. Gifford et al. [194] observed a 45% reduction of the specific respiration rate in roots of CO_2-enriched wheat (*Triticum*

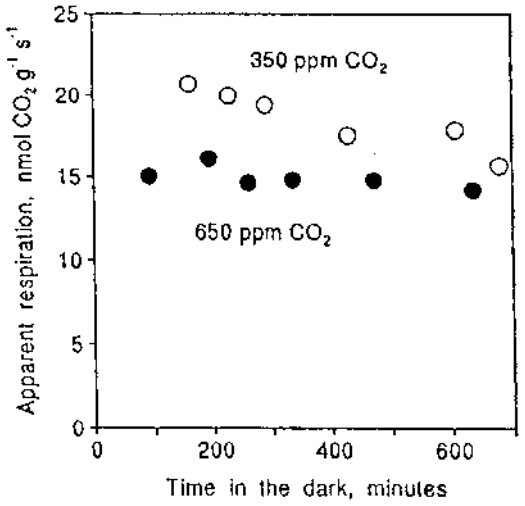

FIGURE 5 Effects of ambient CO_2 levels on apparent respiration rate in leaves of *Rumex crispus.* (From Ref. 192.)

aestivum L.). Long-term effects of CO_2 on respiration are mediated through effects on plant composition, and in particular by an increase in the C/N ratio as CO_2 concentration increases [193,195,196]. Concomitant measures of the growth rate, tissue composition, and respiration rate are required in order to unravel the links between long-term elevated CO_2 levels and respiration and growth [42]. A direct inhibition of respiratory metabolism by CO_2 has the potential to increase susceptibility to various stresses, because it is respiration that supplies much of the energy, reductant, and carbon skeletons used in repair and detoxification processes. The slowing of specific respiration rates with long-term CO_2 enrichment may be greatest at low compared with high temperatures [42,196]. There is a need for measurements of growth and respiratory responses by plants and ecosystems to long-term changes in temperature. Although information is scanty and variable, the effects of increases in global temperature on plant and ecosystem respiration are likely to contribute to positive feedback on increasing atmospheric CO_2 levels [42].

MODIFICATION OF CO_2-ENRICHMENT RESPONSES BY ENVIRONMENTAL CONSTRAINTS

The fact that CO_2 is a greenhouse gas makes higher global temperatures an important consideration in the rising CO_2 debate. Temperature and CO_2 have interactive effects, because a rise in temperature lowers the ratio of CO_2/O_2 in solution, shifts the specificity of Rubisco toward oxygenase, enhances photorespiration and dark respiration, and increases the sink response relative to the source [21]. These photosynthetic gains may or may not be realized in long-term growth and yield owing to an interplay of factors that complicate the issue. For example, leaves compensate for increased air temperatures by greater transpiration, whereas CO_2 enrichment tends to raise foliar temperatues by reducing transpiration [29,197]. Temperature and CO_2 can have greater interactive effects on the net leaf area production than photosynthesis per se [198]. Furthermore, species in the C_3 category differ markedly in the temperature regimens to which they are adapted, and also in their tolerance of the low and high extremes where temperature becomes stressful. Even with a single plant, temperature regimens that enhance CO_2-stimulated vegetative growth can negatively impact reproductive

growth. Thus, the grain yield of CO_2-enriched rice showed about a 10% decline for each 1°C rise above 26°C, and similar scenarios have been reported for soybean and wheat [199], as already discussed. This is because growth and reproduction reflect the integrated temperature response of metabolism and developmental processes and not just photosynthesis alone. As a consequence, species, developmental stage, light regimen, nutrient status, and the temperature range all modify the interactive temperature and CO_2 responses [21,66].

In nature, photosynthesis occurs in both high- and low-light environments; in the latter situation, the processes involved in RuBP regeneration are a greater limitation than the CO_2 supply or Rubisco capacity. Several growth studies demonstrate that CO_2 enrichment enhances light-limited C_3 photosynthesis [80,88,198,200,201], because it reduces O_2 inhibition. A rise in the CO_2 concentration results in a higher quantum yield [21]. Thus, assimilation versus irradiance (A/I) response curves for leaves of soybeans grown and measured at 660 μmol CO_2 mol^{-1} not only showed greater light-saturated rates but also had steeper initial slopes, that is, higher apparent quantum yields, and lower light compensation points than those grown at 330 μmol mol^{-1} [80]. Thus, CO_2 enrichment does not seem to downregulate the photosynthetic electron transport capacity, and limiting light conditions do not eliminate positive enrichment responses [21].

The upward trend in atmospheric CO_2 probably has already enhanced the photosynthesis, WUE, and growth of many of the earth's plants, especially C_3 species, and potentially will continue to do so. However, not all species have the capacity to respond, and those that do can be constrained by environmental parameters. Consequently, debate centers around the degree to which this greater photosynthetic potential will be realized during long-term growth of natural and agroecosystems whether these systems can continue to sequester carbon and how adaptation, competitive interactions, and survival will be influenced [21,29,31,36]. Much of the current data pertain to agricultural systems, and there can be little doubt that most crops will perform better in a higher-CO_2 world and may even require fewer subsidies. Less favorable C/N ratios may diminish crop quality, and higher temperatures may reduce grain yields, but breeding or molecular manipulation should correct these problems. Major changes in precipitation patterns would seem to have the most potential to disrupt current agricultural systems [21]. The situation is less clear with regard to ''natural'' ecosystems. Examples can be cited that both do and do not respond to enrichment; where nutrient availability and/or temperatures are low, responses will probably be constrained. However, many terrestrial and some aquatic ecosystems are likely to encounter marked shifts in species composition and distribution. But just as increases in atmospheric CO_2 are not novel, so continual changes in vegetation patterns are a fact of life on this planet irrespective of whether humans regard them as being beneficial [21].

Interactions Between CO_2 and Air Pollutants

Increased atmospheric CO_2 levels have the potential to mitigate some air pollution injury by virtue of increased photosynthesis (hence increased supply of photoassimilate to be used in various repair and detoxification processes) as well as reduced stomatal conductance (hence slower uptake of the pollutants) [11,68].

CONCLUSIONS

Increased photosynthetic rates are a widely observed response of plants to elevated atmospheric CO_2 [24,202,203]. The photosynthetic enhancement that occurred at elevated CO_2 partial pressures either persisted indefinitely [204] or was partly to fully reversed after weeks of CO_2 enrichment [119,205]. Changes of photosynthetic rates after prolonged exposure to elevated CO_2 were either positive or negative and were variable both among and within species [15,93,183]. The biochemical basis for photosynthetic acclimation to elevated CO_2 is unknown, although a source/sink imbalance

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

[35,158] and carbohydrate accumulation and negative feedback mechanisms have been proposed [202,206,207]. As photosynthesis was far from being saturated at the current ambient CO_2 concentration, considerable further gains in photosynthesis are predicted through continuing increases in CO_2 concentration. The strong interaction with temperature also leads to photosynthesis in different global regions experiencing very different sensitivities to increasing CO_2 concentrations [16].

When growth is limited by water availability, plant growth should be relatively more responsive to CO_2 concentration than under well-watered conditions [208,209]. Under water-limited conditions, growth is essentially determined by the rate of diffusion of CO_2 into the leaf, which in turn is limited by the availability of water for diffusion out of the leaf [16]. On the other hand, growth is dependent not only on carbon gain but also on the availability of nutrients to turn the initial carbon gain into the growth of fully functional plant parts. The availability of nutrients may therefore introduce additional limitations which may reduce growth responses [16,83,210]. This appears to be part of the reason why no sustained growth response was observed in CO_2-enrichment experiments in the tundra [16,112,156].

The C_4 species respond much less than C_3 species. In the case of the long-term photosynthetic response to increased CO_2, there is as yet no firm explanation of what determines whether a species will have either positive or negative photosynthetic adjustment in a given environment. The phosphate-limitation hypothesis of feedback inhibition of photosynthesis helps explain variation in the short-term response to carbon dioxide concentration [15]. Plants with substantial sink capacity, such as crop and competitive-strategy species, have the greatest response to CO_2 enrichment, with an average of 30–40% stimulation of biomass, whereas those with small sinks have the least. Among submersed species, photosynthesis and growth of CO_2 users is only enhanced, but HCO_3^- users show a minimal response. Enrichment can stimulate photosynthesis and growth when water, nutrients, or light are suboptimal and temperatures are high, although extreme conditions can abolish the benefits. The photosynthetic CO_2 stress response is not always the major factor influencing competitive interactions among species, but directly or indirectly rising CO_2 concentration will alter the species distribution and composition of ecosystems [21].

Crop plants have been exposed to large increases in atmospheric CO_2 concentration over the last 200 years from about 270 to 280 μmol mol^{-1} to more than 355 μmol mol^{-1} today. Recent research has led to the following general conclusions concerning crop response to a doubling of atmospheric CO_2 [41]:

1. Production from C_3 crop plants is likely to increase by 30% or more. Production increases from C_4 plants will be less than 10%.
2. Although stomatal conductance may be decreased by about 40%, water use of C_3 plants will be decreased only about 10% or less.
3. Water-use efficiency will increase substantially owing to increases in CER with minor contributions from decreases in TR.
4. The interaction of high temperatures (at least up to a point) with elevated CO_2 should improve photosynthesis and vegetative growth but not necessarily reproductive growth.
5. Decreases in rainfall or disruptions of rainfall patterns, as predicted by some GCMs, would have a greater impact on crop production than would an increase in temperature.
6. How is the photosynthetic rate regulated by CO_2. What are the mechanisms? Why do some plants appear to downregulate, whereas others appear to upregulate it? How should this phenomenon be upscaled to whole canopies throughout the crop life cycle?
7. Elevated CO_2 reduces plant respiration. What are the mechanisms? What are the long-term consequences; that is, does reduced respiration enhance or inhibit plant responses to CO_2? Is there an impact of high nighttime CO_2 exposure level on crop performance?
8. How do plant canopies modify their microenvironments under changing CO_2 levels and climates and how do the modifications affect water use and the physiological response to CO_2 and climate?

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

9. How can we assess the potential for genetic adaptability of crop materials to new ranges of climatic conditions? What are the ranges of crop adaptation that already exist among the present-day climates over the surface of the earth?
10. How can information from the above sets of questions be incorporated into crop models?
11. How can crop physiologists best participate with other disciplines to assess consequences, mitigations, and adaptive responses to rising CO_2?

Increasing atmospheric CO_2 and potential climate change challenge our understanding of the physiology and determination of crop yield. However, the range of climates where agriculture can flourish in the future lies mainly within the range of climates that exist today. Increasing our understanding of processess governing yield will be best served by developing a consciousness and expertise in global environmental plant physiology and crop ecology [41].

In general, the relative enhancement of photosynthesis and plant productivity owing to elevated CO_2 is greatest under stressful conditions, whereas the absolute enhancement is greatest under favorable conditions (i.e., for plants well supplied with water and nutrients at temperatures favorable for growth) [42]. The effects of plant physiological responses to rising atmospheric CO_2 concentration and temperature are summarized in Table 2 [42].

Effect of Increased Atmospheric CO_2 Concentration on Water-Use Efficiency of Plants

JANA POSPÍŠILOVÁ AND JIŘÍ ČATSKÝ
Institute of Experimental Botany
Academy of Sciences of the Czech Republic
Prague, Czech Republic

GLOBAL CLIMATE CHANGE

Carbon is a principal element for life, as it comprises a major part of the dry mass in living organisms. Carbon is required by green plants, taking up CO_2 from the surrounding air. The average atmospheric CO_2 concentration is around 350 μmol mol^{-1} and has increased by about 70 μmol mol^{-1} in the last 200 years, but it is still not saturating for C_3 photosynthesis. In the future, owing to antropogenic processes (mainly fossil fuel combustion and forest destruction), the CO_2 concentration is expected to continue to rising (the recent rate of the increasing CO_2 concentration is about 1.8 μmol mol^{-1} $year^{-1}$ [1]). Other trace gases, such as methane, oxides of nitrogen, and the synthetic chlorofluorocarbons, also have been increasing in concentration. Together, these gases may have the effect of raising the earth's temperature and increasing aridity in some parts of planet. However, much uncertainty remains about the exact magnitude of the change in the climate.

The global climatic change will have important implications for plant photosynthesis. The rate of photosynthesis depends on over 50 individual reactions, each of which potentially has a unique response to an environmental variable. The ability of plants to compensate for environmental effects on photosynthesis is critical for their performance and survival. Moreover, an ineffective response of the photosynthetic apparatus depresses yield, resulting in substantial economic cost [2].

The upward trend in the atmospheric CO_2 concentration probably has already enhanced the photosynthesis and growth of many plants, especially C_3 species, and potentially will continue to do so. CO_2 enrichment is a powerful tool to enhance the production in greenhouses. However, one of the central issues is whether long-term exposure of plants to an elevated CO_2 concentration results in a downregulation of photosynthesis; that is, that the photosynthetic rate at elevated CO_2 is lower than it would be expected based on short-term assessment of photosynthetic rates as a function of CO_2 concentration. In addition, an increased rate of photosynthesis and growth at elevated CO_2

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

seems to be only maintained if the acquisition of other resources—soil nutrients and water—is sufficient as it is usually in agrosystems but not in natural ecosystems. Plant species differ in their responses to CO_2 and these differences can be very large, even among co-occurring species of a community. A CO_2-stimulated increase in plant growth could be of benefit if the stimulated species are economically valuable, but it could be a serious problem if the stimulated species are weeds [3]. If plants are growing more rapidly, a greater amount of organic matter could be stored in vegetation and soils, moderating the increase in atmospheric CO_2 and in the potential for global warming [4–7]. If temperature increases as predicted, plants will be helped or harmed depending on whether they are presently growing at temperatures below or above their optimum [8]. Further details can be found in several books and reviews (e.g., see Refs. 9–13).

The literature on plant responses to elevated CO_2 contains thousands of reports. The growth, photosynthetic rate, stomatal density and conductance, transpiration rate, water-use efficiency, for example, were found to be affected by an enhanced CO_2 concentration.

Many of the ecosystems are highly sensitive to changes in the water supply, because water is a key variable driving their composition and productivity. The growing human population has brought about a continuous effort to increase agricultural production and thus water use. As most of water used in irrigation is lost by transpiration, extensive research is being done on how to increase the efficiency of water use. This practical problem has stimulated the investigation of many theoretical questions; for example, the interrelationships between the stomatal conductance (g_s) and the transpiration rate (E) or photosynthetic rate (P_N), the physical and biochemical basis of the functioning of guard cells, and the effect of changes in metabolic processes in leaves on stomatal opening. In spite of great progress reached in this field, many questions still remain unanswered. Plant traits that increase water-use efficiency (WUE) may conflict with those that promote the growth rate. Plants or cultivars with a high WUE might be most suitable for use in drought conditions, whereas those with a low WUE for use in irrigated conditions [14].

WUE usually means the ratio of P_N to E, but sometimes it also means biomass production per amount of water used. The P_N/E ratio is affected by all environmental factors to which the response of P_N and E is not the same. In addition, every change in g_s brings about the change in the P_N/E ratio, as the effect of g_s on E is usually more marked than that on P_N owing to differences in the transport pathway of water vapor and CO_2. Thus, the P_N/E ratio is usually higher at a lower g_s than at a higher one. Therefore, an increased ambient CO_2 concentration is an ideal antitranspirant, as it positively influences P_N owing to an increased gradient for CO_2 transfer and simultaneously decreases g_s and thus E (for reviews, e.g., see Refs. 15–17). WUE more than doubles after short-term doubling of CO_2 [18].

The chapter focuses on the recent advances made in elucidating the long-term effects of an elevated CO_2 concentration on WUE and on development of water stress. In connection with this, a brief survey of the long-term effects of elevated CO_2 concentration on the stomatal density and conductance, transpiration rate, and net photosynthetic rate is presented. We have selected important up-to-date references from a voluminous body of literature to make the chapter comprehensive and current. As drought is one of the most limiting environmental constraints and global climatic changes may increase the frequency of drought in some areas, the possibility of increasing efficiency of water use ranks uppermost in the hierarchy of advantages brought about by an elevated CO_2 concentration.

STOMATAL DENSITY AND CONDUCTANCE AS AFFECTED BY ELEVATED CO_2 CONCENTRATION

Stomatal conductance (g_s) usually decreases when the ambient CO_2 concentration increases; the stomata closing effect of CO_2 is smaller at high than at low irradiance, and it is affected by air humidity, temperature, water stress, and plant hormones. Stomata from growth chamber-grown plants may have enhanced sensitivity to CO_2 in comparison with greenhouse-grown plants (e.g., in

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

Vicia faba; see Ref. 19). The magnitude of stomatal response varies greatly among species; nevertheless, g_s often changes in such a way that the ratio of ambient and internal CO_2 concentration remains more or less constant. The mechanism of action of CO_2 on guard cells remains uncertain. It might be linked to malate synthesis, which regulates anion channels in the guard cell plasma membrane [20]. However, Esser et al. [21] report that malate does not function as a primary CO_2 signal in stomatal regulation. Probably also the change in cytosolic calcium ion concentration is a component of the CO_2 signal transduction pathway (e.g., see Ref. 22).

Long-term increased atmospheric CO_2 concentration often, but not always, leads to a large decrease in g_s, which is especially important in water-limited areas (for reviews see, e.g., Refs. 23–26). A common response to a doubling of CO_2 is a 30–60% reduction in g_s in C_3 and C_4 species, although there are cases of insensitive stomata [23,24]. Besides contraction of stomatal pores, leaf stomatal density may decline. However, a larger reduction in g_s than in stomatal frequency indicates that stomatal closure predominates [10,27]. Exposure to elevated CO_2 concentration often results in a short-term, reversible decline in g_s as a result of decreased stomatal aperture and a long-term, irreversible decline in g_s as a result of a decreased stomatal density [28]. According to Donoso et al. [29], the effects of elevated CO_2 on stomatal characteristics are very species specific (comparison of *Alternanthera, Ipomoea, Jatropha*, and *Talinum*).

In *Olea europea*, a decrease in stomatal density from the year 1327 BC was observed [30]. Also in *Acer pseudoplatanus, Carpinus betulus, Fagus sylvatica, Populus nigra, Quercus petraea, Q. robur, Rhamnus catharcticus*, and *Tilia cordata*, the stomatal density has decreased in the past 200 years [31]. Woodward and Kelly [32] followed the effect of an elevated CO_2 concentration on stomatal density in 100 species grown in nature. They found a reduction of stomatal density in 74% of tested species. These investigators did not find any significant dependence on growth form (trees vs shrubs or herbs) or stomatal distribution on the leaf (amphistomatous vs hypostomatous). However, in species grown in air-conditioned chambers, they observed the reduction of g_s in 60% of species, lower average reduction, and greater changes in g_s in amphistomatous than in hypostomatous leaves. A significant reduction in stomatal density was found in expanding *Populus* leaves but not in middle and lower leaves [33] (Fig. 1). Plants of *Nardus stricta* from higher altitude showed a greater decline in stomatal density with elevated CO_2 concentration than plants from lower altitude [34]. No differences in stomatal density due to elevated CO_2 concentration were found in *Citrus aurantium* [35], *Phaseolus vulgaris* [36], *Rumex obtusifolius* [37], *Trifolium repens* [38], and *Triticum aestivum* [35,39]. In *Lotus corniculatus* and *Sanguisorba minor*, stomatal density increased at both leaf surfaces, whereas in *Plantago media* and *Anthyllis vulneraria*, it decreased [40]. In *Andropogon gerardii*, reduction of stomatal density was found especially on the abaxial side [41]. In *Vicia faba*, stomatal density increased but significantly only on the adaxial surface [42]. In *Tradescantia fluminensis* plants grown at an elevated CO_2 concentration, the stomatal density did not differ, but the number of subsidiary cells in stomatal complexes was increased and substomatal cavities were enlarged [43].

Very slight or no changes in stomatal density and size in *Avena sativa, Prosopis glandulosa, Schizachyrium scoparium*, and *Triticum aestivum* were found at subambient CO_2 [44].

As was mentioned above, long-term CO_2 enrichment (usually to double the present ambient concentration) decreased stomatal conductance in both C_3 and C_4 species; for example, in *Abies fraseri* [45], *Andropogon gerardii* [46], *Atriplex canescens* [47], *Bellis perennis* [48], *Brassica oleracea* [49], *Capsicum annuum* [50], *Cucumis sativus* [51], *Fagus sylvatica* [52], *Glycine max* [53], *Gossypium hirsutum* [54], *Liquidambar styraciflua* [55], *Lycopersicon esculentum* [51], *Maranthes corymbosa* [56], *Panicum antidotale* and *P. laxum* [57], *Phaseolus vulgaris* [58], *Picea abies* [59], *Picea sitchensis* [60], *Pinus sylvestris* [61,62, Fig. 2], *Platanus occidentalis* [55], *Prosopis glandulosa* [63], *Prunus avium* [64], *Quercus petraea* [65], *Q. pubescens* [66], *Q. robur* [67], *Q. suber* [68], *Schizachyrium scoparium* [47], *Solanum melongena* [69], *Trifolium repens* [70], and *Triticum aestivum* [39,71]. For 41 observations covering 28 species, the average reduction of g_s was 20% [20].

No changes in g_s were found in *Acer saccharum* [55], *Fagus sylvatica* [67], *Pinus taeda*

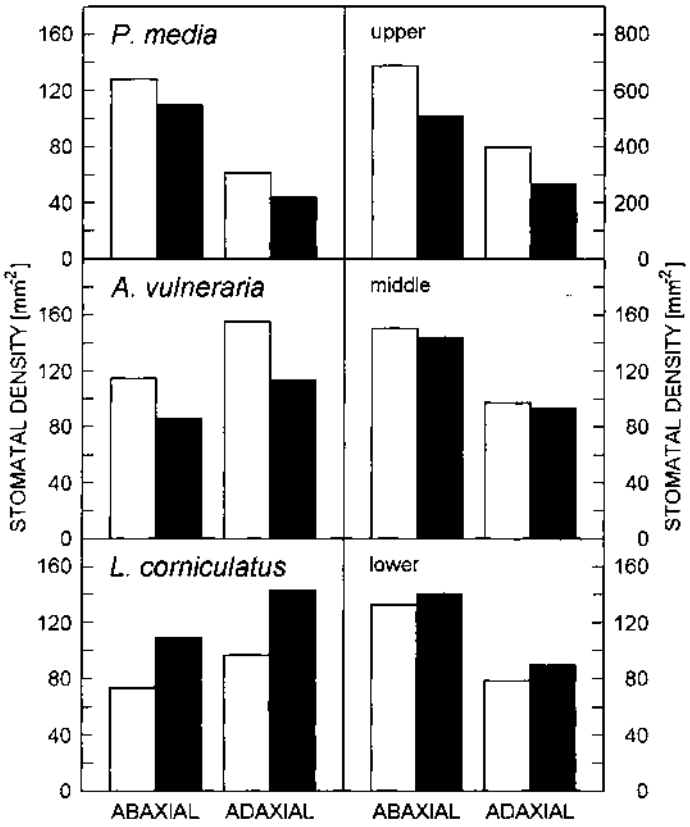

FIGURE 1 Effect of elevated CO_2 concentration (full columns) on stomatal density on abaxial and adaxial epidermes. Comparison of different plant species (*Plantago media, Anthyllis vulneraria* and *Lotus corniculatus*) (on the left) and comparison of poplar (*Populus deltoides* × *P. nigra*) leaves of different insertion (upper, middle and lower) (*on the right*). (Adapted from Refs. 33 and 40 by J. Solárová.)

[72,73,74], and in *Pinus pinaster* [65]. Higher g_s under CO_2 enrichment was observed in *Alnus rubra* [75] and *Quercus robur* [64]. Increased g_s was also found in *Solanum tuberosum* at very high CO_2 concentrations (3 or 14 times higher than ambient [76]). In *Glycine max*, the response of g_s was dependent on CO_2 concentration; g_s decreased, did not change, or increased at CO_2 concentration elevated to 3, 6, and 14 times of ambient, respectively [77]. Stomatal opening in *Lycopersicon esculentum* was enhanced by 4-week enrichment, and the enhancement decreased with time [78].

However, when plants are transferred from an enriched to a normal CO_2 concentration, the g_s recovers over a period of several days to the value typical for plants grown under normal CO_2 concentration [79].

The effect of long-term CO_2 enrichment also is dependent on CO_2 concentration during measurements; for example, in *Trifolium repens*, g_s under saturating irradiance was found to be the highest when plants were grown and measured at ambient CO_2 concentration, and the lowest g_s was in plants grown and measured at elevated CO_2 concentration [60] (see Fig. 3).

In *Rumex obtusifolius*, an elevated CO_2 caused a much greater reduction in g_s for the adaxial surface than for the abaxial surface [37]. As concerns the interactive effects of other environmental factors, the decline in g_s (e.g., in *Glycine max*) was a function of both the leaf temperature and the

leaf to air vapor pressure difference; a relative stomatal sensitivity to air humidity was decreased with an increase in CO_2 concentration and leaf temperature [80]. In *Pinus sylvestris*, long-term elevated CO_2 concentration decreased g_s at almost all levels of irradiance, temperature, vapor pressure deficit, and internal CO_2 concentration [61] (Fig. 2).

During June, when water availability was high, elevated CO_2 resulted in decreased g_s in 10 of 12 species measured. The greatest decrease in g_s (about 50%) occurred in species with the highest potential growth rates. During a dry period in September, the reduction in g_s was found in only two species, whereas increased g_s at elevated CO_2 levels was measured in *Amorpha canescens, Baptisia australis*, and *Symphoricarpus orbiculatus*. These increases were attributed to the enhanced leaf water potential [81]. In *Platanus occidentalis*, reduced g_s was observed only in well-watered trees [82]. In *Triticum aestivum*, CO_2 enrichment caused a higher reduction in g_s under sufficient irrigation than under a low one [83]. In *Acer rubrum*, a reduction of g_s occurred under sufficient water supply but not under water stress [84]. Similarly, in *Mangifera indica*, CO_2 enrichment caused a higher reduction of g_s in the wet than the dry season, and in this way it moderated seasonal changes in g_s [85].

Stomatal conductance in *Andropogon gerardii* reached new steady-state levels more rapidly after abrupt changes in irradiance at elevated CO_2. This was due to the reduction in g_s at elevated CO_2 and also by a more rapid stomatal response [46]. Stomatal sensitivity to internal CO_2 concentration (c_i) was decreased in *Chenopodium album* grown in elevated CO_2 [18]. In *Maranthes corymbosa*, but not in *Eucalyptus tetrodonta*, g_s was more sensitive to the leaf water status (but not to

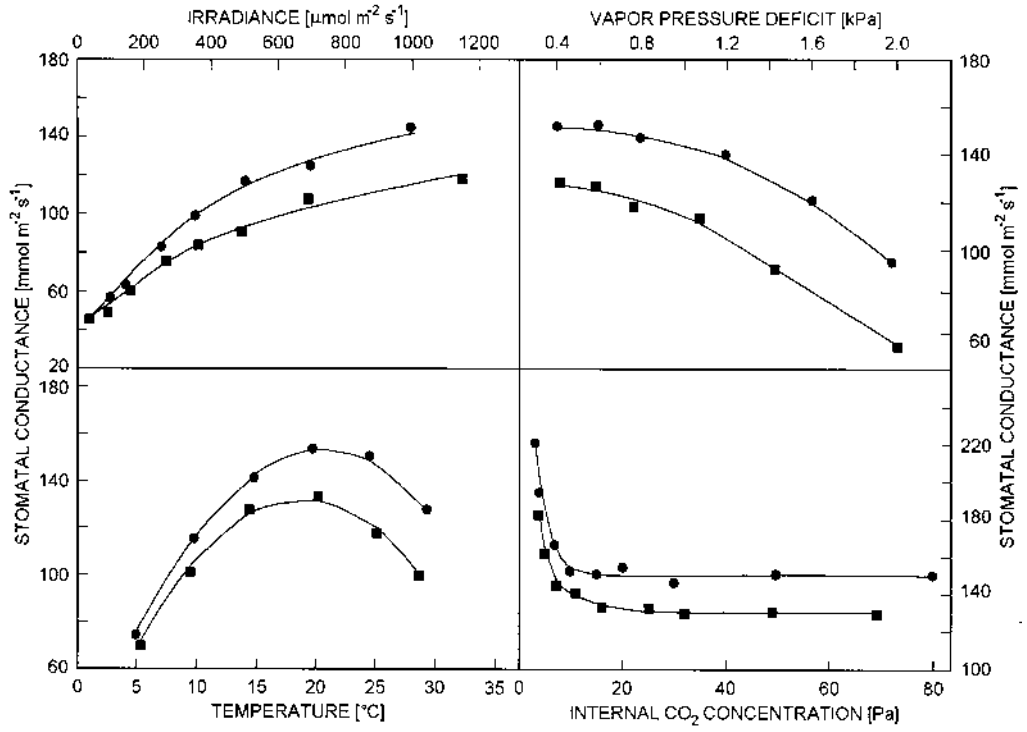

FIGURE 2 Stomatal conductance of *Pinus sylvestris* needles as a function of irradiance, temperature, vapor pressure deficit, and internal CO_2 concentration. Comparison of trees grown under ambient (circles) and elevated (squares) CO_2 concentration for 5 months. (Adapted from Ref. 61 by J. Solárová.)

the addition of abscisic acid) under CO_2 enrichment [28]. The stomata of elevated CO_2-grown *Quercus suber* seedlings were less responsive to high temperature [67]. The response of g_s in *Acer pseudoplatanus* to air humidity was not affected by the CO_2 concentration [31], but in *Pinus sylvestris*, sensitivity of g_s to low air humidity was increased in trees grown at elevated CO_2 concentration [62].

LONG-TERM EFFECTS OF CO_2 CONCENTRATION ON TRANSPIRATION RATE

The transpiration rate (E) depends on the supply of energy and vapor pressure gradient between the evaporating surfaces and the ambient air. E is modified by plant factors such as leaf structure and stomatal behavior. CO_2 concentration mainly affects E through changes in g_s. As g_s often decreased in consequence of CO_2 enrichment, a simultaneous decrease in E was observed (Fig. 3) (for reviews, see, e.g., Refs. 26, 86, and 87).

Under long-term CO_2 enrichment, decreased E per unit leaf area was found in both C_3 and C_4 species; for example, in *Andropogon gerardii* [88], *Begonia* × *hiemalis* [89], *Betula pendula* [90], *Capsicum annuum* [50], *Cucumis sativus* [51], *Dactylis glomerata* [91], *Fagus sylvatica* [52], *Festuca rupicola* [91], *Glycine max* [53,92–94] (Fig. 4), *Gossypium hirsutum* [54], *Lycopersicon esculentum* [51], *Prosopis glandulosa* [63], *Prunus avium* [64], *Quercus robur* [95], *Rosa hybrida*

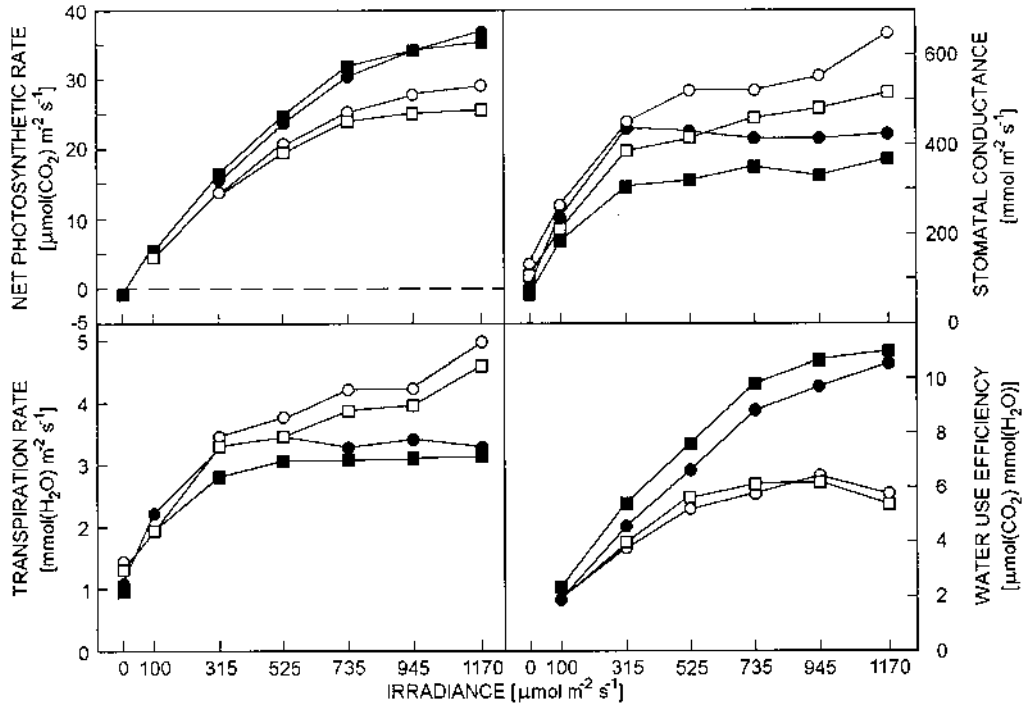

FIGURE 3 Net photosynthetic rate, transpiration rate, stomatal conductance, and water use efficiency of young, fully expanded leaves of *Trifolium repens* as a function of irradiance. Plants were grown at ambient (circles) and elevated (squares) CO_2 concentration and measured at ambient (empty symbols) or elevated (closed symbols) CO_2 concentration. (Adapted from Ref. 69 by J. Solárová.)

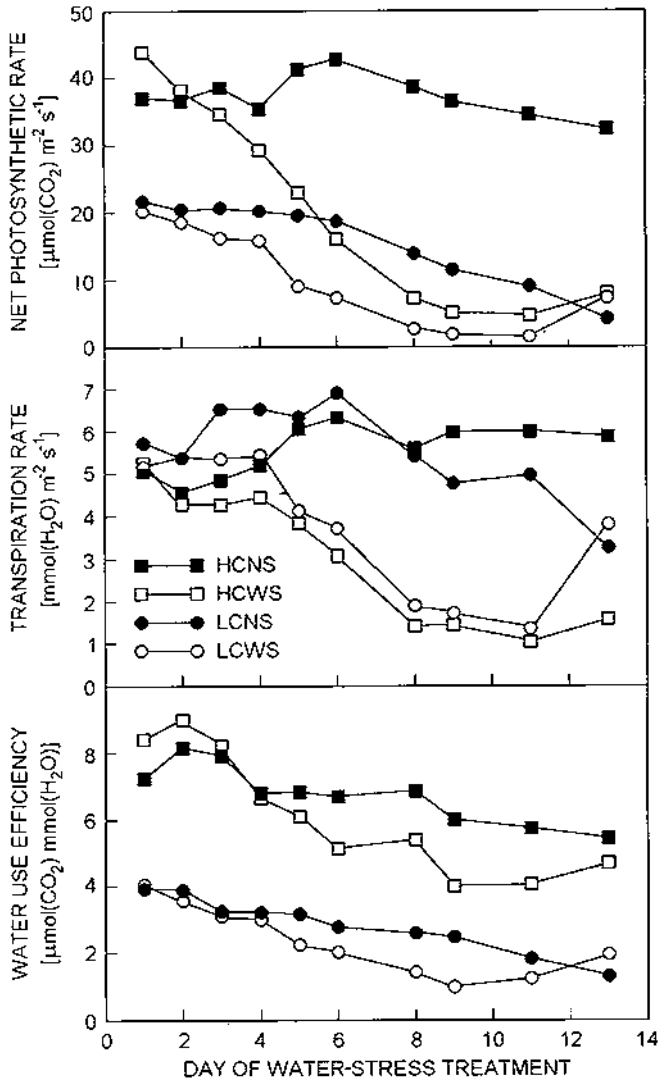

Figure 4. Net photosynthetic rate, transpiration rate, and water use efficiency of leaflets of *Glycine max* plants grown under ambient (LC, circles) or elevated (HC, *squares*) CO_2 concentration. Plants were measured during development of water stress (WS, *empty symbols*) or under sufficient water supply (NS, closed symbols). (Adapted from Ref. 93 by J. Solárová.)

[96], *Rumex obtusifolius* [37], *Solanum melongena* [68], *Sorghastrum nutans* [88], *Sorghum bicolor* [94], *Triticum aestivum* [70,97,98], and *Vernonia baldwini* [88].

On the contrary, in other plant species or as reported by other investigators on the same plant species, no significant differences in E were found; for example, in *Fagus sylvatica* [99] (Fig. 5), *Filipendula vulgaris* [91], *Gossypium hirsutum* [100,101], *Salvia nemorosa* [91], and *Zea mays* [97]. In *Quercus robur*, a slight increase in E was observed [64].

Reduced transpiration was accompanied by reduced sap flow in *Andropogon gerardii, Quercus ilex, Q. pubescens, Q. robur, Sorghastrum nutans*, and *Vernonia baldwini* [67,66,88]. Small

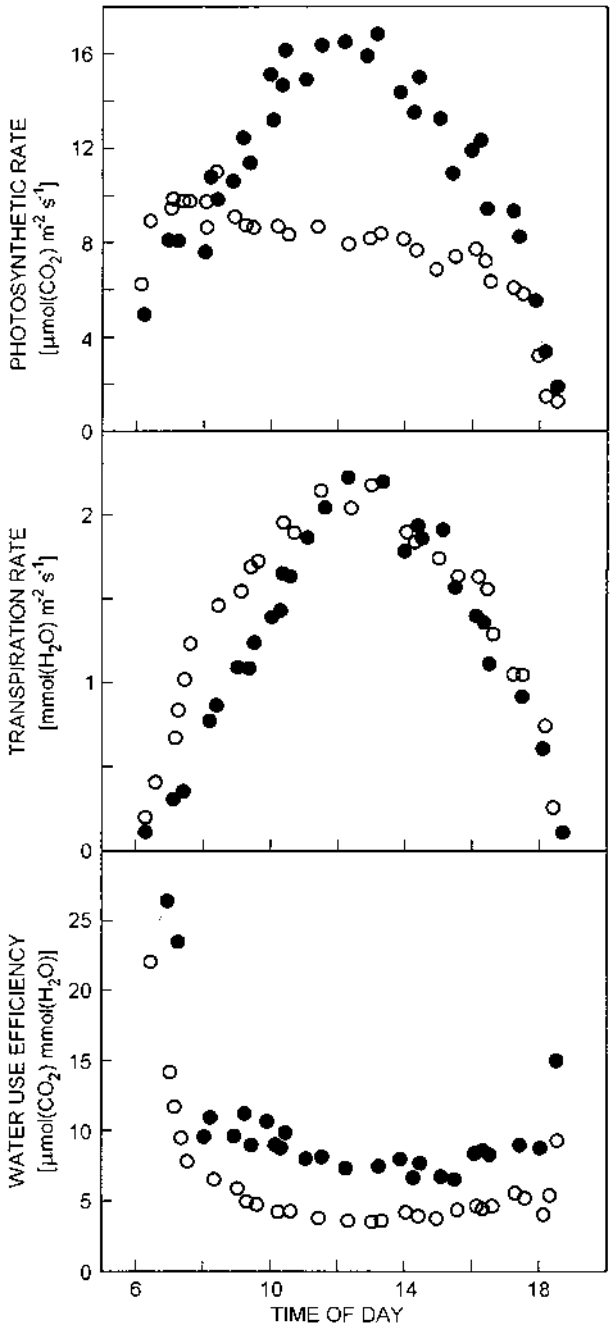

FIGURE 5 Daily course of net photosynthetic rate, transpiration rate and water use efficiency of *Fagus sylvatica* branches grown under ambient (open circles) and elevated (closed circles) CO_2 concentration. (Adapted from Ref. 99 by J. Solárová.)

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

differences in sap flow were found in *Triticum aestivum* [102] and *Fagus sylvatica* [67] and no effect in *Gossypium hirsutum* [101].

At the ecosystem scale, the magnitude of the response of evapotranspiration to CO_2 enrichment is lower in comparison with transpiration at the leaf scale. This difference arises from the effect of decreased g_s on leaf temperature and air humidity in the boundary layer which might increase the driving gradient of water vapor concentration and so the evapotranspiration rate [16,17,26,103–105].

The reduced g_s also can improve the leaf water potential, which can accelerate leaf expansion. Therefore, E per plant may or may not decline because of an increased leaf area. Decreased g_s and no differences in E due to larger leaf area were found, for example, in *Glycine max* [106,107]. Similarly, owing to the leaf area increase, a small effect of elevated CO_2 on evapotranspiration in a grassland ecosystem [26] and a *Lolium perenne* stand [108] was found. Canopy conductances were lower by as much as 20% in *Medicago sativa* and by 60% in *Dactylis glomerata*; however, the evapotranspiration rate never differed by more than 3% in *M. sativa* or by 8% in *D. glomerata* [109].

A reduced E is favorable under insufficient soil moisture; however, it may increase the leaf temperature, particularly under high irradiance, and decrease the transport of those nutrients that are translocated with the transpiration stream [110].

LONG-TERM EFFECTS OF CO_2 CONCENTRATION ON NET PHOTOSYNTHETIC RATE

Carbon dioxide is of primary importance as a substrate in photosynthesis. A low CO_2 concentration lowers P_N, whereas its elevation enhances P_N. Since the natural CO_2 concentration is not saturating for the photosynthesis of C_3 plants, a short-term enhancement of CO_2 concentration increases P_N (approximately 95% of terrestrial plants are C_3 species, about 1% are C_4 species, and 4% use the crassulacean acid metabolism (CAM) pathway [24]). A decrease in CO_2 concentration in dense canopies (due to an insufficient rate of CO_2 transport from the air above the canopy) might contribute to a midday depression of photosynthesis [111].

At low CO_2 and saturating irradiance, the capacity of ribulose-1,5-bisphosphate carboxylase oxygenase (Rubisco) to carboxylate RuBP is limiting for photosynthesis, and the slope of the initial response of P_N to c_i (often termed carboxylation efficiency) is directly dependent on Rubisco activity. In addition to directly increasing the rate of carboxylation, the increased CO_2 concentration increases the rate of CO_2 fixation by depressing RuBP oxygenation and thus photorespiration. The slope of the P_N/c_i response progressively declines as c_i increases (usually above 200 μmol mol^{-1}). P_N is enhanced by increasing c_i to a value (about 1000 μmol mol^{-1}) when the capacity for RuBP regeneration is limiting (for reviews see, e.g., Refs. 20, 24, and 112).

The biochemical pathway of photosynthetic carbon metabolism influences the responses of plants to CO_2: C_4 plants have a more efficient photosynthetic apparatus than C_3 plants at the natural CO_2 concentration and do not increase P_N as much as C_3 plants in response to elevated CO_2 concentration. In general, C_3 plants show increased P_N at the leaf level and whole canopy level when grown at CO_2 enrichment (for recent review, see, e.g., Ref. 87). However, the long-term exposure to increased CO_2 concentration did not always increase the photosynthetic rate. On the contrary, increased CO_2 concentration often lead to downregulation of photosynthesis, as was mentioned in the introduction to this chapter (for reviews, see, e.g., Refs. 2, 17, 24, 113, and 114).

The downregulation of photosynthesis may be in a consequence of (a) decreased stomatal density and partial stomata closure reducing the CO_2 transport to the sites of carboxylation, (b) rapid production of photosynthates leading to an excess amount of starch in the chloroplasts and feedback inhibition of P_N; this inhibition is dependent on the availability of sinks in the plant and also on

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

the availability of nitrogen to balance enhanced availability of carbon, and (c) reduction in the amount or activity of Rubisco.

The species showing reduced g_s at CO_2 enrichment usually had lowered P_N [87,113]. However, according to Drake et al. [20], stomata may not limit photosynthesis with elevation of CO_2 concentration more than they do at normal CO_2 concentration. Downregulation of the Rubisco content and/or activity at elevated CO_2, reported in many species, is not a universal phenomenon; a number of species show either no decline or even an increase in the Rubisco content under this condition (e.g., see Refs. 24 and 79) or an increased ability to regenerate RuBP (e.g., see Refs. 48 and 115). Similarly, the source-sink status of plants is not only species specific but it also depends on the developmental stage and environmental conditions. No downward regulation of photosynthesis during long-term exposure to elevated CO_2 was found in some tree species; for example, *Fagus crenata* and *Quercus crispula* [116] or in the CAM plant *Opuntia ficus-indica* (in the latter species, the enhanced saccharide production was accompanied by higher source-sink photosynthate transport [117]).

Nevertheless, despite acclimation responses, the rate of P_N at saturated irradiance (P_{Nsat}) is usually higher in C_3 plants grown and measured at elevated CO_2 concentration than in those grown and measured at normal CO_2 concentration [24,96]. However, in *Picea abies*, P_{Nsat} was not stimulated by a 4-week exposure to elevated CO_2 and decreased by 24-week exposure [118,119].

The response of P_N is species specific. Under similar conditions, the acclimation of P_N was found to be somewhat downward in *Festuca rupicola*, fully downward in *Dactylis glomerata*, and upward in *Salvia nemorosa* and *Filipendula vulgaris* [91]. It was dependent on CO_2 concentration; in *Glycine max*, P_N increased in the whole range of increased CO_2 concentration (from half to three times of ambient), whereas in *Oryza sativa*, the greatest increase in P_N occurred at CO_2 concentration one and a half of ambient [24]. Also, differences between fast-growing *Populus* clone Beauprè and slow-growing clone Robusta were found: In clone Beauprè, elevated CO_2 resulted in an increase in quantum yield of photosystem 2, P_{Nsat}, chlorophyll content, and Rubisco activity, whereas in clone Robusta, primary reactions of photosynthesis were depressed and Rubisco activity decreased [120]. Acclimation of P_N was dependent on the leaf insertion level in *Pisum sativum* and *Glycine max* [121].

Differences between P_N in plants grown under ambient and elevated CO_2 concentration depend on CO_2 concentration during measurement (see Fig. 3). In *Trifolium repens*, the differences in P_N were found only when measured at the same CO_2 concentration at which they were grown [69]. On the other hand, P_N was similar in the ambient and elevated CO_2-grown *Panicum antidotale* (C_4) and *P. laxum* (C_3) plants when measured at the same CO_2 concentration at which they were grown; however, P_N of elevated CO_2 grown plants was lower when measured at ambient CO_2 concentration [57]. In *Oryza sativa*, comparison of P_N at a wide range of CO_2 concentrations (160–1000 μmol mol^{-1}) indicated that long-term treatments of 350 and 700 μmol (CO_2) mol^{-1} [122] resulted in very little photosynthetic acclimation [123].

P_N is usually more stimulated by long-term CO_2 enrichment at higher than at lower temperatures [87,124,125]. On the contrary, in *Betula platyphylla* grown at elevated CO_2, quantum yield, P_{Nsat}, and carboxylation efficiency were decreased more at higher than at lower temperature [126]. Also, in *Lolium perenne*, the negative effect of elevated CO_2 concentration was accentuated by high temperature, but it was observed under high irradiance but not under low irradiance. P_N was more stimulated by enhanced CO_2 during midday hours than in the morning or evening in *Fagus sylvatica* (see Fig. 5) [99], under water stress than under an adequate moisture supply in *Acer rubrum* [84], *Arachis hypogaea* [27], *Bouteloua gracilis, Pascopyrum smithii* [127], *Picea mariana* [128], and *Triticum aestivum* [129], and similarly in *Mangifera indica* during the dry than during the wet season [85]. In *Glycine max*, however, stimulation of P_N by elevated CO_2 concentration disappeared under severe water stress [93] (see Fig. 4). Downregulation of the photochemical efficiency of photosystem II (F_v/F_m) at CO_2 enrichment was observed in well-watered but not in water-stressed *Eucalyptus macrorhyncha* and *E. rossii* [130], whereas in *Quercus ilex*, it was much higher at severe than at moderate water stress [131].

During leaf senescence, elevated CO_2 concentration mostly decreased P_N in *Acer pennsylvani-*

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

cum, A. rubrum, Betula alleghaniensis, B. populifolia, and *Fraxinus americana* [132]. In *Rumex obtusifolius*, acceleration of the ontogenetic decline in P_N but not the reduction in the leaf life span was observed under elevated CO_2 concentration [133].

Photosynthetic capacities of leaves can be analyzed from the relationship between P_N and c_i and both the initial slope and the CO_2-saturated photosynthetic rate are often affected by CO_2 enrichment (for reviews, see Refs. 2 and 17). The P_N/c_i ratio can be used in order to eliminate the effect of g_s. Under elevated CO_2, an increased P_N/c_i ratio was found; for example, in *Andropogon gerardii* [134] and *Helianthemum nummularium* [48]. However, in some plant species, for example, in *Chenopodium album, Phaseolus vulgaris, Pinus taeda*, and *Zea mays* [58,124,135,136], growth at different CO_2 concentrations had no discernible effect on the short-term response of P_N to c_i. Stomatal limitation of P_N was increased in *Betula platyphylla* grown under elevated CO_2 [126] but decreased in *Bellis perennis, Helianthemum nummularium, Poa alpina, P. annua*, and *Plantago lanceolata* grown and measured at elevated CO_2 concentration [48].

No change or a reduction in dark respiration per leaf area unit with CO_2 enrichment is more prevalent, but the canopy respiration rate increased in association with the greater biomass and the increase in the relative growth rate [20,24,87].

WATER-USE EFFICIENCY

Under long-term elevation of the CO_2 concentration, the increase in WUE is the most common positive effect. An increased P_N/E ratio was observed not only in plants with increased P_N but also in plants where downregulation of P_N was observed, because, in these plants, a decrease in P_N was usually accompanied with a decrease in g_s. The range of the increase in WUE induced by CO_2 enrichment is dependent on the plant species and interactions with other environmental factors, especially with water stress.

Enhanced WUE under CO_2 enrichment was found; for example, in *Acacia smallii* [138], *Betula platyphylla* [126], *Citrus sinensis* [107], *Dactylis glomerata* [91], *Fagus sylvatica* (see Fig. 5) [52,91,99], *Festuca rupicola* [91], *Ficus benjamina* [139], *Filipendula vulgaris* [91], *Glycine max* [92,106,107,140], *Gossypium hirsutum* [141], *Lolium perenne* [108,142,143,144], *Oryza sativa* [107,123,125,145], *Pinus sylvestris* [61], *P. taeda* [73,136], *Salvia nemorosa* [91], *Trifolium repens* [142,143,144], *Triticum aestivum* [71], and *Zea mays* [140]. For many other plant species, see comprehensive tables in reviews elsewhere [10,104,115,146]. According to carbon isotope discrimination, an increased WUE during the last 240 years was found in herbarium specimens [147]. Bert et al. [137] calculated a 30% increase in WUE between the years 1930 and 1980 from changes in carbon discrimination ($\delta^{13}C$) in tree rings.

WUE was increased under both well-watered and drought treatments; for example, in *Glycine max* (see Fig. 4) [93] and *Picea sitchensis* [60]. The combined effect of CO_2 enrichment and drought stress on WUE was significant in *Alnus firma* [148]. In *Anthyllis vulneraria* and *Sanguisorba minor*, WUE increased at elevated CO_2, with a higher average increase under water stress [149]. On the other hand, WUE was greater for trees grown at elevated CO_2, but when subjected to drought, the relative enhancement in WUE was reduced in *Quercus rubra* or even disappeared in *Picea abies* [150]. In *Phaseolus vulgaris*, CO_2 enrichment doubled WUE at a high nutrient supply and tripled at a low nutrient supply [58].

WUE in *Chenopodium album* more than doubled after a short-term doubling of CO_2 concentration. However, WUE of plants grown and measured at elevated CO_2 was only about one and a half times that of plants transiently exposed to elevated CO_2 owing to stomatal acclimation [18]. Similarly, in *Trifolium repens*, the increase in WUE was much more dependent on CO_2 concentration, irradiance, and leaf temperature during the measurement than on CO_2 concentration during growth (see Fig. 3) [69].

However, WUE was not increased under elevated CO_2 concentration in *Abies fraseri* (due to strong downregulation of P_N [45]) and in *Quercus robur* [64], and it even decreased in *Prunus avium* [64].

CO_2 enrichment also increased biomass accumulation per water consumption (WUE_m); for example, in *Atriplex canescens* and *Schizachyrium scoparium* [47], *Pinus pinaster* and *Quercus petraea* [151], *Pseudotsuga menziesii* [152], *Quercus robur* [95], *Sinapis alba* [153], *Triticum aestivum* [98], *Zea mays* [154], and halophytic species (for review, see Ref. 155) or grain production per water consumption in *Triticum aestivum* [156]. In *Gossypium hirsutum, Triticum aestivum*, and *Zea mays*, WUE_m increased under high CO_2 for both wet and dry conditions; however, *Gossypium hirsutum* exhibited a very large leaf area response under wet soil leading to much greater water use per plant [157]. Similarly, in *Lolium perenne*, WUE_m increased at elevated CO_2 with no significant interaction with soil moisture or N supply [158]. Under supraoptimal CO_2 concentration, WUE_m was decreased in *Glycine max* [77] and *Solanum tuberosum* [76].

INCREASED CO_2 CONCENTRATION AND DEVELOPMENT OF WATER STRESS

As mentioned above, the nutrient and water limitations restrict the responses of P_N to increased CO_2; however, the elevated CO_2 would allow plants to cope more successfully with stressful habitats [3,97,159].

In most species and under most circumstances, stomatal conductance is the main limiting factor to the photosynthetic rate under mild water deficit, because the photosynthetic apparatus is usually affected only under severe water stress. Elevated CO_2 concentration may compensate decreased stomatal conductance by an increased gradient of CO_2 concentration between the exterior and interior of the leaf (for review, see, e.g., Ref. 160). In connection with this, an increased P_N/g_s ratio was found in *Quercus petraea* and *Pinus pinaster* [65] but not in *Zea mays* [135].

However, another possible consequence of elevated CO_2 and water stress (and high temperature) might be the change in susceptibility to photoinhibition. The probability of photoinhibition occurrence might be increased owing to a reduction of photorespiration or decreased by a better supply of CO_2 (for review, see Ref. 160).

Many studies have shown that plants at elevated CO_2 concentration tend to dry more slowly as water is withheld, which is consistent with their lower stomatal conductance and slower transpiration rate (Fig. 6) (for reviews see, e.g., Refs. 104 and 159). Decreased water use observed (e.g., by *Oryza sativa* [122], *Triticum aestivum* [161] or by grassland [3]) allowed photosynthesis or growth to continue for some days longer during drought in the enriched CO_2 concentration compared with ambient CO_2 treatment. However, if the leaf area increases, we may expect even higher water use per plant, and so water stress may develop more rapidly [26,162–165]. *Fagus sylvatica* may substantially increase whole-plant water consumption at elevated CO_2 [71]. Similarly, elevated CO_2 concentration in well-watered *Quercus petraea* and *Pinus pinaster* increased water consumption but decreased it under water stress [151]. Increased water uptake also was observed in *Solanum tuberosum* [76]. CO_2-enriched *Triticum aestivum* plants use less water per day during the first 30 days of soil drying but more water per day during the further 10 days [98]. Similarly, under high irrigation, a slight reduction in seasonal water use by *Triticum aestivum* was observed, but under low irrigation, there was even a slight increase in the water use [83]. In *Acacia smallii*, the total water loss was not affected by CO_2 enrichment in spite of declined stomatal conductance and increased WUE [138].

Higher leaf water potentials at elevated CO_2 [134,159] could increase leaf expansion and carbon dioxide fixation and thereby contribute to the stimulation of growth [63,164]. At elevated CO_2, the root/shoot ratio, important in the balance of saccharide allocation and water use by plants, is usually altered in favor of roots (for review, see, e.g., Refs. 24, 63, 87, 104, 159, and 163), which might increase water uptake. However, no changes in the root/shoot ratio in *Betula pendula* and *Picea abies* were observed [90].

Hydraulic conductance at elevated CO_2 concentration increased in *Quercus robur* and *Prunus avium* × *P. pseudocerasus* [64] but decreased in *Glycine max* and *Medicago sativa* [164].

Water-stressed seedlings of *Eucalyptus macrorhyncha* (Fig. 6) [130], salt-marsh plants *Scirpus*

Marcel Dekker, Inc.

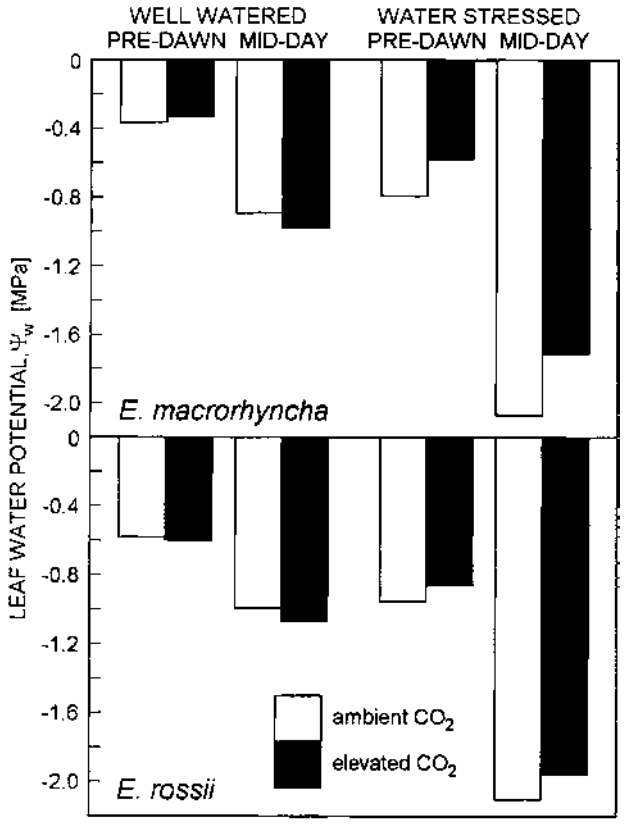

FIGURE 6 Pre-dawn and mid-day water potential in leaves of well-watered and water-stressed seedlings of *Eucalyptus macrorhyncha* or *E. rossii* grown under ambient (empty columns) or elevated (full columns) CO_2 concentration. (Adapted from Ref. 130 by J. Solárová.)

olneyi and *Spartina patens* [166], C_4 grass *Andropogon gerardii* [134], and *Triticum aestivum* [97] had a higher leaf water potential when grown in elevated CO_2, but in *Lolium perenne* [167] and *Zea mays* [97], the leaf water potential did not differ. In *Lolium perenne*, the pressure potential increased at elevated CO_2 in spring and remained similar in summer, and osmotic potential decreased in spring and increased in summer [167]. Leaf water and osmotic potentials in *Lotus, Sanguisorba, Plantago*, and *Anthyllis* decreased and the pressure potential increased at CO_2 enrichment [149,169]. In *Phaseolus vulgaris*, water and osmotic potentials increased and the pressure potential was not affected by elevated CO_2 treatment at cell division and/or cell expansion phases [168]. The increased osmotic potential at zero pressure potential was determined in *Acer saccharum* but not in *Platanus occidentalis* and *Liquidambar styraciflua* [55]. The osmotic potential was not affected by CO_2 treatment in *Prosopis glandulosa* [63]. In *Cucumis sativus, Phaseolus vulgaris*, and *Zea mays*, chilling at elevated CO_2 induced a less decrease in transpiration rate, relative water content, and leaf water potential than chilling at normal CO_2 concentration [170].

Both drought and high CO_2 resulted in osmotic adjustment in *Helianthus annuus*, with drought having a greater effect than CO_2, and their combination being more effective [171]. On the contrary, no indication of enhanced osmotic adjustment under CO_2 enrichment was found in *Pinus taeda* [172]. In *Quercus robur*, a water-stress–induced osmotic adjustment in leaves was found only under

elevated CO_2 in roots under both natural and elevated CO_2 [173]. *Betula populifolia* had a lower osmotic potential and a lower modulus of elasticity at full hydration under xeric conditions and elevated CO_2 concentration than under ambient CO_2 concentration and mesic conditions which enabled it to maintain a positive pressure potential at a lower water potential [174]. At elevated CO_2, the decreased osmotic potential, symplasmic water fraction, and rate of water transport, increased the modulus of elasticity and no changes in the formation of xylem embolism were found in *Quercus pubescens* and *Q. ilex* [66].

Elevated CO_2 concentration had no effect on the rate of rehydration nor on the de novo photosynthesis in desiccated *Xerophyta scabrida* [175].

CONCLUSIONS

Physiological responses to elevated CO_2 are different at the leaf, plant, and stand scale. They depend on CO_2 concentration (subambient, ambient, double, triple, or supraoptimal) and the duration of elevated CO_2 treatment (short-term treatments, long-term treatments lasting for weeks, months, or years). The range of the effects of long-term treatment with elevated CO_2 on individual physiological parameters is further dependent on other environmental factors. In addition, long-term treatment with elevated CO_2 affects not only the absolute values of physiological parameters but also modifies the responses to other environmental factors [61,176].

Greater carbon assimilation per unit of water loss, per unit nitrogen content, or per unit absorbed radiant energy is usually found in plants exposed to elevated CO_2 [20]. Simultaneously, stomatal conductance and transpiration rate often decrease. Thus, WUE is usually enhanced in elevated CO_2; however, this may not necessarily lead to an increased drought tolerance [71]. Similarly, the decrease of long-term water use is uncertain, because CO_2 enrichment may increase the leaf area and thereby increase the water use. However, some plant species seem to cope better with drought stress at elevated CO_2 concentration, and these species may be able to extend their biotope into less favorable sites in the future [115]. Under certain conditions, plants at elevated CO_2 concentration either deplete soil water more slowly at the same growth rate or grow faster for the same rate of soil water depletion. Under water-limiting conditions, this can lead either to a prolongation of the growing period or to a larger biomass accumulation per unit of water used [177].

Beneficial Aspects of Stress on Plants

WILLIAM GRIERSON
University of Florida
Lake Alfred, Florida

INTRODUCTION

More than any other field known to this author, research into plant stress has been curiously biased. A plant that had never been subjected to stress of any kind would probably be as vulnerable as a human being who had somehow been raised in a completely stress-free environment. Every living thing, plant or animal, is the end result of various forms of stress from early evolution, through ontology, to individual development. Nevertheless, plant-stress research has been almost totally focused on combating various ill effects of stress to the almost total exclusion of the logical approach of also acknowledging, and when possible utilizing, potential beneficial aspects. This has been so much so that the previous principal text in this field [1] lacks even a single index entry relating to the beneficial aspects of stress.

How has this bias come about? Two adverse influences are apparent, not that there may not be others. Like it or not, in today's complex society, funding controls the direction in which virtually every field of science develops. As local funding sources continue to shrink, research is increasingly confined to those areas favored by the few individuals who control grant funds. As pointed out elsewhere [2], this often severely distorts what might otherwise be logical development of scientific research. Certainly within the United States, policies of agencies administering grant funds have been totally slanted toward merely alleviating the adverse effects of stresses of various kinds to the total exclusion of support for research on how to utilize beneficial aspects when possible. This is particularly unfortunate in that it has excluded grant support for stress utilization in various commendable efforts to develop nonchemical methods for modern agriculture.

A second, more minor, but increasingly powerful factor is the modern reliance on computer-based literature searches. The computer is a marvelous servant but a poor master. Increasingly, we have research workers who rely almost exclusively on computers for literature search, and usually their computers tend to find only those entries identified by title or by ''key words.'' This is only one small aspect of an increasing pressure toward conformity that this author has strongly decried

MARCEL DEKKER, INC.
270 Madison Avenue, New York, New York 10016

[3]. Such limitation to computer searches can exclude much ''precomputer'' literature. Indeed, it is not ''literature search'' in the classic sense of Dr. Samuel Johnson's (1709–1784) excellent eighteenth century advice: ''The first task is to search books, the next to contemplate nature'' [4]. Almost any text on horticulture (and sometimes on agronomy also), ancient or modern, amateur or professional, can yield examples of beneficial aspects of various forms of deliberately applied stress even though the word *stress* may not itself be used in the text.

This brings us back to ''key words,'' which are all too often limited to the ''buzz words'' currently predominant in a particular field of research. Key words deserve more respect! They are authors' means of access to the attention of research workers (and perhaps funding agencies) who may integrate the reported research into quite unexpected fields of endeavor. The ''ripple effect'' of well-chosen key words should never be underestimated. Too often, research workers do not think to include stress, beneficial or otherwise, among their key words. A very recent example is a paper [5] cited later in a discussion of certain beneficial aspects of applied mechanical stress. Unfortunately, the author did not include the word *stress* in either her title or her key words (although the phrase ''mechanical stress response'' occurs in the first sentence of her paper). Thus, this very worthwhile review will probably be missed in any computer search for literature on stress-related research. In a review of the beneficial aspects of physiological stress [6], my coauthors and I cited 128 papers, texts, and so on. I do not recall any of them being located through ''key words.''

Examples cited in this chapter are heavily slanted toward horticulture, this having been the author's lifelong field of study. Workers in other disciplines can probably find equally cogent examples in their own fields of expertise. Most particularly, research workers in the field of stress alleviation are invited also to consider possible *benefits* of natural or applied plant stresses. Authors in almost any aspect of plant physiology, agronomy, and forestry, indeed almost any biological science, have the possibility of unusually eclectic recognition of their research whenever such key phrases as ''stress alleviation'' or ''stress utilization'' are appropriate.

Definitions

Stress

Stress is here considered to be any external factor that results in a less than optimal growth rate (i.e., any factor that interrupts, restricts, or harmfully accelerates the normal metabolic processes of a plant). When growth is not involved (as with living, harvested plant parts), stress is considered here to be any factor that, if applied in excess, kills the organ or tissue involved.

The benefits of various forms of plant stress can be either biological or economic.

Biological Benefits

These are plant responses to stress that enable the plant to grow, survive, and propagate itself regardless of any interaction with humankind.

Economic Benefits

These are responses to stress that make plants more valuable to humankind. Such benefits are typically in terms of increased monetary yield from crops. However, there also can be other economic benefits. As I watched a documentary film of the building of the replicas of Columbus's ships, I wondered what natural stresses those oak trees had endured to make them grow into the irregular shapes carefully selected for ''knees'' to secure the vessels' ribs to their keelsons.

Stress Research Related to Beneficial Aspects

As noted, there is an increasing volume of valuable research on the beneficial aspects of stress that is never recognized as such in the literature. Much of this has already been reviewed [6], but reports

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

continue to be published that are never collated into the increasing body of research on stress, because they are not so indexed. Such a recent review paper is Latimer's report, ''Mechanical conditioning for control of growth and quality of vegetable transplants'' [5]. As its 81 literature citations attest, this is an extensive review of the beneficial effects obtained by application of various mechanical stresses (bending, brushing, and shaking) on a range of species. Of great importance is her observation that, in some instances, such mechanical stresses can substitute for treatment with growth regulators, such as daminozide (B-Nine or Alar), which are increasingly faced with legal restrictions on their use on food crops.

Until such research is included in the rubric of stress research, plant stress will continue to be a curiously unbalanced field of study.

STRESS AS AN INEVITABLE COMPONENT OF ANY ENVIRONMENT

Stress In Evolution

Overwintering

Seeds of tropical plants usually germinate as soon as they are mature, often immediately after separation from the plant that bore them. If seeds of Temperate Zone plants behaved similarly, their newly sprouted seedings would be destroyed by the first hard frost. Temperate Zone seeds must initially be dormant; dormancy being later broken by the hard but beneficial stresses of winter temperatures. Exceptions to this principle are seeds of Temperate Zone plants that bloom early enough in the spring to be able to establish mature plants before the onset of winter. The dandelion (*Taraxacum officinale*) is a familiar, and usually unwelcome, example.

The dormancy of perennial plants affords an outstanding example of beneficial responses to the gradually increasing stresses exerted by decreasing temperature, shortening day length, and decreased light intensity. With deciduous trees, this effect is particularly obvious as leaves change color and then fall. Under the stresses of autumnal climatic changes, however, even conifers undergo considerable, although invisible, metabolic modifications enabling them to adapt to winter temperatures that would be fatal if experienced during full growth flush [7]. A chapter, or perhaps a book, could be written on such natural responses to beneficial stress. This account, however, must give priority to manipulation of plant stresses for economic benefit. However, first let it be noted that, in all fields, exhaustive, seemingly interminable biochemical and biophysical studies of what happens during stress-induced changes are now giving way to investigation of the growth regulators that mediate and control such phenomena (e.g., see Ref. 10). Understanding such specific mechanisms is increasingly placing them within the reach of control for economic benefit.

Mechanical Stress

Nearly 100 years ago, when Captain Joshua Slocum prepared to build his little sailing vessel, *Spray*, which he was to sail around the world, he looked for an old solitary oak tree that had been wind stressed throughout its long life. As builders of wooden ships have known through the ages, such ''prestressed'' trees were the best source of tough, reliable timber.

When the heavily timbered shores of Canada's British Columbia began to be developed after World War II, planners and builders sought to save some of the magnificent great fir, cedar, and hemlock trees for landscape purposes. Solitary trees that, for one reason or another, had grown alone served well. However, it was soon found that leaving occasional trees as the forest was cleared could be disastrous. Deprived of the shelter provided by their fellows, such unstressed trees tended to fall in the next Pacific gale. This strengthening effect of mechanical stress is not confined to trees. As described here, it can be utilized in improved handling of various crop plants.

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

Aridity

Beneficial responses to various forms of stress have been critical in the evolution of plants adapted to growing in apparently hostile areas. Untold generations subjected to severe drought conditions have selected desert plants capable of surviving by virtue of their various, sometimes elaborate, adaptations for water conservation.

More than simple conservation of moisture is involved in the evolution of the ''desert ephemerals,'' annual flowering plants whose seeds germinate only when there has been a single rainfall sufficient to carry the plant from seed germination through bloom to seed maturation. Before knowledge of growth regulators, how this could work was a mystery. We now know that seeds of desert ephemerals have a growth inhibitor that is leached out by rainfall sufficient to carry the plant through its life cycle. Such a mechanism was obviously developed by natural selection under the severe stresses of advancing desertification. Plants whose seeds germinated with trivial rainfall were selectively discarded; those with increasingly high levels of growth inhibitor survived, which is an elegant example of the beneficial response to stress.

Fire

There can be no greater stress than fire. Nevertheless, fire has played an essential role in the evolution of some plants, providing them with particularly favorable ecological niches.

A number of species of pine trees (*Pinus* spp.), referred to by foresters as ''serotinous,''have cones that require fire to open their scales to release their seeds. Probably the best known of these is the lodgepole pine (*P. contorta*) common in the northern Rocky Mountains of Washington and British Columbia. In such areas, with repeated forest fires, the lodgepole pine increasingly becomes the ecological climax species.

Another, less well-known, example of a pine with serotinous cones is the jack pine (*P. banksiana*) of the U.S. Great Lakes States and adjacent Canada. Other pines benefitting from fire for reseeding, although not completely serotinous, are the pond pine (*P. serotina*) and the pitch pine (*P. rigida*) [8].

A recently discovered, quite different, mechanism for ''propagation by fire'' involves seed germination [9]. In some areas of California subjected to wildfires, it is commonly observed that after dense perennials such as chaparral are burned away, the annual wild flower ''whispering bells'' (*Emmenanthe penduflora*) promptly flourishes. Research workers at Occidental College, Los Angeles, recently found that seeds of (*E. penduflora*) are totally dependent on nitrogen dioxide (at levels that occur in wildfire smoke) for seed germination. There is an irony here. NO_2, so widely decried as an atmospheric pollutant when it comes from automobile exhausts or gas cooking stoves, is essential for the life cycle of at least one plant species and perhaps others also. For that matter, it is ironic to read the endless denunciations of CO_2 as a ''greenhouse gas'' with no acknowledgment that CO_2 is the essential feedstock for photosynthesis on which all higher life forms are dependent.

Other Stresses

There is not space enough here to attempt to cover all the natural stresses that have shaped the evolution of useful plants. Salinity is an obvious example—from strains of barley that have selectively adapted to brackish conditions in which other feed grains cannot survive, to the mangroves that grow in seawater, protecting and extending tropical shorelines. Such selection by chemical stresses, although benefiting the plant, are not necessarily beneficial to people. Within living memory, imported woody asters have invaded selenium-rich soils in parts of Wyoming. Not only do they survive the stress of levels of selenium toxic to most plants, they accumulate it and become highly poisonous to livestock that may graze on them, a property that is definitely protective for the asters but disastrous for ranchers and their herds [11].

There are surely many other examples of plants selectively benefiting from their specific responses to various forms of plant stress.

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

Mechanisms Involved in Stress Adaptation

Abscisic Acid

It is only since World War II that improved instrumental analysis has made possible the identification and quantification of the growth regulators (GRs) that control plant physiological activities as surely as the endocrine hormones control the physiology of vertebrates [12].

Attention is drawn to two publications. In March 1944, the remarkable horticultural scientist W. H. Chandler presented the University of California annual faculty research lecture on the topic of winter hardiness of trees [13]. He reviewed physical and biochemical changes in detail. Growth regulators were not mentioned. In an August 1969 symposium 25 years later on cold hardiness, dormancy, and freeze protection of fruit crops [14], four of seven authors commented on the emerging role of growth regulators in winter hardiness. Today, consideration of GRs would be almost implicit in such a symposium. The use of controlled stress to manipulate GRs is the logical next step.

One of the first such GR studied in detail was abscisic acid (ABA), named because of its visually dramatic effects in the autumnal abscission of the leaves of deciduous trees. It is now known that ABA has many other functions (some of which are discussed below). Dormancy is an obviously beneficial response to climatic stresses at the approach of winter. Dormancy and bud breaking are controlled at least in part by the balance between ABA and gibberellins. The role of ABA in dormancy is still being studied but appears to be related to the synthesis of RNA and protein [15].

Other Growth Regulators

Cytokinins also are associated with autumnal leaf dehiscence [15], but for which deciduous trees would not survive the winter.

Possibly the most ubiquitous GR associated with stress is ethylene, which over the ages has been involved in many traditional uses of stress physiology even though its role was assuredly not understood by the biblical prophet Amos (see later discussion of fig ripening).

Other Mechanisms

Until recently, the various benefits obtained by such deliberately applied stresses as pruning, ''hardening off,'' bending fruit tree limbs, and girdling of fruit trees have been explained in terms of the carbohydrate nitrogen ratio, a mechanism originally proposed to account for the physiological responses of the tomato [16]. It is quite likely that hormonal regulation also is involved.

INTENTIONAL MANIPULATION OF STRESS

There is nothing new in the concept of deliberately applying stress in various ways for the enhancement of crops of various kinds (even though such practices have been ignored in the ''stress literature''). Today, however, imposing controlled stress for crop improvement is greatly facilitated by our increasing understanding of the GR mechanisms involved. Moreover, manipulation of endogenous GR levels is a considerable step in decreasing the overreliance on chemicals for which modern agriculture is so generally criticized.

Tree and Vine Crops

Today, almost all tree fruits and many grapes are grown as a rootstock-scion combination. A single bud or short graft piece is taken from a plant of the desired scion variety and inserted against the cambium layer of a seedling (or rooted cutting) selected for such qualities as vigor of growth, adaptability to soil type, and disease resistance. As soon as the scion piece is growing strongly, the seedling is cut off, an extremely stressful start to a long productive lifetime. From then on, the tree

or vine (now of the scion variety) is often subjected to a further series of applied mechanical stresses to produce a profitable crop.

Various forms of mechanical stress are commonly applied to fruit trees to bring them to bear. One such is tying down branches of nonflowering trees (particularly certain varieties of apples). Early in the season, upward growing branches are bent down and tied in place, thus subjecting them to severe mechanical stress. Another such application of a mechanical stress is ''ringing,'' in which a narrow strip of bark is removed all around the circumference of the trunk. (If done properly, the ''ring'' heals completely before the tree goes dormant in the fall. If not properly done, the ring does not heal and the tree dies). In either case, the bent branch or the ringed tree is usually forced into initiation of flower buds.

Forestry (Silviculture)

Fire, the ultimate stress, has long been used to *prevent* calamitous forest wildfires. Use of frequent controlled burns to remove flammable undergrowth was initially developed in Florida and has become a very general practice across North America. Frequent controlled minor burns prevent the build-up of the dense flammable undergrowth that fosters destructive forest fires [17–20].

Annual Crops

Quite drastic stresses are routinely imposed in the production of many annual crops, particularly those for which individual plants are transplanted from seedling beds to the field (i.e., many types of vegetables, florists' stocks, and tobacco). From time immemorial, growers have known that seedlings transferred in full growth flush often do not survive transplanting. Experience has shown that seedlings need to be ''hardened off'' before transplanting. This normally involves reducing the water supply almost to the wilting point; temperature reduction also is involved for greenhouse-grown seedlings. Such properly stressed plants survive transplanting far better than those in full growth flush. Vague explanations were accepted in the past (''hardening taught the plants to adapt''). We now know that adequate (but not excessive) stress induces the production of protective levels of ABA [21–24].

Fairly recent research has shown that even the act of handling such seedlings, although harmful if done incorrectly, can be highly beneficial. Latimer's review [5] is highly recommended to those interested in the possible use of mechanical conditioning (e.g., by bending, stroking, or shaking) instead of applying exogenous GRs, such as daminozide (B-Nine or Alar), to such seedlings.

A striking example of applied stress to benefit an annual crop is the grazing of winter wheat in the fall. In such climates as Canada and the northern United States, ''winter wheat'' is sown in late summer or early fall. It grows to a height of 25 or 30 cm before going dormant at the onset of winter. As a young farmhand well over 50 years ago, I was incredulous when the very wise farmer for whom I was working told me to turn the dairy herd in to graze on the winter wheat. ''It's good feed and it's good for the wheat.'' Grazing on young plants that are expected to produce a crop of wheat the following summer is a very severe form of stress. But he was correct: ''stooling'' (production of basal shoots to form additional plants) is stimulated by grazing and by the trampling of the cattle.

Pasture Crops

Grazing of winter wheat leads to consideration of the possible beneficial effects of stress on pasture grasses. A thoughtful paper [25] compared continuous overgrazing of U.S. western rangelands with the apparent overgrazing by vast herds of herbivores, such as wildebeest, zebra, and gazelle, on the African savannahs. A good case is made that when the apparent overgrazing is seasonal (as with these strictly migratory animals), the trampling and close cropping before the grasses go dormant for the dry season is, although temporarily stressful, ultimately strongly stimulating to the next

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

season's growth; an example of natural beneficial stress that awaits possible exploitation by cattle ranchers.

Induced Rest Period

As the costs of refrigerated transportation rise (and when access to foreign exchange becomes limiting), an interesting development is that of applying ''false winter stress'' to grow deciduous fruits completely out of their normal ranges. An example is using severe water stress, plus manual or chemical defoliation, to force apple trees grown in a tropical climate, such as that of Java, to go into the rest period necessary for initiation of fruiting buds [26]. This can be so successful that the writer has observed apples and bananas growing side by side in Colombia's Valle del Cauca.

Differential Heat Stress for Pest Control

Enough heat stress can kill any living tissue, but advantage can be taken of the differences in susceptibility to heat stress between host and pathogen. This is not new, as shown by a 1948 report [27] that *Penicillium* mold of citrus fruits can be inhibited by prolonged exposure to temperatures (30–32°C) tolerated by Florida citrus fruits. With increasing public resistance to the use of chemicals for pest control, the use of differential heat stress for pest control is increasingly popular. Some typical recent reports include postharvest heat treatments for leafroller insects infesting avocados [28], *Penicillium* mold of grapefruit [29], anthracnose decay of mangos [30], and control of various fruit flies infesting papayas, carambolas, mangos, and grapefruit [31].

All the above examples (and many more could have been cited) are postharvest treatments. A preplanting heat-stress treatment provided essential control of the root-infesting nematode *Radophilis similis* that in the 1950s threatened to wipe out the Florida citrus industry. Before planting out in the grove, roots of nursery-grown saplings were exposed to water hot enough to kill all stages of the nematode life cycle but which were tolerated by the citrus roots [32,33].

IMPROVEMENT IN PRODUCT QUALITY

Controlled stress, either pre- or postharvest, can be used to improve the postharvest quality of various crops. Although this is more general for horticultural crops, examples are cited here for products as varied as oil seeds, medicinals, and tobacco.

Pruning and Training

Even after many orchard crops are well established, for many types of fruits, product quality must be maintained by pruning, training, and/or thinning. Although such practices are intrinsically stressful, they improve the market grade (and hence monetary value) of the resultant crop as assuredly as the considerable stress involved in castration of a bull calf results in a superior meat animal. Most varieties of apples and grapes, if spared such stressful treatments, ultimately produce heavy crops of small fruit that are virtually worthless on the fresh fruit market.

Applied Water Stress

Kramer [34] cites various authors who have reported that moderate water stress can improve the quality of apples, pears, peaches, and prunes, increase the rubber content of guayule, improve the aromatic constituents of Turkish tobacco, increase the alkaloid content of *Atropa belladonna* and *Hyoscyamus muticus*, and raise the essential oil content of mint and the oil yields of olive oil and of soybeans. (Water stress of cotton plants, by omitting irrigation in August, results in uniform and early opening of the bolls with increased prospects of completing harvest before the first frost [M. Pessarakli, personal observation].) An account from India reports that water stress improved the

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

quality of peanut oil (*Arachis hypogaea*) by increasing the proportion of unsaturated fat [35]. In view of the current emphasis on decreasing saturated fats in the U.S. diet, this latter finding might merit further investigation of other crops yielding edible oils. Current Canadian research indicates that the dry matter content of cannery tomatoes (and hence their monetary value) may be increased by judicious application of water stress (M.A. Dixon, personal communication).

Enforced Delay of Ripening

It can be advantageous to delay ripening of fruits when refrigeration is not available or when the product tolerates refrigeration poorly. (See comments on chilling injury below.) Ripening is initiated by the production of endogenous ethylene. The ethylene-forming enzyme (EFE) system in papayas can be inhibited by closely controlled heat stress [36]. Similarly, ripening of guavas can be delayed by hot-water treatment [37].

Enhancement of Citrus Fruit Color Through Stress

Citrus fruits are more or less fully green at maturity when grown in the fully tropical lowlands where they first evolved in Southeast Asia. Centuries of growing citrus fruits in far more stressful ''Mediterranean-type'' climates have led the world's consumers to expect, and pay for, certain typical stress-induced brilliant peel colors [38]. In particular, orange fruit and orange color are so closely associated that the buying public (anywhere but in the tropics) instinctively resists buying oranges that are not orange in color. Ethylene is a clearly demonstrated product of fruits and vegetables under stress [39]. Cold nights during fruit maturation cause sufficient stress to produce enough ethylene to remove chlorophyll and stimulate the production of the carotenoid pigments resulting in typical ''varietal colors'' [40–42]. In a climate such as Florida's, however, it is necessary to have at least five nights below 10°C to produce the requisite color change [43]. Such conditions often do not occur until the harvesting season is well advanced, so lacking this beneficial preharvest stress, ethylene is applied postharvest to destroy the chlorophyll whose green color is almost invariably considered an indication of immaturity by the buying public [44].

Induced Maturation of Figs

The earliest recorded example of the deliberate use of stress-induced ethylene concerns the edible wild fig (*Ficus sycamorus* L.), the natural maturation of which is dependent on a diminutive wasp (*Sycophaga sycomori* L.). The sycamore fig was endemic in Biblical lands, but at that period, the *Sycophaga* wasp was not. In modern times, Galil [45] showed that the sycamore fig sets parthenocarpically and ripens to edibility in about 4 days only if wounded enough to stimulate the production of endogenous ethylene. Examples of the small curved knives that herdsmen (such as the prophet Amos) used to nick the immature figs have been found in excavations in Egypt. Since then, Maxie and Crane [46] have shown that the same effect can be obtained by sprays of the synthetic growth regulator 2,4,5-trichlorophenoxyacetic acid, which causes sufficient stress to induce the production of enough endogenous ethylene to result in parthenocarpic fruit set.

Astringency Masking in Persimmons

Many varieties of persimmons are too astringent to eat until they are very close to being overripe. Many hundreds of years ago, the Japanese found that sealing mature (but still astringent) persimmons in used sake (rice wine) barrels for a few days removed (more correctly masked) the undesirable astringency. This effect used to be attributed to lingering alcoholic fumes from the sake. It has since been shown to be due to mild stress from short-term exposure to the high carbon dioxide levels accumulated from respiration [47]. Too long an exposure or too high a concentration of carbon dioxide can cause excessive stress, ruining the persimmons.

Irradiation for Varietal Improvement

Gamma irradiation can exert a drastic stress on any living tissue, as the writer and his colleagues found in an unsuccessful search for a radiation dosage high enough to control decay pathogens but low enough not to damage the peel of citrus fruits [48,49]. Nevertheless, gamma irradiation is being used with considerable success in the improvement of various crop plants. The modern consumer of grapefruit prefers red flesh, and the more highly pigmented the better, even though the red pigment (lycopene) has no effect on flavor. However, the buying public has an antipathy to seeds. The Hudson variety has very desirable flesh color but is very seedy. R. A. Hensz of Texas subjected the seeds of the Hudson variety to a mild dose of irradiation. This provided stress enough to produce a seedless mutant with highly pigmented flesh that is now being widely planted in Texas and Florida as the Star Ruby variety [50].

Star Ruby grapefruit is just one of many agricultural products for which improved strains have been obtained by irradiation, a method being widely used all around the world. The 1974 *Encyclopedia Britannica* lists no fewer than 45 improved strains of various crop plants produced by irradiation [51]. Undoubtedly many more have been (such as Star Ruby grapefruit) produced since then. Irradiation is a deadly stress in excess but a very useful tool when used in moderation. How many of these examples would be found in a modern computer search for ''beneficial uses of stress''?

As this chapter is being written, the professional scaremongers, a thriving and prosperous group, are raising a clamor with regard to a recent U.S. Supreme Court ruling that ''genetically improved'' food crops do not have to be submitted to exhaustive (and exceedingly expensive) toxicological testing before release. Let it be noted that, ever since irradiation was first used to improve a food crop, long before the advent of gene manipulation by biotechnology, ''genetically altered'' food plants have been in general use without evidence of any toxicological problems. Fortunately, this beneficial use of stress achieved general worldwide acceptance without the professional alarmists noticing.

Hypovirulent Virus Inoculation

Infection of a crop plant by a virus is usually high on the list of forms of stress to be avoided. Increasingly, however, benefits are being found from inoculation with hypovirulent strains of plant viruses. One such has been known, but not understood, for hundreds of years. In the quest for new and striking color combinations, tulip breeders have long known that the color break factor (giving striking bicolor blooms) did not follow a Mendelian inheritance pattern. Not until 1928 was it recognized that the ''color break factor'' is due to infection with a hypovirulent virus. Today, such hypovirulent viral strains are being used for benefits as diverse as control of animal and plant pests, weed control, and limiting the size of citrus trees. Interested readers are referred to a review by Cohen [52] that covers not only historical and present developments but also future trends and possibilities for the use of these hypovirulent viruses.

Mitigation of the Chilling Injury Syndrome

Many plants and detached plant parts, such as harvested fruits, are susceptible to chilling injury; that is, low-temperature injury at temperatures somewhere below 10°C but well above 0°C. Anyone who has ever placed a banana in a household refrigerator and had it blacken overnight has observed chilling injury (CI). After 25 years of studying and trying to control chilling injury, the writer conducted a series of studies that showed that judiciously applied stress could be a very valuable tool in mitigating CI.

Chilling injury is typically a problem of plants originating in the tropics, although all plants originating in the tropics are not necessarily CI susceptible. For example, we found no evidence of chilling susceptibility with the Golden Star variety of carambola (*Averrhoa carambola* L.) [53],

definitely a tropical fruit. However, Arkin, a new variety released after that report was published, proved to be susceptible. Susceptibility has to be determined species by species, variety by variety, and district by district. Chilling injury also can be a problem in the field, as with cotton seedlings in the spring and maturing tomatoes in the fall, but this discussion is confined to postharvest aspects, for which CI can place severe constraints on the storage and marketing of susceptible fruits (including those vegetables that are botanically fruits).

Even within a given species or cultivar, CI susceptibility can vary considerably with the growing district. Thus, California-grown Valencia oranges are susceptible to CI at temperatures below 5°C [54], but the same variety grown in Florida's very different climate is CI resistant. Thus, Florida Valencia (late season) oranges can be stored and shipped at the same temperatures as those commonly used for apples and other produce not susceptible to CI. However, Florida grows about 75% of the world's grapefruit and it is CI susceptible, thus sharply limiting export shipping temperatures throughout the harvesting season and storage in the 4 summer months when grapefruit are not being harvested. The storage life of grapefruit is terminated either by fungal attack or by CI (which so disfigures the peel as to make the fruit unsalable). Considerable storage life can be obtained at temperatures just above 10°C by using fungicides to the maximum legal limit. However, at such temperatures, the peel turns an atypical deep yellow, which is rejected by the market. Moreover, some of the more effective fungicides being used elsewhere (e.g., Panoctine or Guazatine) are not approved in the United States, and those that are approved are under constant attack by well-meaning but often misinformed consumer groups. The problem, to which the writer and a series of graduate students applied over 25 years of research, becomes that of finding a way of storing and shipping grapefruit at temperatures commonly used for nonchilling susceptible products. This became even more urgent when the federal ban on ethylene dibromide (EDB) fumigation for fruit fly quarantine made ''low-temperature sterilization'' necessary for shipments of grapefruit from quarantined districts to citrus-growing areas, such as Japan. Since this involved research into the basic causes of CI, there was an excellent prospect that research findings would be applicable to other CI-susceptible products.

First, a comment on grapefruit, which is in many ways an ideal test material for such studies: Marketable fruit from a single bloom (usually in late March) can be picked for as long as 8 months (typically from mid September to mid May). Thus, experiments on fruit from a single bloom can be replicated over a period of 8 months. Moreover, since fruit can hang on the tree for as long as 15 months, it is possible to conduct experiments comparing the response of new crop, immature fruit with that of very mature fruit from the previous bloom on the same tree. Additionally, trees being perennials, fruit from the same plants can be used in successive years. One series of experiments involved over 100 harvests of random pickings from the same 28 trees taken over a period of 8 years. Readers interested in the details of such research over many years are referred to various published reports and doctoral dissertations [55–63]. To summarize our findings very briefly:

1. Every season included a mid winter period of remarkable resistance to CI, but the exact dates varied from year to year.
2. Such resistant periods were clearly correlated ($r = 0.93$, $P = .01$) with prevailing temperatures during the dry season [61].
3. Susceptibility to CI often varied more with time between picking and storage than with the postharvest treatments under study.
4. Spraying trees with various growth regulators caused marked (but unpredictable) changes in the susceptibility of the grapefruit to CI [56].

Another line of investigation was inspired by an observation by visiting South Africans that, although grapefruit grown on the Transvaal high veldt was susceptible to CI, after shipment across the Great Karroo Desert in steel, unrefrigerated railcars to the port at Cape Town, it could be ''cold sterilized'' against fruit fly larvae at temperatures a little above 0°C. To simulate this, we added a biweekly treatment in which samples were placed in a metal shed on the roof of our building for

Marcel Dekker, Inc.
270 Madison Avenue, New York, New York 10016

2 days. The results were remarkable in late summer, which was the end of the rainy season, with noon shade temperatures always over 32°C and late afternoon temperatures in the roof shed exceeding 40°C. The ''Karroo Desert treatment'' did the grapefruit no harm and extended successful storage at 4.5°C from 10 to 90 days. This effect decreased sharply when the summer rains ceased and noontime temperatures decreased in the fall. The conclusions were obvious: Fruit picked from trees in good growth flush and stored immediately were very susceptible to CI unless severely stressed before storage. Fruit from trees stressed by the annual winter dry season also were resistant to CI. A painstaking graduate student showed that, just as for seedlings hardened before transplanting, endogenous ABA was involved in the development of resistance to CI [57]. Subsequent research in cooperation with the U.S. Department of Agriculture and the Florida Department of Citrus showed that such postharvest conditioning treatments did not need to be as drastic or as short. With longer periods (e.g., 7 days) and more moderate temperatures (e.g., 15–16°C), grapefruit can be ''cured'' to enable it to withstand storage and transit temperatures low enough to cold sterilize fruit fly larvae (0–2°C) [64]. This protective effect is not peculiar to grapefruit, as shown by a recent report on prestorage conditioning of squash (*Curcubita pepo* L.) to inhibit chilling injury [65]. It appears that conditioning-induced protective levels of ABA are as general for harvested fruits as they are for seedlings of cucumber [66] and cotton [67].

Prestorage conditioning is now becoming general for products as diverse as summer squash [65] and *Opuntia* ''cactus pears'' [68].

Thus, research on the *benefits* of applied stress can undermine apparent truths such as the old precept that perishable products should all be refrigerated as promptly as possible after harvest. Obviously the benefits of prompt refrigeration do not necessarily apply to CI-susceptible products which often need to be preconditioned by precise application of postharvest stress.

CONCLUSIONS

Stress is not merely something to be combated: Stress is one of nature's essential tools. Intelligently employed, stress can be used to obtain many benefits for both research workers and plant industries. In particular, the attention of two groups must be drawn to this dual role of plant stress. The first such group consists of the individuals, committees, and administrators who control grant funds for research on plant stress. The second group involves virtually all those who teach, or otherwise advise, on the handling of horticultural products. For these, it has long been holy writ that a fruit, vegetable, or flower should be refrigerated as soon as possible after harvest. This otherwise excellent principle needs to be reconsidered when chilling-susceptible products are to be stored for any considerable period.
